HAZZARD'S  
GERIATRIC MEDICINE  
AND GERONTOLOGY

### **Notice**

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error and changes in medical sciences, neither the editors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

# HAZZARD'S GERIATRIC MEDICINE AND GERONTOLOGY

*Sixth Edition*

EDITORS

**JEFFREY B. HALTER, MD**

*Professor of Internal Medicine  
Chief, Division of Geriatric Medicine  
Director, Geriatrics Center and Institute of Gerontology  
University of Michigan  
Ann Arbor, Michigan*

**JOSEPH G. OUSLANDER, MD**

*Professor and Associate Dean for Geriatric Programs  
Charles E. Schmidt College of Biomedical Science  
Professor (Courtesy), Christine E. Lynn College of Nursing  
Florida Atlantic University  
Professor of Medicine (Voluntary)  
Division of Gerontology and Geriatric Medicine  
University of Miami Miller School of Medicine  
Boca Raton, Florida*

**MARY E. TINETTI, MD**

*Gladys Phillips Crofoot Professor of Medicine, Epidemiology, and Public Health  
Director, Program on Aging  
Yale University School of Medicine  
New Haven, Connecticut*

**STEPHANIE STUDENSKI, MD, MPH**

*Professor, Department of Medicine (Geriatrics)  
University of Pittsburgh  
Staff Physician, VA Pittsburgh GRECC  
Pittsburgh, Pennsylvania*

**KEVIN P. HIGH, MD, MS**

*Professor of Medicine, Sections on Infectious Diseases,  
Hematology/Oncology and Molecular Medicine  
Chief, Section on Infectious Diseases  
Wake Forest University Health Sciences  
Winston-Salem, North Carolina*

**SANJAY ASTHANA, MD**

*Duncan G. and Lottie H. Ballantine Chair in Geriatrics  
Professor and Head, Section of Geriatrics & Gerontology  
University of Wisconsin School of Medicine and Public Health  
Director, Geriatric Research, Education and Clinical Center (GRECC)  
William S. Middleton Memorial Veterans Hospital  
Associate Director, Wisconsin Alzheimer's Institute  
Madison, Wisconsin*

EDITOR EMERITUS AND SENIOR ADVISOR

**WILLIAM R. HAZZARD, MD**

*Professor of Medicine  
University of Washington  
Director, Geriatrics and Extended Care  
VA Puget Sound Health Care System  
Seattle, Washington*

McGraw-Hill has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

# Contents

Contributors . . . . .	ix
Foreword . . . . .	xxv
Preface . . . . .	xxvii

## Part I PRINCIPLES OF GERONTOLOGY

<b>1. Biology of Aging and Longevity . . . . .</b>	<b>3</b>
<i>Richard A. Miller</i>	
<b>2. Genetics of Age-Dependent Human Disease . . . . .</b>	<b>15</b>
<i>Thomas B. L. Kirkwood</i>	
<b>3. Immunology and Aging . . . . .</b>	<b>23</b>
<i>Birgit Weinberger, Daniela Weiskopf, and Beatrix Grubeck-Loebenstein</i>	
<b>4. Inflammation and Aging . . . . .</b>	<b>37</b>
<i>Jeremy D. Walston</i>	
<b>5. Demography and Epidemiology . . . . .</b>	<b>45</b>
<i>Jack M. Guralnik and Luigi Ferrucci</i>	
<b>6. International Gerontology . . . . .</b>	<b>69</b>
<i>Roberto Bernabei, Len Gray, John Hirdes, Xiaomei Pei, Jean Claude Henrard, Palmi V. Jonsson, Graziano Onder, Giovanni Gambassi, Naoki Ikegami, Annette Hylén Ranhoff, Iain G. Carpenter, Rowan H. Harwood, Brant E. Fries, John N. Morris, and Knight Steel</i>	
<b>7. Psychosocial Aspects of Aging . . . . .</b>	<b>97</b>
<i>Richard Schulz and Steven M. Albert</i>	
<b>8. General Principles of Pharmacology . . . . .</b>	<b>103</b>
<i>Sarah N. Hilmer and Gary A. Ford</i>	
<b>9. Preventive Gerontology: Strategies for Optimizing Health Across the Life Span . . . . .</b>	<b>123</b>
<i>Elizabeth A. Phelan, Miguel A. Paniagua, and William R. Hazzard</i>	

## Part II PRINCIPLES OF GERIATRICS

<b>10. Evaluation, Management, and Decision Making with the Older Patient . . . . .</b>	<b>133</b>
<i>Sharon E. Strauss and Mary E. Tinetti</i>	
<b>SECTION A Assessment</b>	
<b>11. Principles of Geriatric Assessment . . . . .</b>	<b>141</b>
<i>David B. Reuben and Sonja Rosen</i>	
<b>12. Mental Status and Neurological Examination in Older Adults . . . . .</b>	<b>153</b>
<i>James E. Galvin</i>	
<b>13. Assessment of Decisional Capacity and Competencies . . . . .</b>	<b>171</b>
<i>Margaret A. Drickamer and James M. Lai</i>	
<b>14. Principles of Screening in Older Adults . . . . .</b>	<b>177</b>
<i>Louise C. Walter</i>	
<b>SECTION B Organization of Care</b>	
<b>15. Health Care System . . . . .</b>	<b>185</b>
<i>Chad Boulton</i>	
<b>16. Transitions . . . . .</b>	<b>197</b>
<i>William L. Lyons and Eric A. Coleman</i>	
<b>17. Acute Hospital Care . . . . .</b>	<b>209</b>
<i>Scott A. Flanders, Paula M. Podrazik, Chad Whelan, and Caroline Blaum</i>	
<b>18. Emergency Department Care . . . . .</b>	<b>221</b>
<i>Scott T. Wilber and Lowell W. Gerson</i>	
<b>19. Critical Care . . . . .</b>	<b>229</b>
<i>Eric B. Milbrandt and Derek C. Angus</i>	

20. **Subacute Care** ..... 237  
*Edward R. Marcantonio and Mark Yurkofsky*
21. **Nursing Facility Care** ..... 251  
*Mary Pat Rapp and Keith L. Rapp*
22. **Community-Based Long-Term Care and Home Care** ..... 275  
*Jennifer Hayashi and Bruce Leff*
23. **Rural Aging** ..... 283  
*Kenneth Brummel-Smith*

### SECTION C Special Management Issues

24. **Appropriate Approach to Prescribing** ..... 289  
*Paula A. Rochon, Jennifer Tjia, Sudeep S. Gill, and Jerry H. Gurwitz*
25. **Complementary and Alternative Medicine** ..... 303  
*Joseph T. Hanlon, Marc R. Blackman, and Ronald M. Glick*
26. **Team Care** ..... 309  
*Ellen Flaherty, Kathryn Hyer and Terry Fulmer*
27. **Social Work** ..... 317  
*Ruth E. Dunkle and Mary Catherine Dennis*
28. **Self-Management of Health Behavior in Geriatric Medicine** ..... 325  
*W. Jack Rejeski, Lawrence R. Brawley, and Mary E. Jung*
29. **Rehabilitation** ..... 343  
*Cynthia J. Brown and Claire Peel*
30. **Pain Management** ..... 359  
*Bruce A. Ferrell and Susan L. Charette*
31. **Palliative Care** ..... 373  
*Audrey Chun and R. Sean Morrison*
32. **Legal Issues** ..... 385  
*Marshall B. Kapp*
33. **Spirituality** ..... 393  
*Timothy P. Daaleman*
34. **Ethical Issues** ..... 399  
*Jason H. T. Karlawish and Bryan D. James*

### SECTION D Surgical Management

35. **Perioperative Evaluation and Management** ..... 407  
*Preeti N. Malani, Peter V. Vaitkevicius, and Mark B. Orringer*
36. **Anesthesia** ..... 417  
*Jeffrey H. Silverstein and G. Alec Rooke*
37. **Surgical Outcomes** ..... 431  
*Emily Finlayson and John D. Birkmeyer*

### SECTION E Nutrition

38. **Nutrition and Aging** ..... 439  
*Dennis H. Sullivan and Larry E. Johnson*
39. **Weight and Age: Paradoxes and Conundrums** ..... 459  
*Tamara B. Harris*
40. **Malnutrition and Enteral/Parenteral Alimentation** ... 469  
*Jeffrey I. Wallace*

41. **Disorders of Swallowing** ..... 483  
*JoAnne Robbins, Jacqueline Hind, and Steven Barczy*
42. **Oral Cavity** ..... 501  
*Jonathan A. Ship*

### SECTION F Sensory Function

43. **Assessment and Rehabilitation of Older Adults with Low Vision** ..... 511  
*Gale R. Watson*
44. **Age-Related Changes in the Auditory System** ..... 525  
*Su-Hua Sha, Andra E. Talaska, and Jochen Schacht*

### SECTION G Gender and Sexuality

45. **Sex and Gender Across the Human Life Span** ..... 535  
*William R. Hazzard*
46. **Menopause and Midlife Health Changes** ..... 557  
*MaryFran R. Sowers*
47. **Sexuality, Sexual Function, and the Aging Woman** ... 567  
*Stacy Tessler Lindau*
48. **Gynecologic Disorders** ..... 583  
*Karen L. Miller and Tomas L. Griebling*
49. **Sexuality, Sexual Function, Androgen Therapy, and the Aging Male** ..... 595  
*J. Lisa Tenover*
50. **Benign Prostate Disorders** ..... 607  
*Catherine E. DuBeau*

## Part III GERIATRIC SYNDROMES

51. **Aging and Homeostatic Regulation** ..... 621  
*George A. Kuchel*
52. **Frailty** ..... 631  
*Linda P. Fried, Jeremy D. Walston, and Luigi Ferrucci*
53. **Delirium** ..... 647  
*Sharon K. Inouye, Michael A. Fearing, and Edward R. Marcantonio*
54. **Falls** ..... 659  
*Mary B. King*
55. **Sleep Disorders** ..... 671  
*Mairav Cohen-Zion and Sonia Ancoli-Israel*
56. **Dizziness** ..... 683  
*Aman Nanda and Richard W. Besdine*
57. **Syncope** ..... 693  
*Rose Anne Kenny*
58. **Pressure Ulcers** ..... 703  
*Barbara M. Bates-Jensen*
59. **Incontinence** ..... 717  
*Theodore M. Johnson II and Joseph G. Ouslander*
60. **Elder Mistreatment** ..... 731  
*Mark S. Lachs*

## Part IV ORGAN SYSTEMS AND DISEASES

### SECTION A Human Brain

61. Cellular and Neurochemical Aspects of the Aging Human Brain ..... 739  
*Mark P. Mattson*
62. Cognitive Changes Associated with Normal and Pathological Aging ..... 751  
*Suzanne Craft, Brenna Cholerton, and Mark Reger*
63. Psychoactive Drug Therapy ..... 767  
*Bruce G. Pollock, Todd P. Semla, and Christina E. Forsyth*
64. Cerebrovascular Disease ..... 779  
*Eric Edward Smith, Ferdinand Buonanno, Aneesh Bhim Singhal, and J. Philip Kistler*
65. Dementia Including Alzheimer's Disease ..... 797  
*Cynthia M. Carlsson, Carey E. Gleason, Luigi Puglielli, and Sanjay Asthana*
66. Parkinson's Disease and Related Disorders ..... 813  
*Stanley Fahn*
67. Other Neurodegenerative Disorders ..... 823  
*Victor Valcour and Bruce Miller*
68. Traumatic Brain Injury ..... 833  
*Sterling C. Johnson*
69. Epilepsy ..... 841  
*Ilo E. Leppik*
70. Late-Life Mood Disorders ..... 849  
*Dan G. Blazer*
71. Schizophrenia ..... 859  
*Danielle L. Anderson and Peter V. Rabins*
72. General Topics in Geriatric Psychiatry ..... 865  
*Mustafa M. Husain, Shawn M. McClintock, Kip E. Queenan, Aaron Van Wright, and Rajbir Bakshi*
73. Management of Agitation in Dementia ..... 873  
*Marcella Pascualy, Eric Petrie, Lucy Y. Wang, Suzanne B. Murray, and Elaine Peskind*

### SECTION B Cardiology

74. Effects of Aging on Cardiovascular Structure and Function ..... 883  
*Dalane W. Kitzman and George Taffet*
75. Aging and Atherosclerosis ..... 897  
*Susan Cheng, Susan M. Bell, and Susan J. Zieman*
76. Coronary Heart Disease ..... 909  
*Eric D. Peterson and Shahyar M. Gharacholou*
77. Valvular Heart Disease ..... 921  
*Nikhila Deo and Niloo M. Edwards*
78. Heart Failure ..... 931  
*Michael W. Rich*
79. Cardiac Arrhythmias ..... 951  
*Xiao-Ke Liu, Arshad Jahangir, and Win-Kuang Shen*
80. Peripheral Vascular Disease ..... 967  
*Andrew W. Gardner, John D. Sorokin, and Azhar Afaq*

81. Hypertension ..... 975  
*Mark A. Supiano*

### SECTION C Respiratory System

82. Aging of the Respiratory System ..... 983  
*Paul L. Enright*
83. Chronic Obstructive Pulmonary Disease ..... 987  
*Sachin Yende, Anne B. Newman, and Don Sin*
84. Diffuse Parenchymal Lung Disease ..... 1003  
*Victor J. Thannickal and Galen B. Toews*

### SECTION D Nephrology

85. Changes in Kidney Function ..... 1009  
*Jocelyn Wiggins and Sanjeevkumar R. Patel*
86. Renal Disease ..... 1017  
*Lynn Schlanger, Jeff M. Sands, and James L. Bailey*
87. End-Stage Renal Disease ..... 1035  
*Mark L. Unruh*
88. Disorders of Fluid Balance ..... 1047  
*Myron Miller*

### SECTION E Gastroenterology

89. Effect of Aging on Gastrointestinal Function ..... 1059  
*Karen E. Hall*
90. Hepatic, Biliary, and Pancreatic Disease ..... 1065  
*Justin C. Rice, Courtney Barancin, Mark Benson, and Michael Lucey*
91. Upper Gastrointestinal Disorders ..... 1075  
*Alberto Pilotto and Marilisa Franceschi*
92. Common Large Intestinal Disorders ..... 1091  
*Leon S. Maratchi and David A. Greenwald*
93. Constipation ..... 1103  
*Danielle Harari*

### SECTION F Oncology

94. Oncology and Aging: General Principles ..... 1123  
*Arati V. Rao and Harvey Jay Cohen*
95. Breast Disease ..... 1137  
*Gretchen G. Kimmick and Hyman B. Muss*
96. Prostate Cancer ..... 1149  
*Kenneth J. Pienta*
97. Lung Cancer ..... 1159  
*Daniel Morgensztern, Ramaswamy Govindan, and Michael C. Perry*
98. Gastrointestinal Malignancies ..... 1167  
*Nadine A. Jackson and Peter C. Enzinger*
99. Intracranial Neoplasms ..... 1177  
*Noelle K. LoConte, Julie E. Chang, and H. Ian Robins*
100. Skin Cancer ..... 1183  
*Mathew W. Ludgate, Timothy M. Johnson, and Timothy S. Wang*

**SECTION G Hematology**

- 101. Aging of the Hematopoietic System** ..... 1193  
*Gurkamal S. Chatta and David A. Lipschitz*
- 102. Anemia** ..... 1201  
*Paulo H. M. Chaves*
- 103. White Cell Disorders** ..... 1215  
*Heidi D. Klepin and Bayard L. Powell*
- 104. Non-Hodgkin's and Hodgkin's Lymphomas and Myeloma** ..... 1229  
*William B. Ershler and Dan L. Longo*
- 105. Thrombosis** ..... 1243  
*Martin O'Donnell, Jeffrey S. Ginsberg, and Clive Kearon*
- 106. Hemorrhagic Disorders** ..... 1253  
*Julia A. M. Anderson and Agnes Y. Y. Lee*

**SECTION H Endocrinology and Metabolism**

- 107. Aging of the Endocrine System and Selected Endocrine Disorders** ..... 1267  
*David A. Gruenewald and Alvin M. Matsumoto*
- 108. Thyroid Diseases** ..... 1287  
*Jerome M. Hershman, Sima Hassani, and Mary H. Samuels*
- 109. Diabetes Mellitus** ..... 1305  
*Annette M. Chang and Jeffrey B. Halter*
- 110. Dyslipoproteinemia** ..... 1325  
*Leslie I. Katzel, Jacob Blumenthal, John D. Sorkin, and Andrew P. Goldberg*
- 111. Hyperparathyroidism and Paget's Disease of Bone** .. 1343  
*Kenneth W. Lyles*

**SECTION I Mobility and Musculoskeletal System**

- 112. Aging of the Muscles and Joints** ..... 1355  
*Richard F. Loeser, Jr. and Osvaldo Delbono*
- 113. Biomechanics of Mobility** ..... 1369  
*James A. Ashton-Miller and Neil B. Alexander*
- 114. Exercise: Physiologic and Functional Effects** ..... 1381  
*Robert S. Schwartz and Wendy M. Kohrt*
- 115. Mobility** ..... 1397  
*Jennifer Brach, Caterina Rosano, and Stephanie Studenski*

- 116. Osteoarthritis** ..... 1411  
*Shari M. Ling and Yvette L. Ju*
- 117. Osteoporosis** ..... 1421  
*Gustavo Duque and Bruce R. Troen*
- 118. Hip Fractures** ..... 1435  
*Ram R. Miller, Colleen Christmas, and Jay Magaziner*
- 119. Myopathy, Polymyalgia Rheumatica, and Temporal Arteritis** ..... 1445  
*Yuri R. Nakasato and Bruce A. Carnes*
- 120. Rheumatoid Arthritis and Other Autoimmune Diseases** ..... 1453  
*Raymond Yung*
- 121. Back Pain and Spinal Stenosis** ..... 1471  
*Leo M. Cooney, Jr.*

- 122. Primary Considerations in Managing the Older Patient with Foot Problems** ..... 1479  
*Arthur E. Helfand*

- 123. Fibromyalgia and Myofascial Pain Syndromes** ..... 1491  
*Cheryl D. Bernstein and Debra K. Weiner*

**SECTION J Infectious Diseases and Immunology**

- 124. Infection in the Elderly** ..... 1507  
*Kevin P. High*
- 125. General Principles of Antimicrobial Selection** ..... 1517  
*Maureen Bolon and Stephen G. Weber*
- 126. Pneumonia** ..... 1531  
*Thomas J. Marrie*
- 127. Urinary Tract Infections** ..... 1547  
*Lindsay E. Nicolle*
- 128. Human Immunodeficiency Virus Infection** ..... 1561  
*Amy C. Justice*
- 129. Herpes Zoster** ..... 1567  
*Jack I. Twersky and Kenneth Schmader*
- 130. Influenza and Respiratory Syncytial Virus** ..... 1577  
*Mark B. Loeb*

*Index* ..... 1583

*Color Plate appears between pages 772 and 773.*

## CHAPTER AUTHORS

*Numbers in brackets refer to the chapters written or co-written by the contributor*

### **Azhar Afaq, MD**

Fellow, Department of Endocrinology  
University of Oklahoma Health Sciences Center  
Oklahoma City, Oklahoma [80]

### **Steven M. Albert, PhD, MSPH**

Professor of Behavioral & Community Health Sciences  
Graduate School of Public Health  
University of Pittsburgh  
Pittsburgh, Pennsylvania [7]

### **Neil B. Alexander, MD**

Professor of Internal Medicine  
Division of Geriatric Medicine  
Director, Mobility Research Center  
Research Professor, Institute of Gerontology  
University of Michigan  
Director, VA Ann Arbor Health Care System GRECC  
Ann Arbor, Michigan [113]

### **Sonia Ancoli-Israel, PhD**

Professor of Psychiatry  
University of California, San Diego  
Director, Sleep Disorders Clinic  
VA San Diego Health System  
San Diego, California [55]

### **Danielle L. Anderson, MD**

Postdoctoral Fellow, Section of Geriatric Psychiatry and  
Neuropsychiatry  
Johns Hopkins University  
Baltimore, Maryland [71]

### **Julia A.M. Anderson, MBChB, BSc, MD, FRCP(Edin), FRCPATH**

Associate Professor, Consultant Hematologist  
Department of Clinical and Laboratory Hematology  
Royal Infirmary of Edinburgh  
Edinburgh, United Kingdom [106]

### **Derek C. Angus, MD, MPH**

Professor and Chair, Department of Critical Care Medicine  
University of Pittsburgh School of Medicine  
Pittsburgh, Pennsylvania

### **James A. Ashton-Miller, PhD**

Albert Schultz Collegiate Research Professor of  
Mechanical Engineering  
College of Engineering,  
Research Professor, Institute of Gerontology  
University of Michigan  
Ann Arbor, Michigan [113]

### **Sanjay Asthana, MD, FRCP(C)**

Duncan G. and Lottie H. Ballantine Chair in Geriatrics  
Professor and Head, Section of Geriatrics & Gerontology  
University of Wisconsin School of Medicine and Public Health  
Director, GRECC  
William S. Middleton Memorial Veterans Hospital  
Associate Director, Wisconsin Alzheimer's Institute  
Madison, Wisconsin [65]

### **James L. Bailey, MD**

Professor of Medicine, Renal Division  
Emory University School of Medicine  
Atlanta, Georgia [86]

### **Rajbir Bakshi, MD**

Assistant Professor of Psychiatry  
University of Texas Southwestern Medical Center  
Dallas, Texas [72]

### **Courtney Barancin, MD**

Instructor in Medicine  
Division of Gastroenterology and Hepatology  
University of Wisconsin  
Madison, Wisconsin [90]

**Steven Barczi, MD**

Associate Professor of Medicine  
 Director, Geriatric Medicine Fellowship  
 University of Wisconsin Medical School  
 Associate Director—Clinical  
 William S. Middleton Memorial Veterans Hospital GRECC  
 Madison, Wisconsin [41]

**Barbara Bates-Jensen, RN, PhD**

Associate Adjunct Professor of Medicine  
 Division of Geriatrics  
 Anna & Harry Borun Center for Gerontological Research  
 David Geffen School of Medicine at UCLA  
 Reseda, California [58]

**Susan M. Bell, MBBS, BSc**

Clinical Fellow, Division of Cardiovascular Medicine  
 Vanderbilt University Medical Center  
 Nashville, Tennessee [75]

**Mark Benson, MD**

Fellow, Division of Gastroenterology and Hepatology  
 Department of Medicine  
 University of Wisconsin  
 Madison, Wisconsin [90]

**Roberto Bernabei, MD**

Professor of Internal Medicine  
 Università Cattolica del Sacro Cuore  
 Dipartimento di Scienze Gerontologiche-Geriatriche e Fisiatriche  
 Roma, Italy [6]

**Cheryl D. Bernstein, MD**

Assistant Professor of Anesthesiology  
 UPMC Pain Medicine  
 University of Pittsburgh  
 Pittsburgh, Pennsylvania [123]

**Richard W. Besdine, MD, FACP, AGSF**

Professor of Medicine  
 Division of Geriatric Medicine  
 Center for Gerontology and Health Care Research  
 Brown Medical School  
 Providence, Rhode Island [56]

**John D. Birkmeyer, MD**

George D. Zuidema Professor of Surgery  
 Chair, Surgical Outcomes Research  
 University of Michigan  
 Ann Arbor, Michigan [37]

**Marc R. Blackman, MD**

Veteran's Affairs Medical Center  
 Washington, DC [25]

**Caroline Blaum, MD**

Associate Professor of Internal Medicine  
 Division of Geriatric Medicine  
 University of Michigan  
 Research Scientist, VA Ann Arbor Healthcare System GRECC  
 Ann Arbor, Michigan [17]

**Daniel G. Blazer, MD, PhD**

Professor of Psychiatry  
 Duke University Medical Center  
 Durham, North Carolina [70]

**Jacob B. Blumenthal, MD**

Assistant Professor of Medicine  
 Division of Gerontology and Geriatric Medicine  
 University of Maryland School of Medicine  
 Veteran Affairs Maryland Health Care System  
 Baltimore, Maryland [110]

**Maureen Bolon, MD, MS**

Assistant Professor of Medicine  
 Division of Infectious Diseases  
 Northwestern University Feinberg School of Medicine  
 Chicago, Illinois [125]

**Chad E. Boulton, MD, MPH, MBA**

Professor of Health Policy and Management  
 Director, Lipitz Center for Integrated Health Care  
 Johns Hopkins School of Public Health  
 Baltimore, Maryland [15]

**Jennifer S. Brach, PhD, PT, GCS**

Assistant Professor of Physical Therapy  
 University of Pittsburgh  
 Pittsburgh, Pennsylvania [115]

**Lawrence R. Brawley, PhD**

Canada Research Chair in Physical Activity in Health  
 Promotion and Disease Prevention  
 University of Saskatchewan  
 Saskatoon, Saskatchewan, Canada [28]

**Cynthia J. Brown, MD, MSPH**

Assistant Professor of Medicine  
 Division of Gerontology and Geriatric Medicine  
 University of Alabama-Birmingham  
 Birmingham, Alabama [29]

**Kenneth Brummel-Smith, MD**

Charlotte Edwards Maguire Professor and Chair  
 Department of Geriatrics  
 Florida State University  
 College of Medicine  
 Tallahassee, Florida [23]

**Ferdinand Buonanno, MD**

Assistant Professor of Neurology  
 Harvard Medical School  
 Massachusetts General Hospital  
 Stroke Service  
 Boston, Massachusetts [64]

**Cynthia M. Carlsson, MD, MS**

Assistant Professor of Medicine  
 Section on Geriatrics and Gerontology  
 University of Wisconsin School of Medicine and Public Health  
 William S. Middleton Memorial Veterans Hospital GRECC  
 Madison, Wisconsin [65]

**Bruce A. Carnes, PhD**

Professor, Donald W. Reynolds Department of Geriatric Medicine  
University of Oklahoma Health Sciences Center  
Oklahoma City, Oklahoma [119]

**Iain G. Carpenter, MD**

Professor, Centre for Health Services Studies  
University of Kent  
Canterbury, Kent, United Kingdom [6]

**Annette M. Chang, MD**

Assistant Professor of Internal Medicine  
Division of Metabolism, Endocrinology & Diabetes  
University of Michigan Health System  
VA Ann Arbor Healthcare System  
Ann Arbor, Michigan [109]

**Julie E. Chang, MD**

Assistant Professor of Medicine  
Section on Hematology/Oncology  
University of Wisconsin School of Medicine and Public Health  
Madison, Wisconsin [99]

**Susan L. Charette, MD**

Geriatric Medicine  
University of California, Los Angeles Health System  
Los Angeles, California [30]

**Gurkamal S. Chatta, MD**

Associate Professor of Medicine  
Division of Hematology-Oncology  
UPMC Cancer Institute  
University of Pittsburgh Medical Center  
Chief, Hematology-Oncology  
VA Pittsburgh Health Care System  
Pittsburgh, Pennsylvania [101]

**Paulo H.M. Chaves, MD, PhD**

Assistant Professor of Medicine  
Division of General Internal Medicine  
Core Faculty, Center on Aging and Health  
Johns Hopkins University  
Baltimore, Maryland [102]

**Susan Cheng, MD**

Fellow, Cardiovascular Medicine, Brigham and Women's  
Hospital  
Department of Medicine  
Divisions of Gerontology and Geriatric Medicine and  
Cardiovascular Medicine  
Harvard Medical School  
Boston, Massachusetts [75]

**Brenna Cholerton, MD**

Clinical Assistant Professor of Psychiatry and Behavioral  
Sciences  
University of Washington School of Medicine  
VA Puget Sound Health Care System GRECC  
Seattle, Washington [62]

**Colleen Christmas, MD**

Assistant Professor of Medicine  
Division of Geriatric Medicine  
Johns Hopkins University School of Medicine  
Baltimore, Maryland [118]

**Audrey Chun, MD**

Assistant Professor, Brookdale Department of  
Geriatrics and Adult Development  
Director, Martha Stewart Center for Living  
Mt. Sinai School of Medicine  
New York, New York [31]

**Harvey Jay Cohen, MD**

Walter Kempner Professor and Chair, Department of Medicine  
Director, Center for the Study of Aging and Human  
Development  
Duke University Medical Center  
Durham, North Carolina [94]

**Mairav Cohen-Zion, PhD**

Assistant Research Scientist, Department of Psychiatry  
University of California, San Diego  
San Diego, California [55]

**Eric A. Coleman, MD, MPH**

Professor of Medicine  
Division of Health Care Policy and Research  
University of Colorado Health Sciences Center  
Aurora, Colorado [16]

**Leo M. Cooney, Jr. MD**

Humana Foundation Professor of Medicine  
Chief, Section of Geriatric Medicine  
Yale University School of Medicine  
Yale-New Haven Hospital  
New Haven, Connecticut [121]

**Suzanne Craft, PhD**

Professor of Psychiatry and Behavioral Sciences  
University of Washington School of Medicine  
VA Puget Sound Health Care System  
Seattle, Washington [62]

**Timothy J. Daaleman, DO, MPH**

Associate Professor of Family Medicine  
Research Fellow, Program on Aging, Disability &  
Long-Term Care  
Cecil G. Sheps Center for Health Services Research  
University of North Carolina at Chapel Hill  
Chapel Hill, North Carolina [33]

**Oswaldo DelBono, MD, PhD**

Professor of Internal Medicine  
Section on Gerontology and Geriatric Medicine  
Wake Forest University School of Medicine  
Winston-Salem, North Carolina [112]

**Mary Catherine Dennis, MSW**

Doctoral Candidate, Joint Program in Social Work  
and Social Science  
School of Social Work  
University of Michigan  
Ann Arbor, Michigan [27]

**Nikhila Deo, BS, MEng**

University of Wisconsin School of Medicine and Public Health  
Madison, Wisconsin [77]

**Margaret A. Drickamer, MD**

Associate Professor of Medicine  
Section of Geriatric Medicine  
Yale University School of Medicine  
New Haven, Connecticut [13]

**Catherine E. DuBeau, MD**

Professor of Medicine  
Section of Geriatrics  
Director, Geriatric Continence Clinic  
University of Chicago  
Chicago, Illinois [50]

**Ruth E. Dunkle, PhD**

Wilbur J. Cohen Collegiate Professor of Social Work  
School of Social Work  
University of Michigan  
Ann Arbor, Michigan [27]

**Gustavo Duque, MD, MPH**

Associate Professor of Medicine  
Head of the Discipline of Geriatric Medicine  
Director of the Aging Bone Research Program at Nepean  
Clinical School  
University of Sydney  
Sydney, Australia [117]

**Niloo M. Edwards, MD**

Professor and Chairman, Division of Cardiothoracic Surgery  
University of Wisconsin School of Medicine and Public Health  
Madison, Wisconsin [77]

**Paul L. Enright, MD**

Professor of Medicine  
College of Public Health  
University of Arizona  
Tucson, Arizona [82]

**Peter C. Enzinger, MD**

Instructor in Medicine  
Harvard Medical School  
Boston, Massachusetts [98]

**William B. Ershler, MD**

Deputy Clinical Director  
National Institute on Aging  
Baltimore, Maryland [104]

**Stanley Fahn, MD**

Professor of Neurology  
Neurological Institute  
Columbia University Medical Center  
New York, New York [66]

**Michael A. Fearing, PhD**

Research Fellow, Aging Brain Center  
Institute for Aging Research  
Harvard Medical School  
Boston, Massachusetts [53]

**Bruce A. Ferrell, MD**

Professor of Clinical Medicine  
Division of Geriatrics  
UCLA David Geffen School of Medicine  
Los Angeles, California [30]

**Luigi Ferrucci, MD, PhD**

Director, Baltimore Longitudinal Study of Aging  
National Institute on Aging  
Baltimore, Maryland [5] [52]

**Emily Finlayson, MD, MS**

Assistant Professor of Surgery  
Division of Colon & Rectal Surgery  
University of Michigan  
Ann Arbor, Michigan [37]

**Ellen Flaherty, PhD, APRN, BC**

Vice President for Quality Improvement  
Village Care of New York  
New York, New York [26]

**Scott A. Flanders, MD**

Associate Professor of Medicine  
University of Michigan  
Ann Arbor, Michigan [17]

**Gary A. Ford, MB, BCh**

Professor of Pharmacology of Old Age  
Director, Clinical Research Centre  
School of Clinical & Laboratory Sciences  
University of Newcastle upon Tyne  
Newcastle upon Tyne, United Kingdom [8]

**Christina E. Forsyth, HSc**

Rotman Research Institute at Baycrest  
Toronto, Ontario, Canada [63]

**Marilisa Franceschi, MD**

Research Fellow Istituto di Ricovero e Cura a  
Carattere Scientifico (IRCCS)  
Casa Sollievo della Sofferenza Hospital  
San Giovanni Rotondo, Italy [91]

**Linda P. Fried, MD, MPH**

Dean and DeLamar Professor of Public Health  
Professor of Epidemiology and Medicine  
Senior Vice President, Columbia University Medical Center  
New York, New York [52]

**Brant E. Fries, PhD**

Professor of Health Management and Policy  
School of Public Health  
Research Professor, Institute of Gerontology  
University of Michigan  
Chief, Health System Research  
VA Ann Arbor Healthcare System GRECC  
Ann Arbor, Michigan [6]

**Terry Fulmer, PhD, RN, FAAN**

Dean of the College of Nursing and the Erline  
Perkins McGriff Professor  
New York University  
New York, New York [26]

**James Galvin, MD, MPH**

Associate Professor of Neurology, Psychiatry and Neurobiology  
Director, Memory Diagnostic Center  
Hope Center for Neurological Disorders  
Washington University School of Medicine  
St. Louis, Missouri [12]

**Giovanni Gambassi, MD**

Associate Professor, Centro Medicina dell'Invecchiamento  
Universita Cattolica del Sacro Cuore  
Rome, Italy [6]

**Andrew W. Gardner, PhD**

CMRI Hobbs-Rechnagel Professor  
General Clinical Research Center  
University of Oklahoma Health Sciences Center  
Oklahoma City, Oklahoma [80]

**Lowell W. Gerson, PhD**

Professor Emeritus of Epidemiology  
Department of Community Health Sciences  
Northeastern Ohio Universities College of Medicine  
Senior Scientist, Emergency Medicine Research Center  
Bonita Springs, Florida [18]

**Shahyar M. Gharacholou, MD**

Fellow, Divisions of Geriatrics and Cardiology  
Duke University Medical Center  
Durham, North Carolina [76]

**Sudeep S. Gill, MD, MSc, FRCPC**

Assistant Professor of Medicine  
Queens University, St. Mary's of the Lake Hospital  
Kingston, Ontario, Canada [24]

**Jeffrey Ginsberg, MD**

Professor of Medicine  
Division of Hematology and Thromboembolism  
McMaster University  
Hamilton, Ontario, Canada [105]

**Cary E. Gleason, PhD**

Senior Scientist, Department of Medicine  
Section of Geriatrics and Gerontology  
University of Wisconsin School of Medicine and Public Health  
William S. Middleton Memorial Veterans Hospital GRECC  
Madison, Wisconsin [65]

**Ronald M. Glick, MD**

Assistant Professor of Psychiatry and Physical Medicine and  
Rehabilitation  
Medical Director, Center for Integrative Medicine  
University of Pittsburgh Medical Center  
Pittsburgh, Pennsylvania [25]

**Andrew P. Goldberg, MD**

Professor of Medicine, Division of Gerontology  
University of Maryland School of Medicine  
Director, GRECC, Baltimore VA Maryland Health Care System  
Baltimore, Maryland [110]

**Ramaswamy Govidan, MD**

Associate Professor of Medicine, Division of Oncology  
Washington University School of Medicine  
St. Louis, Missouri [97]

**Len Gray, MB, BS, MMed, PhD, FRACP**

Professor of Geriatric Medicine  
Department of Medicine  
University of Queensland  
Princess Alexandra Hospital  
Woolloongabba, Australia [6]

**David A. Greenwald, MD**

Associate Professor of Clinical Medicine  
Division of Gastroenterology  
Montefiore Medical Center  
Bronx, New York

**Tomas Griebling, MD**

Associate Professor and Vice Chair of Urology  
Assistant Scientist, Center on Aging  
University of Kansas School of Medicine  
Kansas City, Kansas [48]

**Professor Beatrix Grubeck-Loebenstein**

Director, Institute for Biomedical Aging Research  
Austrian Academy of Sciences, Immunology Division  
Innsbruck, Austria [3]

**David A. Gruenewald, MD**

Associate Professor of Medicine  
University of Washington School of Medicine  
VA Puget Sound Health Care System  
Seattle, Washington [107]

**Jack M. Guralnik, MD, PhD**

Senior Investigator  
Chief, Epidemiology and Demography Section  
National Institute on Aging  
Bethesda, Maryland [5]

**Jerry H. Gurwitz, MD**

Executive Director, Myers Primary Care Institute  
University of Massachusetts  
Worcester, Massachusetts [24]

**Karen E. Hall, MD, PhD**

Associate Professor of Internal Medicine  
 Division of Geriatric Medicine  
 University of Michigan Health System  
 Research Scientist, GRECC  
 Ann Arbor VAMC  
 Ann Arbor, Michigan [89]

**Jeffrey B. Halter, MD**

Professor of Internal Medicine  
 Chief, Division of Geriatric Medicine  
 Director, Geriatrics Center and Institute of Gerontology  
 University of Michigan  
 Ann Arbor, Michigan [109]

**Joseph T. Hanlon, PharmD, MS**

Professor of Medicine, Division of Geriatrics  
 Research Health Scientist  
 University of Pittsburgh  
 Pittsburgh, Pennsylvania [25]

**Danielle Harari, MB, BS**

Consultant Physician & Clinical Lead in Elderly Medicine  
 Honorary Senior Lecturer (KCL)  
 Department of Ageing and Health  
 St. Thomas' Hospital  
 London, England [93]

**Tamara B. Harris, MD, MS**

Senior Investigator and Chief, Geriatrics Epidemiology Section  
 Laboratory of Epidemiology, Demography, and Biometry  
 Intramural Research Program  
 National Institute on Aging  
 Bethesda, Maryland [39]

**Rowan H. Robins Harwood, MSc, MD**

Professor, Community Health Sciences  
 Nottingham City Hospital  
 Nottingham, United Kingdom [6]

**Sima R. Hassani, DO**

Clinical Instructor in Medicine  
 David Geffen School of Medicine at UCLA  
 Kaiser Permanente Medical Center  
 Woodland Hills, California [108]

**Jennifer Hayashi, MD**

Assistant Professor of Medicine  
 Johns Hopkins University School of Medicine  
 Baltimore, Maryland [22]

**William R. Hazzard, MD**

Professor of Medicine  
 University of Washington  
 Director, Geriatrics and Extended Care  
 VA Puget Sound Health Care System  
 Seattle, Washington [9][45]

**Arthur E. Helfand, DPM**

Professor Emeritus and Retired Chair  
 Department of Community Health, Aging & Health Policy  
 Temple University School of Podiatric Medicine  
 Narbeth, Pennsylvania [122]

**Jean Claude Henrard, MD**

Professor, Centre de Gerontologie  
 Hospital Sainte Perine  
 Paris, France [6]

**Jerome M. Hershman, MD, MACP**

Distinguished Professor of Medicine  
 David Geffen School of Medicine at UCLA  
 VA Greater Los Angeles Healthcare System  
 Los Angeles, California [108]

**Kevin P. High, MD, MS, FACP**

Professor of Medicine, Sections on Infectious Diseases,  
 Hematology/Oncology and Molecular Medicine  
 Chief, Section on Infectious Diseases  
 Wake Forest University Health Sciences  
 Winston-Salem, North Carolina [124]

**Sarah N. Hilmer, PhD, FRACP**

Senior Lecturer in Medicine  
 Department of Clinical Pharmacology and Aged Care  
 University of Sydney, Royal North Shore Hospital  
 St. Leonards, New South Wales, Australia [8]

**Jacqueline Hind, MS, CCC-LP, BRS-S**

Outreach Program Manager  
 University of Wisconsin School of Medicine and Public Health  
 William S. Middleton Memorial VA Hospital  
 Madison, Wisconsin [41]

**John Hirdes, PhD**

Professor of Health Studies and Gerontology  
 University of Waterloo  
 Waterloo, Ontario, Canada [6]

**Mustafa M. Husain, MD**

Professor of Psychiatry and Internal Medicine  
 Chief, Division of Geriatric Psychiatry  
 University of Texas Southwestern Medical Center  
 Dallas, Texas [72]

**Kathryn Hyer, PhD, MPP**

Associate Professor, School of Aging Studies  
 Florida Policy Exchange Center on Aging  
 University of South Florida  
 Tampa, Florida [26]

**Naoki Ikegami, MD**

Professor and Chair of Health Policy and Management  
 Keio University School of Medicine  
 Shinjuku-ku, Tokyo, Japan [6]

**Sharon K. Inouye, MD, MPH**

Professor of Medicine  
Harvard Medical School  
Beth Israel Deaconess Medical Center  
Institute for Aging Research  
Roslindale, Massachusetts [53]

**Nadine A. Jackson, MD, MPH**

Clinical Fellow, Medical Oncology  
Dana-Farber Cancer Institute  
Boston, Massachusetts [98]

**Arshad Jahangir, MD**

Associate Professor of Medicine  
Mayo Clinic  
Scottsdale, Arizona [79]

**Brian D. James, M Bioethics**

Center on Aging and Health  
Johns Hopkins Bloomberg School of Public Health  
Baltimore, Maryland [34]

**Larry E. Johnson, MD, PhD**

Associate Professor of Geriatrics & Family and Preventive  
Medicine  
University of Arkansas for Medical Sciences  
Central Arkansas Veteran's Healthcare System  
North Little Rock VA Hospital  
North Little Rock, Arkansas [38]

**Sterling C. Johnson, PhD**

Associate Professor of Medicine  
University of Wisconsin School of Medicine and Public Health  
William S. Middleton Memorial Veterans Hospital  
Madison, Wisconsin [68]

**Theodore M. Johnson, II, MD, MPH**

Associate Professor of Medicine  
Emory University  
Manager, Geriatrics and Extended Care Service Line  
Atlanta VA Medical Center  
Decatur, Georgia [59]

**Timothy M. Johnson, MD**

Lewis and Lillian Becker Professor of Dermatology  
University of Michigan  
Ann Arbor, Michigan [100]

**Palmi V. Jonsson, MD, FACP**

Professor and Chief of Geriatrics  
Landspítali University Hospital  
University of Iceland School of Medicine  
Reykjavik, Iceland [6]

**Yvette L. Ju, DO**

Intramural Research Program  
National Institute on Aging  
Bethesda, Maryland [116]

**Mary E. Jung, MSc**

University of Saskatchewan  
Saskatoon, Saskatchewan, Canada [28]

**Amy C. Justice, MD, PhD**

Associate Professor of Medicine  
Yale University School of Medicine  
Chief, Section of General Medicine  
West Haven VA Healthcare System  
West Haven, Connecticut [128]

**Marshall B. Kapp, JD, MPH, FCLM**

Garwin Distinguished Professor of Law & Medicine  
Co-Director, Center for Health Law & Policy  
Southern Illinois University School of Law  
Carbondale, Illinois [32]

**Jason H.T. Karlawish, MD**

Professor of Medicine  
Ralston-Penn Center  
University of Pennsylvania  
Philadelphia, Pennsylvania [34]

**Leslie I. Katzel, MD, PhD**

Associate Professor of Medicine  
Division of Gerontology and Geriatric Medicine  
University of Maryland School of Medicine  
Associate Director, Clinical  
Veteran Affairs Maryland Health Care System GRECC  
Baltimore, Maryland [110]

**Clive Kearon, MB, MRCP (I), FRCP (C), PhD**

Professor of Medicine  
McMaster University  
Head, Clinical Thrombosis Service  
Henderson General Hospital  
Hamilton, Ontario, Canada [105]

**Rose Anne Kenny, MD, FRCPI, FRCP**

Professor, Geriatric Medicine/Consultant  
Medical Gerontology  
Trinity Centre, St. James Hospital  
Trinity College Dublin, College Green  
Dublin, Ireland [57]

**Gretchen G. Kimmick, MD, MS**

Associate Professor of Medicine  
Division of Medical Oncology  
Duke University Medical Center  
Durham, North Carolina [95]

**Mary B. King, MD**

Assistant Professor of Clinical Medicine  
University of Connecticut School of Medicine  
Hartford Hospital Geriatric Program  
Hartford, Connecticut [54]

**Thomas B.L. Kirkwood, PhD**

Professor of Medicine and Institute Director  
 Institute for Aging and Health  
 Newcastle University  
 Newcastle upon Tyne, United Kingdom [2]

**J. Philip Kistler, MD**

Professor of Neurology  
 Harvard Medical School  
 Director, Stroke Service  
 Massachusetts General Hospital  
 Boston, Massachusetts [64]

**Dalane W. Kitzman, MD**

Professor of Internal Medicine  
 Sections on Cardiology and Gerontology and Geriatric Medicine  
 Wake Forest University Health Sciences  
 Winston-Salem, North Carolina [74]

**Heidi D. Klepin, MD**

Assistant Professor of Internal Medicine  
 Section on Hematology and Oncology  
 Wake Forest University Health Sciences  
 Winston-Salem, North Carolina [103]

**Wendy M. Kohrt, PhD**

Professor of Medicine, Division of Geriatrics  
 University of Colorado Denver  
 Aurora, Colorado [114]

**George A. Kuchel, MD, FRCP**

Professor of Medicine  
 Travelers Chair in Geriatrics and Gerontology  
 Director, UConn Center on Aging  
 Chief, Division of Geriatric Medicine  
 University of Connecticut Health Center  
 Farmington, Connecticut [51]

**Mark S. Lachs, MD, MPH**

Professor of Medicine  
 Co-Director, Division of Geriatric Medicine and Gerontology  
 Weill Medical College of Cornell University  
 New York, New York [60]

**James M. Lai, MD**

Postdoctoral Fellow, Section of Geriatrics  
 Yale University School of Medicine  
 New Haven, Connecticut [13]

**Agnes Y.Y. Lee, MD, MSc, FRCPC**

Associate Professor of Medicine  
 Division of Hematology and Thromboembolism  
 Medical Director, Thrombosis Program  
 McMaster University  
 Hamilton, Ontario, Canada [106]

**Bruce Leff, MD**

Associate Professor of Medicine  
 Johns Hopkins University School of Medicine  
 Baltimore, Maryland [22]

**Ilo E. Leppik, MD**

Professor of Neurology  
 University of Minnesota School of Medicine  
 MINCEP Epilepsy Care  
 Minneapolis, Minnesota [69]

**Stacy Tessler Lindau, MD, MAPP**

Assistant Professor  
 Departments of Obstetrics and Gynecology and  
 Medicine-Geriatrics  
 Chicago Core on Biomeasures in Population Based  
 Health and Aging Research  
 University of Chicago  
 Chicago, Illinois [47]

**Shari M. Ling, MD**

Staff Clinician, Clinical Research Branch  
 Translational Research and Medical Services Section  
 National Institute on Aging  
 Baltimore, Maryland [116]

**David A. Lipschitz, MD, PhD**

Longevity Center-St Vincent Senior Health  
 Little Rock, Arkansas [101]

**XiaoKe Liu, MD**

Heart Center for Excellence  
 Kalamazoo, Michigan [79]

**Noelle K. LoConte, MD**

Assistant Professor of Medicine  
 Section of Hematology/Oncology  
 University of Wisconsin School of Medicine and Public Health  
 Madison, Wisconsin [99]

**Mark B. Loeb, MD**

Professor of Pathology and Molecular Medicine and of Clinical  
 Epidemiology and Biostatistics  
 McMaster University  
 Hamilton, Ontario, Canada [130]

**Richard F. Loeser, Jr., MD**

The Dorothy Rhyne Kimbrell and Willard Duke Kimbrell  
 Professor of Arthritis and Rheumatology  
 Chief, Section on Molecular Medicine  
 Wake Forest University Health Sciences  
 Winston-Salem, North Carolina [112]

**Dan L. Longo, MD**

Scientific Director  
 National Institute on Aging  
 Baltimore, Maryland [104]

**Michael Lucey, MD**

Professor of Medicine  
 Head, Section of Gastroenterology and Hepatology  
 University of Wisconsin School of Medicine and Public Health  
 Madison, Wisconsin [90]

**Mathew W. Ludgate, MB, ChB**

Lecturer, Department of Dermatology  
University of Michigan  
Ann Arbor, Michigan [100]

**Kenneth W. Lyles, MD**

Professor of Medicine  
Vice-Chair for Clinical Research  
Duke University Medical Center  
VA Medical Center  
Durham, North Carolina [111]

**William L. Lyons, MD**

Assistant Professor of Internal Medicine  
Section of Geriatrics and Gerontology  
University of Nebraska Medical Center  
Omaha, Nebraska [16]

**Jay Magaziner, PhD, MSHyg**

Professor and Director, Division of Gerontology  
Department of Epidemiology and Preventive Medicine  
University of Maryland School of Medicine  
Baltimore, Maryland [118]

**Preeti N. Malani, MD**

Assistant Professor of Internal Medicine  
Divisions of Geriatric Medicine and Infectious Diseases  
University of Michigan Health System  
Veterans Affairs Ann Arbor Healthcare System  
Ann Arbor, Michigan [35]

**Leon S. Maratchi, MD**

Gastroenterology Consultants, P.A. – Hollywood  
Hollywood, Florida

**Edward R. Marcantonio, MD, SM**

Associate Professor of Medicine  
Harvard Medical School  
Director of Research, Division of General Medicine and  
Primary Care  
Beth Israel Deaconess Medical Center  
Brookline, Massachusetts [20][53]

**Thomas J. Marrie, MD**

Professor of Medicine  
Dean, Faculty of Medicine and Dentistry  
University of Alberta  
Edmonton, Alberta, Canada [126]

**Alvin M. Matsumoto, MD**

Professor of Medicine  
University of Washington School of Medicine  
Associate Director, GRECC  
VA Puget Sound Health Care System  
Seattle, Washington [107]

**Mark P. Mattson, PhD**

Gerontology Research Center  
National Institute on Aging  
Baltimore, Maryland [61]

**Shawn M. McClintock, PhD**

Postdoctoral Fellow, Department of Psychiatry  
University of Texas Southwestern Medical Center  
Dallas, Texas [72]

**Eric B. Milbrandt, MD, MPH, FCCP**

Assistant Professor, CRISMA Laboratory  
Department of Critical Care Medicine  
University of Pittsburgh School of Medicine  
Pittsburgh, Pennsylvania [19]

**Myron Miller, MD**

Professor of Medicine  
Johns Hopkins University School of Medicine  
Baltimore, Maryland [88]

**Bruce Miller, MD**

Professor of Neurology  
Director, UCSF Alzheimer's Disease Research Center  
University of California, San Francisco  
San Francisco, California [67]

**Karen L. Miller, MD**

Associate Professor of Obstetrics and Gynecology  
University of Utah  
Salt Lake City, Utah [48]

**Ram R. Miller, MD, CM**

Assistant Professor  
Epidemiology and Preventive Medicine  
University of Maryland School of Medicine  
Baltimore, Maryland [118]

**Richard A. Miller, PhD**

Professor of Pathology  
Associate Director, Geriatric Center  
University of Michigan  
Investigator, VA Ann Arbor, GRECC  
Ann Arbor, Michigan [1]

**Daniel Morgensztern, MD**

Assistant Professor of Medicine  
Section on Medical Oncology  
Washington University School of Medicine  
St. Louis, Missouri [97]

**John N. Morris, PhD**

Co-Director, Hebrew Senior Life Institute for Aging Research  
The Alfred A. and Gilda Slifka Chair in Social Gerontological  
Research  
Harvard Medical School  
Boston, Massachusetts [6]

**R. Sean Morrison, MD**

Director, National Palliative Care Research Center  
Hermann Merkin Professor of Palliative Care  
Professor of Geriatrics and Medicine  
Brookdale Department of Geriatrics and Adult Development  
Mt. Sinai School of Medicine  
New York, New York [31]

**Suzanne B. Murray, MD**

Assistant Professor of Psychiatry and Behavioral Sciences  
University of Washington School of Medicine  
Seattle, Washington [73]

**Hyman B. Muss, MD**

Professor of Medicine  
University of Vermont and Vermont Cancer Center  
Burlington, Vermont [95]

**Yuri R. Nakasato, MD, MBA**

Assistant Professor of Rheumatology and Geriatrics  
Department of Rheumatology  
University of North Dakota  
MeritCare Health Systems  
Fargo, North Dakota [119]

**Aman Nanda, MD**

Assistant Professor of Medicine  
Division of Geriatrics  
Rhode Island Hospital  
Brown Medical School  
Providence, Rhode Island [56]

**Anne B. Newman, MD, MPH**

Professor of Epidemiology and Medicine  
Director, Center for Aging and Population Health  
University of Pittsburgh  
Pittsburgh, Pennsylvania [83]

**Lindsay E. Nicolle, MD**

Professor of Medicine and Medical Microbiology  
University of Manitoba  
Winnipeg, Manitoba, Canada [127]

**Martin O'Donnell, MB, PhD, MRCPI**

Associate Professor of Medicine  
McMaster University  
Hamilton General Hospital  
Hamilton, Ontario, Canada [105]

**Graziano Onder, MD, PhD**

Assistant Professor, Centro Medicina dell'Invecchiamento  
Universita Cattolica del Sacro Cuore  
Rome, Italy [6]

**Mark B. Orringer, MD**

John Alexander Distinguished Professor of Thoracic Surgery  
Head, Department of Thoracic Surgery  
University of Michigan  
Ann Arbor, Michigan [35]

**Joseph G. Ouslander, MD**

Professor and Associate Dean for Geriatric Programs  
Charles E. Schmidt College of Biomedical Science  
Professor (Courtesy), Christine E. Lynn College of Nursing  
Florida Atlantic University  
Professor of Medicine (Voluntary)

# Foreword

Publication of the 6<sup>th</sup> edition marks an important milestone in the evolution of this work-in-progress—passing the baton from the last of the original editors to a new (albeit thoroughly seasoned) group from the next generation of geriatricians and gerontologists, expanded now to 6 under the senior leadership of Jeffrey Halter, who bring the latest and the best in this growing field to students and practitioners of our discipline on behalf of the aging patients we serve.

This orderly succession gives me an enormous sense of pride and confidence that the progressive maturation of this textbook over the first 5 editions will continue unabated for the foreseeable future. From the outset this has been buttressed by the unflagging commitment to our field demonstrated by McGraw-Hill since this project was but a gleam in the eye of Derek Jeffers, senior publisher's editor for *Harrison's Principles of Internal Medicine*. In the late 1970s he conceived it as an important and timely initiative on behalf of our new field to bring students and practitioners up to modern standards in caring for the already burgeoning numbers of elderly patients. He first enlisted the collaboration of Edwin L. Bierman, who had recently added Gerontology to his title as head of the Division of Metabolism in the Department of Medicine at the University of Washington, to develop a new textbook for our field to serve as a companion to *Harrison's* and the first such American contribution in this discipline. Ed, mentor from metabolism fellowship days at the University of Washington, turned in rapid order first to his long-time friend and colleague, Reubin Andres, clinical director of the Gerontology Research Center (GRC) of the National Institute on Aging in Baltimore, to serve as senior editor and soon thereafter to me, as a junior member of his division, to join in a tripartite effort to launch the first edition of the *Principles of Geriatric Medicine and Gerontology*. This came to fruition over the next 5 years, during which I moved to Baltimore to join the Department of Medicine at Johns Hopkins as vice-chairman and to develop a new Geriatric program based principally at the East Baltimore (now Hopkins Bayview) campus that was the site of the GRC. And with the steady support of Jeffers and the editorial assistance of Ellen Hazzard, in 1985 the first edition was published, receiving favorable reviews and an enthusiastic reception from members of our still fledgling field.

Encouraged by this promising beginning, the accelerating pace of progress in aging research, and the recognition of Geriatrics as a legitimate, scientifically-based medical discipline (and by the thousands of practitioners and fellows who were certified through the first examination developed as a joint effort by the American Board of Internal Medicine and the American Board of Family Practice in 1988), we proceeded to assemble the 2<sup>nd</sup> edition as an expanded volume, notably through the contributions of a fourth editor for the neural sciences (John Blass), and a section devoted to the Geriatric Syndromes, which was published in 1990. With its solid reputation established, the 3<sup>rd</sup> edition (with Nancy Woolard as editorial assistant) followed in 1994, with additional editors in Jeffrey Halter (another endocrinologist turned geriatrician) and Walter H. Ettinger, Jr. (a rheumatologist but also the first fellowship-trained geriatrician on the panel), and the first turnover on the editorial board in the retirement of Andres from the panel. The 4<sup>th</sup> edition was published in 1999 with Joseph Ouslander, another trained geriatrician, succeeding Ed Bierman following his death in 1995. Subsequently, as Ettinger left the board, he was succeeded by Mary Tinetti, another card-carrying geriatrician, and the 5<sup>th</sup> edition was published in 2003. A token of appreciation given to all contributors to the 5<sup>th</sup> edition visually summarized this history of the *Principles of Geriatric Medicine and Gerontology*: a photograph on a mouse pad of the first five volumes standing between the book-ends that exemplify the enduring philosophy of editions of this textbook: our enduring commitment to aging, both “successful” and “usual” (Figure 1), portraying a striving runner on one end symbolizing the price and rewards of a robust old age while on the other end the discouraged, frail old person to whom much of our professional effort is devoted with heart, mind, and soul.

Now with the publication of the 6<sup>th</sup> edition in 2009 the editorial succession is complete as the last members of the early boards leave with the retirement of John Blass and my “promotion” to emeritus status, Jeffrey Halter assumes the reins of leadership, and three vigorous new members join to expand and broaden the effort: Sanjay Asthana, a geriatrician with primary professional expertise in the neural sciences (notably Alzheimer's Disease and related disorders); Kevin High, an infectious disease subspecialist with broad interests and ties in subspecialty internal medicine and

**FIGURE 1.**

geriatrics; and Stephanie Studenski, a geriatrician and rheumatologist/rehabilitation specialist.

I am proud to remain associated with this tradition of excellence and I am entirely confident that the solid principles upon which this textbook were founded will assuredly remain undiminished with the strong support of James Shanahan at McGraw-Hill and the leadership of the board of editors of the 6<sup>th</sup> edition:

- To publish a timely, comprehensive, state-of-the-art textbook as an icon and practical, day-to-day tool of our discipline that is anchored in science, evidence-based medicine, and the balanced, patient-centered practice of our specialty.

- To focus our information and our chapters upon the learning needs of those who will lead our field as it continues to evolve and its scientific underpinnings become evermore secure and comprehensive: most clearly the fellows in training who will become the future practitioners, researchers, and educators in this rapidly advancing field and whose contributions will be leveraged maximally among the broad array of students and practitioners whom they instruct and with whom they collaborate.
- To hold our aging and elderly patients squarely in the center of our vision for the future of our field, for they are and always will be the *raison d'être* of our discipline.

William R. Hazzard  
2009

# Preface

On behalf of the Editors, it is an honor and privilege to provide this Preface to *Hazzard's Geriatric Medicine and Gerontology*, 6<sup>th</sup> Edition. In an accompanying Foreword for the 6<sup>th</sup> edition, Bill Hazzard provides a brief history of this textbook, which has become a mainstay of the rapidly developing field of geriatric medicine. Adding to the already rich history of this book, first published in 1985, the 6<sup>th</sup> edition emerges renewed and vibrant. It is particularly special that it is the first edition of this textbook to carry the name of its founding editor Bill Hazzard in its title. What we and our publisher McGraw-Hill have done is to simply formalize the reality of the imprint that Bill Hazzard has made, as the textbook has been known informally as Hazzard's Textbook already for many years.

The 6<sup>th</sup> edition is substantially different from its predecessors, reflecting the substantial growth and increasing sophistication of geriatrics as a defined medical discipline. The main sections of this edition have been reorganized to make the sections more functionally aligned. Vitality and continued rejuvenation has been enhanced through the addition of 9 new chapters: Inflammation and Aging, International Gerontology, General Principles of Pharmacology, Transitions (of care), Emergency Room Care, Rural Aging, Social Work, Psychoactive Drug Therapy, and Appropriate Antibiotic Use. Furthermore, we have recruited new authors for over 40% of the chapters. As Bill Hazzard has outlined in his Foreword, three new editors have played a critical role in the renewal of this textbook: Sanjay Asthana, Kevin High and Stephanie Studenski. They have joined me (my 4<sup>th</sup> edition), Joe Ouslander (his 3<sup>rd</sup> edition) and Mary Tinetti (her 2<sup>nd</sup> edition) to make a vital new editorial team. Fortunately for all of us, Bill Hazzard has stayed actively involved as Editor Emeritus and Senior Advisor.

The 6<sup>th</sup> edition acknowledges and recognizes the worldwide growth of the field of geriatric medicine in several ways. A distinguished International Advisory Board has been created; the previously mentioned, new chapter on International Gerontology summarizes a number of important issues around the world; and we are very pleased that 11 of the chapters in the 6<sup>th</sup> edition have been written by authors who are in countries outside of the United States. Overall, our authors are a large and diverse group including many geriatricians but also a substantial number of other specialists, who come from a range of medical and surgical disciplines. In addition

multiple health professions and disciplines are represented among the authors. Two of the textbook's editors are women, and nearly 30% of the lead authors of chapters, as well as many other co-authors, are women.

A major step forward is the online version of the 6<sup>th</sup> edition. One of the original goals of working with McGraw-Hill as the publisher of this textbook, as described in Bill Hazzard's Foreword, was to provide a link with *Harrison's Principles of Internal Medicine*. While there have been a number of parallels with Harrison's over previous editions, the link becomes substantial with the online version of *Hazzard's Geriatric Medicine and Gerontology*, 6<sup>th</sup> Edition. Both Harrison's Online and Hazzard's are part of McGraw-Hill's Access Medicine, a comprehensive online resource for medical students, residents, clinicians, and researchers. In addition to Harrison's Online and Hazzard's, Access Medicine includes the ability to quickly search across more than 50 titles from McGraw-Hill's Clinical and Lange Libraries. There are a number of important implications of our textbook becoming a part of McGraw-Hill's Access Medicine. First, it adds a living presence to the textbook as additional material can be added as needed as online updates. We anticipate that such updates will be available for many chapters of the textbook on a regular basis. We are especially pleased that students of the health professions, both undergraduate and postgraduate, will have full access to our textbook through the online version if they are at an institution that subscribes to Access Medicine. Finally, our authors are no longer encumbered by page limits for the published text. Additional complementary material and illustrations, as well as educational materials, can now be made available through the online edition.

Thus just as our population is inexorably aging, and medicine is faced with an ever growing number of older patients with multiple and complex problems, we have been able to bring together the best minds and leaders in the field to provide authoritative guidance, including a highly diverse and breadth of thinking that has not previously existed in our textbook of geriatric medicine. We hope to reach a broader audience through the availability of the electronic version of the textbook and to keep it a living and growing document that encompasses the rapid stream of new information which is helping us to provide an evidence base for more effective care for our elderly population.

Putting together a textbook of this magnitude requires enormous effort by many people. Again on behalf of the editors, I wish to particularly thank the many chapter authors who have contributed to the book. Their dedication and commitment is exemplified by Jonathan Ship, whose untimely death in 2008 is a major loss to the field of geriatric dentistry. Jonathan wrote the Oral Cavity chapter for the last three editions. Because it has become a classic, I asked Jonathan if he would be willing to revise and update the chapter for the 6<sup>th</sup> edition. We both knew that he had a terminal diagnosis and would not likely live to see the final publication. However, I was not surprised when Jonathan immediately accepted the invitation to revise his chapter, which he did with his usual vigorous and thorough effort. A little bit of Jonathan thus lives on in the 6<sup>th</sup> edition.

The editors also greatly appreciate the strong and effective working relationship that we have with McGraw-Hill. This relationship

is made possible by the outstanding efforts of James Shanahan and colleagues who have ensured the progress of the publication and the important next steps in the textbook's evolution. We especially appreciate the efforts of Nancy Woolard from Wake Forest University School of Medicine, who has served as a senior editorial assistant for four previous additions. Her role has been critical to provide a strong link to our past history and as the final common pathway for assembly of the 6<sup>th</sup> edition. We also wish to acknowledge the staff that provided support for editorial efforts from our academic offices. These include Jane Harlow and Beverly Williams at the University of Michigan, Jane Mallory at Yale University, Lori Hasse at the University of Wisconsin, Sheila Rutledge at Wake Forest University, and Susan Ratliff at Emory University.

I  
PART

# PRINCIPLES OF GERONTOLOGY

*This page intentionally left blank*

# Biology of Aging and Longevity

*Richard A. Miller*

Aging is the process that converts young adults, most of them healthy and in no need of assistance from physicians, into older adults whose deteriorating physiological fitness leads to progressively increasing risks of illness and death. The effects of aging are so familiar to health professionals and aging adults that it is viewed by both parties as something immutable, taken for granted, an arena in which diseases and their treatments take place, but not itself subject to intervention or modulation. The major discovery in biogerontology, gradually emerging from decades of work in animal model systems, is that this old-fashioned viewpoint is wrong, and that the aging process can be delayed or decelerated in mammals, built very much like human beings, by simple manipulations of nutritional signals and genetic circuits similar to those already well-documented in people. It is now absolutely routine to extend lifespan, in rats and mice, by about 40%, i.e., about 10 times the increase in active life expectancy that would ensue from a complete elimination of all neoplastic illnesses, or all heart attacks, in a human population. It thus seems plausible that a more detailed understanding of the factors that determine aging and the processes by which aging increases the risk of such a wide range of lethal and nonlethal illnesses and disabilities could, in the foreseeable future, have a profound impact on preventive medicine.

Aging is a mystery, in the same sense that infectious disease was once a mystery, and consciousness still is: an area of investigation in which well-informed researchers cannot really be confident that they have selected a line of investigation bound to be productive. Until recently, most published papers in biogerontology journals consisted of descriptions of the ways in which young mice, rats, or people differed from older ones, originally in terms of anatomy and physiology, as indicated by levels of enzymes or hormones, and more recently by exhaustive catalogs of protein and mRNA levels. This descriptive era is gradually being superseded by one focused on specific molecular hypotheses about the key factors that regulate aging. The foundation of this modern approach to the biology of aging was the development of genetic models and nutritional manipulations which could delay aging, and the exploitation of this leverage to

test molecular ideas about the basis for the retardation of the aging process.

## WHAT IS AGING?

This question—what is aging?—is posed not as an invitation to semantic quibbling, but to initiate reexamination of facts so familiar that they are seldom examined. A case history of an individual who has mild arthritis, some loss of hearing acuity, some evidence of incipient cataract, loss of muscle mass and strength, a progressive decline in capacity for aerobic exercise, troubles with learning and remembering, and an increased vulnerability to infectious illness would lead any physician to assume that the individual described is a man or woman of 60 or more years of age. But the list of signs and symptoms refers with equal accuracy to a 20-year-old horse, or a 10-year-old dog, or a 2-year-old mouse. The specific list of deficits and impairments shifts a bit from person to person, and from species to species, but it is extremely rare to find an 80-year-old person, or 3-year-old mouse, or 14-year-old dog that has avoided all of these age-associated problems. The aging process is synchronized, in that it is common to see all of these difficulties in older people, horses, dogs, and mice, but rare to encounter any of them in young adults just past puberty. This synchrony, though entirely familiar to schoolchildren, physicians, and scientists alike, is the central challenge in biological gerontology: how is it that such a process affects so many cells, tissues, organs and systems at a rate that varies, even among mammals, over a 100-fold range from the shortest lived shrews to the longest lived whales? Structural features of shrews, mice, dogs, and people are remarkably similar at scales from the arrangement of DNA and histones in the nucleus, to the architecture of the kidney, heart, and thymus, to the role of the central nervous system (CNS) and endocrine systems in regulating responses to heat and cold, hunger and thirst, infection, and predators. Why, then, in molecular terms, will the eye, kidney, immune system, brain, and

joints of a mouse last only 2 to 3 years under optimal conditions, while the same cells and organs and systems persevere for 50 or more years in people, and longer still in some species of whales?

The definition proposed at the beginning of this chapter—aging as a process for turning young adults into distinctly less healthy old ones—is straightforward enough to appear simple-minded, but in practice draws some prominent distinctions. In this view, aging is not a disease: Diseases are certainly among the most salient consequences of aging, but aging produces many changes not classified as diseases, and many diseases also affect young people. Similarly, lifespan and mortality risks are influenced by many factors besides aging. Thus, evidence that a gene or diet or public health measure has altered life expectancy, upwards or downwards, does not imply that the effects have been achieved by an effect on aging. In the context of the whole organism definition of aging used in this chapter, it is hard to interpret the meaning of changes that occur as individual cells “age” in tissue culture. While cell culture studies can provide valuable information of great relevance to ideas about aging, the two processes are likely to be fundamentally different.

From a biological standpoint, a critical distinction is the difference between aging and development. Development creates a healthy young adult from a fertilized egg, and is strongly molded by natural selection. Genetic mutations that impair development, creating a slower falcon, a near-sighted chipmunk, or a chimpanzee uninterested in social cues, are rapidly weeded from the gene pool. But the force of natural selection diminishes dramatically at ages that are seldom reached. Mice, for example, typically live only 6 months or so in the wild, before they succumb to predation, starvation, or other natural hazard. There is strong selective pressure against mutations that cause cataracts in the first few months of mouse life, but little or no pressure against genotypes that postpone cataract formation for 2 years. Mice protected, in a laboratory setting, against predation, starvation, and other risks typically do develop cataracts in their second or third year. In wolves, however, a genotype that delayed cataracts for only 2 years would be a disaster; natural selection favors wolf genes that preserve lens transparency for a decade or more. A similar process, working on our ancestors in environments where survival to 15 was common, but survival to 55 distinctly uncommon, has filled our own genome with alleles that postpone cancer, osteoarthritis, coronary disease, Alzheimer’s, presbycusis, cataracts, sarcopenia, immune senescence, and many other familiar maladies, for about 50 to 60 years. Thus, although aging and development seem, superficially, to be similar processes in that both lead to changes in form and function, they are different in a fundamental and critical way: Development is molded directly by the forces of Darwinian selection and the changes of aging are the consequence of the failure of these selective processes to preserve function at ages seldom reached by individuals in any given species.

### Aging as a Coordinated, Malleable Process

The definition of aging as a process that turns young adults into old ones conflicts with a view of aging as instead a collection of processes, some that lead to arterial disease, some that affect endocrine function, some that impair cognition or cause neoplastic transformation, etc. Because each of these ailments is itself the outcome of a complex interaction among many factors, including genes, diet, accidents, viruses, toxins, antibiotics, and physicians, and because each of these diseases, and many others, seems an inextricable part of

aging, it has seemed implausible to regard aging as less complex than its (apparent) constituents. Considering aging as a process, rather than a collection of complex processes, has thus seemed to be an oversimplification.

However, two lines of evidence support the merits of the view of aging as a unitary process, with its own (still ill-defined) physiological and molecular basis, which underlies and tends to synchronize the multiple changes seen in older individuals. The first of these discoveries was caloric restriction: The observation that rodents allowed to eat only 60% of the amount of food they would voluntarily consume would live 40% longer than controls permitted free access to food. This observation, first made by McCay in the 1930s, has now been repeated in more than a dozen species in scores of laboratories, and ongoing studies in rhesus monkeys have now produced preliminary, but highly suggestive, evidence that similar benefits may accrue in our own order of mammals. The key point is not merely that lifespan is extended, but that nearly all of the consequences of aging are coordinately delayed. Caloric restriction delays changes in cells that proliferate continuously (such as gut epithelial cells), cells that can be triggered to proliferate when called upon (such as lymphocytes), and those that never proliferate (such as most neurons), as well as on tissues that are extracellular or acellular (such as lens tissue and extracellular collagen fibrils). It delays aspects of aging characterized by excess proliferation, such as neoplasias, and those characterized by failure to proliferate (such as immune senescence). It delays or decelerates age change at the tissue level (such as degradation of articular cartilage) and those involving complex interplay among multiple cells and tissues (such as loss of cognitive function and endocrine control circuits). Because caloric restriction alters, in parallel, so vast an array of age-associated changes, it seems inescapable that these many changes, distinct as they are, must be in some measure timed, i.e., synchronized by a mechanism altered by caloric intake.

A second, more recent, set of experiments leads to the same inference. In 1996, Bartke and his colleagues showed that Ames dwarf mice, in which a developmental defect in the pituitary impairs production of growth hormone (GH), thyrotropin, and prolactin, had an increase of more than 40% in both mean and maximal lifespan compared to littermates with the normal allele at the same locus. Since then studies of this mutant, and the closely similar Snell dwarf, have documented delay in kidney pathology, arthritis, cancer, immune senescence, collagen cross-linking, cataracts, and cognitive decline, making a strong case that these genetic changes in endocrine levels do indeed modulate the aging process as a whole, with consequent delay in a very wide range of age-synchronized pathology. Since 1996, mouse researchers have documented increased lifespan in at least nine other mutations, of which five others, like the Ames and Snell mutations, lead to lower levels of or responses to GH and/or its mediator insulin-like growth factor I (IGF-I).

These observations, on calorically restricted (CR) rodents and now also in mutant mice, justify a sea change in thinking about aging and its relationship to disease. The new framework includes two key tenets: (1) the aging process, despite the complexity of its many effects, can usefully be considered as a single, coordinating mechanism and (2) the rate at which aging progresses can be decelerated in mammals as well as in other taxa. From this perspective, a fundamental challenge to biogerontologists is to develop and test models of how age-dependent changes are themselves coregulated, during middle age, to produce old people or old mice or old worms. Studies of the aged, as opposed to studies of aging, are relevant to this

challenge only insofar as they are exploited to generate or test ideas about coregulation and synchrony, rather than ideas about disease-specific pathogenesis. The key resource for meeting the challenge is not comparisons between young and old donors, but rather comparisons between young or middle-aged adults who are known to be aging at different rates. Fortunately, the same experiments that have documented the malleability of aging rate have done so by producing sets of animals that do indeed age at normal or slower-than-normal paces. With luck, future studies may produce at least tentative answers to the two key questions in biogerontology: How does aging produce the signs and symptoms of aging and what controls the rate of this process in mammals?

### Key Themes from Studies of Invertebrate Models

Four main ideas have emerged, in the period 1990–2008, from studies of genetically convenient invertebrate models, the nematode worm *Caenorhabditis elegans* and the fruit fly *Drosophila melanogaster*. (1) Single gene mutations—lots of them—can extend lifespan in worms and flies (and mice). Most mutations discovered so far are “loss of function,” in which eliminating or crippling the gene product leads to slower aging and lifespan extension. (2) The genes whose elimination slows aging are typically those used by the normal animal to notice and respond to environmental poverty; they are selected, by evolution, to permit the animal to take on alternate forms or functions to deal with the relative absence of nutritional conditions optimal for rapid growth and reproduction. Many of these genes are familiar to physicians and biological scientists: they encode insulin, insulin-like growth factors, possibly thyroid hormones, and other regulators of fuel usage and metabolic fluxes, as well as the intracellular proteins that change cell properties in response to these hormones. (3) The mutations that extend lifespan in worms and flies (and perhaps in mice) render the animals more resistant to lethal injury, such as that resulting from heavy metals, ultraviolet irradiation, heat, oxidizing agents, and chemicals that damage DNA. It thus seems plausible that augmentations of stress resistance are the mechanism by which these mutant genes slow aging. (4) This three-way association, connecting aging to stress to signals about nutrition, has very deep evolutionary roots and can be noted (albeit with species-specific nuances) in yeast, flies, worms, and mice. The suggestion here is that the pathways tying nutrition to stress to aging rate evolved extremely early in the eukaryotic lineage, in an ancestor predating the branch points between yeast, flies, worms, and vertebrates. The key implication is that investigations into the cell biology of these linked processes in conveniently short-lived organisms may provide valuable insights into aging and disease in humans.

### Molecular Leads for Further Study

Studies of the invertebrate model systems have also called attention to a range of intracellular pathways that influence longevity, perhaps through regulation of resistance to a variety of forms of lethal and metabolic stress. Components of these pathways are now under scrutiny to see if they also affect aging and disease in rodents. Many of the antiaging mutations in worms, for example, act by increasing the actions of a DNA-binding factor called Daf-16, whose targets include genes that modulate resistance to oxidative damage, DNA repair, and other modes of cellular defense. The mammalian equivalent to Daf-16, a member of the FoxO group of transcription factors,

has already been implicated in control of cell death in human and rodent cells, and studies of the role of FoxO family members in aging are under way. A second family of proteins, the sirtuins, was initially implicated in lifespan regulation in studies of the budding yeast *Saccharomyces cerevisiae*, but then shown also to be able to increase lifespan in nematode worms. There is some evidence that members of the sirtuin family may contribute to the improved health and longevity of mice on a calorie-restricted diet, and interest in these proteins has been spurred by observations that median lifespan of mice on a diet high in saturated fat can be increased significantly by resveratrol, whose many biochemical effects include stimulation of sirtuin activity. Work with invertebrates has also brought new attention to the possible role of TOR, the “target of rapamycin,” in control of lifespan and responses to dietary interventions. TOR plays a major role, conserved throughout the evolutionary tree, in regulating protein translation rates in response to both external cellular stress and the available supply of amino acids. TOR inhibition by rapamycin is a mainstay of clinical immunosuppressive therapy after organ transplantation, and TOR inhibitors also show promise as antineoplastic agents. Other molecular circuits, including those triggered by the p66 (shc) protein, the tumor-suppressor p53, and the stress-responsive kinase JNK, were initially discovered through work with rodents and now are also being examined in the context of invertebrate models for aging. Each of these biochemical pathways has powerful and still only partially defined links to hormonal signals, neoplastic transformation, stem cell homeostasis, and the balance between cell growth and cell death, so their elucidation is likely to provide both rationale and direction for translational work aimed at slowing the aging process and retarding age-related disease and dysfunction.

### Delayed Aging in Mice and Rats

#### Caloric Restriction

Mice or rats fed approximately 30% or 40% less food than they would ordinarily consume typically live up to 40% longer than freely fed animals. These CR animals stay healthy and active, with good physical, sensory, and cognitive function, at ages at which most of the controls have already died. The intervention extends lifespan if initiated at very young ages (e.g., at weaning), or when started early in adulthood (e.g., at 6 months, in a species where puberty occurs at 2 months and median survival is about 28 months). Whether CR diets extend lifespan when initiated in animals already older than half the median lifespan is controversial, with some early studies suggesting little or no response, and some more recent experiments leading to a positive result. Lifespan can be extended using CR diets of widely varying composition, and there is strong evidence that total caloric intake, rather than proportions of specific fuel sources (carbohydrates, fats, proteins), is responsible for the beneficial effects. CR diets do not, except in the first few months after their imposition, alter metabolic rate or oxygen consumption per gram of lean body mass because CR rodents lose weight, or if adolescent fail to gain weight, so that lean body mass matches calorie supply once equilibrium is established. Although CR rodents are less obese than control animals, it seems unlikely that the effect of CR diets on aging is caused entirely by avoidance of obesity, in part because CR diets extend lifespan in mice genetically engineered to lack leptin (ob/ob mice). When placed on a CR diet, ob/ob mice are both longer lived

and more obese than normal mice with normal caloric intake. There is some evidence that CR diets can delay at least some aspects of aging, for example, changes in immune function, in nonobese rhesus monkeys, but definitive evidence, based on lifespan data, is not yet available.

Mice and rats on CR diets show delay or deceleration in a very wide range of age-dependent processes, including neoplastic and nonneoplastic diseases, changes in structure and function of nearly all tissues and organs evaluated, endocrine and neural control circuits, and ability to adapt to metabolic, infectious, and cardiovascular challenges. Mouse stocks that have been engineered for vulnerability to specific lethal diseases, such as models of lupus or early neoplasia, also tend to live longer when placed on a CR diet. Intensive study of CR rodents in the past 20 years has suggested many ideas about the mechanism of its effects, including ideas about altered levels and responses to glucocorticoids and/or insulin, increases in stress-resistance pathways including resistance to oxidative injury, diminished inflammatory responses, changes in stem cell self-renewal, and many others, each plausible, none of them at this point more than plausible. Further work on the early and midterm effects of CR diets is among the most attractive avenues for testing basic ideas about aging in mammals.

### Methionine-Restricted Diets

Rats fed a diet containing much reduced levels of the essential amino acid methionine were shown, in 1993, to live 40% longer than rats, on a standard diet, and more recent work has shown a similar, though smaller, effect on mice. These animals are not calorically restricted—they eat more calories, per gram of lean body mass, than control rats, and rats pair-fed normal food at levels that match the total caloric intake of a methionine-restricted (MR) rat show a much smaller degree of lifespan extension. MR diets could, in principle, affect aging by causing changes in protein translation or rate of protein turnover, by changes in DNA methylation (which depends upon metabolites of methionine), by alterations in levels or distribution of the antioxidant glutathione (also a metabolite of methionine), by changes in hormone levels (MR mice show low levels of insulin, glucose, and insulin-like growth factor 1, IGF-I), or by induction, through hormesis, of augmented stress response pathways at the cellular level. Some of these ideas could be tested using diets that restrict levels of other amino acids, and there is older, fragmentary evidence that such diets, too, may induce lifespan extension in rodents. MR is thus the second confirmed method for extending lifespan in mammals and comparisons of similarities and differences between CR and MR rodents are likely to prove highly informative.

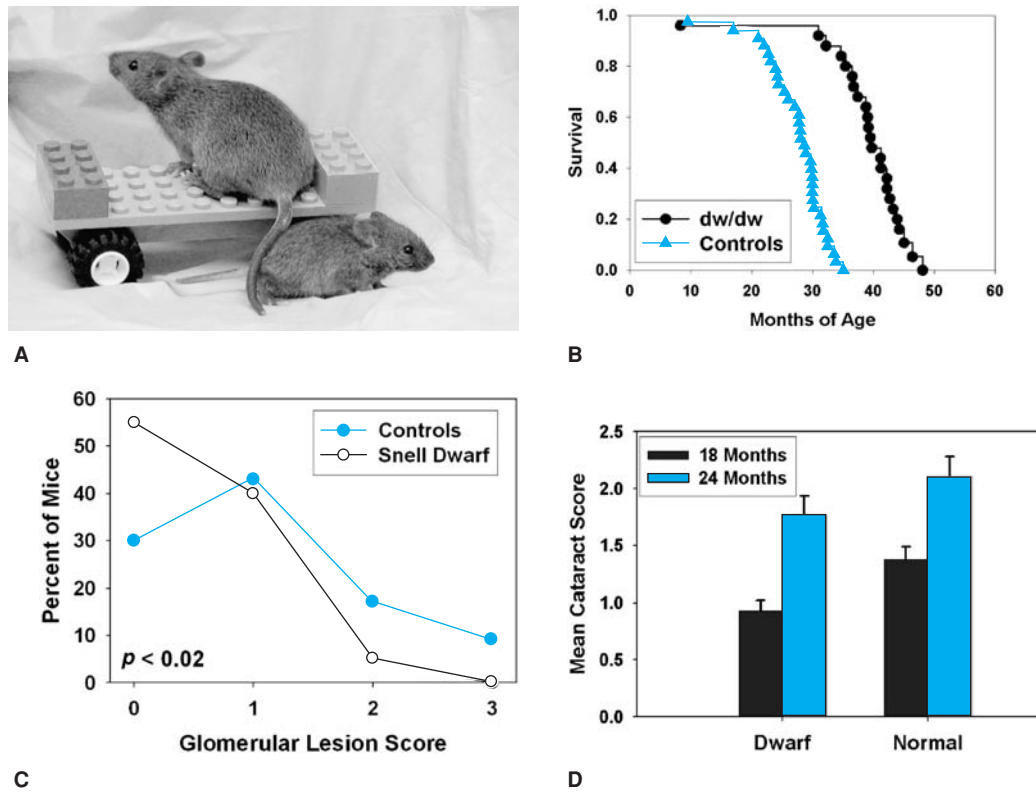

### Single-Gene Mutations That Extend Mouse Lifespan

The initial reports in the 1980s and 1990s that mutations of single genes in worms, and then in flies, could produce dramatic increases in lifespan were the strongest support, along with the CR data, for viewing aging as a unitary process that could be decelerated. The report in 1996 by Bartke and his colleagues that the lifespan of mice could be extended more than 40% by mutation of a gene required for pituitary development opened the door to new genetic models for study of aging in mammals. This Ames dwarf gene (*Prop1*) leads to an endocrine syndrome featuring low levels of growth hormone (GH), IGF-I, thyrotropins and the thyroxines, and prolactin. The observation that longevity in mice could be improved by reduction

of hormones in the insulin/IGF family, i.e., the same family of signals implicated in lifespan extension in worms and (later) flies, provided a key foundation for exploiting comparative cell biology in biogerontology research. Subsequent work then showed that similar degrees of lifespan extension could be seen in Snell dwarf mice, whose endocrine defects are very similar to those of Ames dwarfs, and also in mice that lack the GH receptor (GHR-KO mice) (Figure 1-1). This last observation, together with documented lifespan extension in mice lacking GH-releasing hormone receptor (GHRHR) and in mice with diminished expression of the IGF-I receptor (IGF1R heterozygotes), suggested strongly that a common factor, i.e., low production of or response to IGF-I, is a major cause of lifespan extension in all five models, although it is certainly possible that other factors, such as altered insulin sensitivity, thyroid tonicity, adipokine levels, etc., may contribute to antiaging effects in some of these mouse models. Male and female mice are affected by each of these mutations except that the effect of the IGF1R mutation seems stronger in females than in males. Mice in which tissue levels of IGF-I are reduced by genetic manipulation of a protease that controls local concentrations of IGF-I binding proteins are also long-lived, again consistent with models in which abnormally low IGF-I levels cause lifespan extension in mice. Studies of Snell and Ames dwarf mice have shown that the exceptional longevity of these mice is accompanied by a delay or deceleration of age-dependent changes in T lymphocytes, skin collagen, renal pathology, lens opacity, cognitive function, and neoplastic progression; taken with the lifespan data, these observations suggest strongly that these mutations, like the CR diet, act to slow the aging process itself.

In addition to the six mutations that lead to lower levels of IGF-I signals, there are now five other mutations that have been shown, in each case in a single unreplicated report, to extend lifespan in mice. Table 1-1 presents a summary of these 11 published mutations that extend maximal lifespan in mice. Transgenic overexpression of urokinase-type plasminogen activator in the brain has been reported to produce a significant extension of lifespan, perhaps by suppression of appetite with consequent mimicry of a CR diet. Mice in which the insulin receptor has been inactivated specifically in adipose tissue show an 18% lifespan increase, consistent with the idea that altered insulin sensitivity or adipokine levels might play a role in aging rate in this species. Transgenic mice overexpressing the *klotho* protein, a cofactor for fibroblast growth factor (FGF) signals whose absence leads to early death by elevation of vitamin D levels, have been reported to live 19% to 31% longer than controls, perhaps reflecting the ability of *klotho* to block insulin or IGF-I signals. A mutation that inactivates the 66 kDa splice variant of the *Shc* protein, involved in the pathway to programmed cell death after exposure to hydrogen peroxide or ultraviolet light, also extends longevity (by about 28%), as does transgenic overexpression, in mitochondria, of catalase, an enzyme involved in detoxification of hydrogen peroxide (a 20% lifespan increase). These last two reports, if confirmed in other laboratories, may give new insights into the connections linking aging and late-life diseases to agents that damage DNA or induce oxidative injury at intracellular sites.

More work is needed to determine to what extent these mutations influence common pathways, to see whether they do or do not influence aging through the same mechanism. It is possible, for example, that some of these mutations diminish risk of cancer, a common cause of death in many inbred mouse strains, without effect on any other age-dependent trait, while others may modulate the effects of aging on multiple organ systems, thus diminishing mortality risk

**FIGURE 1-1.** (A) A young adult Snell dwarf mouse, with a littermate control (on the vehicle). (B) Survival curves for Snell dwarf (*dw/dw*) mice and littermate controls. (C) Glomerular basement pathology scores, at terminal necropsy, for Snell dwarf ( $N = 40$ ) and control ( $N = 46$ ) mice. Higher scores indicate a greater degree of kidney pathology. Despite living 40% longer, a higher percent of Snell dwarfs had 0 scores at necropsy and a smaller percent had scores of 2 or 3. (D) Cataract scores determined by slit lamp examination in Snell dwarf and littermate control mice at 18 and 24 months of age.  $p < 0.001$  for the difference between dwarfs and controls at each age. (B) Data from Flurkey K, Papaconstantinou J, Miller RA, Harrison DE. Lifespan extension and delayed immune and collagen aging in mutant mice with defects in growth hormone production. *Proc Natl Acad Sci U S A.* 2001;98(12):6736–6741. (C and D) Data from Vergara M, Smith-Wheelock M, Harper JM, Sigler R, Miller RA. Hormone-treated Snell dwarf mice regain fertility but remain long-lived and disease resistant. *J Gerontol Biol Sci.* 2004;59:1244–1250.

from both neoplastic and nonneoplastic diseases. There are hints, for example, that CR diets and the Ames dwarf gene may affect longevity by different mechanisms. As shown in Figure 1-2, caloric restriction extends lifespan in normal as well as in dwarf mice, and the Ames mutation extends lifespan on both CR and control diets, showing

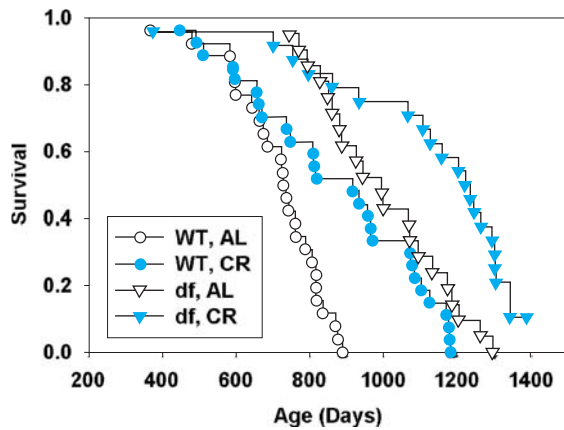

that the effects are at least partly additive. The survival curves in Figure 1-2 also suggest that the Ames dwarf mutation may be affecting the age at which deaths begin to occur (“delay” of aging), and that the CR diet may affect, instead, the rate at which deaths occur once mortality risks become detectable (“deceleration” of aging). Dwarf

**TABLE 1-1**

**Mouse Mutants That Improve Longevity**

MUTATION	EFFECT ON LIFESPAN (%)	COMMENT
Ames dwarf ( <i>df</i> ), <i>Prop1</i>	50	Low GH, IGF-I, thyrotropin, thyroxine, prolactin
Snell dwarf ( <i>dw</i> ), <i>Pit</i>	42	Low GH, IGF-I, thyrotropin, thyroxine, prolactin
GHRHR ( <i>lit</i> , <i>litt</i> )	23	Low GH, IGF-I Survival increase on low-fat diet only
GHR-KO	42	Low IGF-I
IGF-I receptor	26	Heterozygous mice; significant only in females only
Pregnancy-associated plasma protein A, PAPP-A	38	Protease for IGF-I binding proteins
Klotho transgenic	19–31	Impairs insulin and IGF-I signals
Insulin receptor; FIRKO	18	Receptor diminished in adipose cells only
Shc-66	28	Lower apoptosis after UV, H <sub>2</sub> O <sub>2</sub>
Urokinase-type plasminogen activator, uPA	18	Transgenic, expressed in brain; may suppress appetite.
Catalase transgenic, MCA1	19	Overexpression in mitochondria only

FIRKO, fat-specific insulin receptor knockout; GH, growth hormone; GHRHR, growth hormone–releasing hormone receptor; GHR-KO, growth hormone receptor knockout; IGF-I, insulin-like growth factor 1; MCA1, mitochondria-specific catalase transgenic; PAPP-A, pregnancy-associated plasma protein A; UV = ultraviolet; Pit-1, POU domain, class 1, transcription factor 1; Prop-1, prophet of Pit-1; Shc-66, 66 kDa splicing isoform of Src homology 2 domain containing transforming protein 1.

**FIGURE 1-2.** Survival curves for genetically normal (wild-type [WT]) or Ames dwarf (df) mice on caloric-restricted diet (CR) or on unrestricted ad libitum (AL) food intake. Each symbol represents a mouse dying at the indicated age. The dwarf mice live longer than the WT mice on either diet, and the CR diet extends the life span of mice of either genotype. *Reproduced with permission from Bartke A, Wright JC, Mattison JA, Ingram DK, Miller RA, Roth, GS. Extending the lifespan of long-lived mice. Nature. 2001;414:412.*

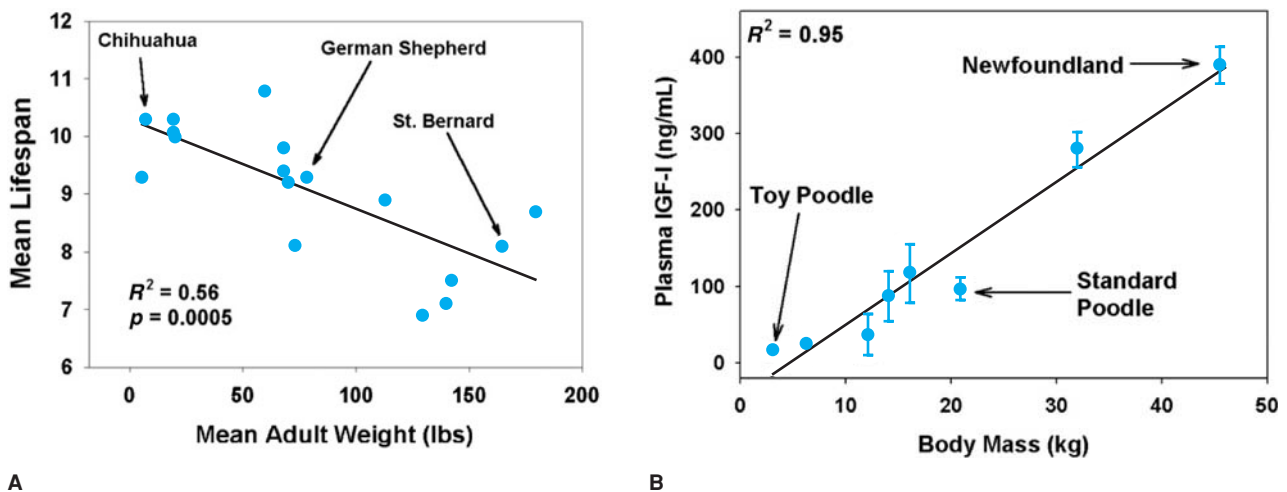

and CR mice also differ dramatically in adiposity (CR mice are extremely lean; dwarf mice have average or above-average proportions of fat), and in resistance to liver toxicity induced by acetaminophen poisoning. Analysis of the mechanisms by which each of the mutations shown in Table 1-1 affects lifespan and age-dependent traits will help to sort out questions about whether initial mortality rate and mortality rate doubling time are under separate physiological control.

As Table 1-1 suggests, the evidence from mice indicates that diminution of IGF-I levels, either in early life, adult life, or perhaps both, can create mice that are long-lived compared to controls. The association has also been noted using experimental designs in which individual mice are tested for IGF-I levels as young adults: those mice with the lowest IGF-I levels were found to live significantly longer than those with higher IGF-I concentrations. Similarly,

mouse stocks bred by selection for slow early life growth trajectory are found to be smaller than controls and also longer-lived. There is also highly suggestive evidence for a similar relationship between IGF-I, body size, and lifespan in dogs and horses. For dogs, several studies have shown greater longevity in small-size breeds than in large breeds, and a strong relationship between body size and life expectancy among mixed-breed (mongrel) dogs as well (Figure 1-3). Anecdotal and limited published data suggest that pony breeds of horses are also substantially longer lived than horses of full-sized breeds. The relationship between body size and life expectancy in humans is complicated by the strong effects of socioeconomic status on both endpoints: wealthier people tend to be both taller and longer-lived than poor people. On the whole, tall stature is associated with lower mortality risks from cardiovascular diseases, which are a major cause of mortality in developed countries. In contrast, a remarkably consistent set of studies (Table 1-2) show that tall stature is associated with significantly higher mortality risk from a wide range of neoplastic diseases. There is also limited data that centenarians, on average, were shorter as mature adults than those who do not attain centenarian status. Testing the idea that short midlife stature is associated with delayed or decelerated aging in humans will depend on measuring a wide range of age-dependent traits, rather than merely lifespan, on large populations of middle-aged people.

### Stress Resistance and Aging

Mutations that extend lifespan in invertebrates typically render the animals resistant to multiple forms of lethal injury, whether the threat comes from oxidative agents, heat, heavy metals, or irradiation. Indeed, this stress resistance seems likely to represent the mechanism by which these mutations delay the aging process. Thus presumably much of the cellular and extracellular pathology that produces dysfunction and increases mortality risk in older animals is held in abeyance by the same, poorly defined, defenses that permit nematodes and flies to survive when exposed to external stress in an experimental setting. Genetic dissection of the relevant pathways has

**FIGURE 1-3.** Longevity, size, and insulin-like growth factor I (IGF-I) levels among breeds of purebred dogs. Left panel shows mean breed lifespan as a function of mean breed weight for each of 16 breeds of dogs; three breeds are indicated by arrows. *Data from Li Y, Deeb B, Pendergrass W, Wolf N. Cellular proliferative capacity and life span in small and large dogs. J Gerontol A Biol Sci Med Sci. 1996;51(6):B403-B408.* Right panel shows mean plasma IGF-I levels as a function of body mass in eight breeds of purebred dogs. *For details and citations see Miller and Austad. Growth and aging: why do big dogs die young? In: Masoro EJ, Austad, SN, eds. Handbook of the Biology of Aging. 6th ed., New York, New York: Academic Press; 2006.*

TABLE 1-2

## Population-Based Association Between Short-Stature and Lower Mortality Risk for Multiple Neoplastic Diseases

TEST POPULATION	TALL PEOPLE DO BETTER	SHORT PEOPLE DO BETTER
15 000 Scots	All-cause stroke Coronary disease	Colorectal, prostate, hematopoietic cancers
12 000 NHANES (United States); men		Cancers; 40–60% effect; adjusted for race, smoking, income
NHANES women		Breast and colorectal cancer
22 000 U.S. male physicians		Cancer; adjusted for age, BMI, exercise, smoking
570 000 Norwegian women		Breast cancer
400 000 American women		Breast cancer, postmenopause
1.1 million Norwegians		Esophageal cancer
England and Wales (by county)	All-cause mortality Ischemic heart disease	Breast, prostate, ovarian cancer

NHANES, National Health and Examination Survey.

shown, surprisingly, that in normal, nonmutant worms, the levels of stress resistance, and thus resistance to aging, are actively diminished by specific DNA-binding transcription factors. These factors, whose human homologs are members of the FoxO family, are retained by evolutionary pressures because they provide reproductive advantages in the natural environment, in which animals must be able to quickly take advantage of transient access to nutrients. Genetic inactivation of these FoxO pathways in the laboratory produces mutant animals that are not ideally suited for natural conditions, but which are resistant to many kinds of stress and which age more slowly than normal. Studies of gene expression patterns in the long-lived mutant worms have shown that the FoxO proteins can trigger transcription of over 100 genes that together protect against many different forms of cellular damage. The list includes enzymes that destroy free radicals, heat shock proteins, and other chaperones that guard against misfolded proteins, proteins that protect against infection, and chelating agents that bind toxic metal ions, among others.

The connection between induction of these stress-resistance pathways and late-life diseases has been shown by two sets of informative experiments. In the first, genetically identical worms were exposed to a brief, nonlethal heat stress, and physically separated into those that showed a strong response of chaperone proteins and those that did not. Worms with the most robust response to transient stress were found to be longer lived than those with lower stress responses. A second approach involved worms bearing genetic variants that cause aggregation of proteins and neurodegeneration (Huntington's disease) in people; neurological dysfunction in these worms can be delayed, and in some cases prevented entirely, by augmentation of the FoxO-dependent stress-resistance pathways. Similarly, age-dependent increases in susceptibility to stress-induced cardiac arrhythmias in *Drosophila* can be significantly postponed by activation of FoxO-dependent protective pathways.

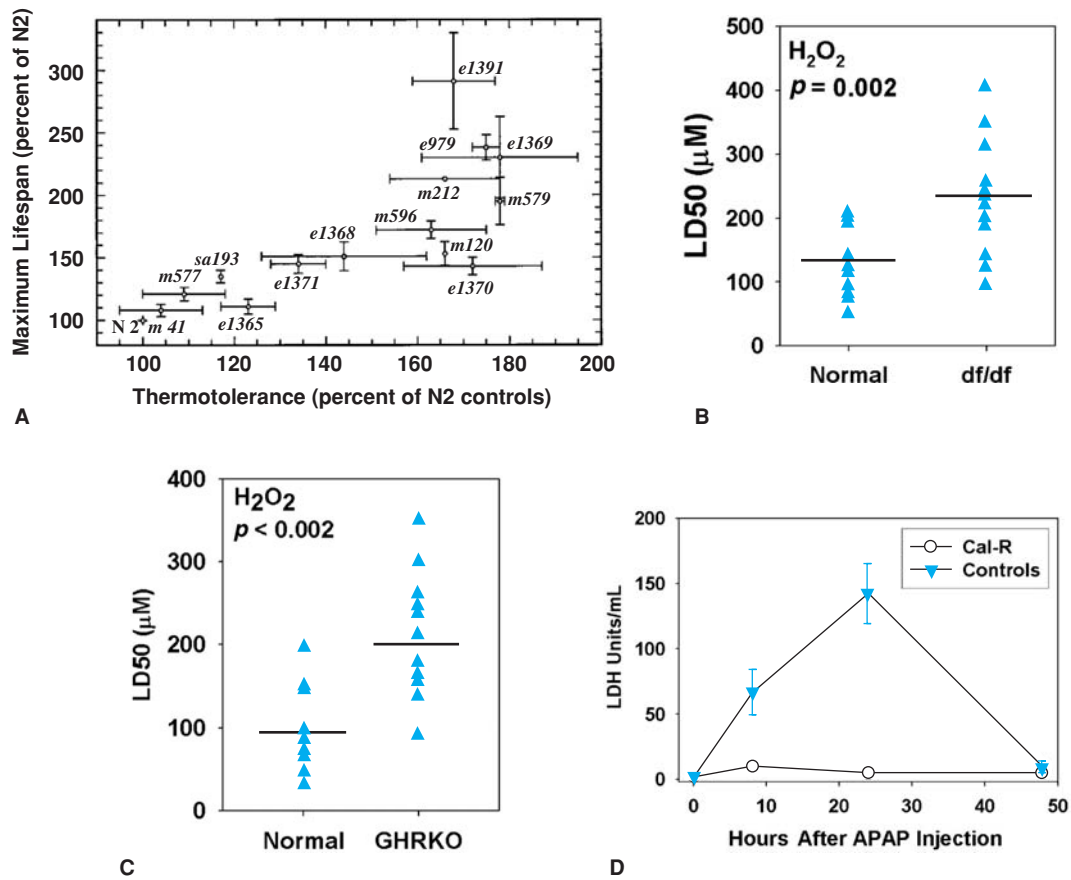

Studies of the relationship of stress resistance to aging in mammals are underway, but suggestive data have begun to emerge. Both CR diets and at least some of the long-lived endocrine mutant stocks show elevated levels of enzymes with antioxidant action, heavy metal chelators, and intracellular chaperone proteins, as well as have lower levels of oxidative damage to DNA, proteins, and lipids. Cells grown, in tissue culture, from long-lived Snell and Ames dwarf mutant mice, or from mice lacking GH receptor, are resistant to lethal injury caused

by cadmium, peroxide, heat, a DNA alkylating agent (MMS), ultraviolet light, and paraquat (which induces mitochondrial damage by free radical generation). Mice prepared by CR or MR diets are resistant to liver damage induced by the oxidative hepatotoxin acetaminophen, and long-lived mutant mice are somewhat more resistant to death induced by paraquat injection. Stress resistance also seems to play a role in evolution of long-lived species in that cells from long-lived rodents and other mammals are resistant in culture to several forms of oxidative and nonoxidative damage. This work provides initial support for models that attribute variations in aging rate to differences in stress resistance pathways, but many questions remain unanswered at this early stage. Figure 1-4 shows representative results for resistance to stress in long-lived mutant worms and cells from long-lived mutant mice, as well as data on resistance of CR and MR mice to an oxidative hepatotoxin. Figure 1-5 presents data from two studies showing stress resistance in culture of cells from longer-lived mammalian species.

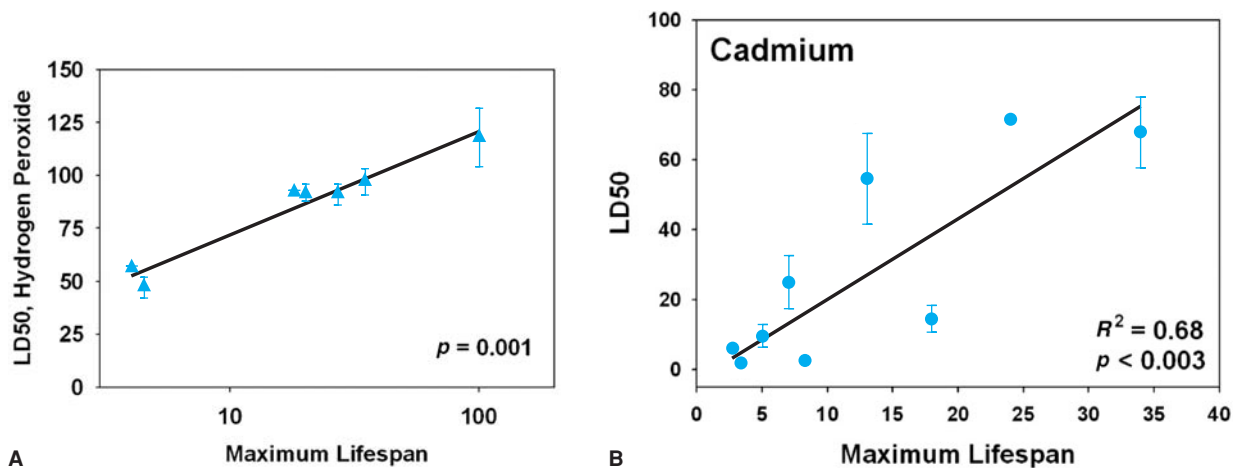

### Genetic Approaches to Analysis of Aging in Humans

Attempts to find genetic variations that influence aging in humans have been plagued with practical and conceptual problems in addition to the obvious difficulty that selection of mating partners is not amenable to experimental control. For one thing, heritability calculations show that only about 15% to 20% of the variation in lifespan among humans can be attributed to genetic factors. Furthermore, an unknown but potentially large fraction of this genetic variation probably reflects genetic variants that influence susceptibility to diseases of childhood, infectious agents, and specific common illnesses of old age. For example, genetic variants that cause Huntington's disease or type 1 diabetes or which triple the normal risk of myocardial infarction by the age of 50 years would all contribute to the measured heritability of lifespan, but do so by altering mortality risks from a specific form of illness rather than by alteration of aging with its effects on multiple late-life traits. Thus genetic variants that mold lifespan by effects on aging per se, if they exist at all, are likely to influence only a small fraction of variation (perhaps 5%) in how long people live.

Formal analyses of the genetics of human aging have so far relied mostly on candidate gene approaches, in which the investigator

**FIGURE 1-4.** Association of stress resistance to longevity. (A) Resistance to heat shock (thermotolerance) is higher in mutant worms that have extended longevity. Each point is the mean for one mutant strain. (B) Resistance of skin-derived fibroblasts to lethal hydrogen peroxide concentrations is higher in cells from Ames dwarf (*df/df*) mice compared to controls. Each symbol shows an individual mouse. (C) Hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) resistance of skin-derived fibroblasts from long-lived growth hormone receptor knock out (GHRKO) mice. LD50 is the amount of peroxide that kills 50% of the cells. (D) Resistance of calorie-restricted (Cal-R) mice to liver injury induced by injection of acetaminophen (APAP); serum LDH levels indicate the level of damage to hepatocytes at varying intervals after a single injection (unpublished data of Chang and Miller). **FIGURE 1-5.** Stress resistance in fibroblasts from animals of long-lived species. Left panel: Resistance of cultured skin fibroblasts to hydrogen peroxide as a function of species maximum lifespan in years. Species, from left to right, are hamster, rat, rabbit, sheep, pig, cow, and human. Reproduced with permission from Kapahi P, Boulton ME, Kirkwood TB. Positive correlation between mammalian life span and cellular resistance to stress. *Free Radic Biol Med*. 1999;26(5–6):495–500. Right panel: Resistance of cultured skin fibroblasts to cadmium as a function of species maximum lifespan in years. Species, left to right, are laboratory mouse, wild-caught mouse, rat, red squirrel, white-footed mouse, deer mouse, fox squirrel, porcupine, beaver, and little brown bat. LD50 is the amount of hydrogen peroxide or cadmium that kills 50% of the cells. Reproduced with permission from Harper JM, Salmon AB, Leiser SF, Galecki AT, Miller RA. Skin-derived fibroblasts from long-lived species are resistant to some, but not all, lethal stresses and to the mitochondrial inhibitor rotenone. *Aging Cell*. 2007;6:1–13.

evaluates long-lived and control populations for variations at one or a small number of genetic loci, selected on theoretical grounds as most likely to be involved in aging or disease processes. The alternate approach, whole genome screening of large populations for association of longevity to hundreds of thousands of genetic variants, is also beginning to produce initial results at an accelerating pace. Although most of the published studies, and those in progress, focus on nuclear genes, there are tantalizing suggestions from studies of large families that a surprisingly high proportion of inherited effects on lifespan may come through the maternal line alone, suggesting that variations in mitochondrial gene sequences (which are inherited almost entirely from mothers to both sons and daughters) may also influence life expectancy in humans.

A major problem with all these approaches, from the perspective of biological gerontology, is the lack of a defensible phenotype: a measure of aging better than lifespan. There are now several dozen reports of candidate loci at which particular alleles are overrepresented among centenarians or near-centenarians, and advocates of this strategy hope that among this collection are some loci that control aging rate. But skeptics note that alleles that increase risk of cardiac disease, or Alzheimer's disease, or stroke, or various common forms of cancer, or severe osteoporosis are likely to have contributed to disease and death before the age of 90 or 100 years, and thus to have been eliminated or greatly reduced among the very old. Thus it should be assumed that a collection of genetic loci whose frequency discriminates very old people from others of the same birth cohort will include many genes with influence over common forms of lethal illnesses rather than genes that modulate aging per se. This problem is not one that can be solved by technological innovation or larger numbers of tested subjects; it requires development of a phenotype that provides more information about health in old age than merely a record of the age at death. For example, a genetic allele that identified, among 70-year-old people, those most likely to have excellent eyesight and hearing, no history of cancer, angina, diabetes, or arthritis, above-average responses to vaccination, and retention of baseline levels of cognition and muscle strength would be a much stronger candidate for an authentic "antiaging" gene than one that predicted survival to the age of 100 years.

### Models of Accelerated Aging

There are a small number of rare, inherited, diseases, of which Werner's syndrome and Hutchinson-Gilford syndrome are the most celebrated, that have been mooted as possible examples of "accelerated" aging. Some of the physical features and symptoms of these diseases do resemble, at least superficially, some of the changes that typically affect older people, including in particular changes in skin and connective tissues. Hutchinson-Gilford syndrome, sometimes called "progeria," is now known to be caused by mutations in the gene for Lamin A, a component of the nuclear membrane. Werner's syndrome patients usually have mutations in an enzyme ("WRN") that has activity as a DNA helicase (unwinding coiled DNA) and as an endonuclease. Patients with Hutchinson-Gilford syndrome typically survive to their early teens, and Werner's syndrome patients frequently survive to their mid-forties, about 10 years after the age of typical diagnosis.

However, it is highly debatable whether either of these diseases provides strong clues about the molecular or cellular basis for age-related changes in normal individuals. Werner's patients do resemble

elderly people in some ways: they frequently suffer from cataracts and premature graying of the hair, and by their early thirties often develop osteoporosis, diabetes, and atherosclerosis. On the other hand, many features of normal aging are not seen in Werner's patients and many features of Werner's syndrome are not seen in normal old individuals. Werner's syndrome patients, for example, do not show signs of Alzheimer's disease or other amyloidoses, hypertension, or immune failure. Mesenchymal tumors, which are rare in normal people, are about 100-fold more frequent in Werner's patients, but the epithelial and hematopoietic tumors characteristic of normal aging are not seen in Werner's syndrome patients. Furthermore, Werner's patients exhibit many features that are not seen in normal aging, including subcutaneous calcifications, altered fat distribution, vocal changes, flat feet, malleolar ulcerations, high levels of urinary hyaluronic acid, and a number of other idiosyncrasies not seen commonly in elderly individuals. Mice with mutations in the WRN gene live a normal lifespan and do not show signs of premature senescence. It seems possible that investigation of the pathogenesis of Werner's syndrome may provide key clues to the mechanisms of age-related diseases. But it seems at least equally plausible that the WRN mutation, perhaps through alteration of cells responsible for connective tissue maintenance, induces multiorgan failure through processes quite distinct from the changes that impair some of the same organs in normal aging.

### AGING, CELLULAR SENESCENCE, TELOMERES, AND CANCER

The famous observation of Hayflick that human diploid fibroblasts cease to grow in culture after a limited number of population doublings sparked a line of experimentation that continues to yield important insights into the molecular control of cell growth, differentiation, and neoplastic transformation. Human fibroblasts placed in tissue culture will continue to divide until approximately 50 cell doublings have occurred, after which the remaining cells can survive indefinitely in a healthy but nondividing state. In the 1970s and 1980s, this "clonal senescence" model seemed to be an attractive approach to study the genetics and cell biology of aging. It is now clear that growth cessation of continuously passaged human fibroblasts is caused principally by the progressive loss of telomeric DNA at the ends of each chromosome at each mitosis. The chemistry of DNA replication requires that duplication of the end of each DNA molecule be conducted by a specialized enzyme complex called telomerase, and telomeres will therefore become shorter at each cell division except in cells, like most tumor cells, that express telomerase. The very short telomeres that eventually develop in proliferating cells then trigger, through steps not yet fully defined, expression of new genes that block further mitotic cycles but do not lead to cell death.

The challenge of showing that this *in vitro* system can deliver important clues about the biology of aging, that is, about the process that converts healthy young adults into old people, has remained a serious hurdle. The most obvious possibility is that some of the diseases and disabilities of the elderly population might represent a loss, with age, in proliferative capacities of one or more cell types. But there are many reasons to be skeptical of analogies between growth cessation of cells in continuous culture and the complex network of reinforcing failures that lead to aging of intact organisms. For one thing, aging clearly leads to dysfunction of many cell types that do

not divide at all, like neurons and skeletal muscle myocytes, and to dysfunction of extracellular structures like teeth, cartilage, and lens, and it is difficult to see how clonal senescence can affect these processes. Telomere erosion has been postulated to contribute to dysfunction of memory T cells in elderly subjects; but it is hard on this ground to explain the equally poor function, in the same subjects, of naïve memory T cells, whose telomeres are similar in old age to those of memory cells found in young adults. In addition, there are many cell types, such as intestinal crypt stem cells and hematopoietic progenitor cells, that can divide many thousands of times over the course of a lifespan, but which nonetheless show age-related functional decline. In addition, telomere-dependent replicative failure cannot be responsible for the effects of aging in mice or rats, or indeed in the many other species known to have longer telomeres and shorter lives than humans. If 70 years of human lifespan are just sufficient to produce perceptible shortening of the 6 to 10 kilobases of human telomeres, it is hard to see how the 2 to 3 years of rodent lifespan could have much impact on the 20 to 100 kilobases of telomeric deoxyribonucleic acid (DNA) with which rats and mice are endowed. Furthermore, genetic manipulations have produced lines of mice whose telomeres are indeed at the same, short length seen in proliferating cell types in elderly humans. While these mice show specific abnormalities (skin ulceration, infertility, frequently lethal gastrointestinal lesions, and increased frequencies of certain forms of neoplasia), they do not resemble normal aged mice in most respects.

The possibility that clonal senescence might contribute to some of the signs of aging thus faces some serious obstacles, but perhaps not insuperable ones. There is evidence that the cellular changes (“cell senescence”) induced in human cells by overshoot telomeres might be triggered, in human and nonhuman cells, as a response to other forms of DNA damage, and it is thus possible that senescent cells could accumulate, with advancing age, through different mechanisms in long-lived and short-lived species. Early work based on histological assays suggested that senescent cells were rare (less than 0.1%), even in biopsies from very old donors, although new methods for detecting other aspects of the senescent phenotype have led to upward revisions of this estimate. It remains a challenge, however, to develop and test models to explain how properties of tissues, organs, and multiorgan systems (like the brain and endocrine circuits) might be altered by the presence of a small admixture of nondividing senescent cells. Senescent cells *in vitro* express a suite of secreted enzymes and cytokines that are not produced by dividing fibroblasts and it is possible that these may contribute to aging at the tissue or organ level.

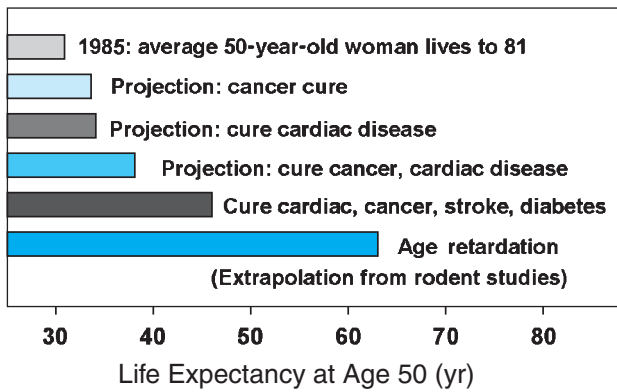

Telomere-dependent clonal senescence does seem to play a critical role in the protection of humans from many forms of late-life cancer. The key finding was the observation that telomerase is turned on, and telomere diminution prevented or reversed, in approximately 90% of clinically significant human neoplasias. It thus seems likely that short telomeres and stringently repressed telomerase gene expression evolved during the course of human evolution to protect us against fatal neoplasias that would otherwise arise early in life. Because most cancers are clonal, and each clinically significant tumor represents the outcome of several stages of selection for rare cellular variants for independence from growth control, resistance to immune defenses, and barriers to metastasis, evolution of large-bodied species, with a much higher number of potential target cells for neoplas-

tic transformation should require development of strong antitumor defenses not needed in smaller creatures. The average human has approximately 3000 times as many cells as a mouse; if each had the same annual likelihood of neoplastic transformation as a mouse cell, the annual cancer incidence in humans would be 3000 times higher than in mice. In fact, however, humans usually avoid neoplasia over a lifetime that is 30 times longer than the mouse’s lifespan; evolution has developed strategies that reduce per cell transformation rate by a factor of about 90 000 in evolving humans from shorter-lived, smaller progenitor species. These defenses may well include telomere-based clonal senescence responses, as well as improvements in repair of somatic mutations and reduction of intracellular levels of DNA-modifying agents. There is no reason to believe, however, that evolved defenses against cancer in humans could not be further improved: similar considerations show that whale cells, for example, are about 10 000-fold more resistant than human cells to neoplastic transformation.

Recent work on stem cell biology has suggested a key role for a specific protein, p16/INK4a, as a mediator of the balance between anticancer and antiaging mechanisms. INK4a is induced as part of the process by which cellular senescence halts cell proliferation. An increase in levels of INK4a in many tissues of aging mice, but particularly in stem cells, has suggested that senescent stem cells may indeed accumulate as a consequence of normal aging and may represent an evolved mechanism to prevent early life neoplasia. New evidence suggests that INK4a may lead, in parallel, to diminished stem cell function in the aging bone marrow, brain, and pancreas. Mice engineered to have lower levels of INK4a have now been shown to retain stem cell activities at ages at which these cells perform poorly in normal animals, even though the same mice are somewhat more cancer-prone than normal controls. Interventions that prevent age-related induction of INK4a might be an attractive approach to diminishing many forms of late-life illness in parallel if the intervention did not simultaneously increase cancer risk.

## AGING RESEARCH AND PREVENTIVE MEDICINE

The central rationale for biological gerontology is the hope that discoveries in this field will lead to innovations in preventive medicine: an authentic antiaging drug that produced the same demographic changes seen in rodents on CR or MR diets would yield about 10-fold greater improvement in mean life expectancy than would the complete elimination of cancers or of myocardial infarctions (Figure 1-6). A detailed understanding of the molecular pathways that lead to coordinated stress resistance in cells of dwarf mice, or of the adjustments that render CR rats resistant to autoimmune, neoplastic, and degenerative diseases, or of the evolutionary changes that permit large animals to survive cancer-free and cataract-free for many decades should in principle suggest avenues to preventive medical care that could dramatically postpone disability and lethal illnesses. Empirical testing of drugs that are thought likely to slow the aging process in mice has already documented two compounds that can extend median lifespan significantly, either in mice consuming a high-fat diet (resveratrol) or in mice consuming a normal diet (nordihydroguaiaretic acid); data on extension of maximum lifespan extension from these or other agents are likely to emerge in the next few years.

**FIGURE 1-6.** Theoretical remaining life expectancy of a 50-yr-old white woman in the United States under a variety of demographic assumptions. The top bar shows remaining life expectancy with disease-specific mortality rates that prevailed in 1985. The four middle bars show projected life expectancy under the assumption that mortality risks for the indicated diseases were in fact zero. Data from Olshansky SJ et al. *Science* 1990;250:634. The bottom line shows projected longevity if it were possible to retard human aging to the same degree that is obtained in the typical study of caloric restriction in rats or mice. Figure reprinted with permission from Miller RA. *Extending life: scientific prospects and political obstacles.* *Milbank Quart* 2002;80:155–174.

But the pathway connecting discovery in this area of basic science to intervention is strewn with obstacles, some scientific, but others political, economic, and legal. Even if research in mice or rats were to demonstrate a dramatic effect of a specific agent on the aging process, producing (for example) a 40% increase in mean and maximal lifespan, showing that the agent was able to safely extend human lifespan would require vast resources and treatment of young or middle-aged adult subjects for many decades. Pharmaceutical firms have little commercial incentive for embarking on expensive tests that might (or might not) demonstrate safety and efficacy of an agent many decades in the future, and governmental agencies, already strained by limited resources and competition among medical researchers with alternate priorities, are also unlikely to be able to support such an ambitious long-term undertaking. Indeed, the laws that govern testing of candidate drugs in the United States permit investigative studies only of agents proposed to treat or prevent a specific disease and explicitly exclude aging from consideration as a “disease” for the purposes of this classification. Nor are many scientists eager to devote their careers to an experiment whose conclusions are unlikely to emerge around the time of their own planned retirement. A hypothetical agent that is active in those already old could, in principle, be tested with a relative short follow-up, i.e., over a period of 5 to 10 years. However, there is at present no empirical evidence, or theoretical basis, for assuming that interventions that retard the aging process could be effective in older subjects in which this process has already led to major disruptions in cellular and tissue functions.

Introduction of authentic antiaging compounds into the practice of health care is thus likely to involve relatively unconventional pathways. The public has shown an unbridled appetite for consumption of compounds and mixtures, labeled as “nutritional supplements,” which are exempt from laws that govern prescription and nonprescription drugs, and are purported to oppose the effects of aging. Thus far, there is no evidence that any of the agents so touted, in-

cluding melatonin, dehydroepiandrosterone (DHEA), homeopathic remedies, and many others, can retard, delay, or reverse aging in humans or animal models. However, it seems possible that agents that did prove, in animal studies, to have the ability to delay or decelerate aging might make their way into human use, or into clinical trials. The high value placed by many dog and cat owners on the health of their pets may lead to sponsorship of trials of antiaging medications in these carnivores, whose lifespan is intermediate between rodents and humans; such trials might lead to further evidence of health and efficacy of the agents tested in a large mammal model. If a promising agent can be shown through typical short-term clinical tests to be useful for the treatment or prevention of a specific disease, Food and Drug Administration (FDA) approval for administration of the agent might then lead to further study of disease prevention and enhanced survival.

### ANTIAGING RESEARCH: SOCIAL OBSTACLES AND ETHICAL CONCERNS

Serious research into the basic biology of aging, and proposed translational research to turn gerontological discoveries into antiaging medicines have long been hobbled by pessimism, specifically the assumption that aging is immutable, and by stigma, arising from claims made for allegedly effective antiaging potions promoted unscrupulously for commercial gain. For these reasons, many political and scientific leaders have been understandably shy of lending support for research efforts whose goal is to develop antiaging interventions for human use. Journalists, who are often aware of promising discoveries in biological gerontology, are nonetheless often drawn ineluctably toward promotion of extreme claims, which, while entertaining, go well beyond scientific evidence and thus further impair the credibility of the antiaging research enterprise. Although several decades of evidence has now clearly refuted the common assumption that the aging process is too complex or too stable to be altered, the attitudes and expectations of opinion leaders and the lay public greatly undermine and complicate efforts to attract support for this research agenda.

A related concern is often posed as a question of ethics: if the goal of antiaging research is to help keep people alive and healthy for several decades beyond their current “natural” lifespan, would not realization of this goal greatly complicate efforts to solve the current set of Malthusian dilemmas? In a world where resource depletion, food shortages, and environmental degradation already consign billions to great suffering, would not methods that delay aging and death lead to unacceptable exacerbations of these and related problems? Arguments along these lines are often influenced by the unstated assumption that old people are typically ill, unhappy, and unproductive, and a desire to avoid creating a society in which an ever-increasing proportion of the population has the problems that can afflict people at the very end of life.

This concern that development of antiaging medicines would be unethical is widespread, but easy to refute. Most of modern medical research is designed to help prevent or treat diseases with a high risk of mortality and thus to increase the likelihood that patients will enjoy additional years or decades of good health. Efforts to develop vaccines for influenza, or to eradicate residual tumor burden by adjuvant chemotherapy, or to correct arrhythmias, or the symptoms

of diabetes or gall stones are all designed to allow patients to remain healthy and active as long as possible. These research efforts are appropriately considered ethical and indeed heroic, even though patients so treated are quite likely to encounter additional illnesses, often associated with suffering, at later ages. A similar motivation and justification underlies translational research in biological gerontology. Clearly, there is no pressing need for agents that merely prolong life in people who are in the final stages of a dementing illness or nearing death in great pain, and developing drugs that extend lifespan without improvements in health would not be an attractive goal. Fortunately, each of the dietary and genetic manipulations shown in rodent models to extend longevity does so by an increase in the length of healthy lifespan; postponement of death goes hand in hand (and is almost certainly caused by) postponement of a very wide range of diseases and forms of disabilities. A society in which many people remain active and productive at ages of 80–100 years or so would indeed require economic adjustments and alterations of assumptions about retirement ages and family structure, just as adjustments of this kind have been required as societies have experienced reductions in infant and childhood mortality that greatly increase the proportion of newborns that reach the ages of 20 to 50 years. Such adjustments are not trivial, but such fears have not raised concerns about the ethical merit of insulin therapy, vaccination programs, smoking cessation clinics, or adjuvant chemotherapy, and from this perspective it is hard to understand why success in antiaging research should be considered pernicious.

There is, however, a serious ethical concern about antiaging interventions that deserves more attention than it has received. There is some basis for believing that agents that decelerate aging, either by alteration of IGF-I signals or through the still undiscovered mechanisms used by CR and MR diets, might be more effective if imposed early in life, perhaps as early as the childhood years. In such a case, decisions about use of such preventive treatments might have to be made by parents on behalf of their young children. If such agents had side effects, such as postponement of puberty, or permanent short stature, would parents be acting ethically to impose these side effects on their children in order to provide them with additional decades of excellent health in adult life? Conversely, would parents be acting ethically to deny their children additional decades of healthy life just to allow them to grow to what is now considered “normal” height? Questions of this kind are harder to answer than concerns about whether postponement of late-life illnesses is or is not desirable on its own merits.

## ACKNOWLEDGMENTS

Preparation of this chapter, and some of the unpublished data, was supported by NIH grants AG024824 and AG023122. I appreciate the willingness of several colleagues, mentioned in the figure legends, to share with me some of their own data for inclusion in this chapter.

# Genetics of Age-Dependent Human Disease

*Thomas B. L. Kirkwood*

## THE BIOLOGICAL NATURE OF INTRINSIC AGING

Understanding the biology of intrinsic aging is important for geriatricians because of the insights it provides into: (i) why and how the body becomes progressively more vulnerable to disability and disease as we grow older; (ii) how we might intervene in the underlying mechanisms; and (iii) what is the exact nature of the relationship between “normal” aging and age-related diseases. Although there is significant variability in how aging affects individuals, certain underlying processes appear to follow a common course. Furthermore, humans share some features of aging with a wide range of other animal species. Thus, even though much of the research on intrinsic aging is done using simple animal models such as the roundworm *Caenorhabditis elegans* or the fruitfly *Drosophila melanogaster*, it appears that common regulatory pathways are at least partially conserved across the spectrum that includes mammals, and in particular humans. This is especially the case for fundamental mechanisms that protect cells against shared threats such as damage to DNA arising from endogenous stressors like reactive oxygen species (ROS), which are essential molecular by-products of the body’s dependence on oxygen to provide energy.

### Why Aging Occurs

One of the central questions in the biology of aging is the nature of the genetic contribution to longevity. How do genes act on the aging process, and how does an individual’s genetic endowment contribute to their longevity?

Aging and longevity are clearly influenced by genes. Firstly, the life spans of human monozygotic twin pairs are more similar than life spans of dizygotic twins. Secondly, there are differences in life span between different genetically inbred strains of any given laboratory animal, such as the mouse. Thirdly, studies of simple organisms like fruit flies, nematode worms, and yeast have identified gene muta-

tions that affect duration of life. However, although genes influence longevity, genes appear to account for only about 25% of the variance in human life span.

The nature of the genetic contribution to the aging process has received much attention, both from the perspective of evolutionary theory and through experimentation. The evolutionary angle is valuable because it can tell us a great deal about the kinds of genes that are likely to underlie the aging process. A commonly held belief is that aging evolved as an evolutionary necessity—for instance, to remove older individuals who might otherwise consume resources needed by the young. However, there is little support for the idea that aging does actually fulfill such a role. In nature, the vast majority of animals die young, long before they could become obstructive to the interests of the next generation. Out of a population of newborn wild mice, for example, nine out of 10 of them will be dead before 10 months even though half of the same animals reared in captivity would still be alive at 2 years. Thus, aging in mice is seen only in protected environments, and until relatively recently the same would have been true for human populations. It is only in the last 200 years that human life expectancy, even in the most advantaged countries, exceeded 40 years.

Since it is rare that an animal survives long enough to show any sign of aging, a genetically programmed means to limit population size and avoid overcrowding, if it exists, is not often brought into play. Furthermore, the idea that aging could be beneficial needs to be set against the fact that even if an animal did reach older age, the adverse effects of intrinsic senescence on fertility and risk of dying are far from beneficial as far as the individual is concerned. The idea of programmed aging rests on the notion that organisms should weaken and die altruistically, for the “good of the species.” While there may be instances where natural selection has produced apparently altruistic outcomes, evolutionary biologists have carefully delineated the rather special circumstances required for this kind of selection force to work. Aging does not fit these requirements. The argument against programmed aging can be summarized by

observing that if such a program did exist, what would prevent a mutation occurring that abrogated the program and allowed the mutant to survive indefinitely? The fact that such mutants are never observed is empirical support that backs up the other objections.

The evidence from nature is that instead of being programmed to die, organisms are genetically programmed to survive. However, in spite of a formidable array of survival mechanisms, most species appear not to be programmed well enough to last indefinitely. A key to understanding why this should be so, and what governs how long a survival period there should be, comes from studying survival patterns in wild populations. If 90% of wild mice are dead by the 10 months, any investment in programming for survival much beyond this point can benefit at most 10% of the population. This immediately suggests that there will be little evolutionary advantage in programming long-term survival capacity into a mouse. The argument is further strengthened by the observation that nearly all of the survival mechanisms required by the mouse to combat intrinsic deterioration (DNA damage, protein oxidation, etc.) require metabolic resources. Metabolic resources are scarce, as is evidenced by the fact that the major cause of mortality for wild mice is cold, due to insufficient energy to maintain body temperature. From a Darwinian point of view, the mouse will benefit more from investing any spare resource into thermogenesis or reproduction than into better DNA repair capacity than its need for longevity.

This concept, with its explicit focus on evolution of optimal levels of cell maintenance, is termed the “disposable soma” theory. In essence, the investments in durability and maintenance of somatic (nonreproductive) tissues are predicted to be sufficient to keep the body in good repair through the normal expectation of life in the wild environment, with some measure of reserve capacity. Thus, it makes sense that mice (with 90% mortality by 10 months) have intrinsic life spans of around 3 years, while humans (who probably experienced something like 90% mortality by the age of 50 years in our ancestral environment) have intrinsic life spans limited to about 100 years. The distinction between somatic and reproductive tissues is important because the reproductive cell lineage, or germ line, must be maintained at a level that preserves viability across the generations, whereas the soma needs only to support the survival of a single generation.

This concept helps to explain why species differ in their intrinsic life spans. It is noteworthy, for example, that species of birds and bats tend to have greater longevity than flightless species. The reason is thought to be that flight is a very successful way of reducing an animal’s mortality risk, since it is possible to escape many predators and to forage over a greater range, thereby lessening the risk of starvation caused by a local food shortage. If risk is reduced, the statistical chance of living a bit longer is increased, and so it becomes worthwhile to invest in a higher level of somatic maintenance and repair. Studies comparing the biochemistry of cellular repair among long- and short-lived species bear this prediction out. Cells from long-lived organisms exhibit greater capacity to repair molecular damage and withstand biochemical stresses than cells from short-lived species.

The disposable soma theory provides a bridge between understanding not only why aging occurs but also how aging is caused in molecular and cellular terms. It thus extends earlier considerations by Medawar, who suggested that because organisms die young there is little force of selection to oppose the accumulation within the genome of mutations with late-acting deleterious effects, and

by Williams, who suggested that genes with beneficial effects would be favored by selection even if these genes had adverse effects at later ages. This is known as the theory of “antagonistic pleiotropy,” the term pleiotropy meaning that the same gene can have different effects in different circumstances.

The current synthesis of evolutionary ideas about why aging occurs can thus be summarized in four points:

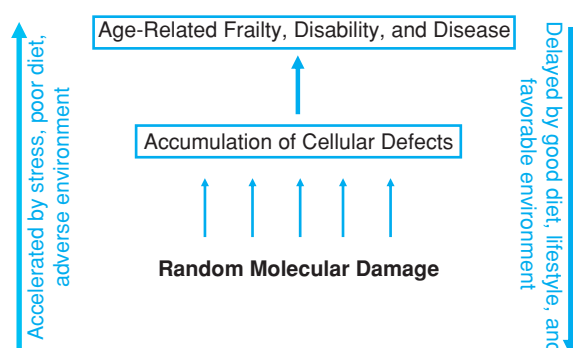

1. There are no specific genes for aging.
2. Genes of particular importance for aging and longevity are those governing durability and maintenance of the soma.
3. There may exist other genetically determined trade-offs between benefits to young organisms and their viability at older ages.
4. There may exist a variety of gene mutations with late deleterious effects that contribute to the senescent phenotype.

Given these points, it is clear that multiple genes contribute to the aging phenotype. A cornerstone of the current research agenda is to identify these genes and discover which are the most important.

## Mechanisms of Aging

Aging appears to be driven by the progressive accumulation through life of a variety of random molecular defects that build up within cells and tissues. These defects start to arise very early in life, probably *in utero*, but in the early years, both the fraction of affected cells and the average burden of damage per affected cell are low. However, over time the faults increase, resulting eventually in age-related functional impairment of tissues and organs (Figure 2-1). This concept makes clear the life-course nature of the underlying mechanisms. Aging is a continuous process, starting early and developing gradually, instead of being a distinct phase that begins in middle to late life.

Since there are multiple kinds of molecular and cellular damage, and a corresponding variety of mechanisms to protect against and repair them, aging is a highly complex process involving multiple mechanisms at different levels. This multiplicity of candidate mechanisms can easily become confusing, particularly since those researching a specific mechanism have a tendency to suggest that their preferred choice is *the* mechanism that drives aging. It will be

**FIGURE 2-1.** The aging process is driven by a lifelong accumulation of molecular damage, resulting in gradual increase in the fraction of cells carrying defects. After sufficient time has passed, the increasing levels of these defects interfere with both the performance and functional reserves of tissues and organs, resulting in age-related frailty, disability, and disease. Stress, adverse environment, and poor nutrition can increase the rate at which molecular damage arises. Intrinsic maintenance mechanisms, such as DNA repair and antioxidants, can slow the rate of accumulation.

apparent from the previous section that, in fact, it is highly unlikely that any single mechanism can tell the whole story. We will consider the prominent hypothesized mechanisms below. For each mechanism, there is evidence supporting the hypothesis that it is indeed an agent of senescence. However, the extent of the contribution to senescence is generally too small for the mechanism to be a sufficient explanation of age-related degeneration. The clear inference is that aging is multicausal and that the various mechanisms all play their part and are likely to interact synergistically. For example, a build-up of mitochondrial DNA mutations will lead to a decline in the cell's energy production, and this will reduce the capacity to carry out energy-dependent protein clearance. In recent years, novel methods based on computer modeling of interactions and synergism between different aging mechanisms have begun to build a better integrated picture of how cells break down with age and there is growing experimental evidence that interactions between multiple mechanisms are important.

### Oxidative Damage

An important theme linking several different kinds of damage is the action of ROS (also known as free radicals), which are produced as by-products of the body's essential use of oxygen to produce cellular energy. Of particular significance are the contributions of ROS-induced damage to cellular DNA through (i) damage to the chromosomal DNA of the cell nucleus, resulting in impaired gene function, (ii) damage to telomeres—the protective DNA structures that appear to “cap” the ends of chromosomes (analogous to the plastic tips of shoelaces), and (iii) damage to the DNA that exists within the cell's energy-generating organelles, the mitochondria, resulting in impaired energy production.

### DNA Damage and Repair

Damage to DNA is particularly likely to play a role in the lifelong accumulation of molecular damage within cells, since damage to DNA can readily result in permanent alteration of the cell's DNA sequence. Cells are subject to mutation all the time, both through errors that may become fixed when cells divide and as a result of ROS-induced damage, which can occur at any time. Numerous studies have reported age-related increases in somatic mutation and other forms of DNA damage, suggesting that an important determinant of the rate of aging at the cell and molecular level is the capacity for DNA repair.

A key player in the immediate cellular response to DNA damage is the enzyme poly(ADP-ribose) polymerase-1 (PARP-1). There is a strong, positive correlation of PARP-1 activity with the life span of the species: cells from long-lived species having higher levels of PARP-1 activity than cells from short-lived species. Similarly, human centenarians, who have often maintained remarkably good general health, appear to have a greater poly(ADP-ribosyl)ation capacity than the general population.

### Telomeres

In many human somatic tissues, a decline in cellular division capacity with age appears to be linked to the fact that the telomeres, which protect the ends of chromosomes, get progressively shorter as cells divide. This is due to the absence of the enzyme telomerase, which

in humans is normally expressed only in germ cells (in testis and ovary) and in certain adult stem cells. Some studies have suggested that in dividing somatic cells, telomeres act as an intrinsic “division counter,” perhaps to protect us against runaway cell division as happens in cancer but causing aging as the price for this protection. Erosion of telomere length below a critical length appears to trigger activation of cell cycle “checkpoints,” especially the p53/p21/pRb system, resulting in permanent arrest of the cell's capacity for further division.

The loss of telomeric DNA is often attributed mainly to the so-called “end-replication” problem—the inability of the normal DNA copying machinery to copyright to the very end of the strand in the absence of telomerase. However, biochemical stress has an even bigger effect on the rate of telomere loss. Telomere shortening is greatly accelerated (or slowed) in cells with increased (or reduced) levels of stress. The clinical relevance of understanding telomere maintenance and its interaction with biochemical stress is considerable. A growing body of evidence suggests that telomere length is linked with aging and mortality. Not only do telomeres shorten with normal aging in several tissues (e.g., lymphocytes, vascular endothelial cells, kidney, liver), but also their reduction is more marked in certain disease states. For example, there appears to be a 100-fold higher incidence of vascular dementia in people with prematurely short telomeres. Furthermore, the psychological stress associated with provision of long-term care for those with chronic illness has also been associated with premature shortening of telomeres, presumably through biochemical sequelae to the chronic activation of stress hormones. Short telomeres may therefore serve as a general indicator of previous exposure to stress and as a prognostic indicator for disease conditions in which stress plays a causative role.

### Mitochondria

An important connection between oxidative stress and aging is suggested by the accumulation of mitochondrial DNA (mtDNA) deletions and point mutations with age. Mitochondria are intracellular organelles, each carrying its own small DNA genome, which are responsible for generating cellular energy. As a by-product of energy generation, mitochondria are also the major source of ROS within the cell, and they are therefore both responsible for, and a major target of, oxidative stress. Any age-related increase in the fraction of damaged mitochondria is likely to contribute to a progressive decline in the cell and tissue capacity for energy production. Age-related increases in frequency of cytochrome *c* oxidase (COX)-deficient cells have been reported in human muscle and brain, associated with increased frequency of mutated mtDNA.

Initial evidence for age-related accumulation of mtDNA mutations came mainly from tissues such as brain and muscle where cell division in the adult, if it occurs at all, is rare. This led to the idea that accumulation of mtDNA mutation was driven mainly by the dynamics of mitochondrial multiplication and turnover within nondividing cells. However, there is now strong evidence of age-dependent accumulation of mtDNA mutations in human gut epithelium, which has the highest cell division rate of any tissue in the body. Thus, it appears that accumulation of defects in mitochondria may be a widespread phenomenon. This is also supported by the discovery that mitochondrial dysfunction may be an important driver of the contribution to cellular senescence that is made by the

shortening of telomeres, confirming the synergism and interaction between different molecular mechanisms of aging.

### Proteins

In addition to damage affecting cellular DNA, damage to protein molecules occurs to a considerable extent, and accumulation of faulty proteins contributes to important age-related disorders such as cataract, Parkinson's disease, and Alzheimer's disease. In some ways, the accumulation of defective proteins is harder to explain than the accumulation of DNA damage, since individual protein molecules are subject to a continual cycle of synthesis and breakdown. Thus, damaged individual protein molecules should be cleared as soon as that molecule is degraded. However, there is evidence that the protein degradation mechanisms themselves deteriorate in function with aging. This is thought to occur because these mechanisms eventually become overwhelmed by a build-up of defective protein molecules that are resistant to breakdown, for example, because they form aggregates large enough to withstand the normal removal systems. It is the build-up of such aggregates that is commonly linked with cell and tissue pathology.

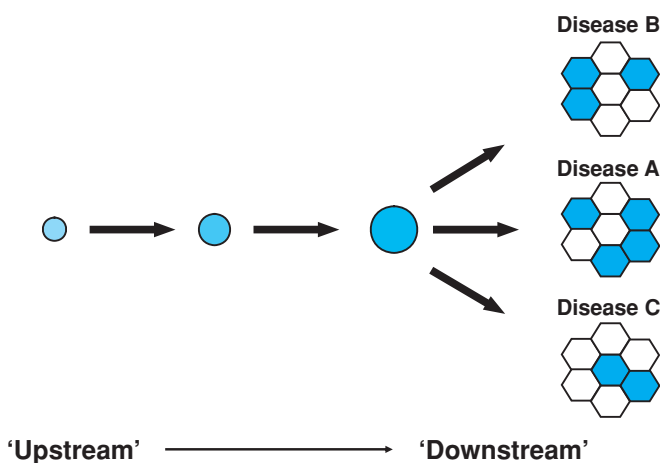

## THE RELATIONSHIP BETWEEN NORMAL AGING AND DISEASE

The relationship between normal aging and age-related disease has long been controversial. At stake is the question of whether the term "normal aging" should be reserved for individuals in whom identifiable pathology is absent, whereas specific age-related diseases, such as Alzheimer's disease, are seen as distinct entities. However, this concept gives rise to a conundrum. As a cohort ages, the fraction that can be said to be aging "normally" declines to a very low level. Whether the word "normal" can usefully be applied to such an atypical subset is debatable.

In a clinical context, it often makes sense to try and draw a distinction between normal aging and disease, since this may have implications for treatment. However, if the aim is to understand the *mechanisms* responsible for age-related conditions, such a distinction can obscure what is really going on, since the boundary between aging and disease pathogenesis may be somewhat arbitrary. For the vast majority of chronic, degenerative conditions, such as dementia, osteoporosis, and osteoarthritis, age is the biggest single risk factor predisposing to the disease in question. What is it about aging that renders the older cell or tissue more vulnerable to pathology?

Aging involves the progressive accumulation of cellular and molecular lesions, and the same is generally true of the age-associated diseases. Thus, there is considerable potential for overlap between the causative pathways leading to normal aging and age-related diseases. In the case of osteoporosis, for example, progressive bone loss from the late twenties onwards is the norm. Whether an individual reaches a critically low bone density, making him or her highly susceptible to fracture, is governed by how much bone mass they had to start with and by their individual rate of bone loss. The process that leads eventually to osteoporosis is thus entirely "normal," but what distinguishes whether or not this process results in an overtly pathological outcome is a range of moderating factors. In the case of Alzheimer's disease, most people above the age of 70 years have extensive cortical amyloid plaques and neurofibrillary tangles (the

## Multistage Progression of Age-Related Disease

**FIGURE 2-2.** Multistage progression of age-dependent diseases. The intrinsic aging process, as well as most age-dependent diseases, are driven by the gradual accumulation of molecular and cellular faults. Although individual age-dependent diseases may be defined by particular "end-stage" cellular pathology, common upstream processes, such as DNA damage or oxidative damage to proteins, are shared between many age-related diseases and intrinsic aging. Intervention in these upstream processes has the potential, therefore, to be effective against multiple age-related diseases.

so-called hallmarks of classic Alzheimer's disease) even though they may show no evidence of major cognitive decline. In this instance, what determines whether or not the diagnosis of Alzheimer's disease is called for may be not so much the presence of lesions as which specific targets are affected.

As the upstream mechanisms giving rise to age-related diseases often involve the kind of damage that is thought to contribute to intrinsic aging, similar damaging processes may contribute to the pathogenesis of multiple disorders, even though the final nature of the end-stage lesions may be different (Figure 2-2). For example, oxidative stress may be a factor in protein aggregation in neurodegenerative diseases, in cell defects contributing to atherogenesis in cardiovascular diseases, and in impaired function of osteoblasts in osteoporosis. If this concept is correct, future interventions that target underlying processes of normal aging may postpone multiple age-related diseases.

The role played by basic cell maintenance systems both in securing longevity and in protecting against a spectrum of age-associated conditions is nicely illustrated by the human CDKN2a locus, which intriguingly codes for two different proteins via different open reading frames. One of these proteins is p16<sup>INK4a</sup>, a cyclin-dependent protein kinase inhibitor; the other is ARF, a potent regulator of p53. The level of p16<sup>INK4a</sup> is associated with cellular aging in skin, pancreatic islets, and hematopoietic and neuronal stem cells, and p16<sup>INK4a</sup>, together with ARF, is involved in regulating cell senescence and tumor suppression. At the population level, polymorphism at the CDKN2a locus is associated with risk for type 2 diabetes and with the preservation of physical function at older age. It seems likely that further study of the gene and its protein products will reveal important interconnections with aging and age-related diseases.

Through increased understanding of how fundamental maintenance systems are involved in protection against both aging and disease, it can be expected that future interventions will be found

that can target underlying processes of normal aging, with the benefit of postponing multiple age-related diseases.

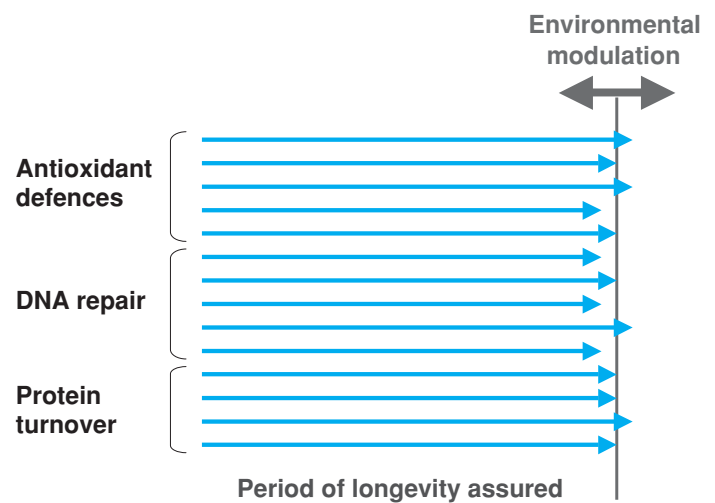

## GENETIC AND NONGENETIC EFFECTS ON AGING

The disposable soma theory predicts that at the heart of the evolutionary explanation is the principle that organisms have been acted upon by natural selection to optimize the utilization of metabolic resources (energy) between competing physiological demands, such as growth, maintenance, and reproduction. Consistent with this prediction, it is striking that insulin signaling pathways appear to have effects on aging that may be strongly conserved across the species range. Insulin signaling regulates responses to varying nutrient levels. Allied to the role of insulin signaling pathways is the discovery that a class of proteins called sirtuins appears to be centrally involved in fine-tuning metabolic resources in response to variations in food supply. As described in Chapter 1, restricted intake of calories in laboratory rodents simultaneously suppresses reproduction and upregulates a range of maintenance mechanisms, resulting in an extension of life span and the simultaneous postponement of age-related diseases. Although dietary restriction may not have an effect of similar magnitude in humans, it will be surprising if there are no metabolic consequences of varying food supply.

One of the clearest examples of how metabolic signaling affects aging and longevity comes from a study on genes of the insulin/insulin-like growth factor 1 (IGF-1) signaling pathway in *C. elegans*. When threatened with overcrowding, which the larval worm detects by the increasing concentration of a pheromone, its development is diverted from the normal succession of larval molts into a long-lived, dispersal form called the “dauer” larva. Dauers show increased resistance to stress and can survive very much longer than the normal form, reverting to complete their development should more favorable conditions be detected. An insulin/IGF-1-receptor gene, *daf-2*, heads the gene regulatory pathway that controls the switch into the dauer form, and mutations in *daf-2* produce animals that develop into adults with substantially increased life spans. In common with other members of the evolutionarily conserved insulin/IGF-1 signaling pathway, *daf-2* also regulates lipid metabolism and reproduction. The *daf-2* gene product exerts its effects by influencing “downstream” gene expression, in particular via the actions of another gene belonging to the dauer-formation gene family, *daf-16*, which it inhibits.

Gene expression profiling has identified more than 300 genes that appear to have their expression levels altered by *daf-16* regulation. This large number suggests that, as predicted by the evolutionary theory, many genes are involved in determining longevity. The genes modulated by *daf-16* can be grouped into several broad categories. The first category includes a variety of stress-response genes, including genes for antioxidant enzymes. A second group of genes encode antimicrobial proteins, which are important for survival in this organism because its death is commonly caused by proliferation of bacteria in the gut. A miscellaneous third group included genes involved in protein turnover, which is an important cellular maintenance system.

The picture that emerges from both evolutionary theory and the empirical evidence is that the genetic control of longevity is mediated through a large array of mechanisms specifying individual maintenance and repair systems (Figure 2-3). Acting above these may exist a hierarchy of genes that serve to sense the quality of the

**FIGURE 2-3.** Gene regulation of longevity is effected through the genetic specification of many individual pathways for maintenance and repair of somatic cells and tissues. Among these pathways are those for antioxidant defense, DNA repair, and protein turnover. Natural selection is thought to have tuned these mechanisms to provide similar periods of “longevity assured” before the lesions resulting from the imperfect nature of the maintenance and repair processes give rise to age-dependent frailty, disability, and disease. In some organisms, there appears to have evolved a capacity to respond to changes in the environment, e.g., the availability of food, to fine-tune the overall settings of maintenance and repair processes so as to optimize the investments in maintenance and repair to suit different circumstances. One such example is the effect of dietary restriction in small animals, which results in suspension of reproduction and a coordinated increase in maintenance and repair, which in turn postpones both intrinsic aging and age-dependent diseases. The extent to which such capacity for environmental modulation exists in humans is as yet unclear, but it is likely to be less than in small animals for which reproduction constitutes a much greater fraction of the organism’s energy budget.

environment, e.g., the abundance of food, and adjust metabolism accordingly. The discoveries that have been made during the current expansion of research on genetic and nongenetic factors affecting aging in nonhuman animal models are now beginning to be extended to human health and disease. Broad similarities are expected to exist, although in view of the different ecological circumstances affecting humans, as compared to a small animal like a nematode worm, the existence and nature of the higher-level, environment-sensing genetic pathways cannot be assumed to be identical.

## GENETICS OF HUMAN LONGEVITY AND THE IMPLICATIONS FOR AGE-DEPENDENT DISEASE

While genetics is unlikely to have played any important part in the near doubling of human life expectancy over the last two centuries, the emergence of large numbers of people attaining great age has revealed information about the genetic contribution to human longevity that was unavailable previously. Population genetics explains how much of the variation in a trait—in this case, longevity—is due to innate differences in gene endowment and how much is due to the environment. When few individuals survived to the limit of the biological potential, the genetic contribution was masked by the large contribution to variance that arose from the environment and also, of course, from luck. During the last two decades, the possibility

of applying genetic techniques to understanding the heritability of innate factors influencing longevity has seen the burgeoning of studies on the genetics of human longevity. Initially, these examined longevity records for monozygotic and dizygotic twins. From these analyses emerged the finding that, in the population at large, gene differences account for 20% to 30% of the variation in human life span. More recently, studies of families with extreme longevity, such as centenarians, support the idea that there is an important genetic contribution to an individual's chance of attaining great age. Siblings of centenarians are more likely to become centenarians themselves, and these effects extend also to other family members. A number of candidate-gene studies have tested the hypothesis that specific alleles associated with reduced risk of disease, or with improved somatic maintenance, may be found to be more prevalent in centenarians than in younger age groups. The positive results reported from such studies support the notion that, out of an initially heterogeneous cohort, those with a genetic endowment predisposing to somatic durability and freedom from disease will become increasingly numerous, as a fraction of the surviving members, while the cohort grows ever older.

The advent of rapid genome analysis techniques has made possible the scanning of the entire human genome for genetic markers that are associated with longevity in kin groups, without requiring any prior hypothesis as to the nature of the genes associated with these markers. Several current studies are exploiting these techniques using, for example, DNA from surviving nonagenarian siblings to search for markers that might confer familial predisposition for healthy aging. The rationale for these studies is that while, for an individual, surviving to great age might be a matter of chance, the fact that two or more individuals from the same family have done so makes it more likely that something in their shared genetic endowment is responsible.

Early results from genetic studies on human longevity are now emerging. In line with the evidence from nonhuman animal models, there is some indication that long-lived humans have decreased levels of IGF-1, consistent with the hypothesis that insulin/IGF-1 response is associated with longevity. Further studies on gene polymorphisms linked to the insulin/IGF-1-signaling pathways are likely to reveal this association in further detail. Similarly, there is growing interest in the possibility that polymorphisms in members of the sirtuin gene family (proteins that influence the activity of essential factors regulating the general patterns of gene expression), already shown to be important in connection with longevity-associated metabolism in yeast and animal models, may have connections with life span regulation in humans.

Among the factors that directly affect cellular maintenance, predicted by evolutionary theory to be central to regulating aging and longevity, there is growing evidence that genes regulating fundamental DNA repair processes are linked to life span. The human progeroid condition Werner's syndrome is caused by mutation in the *WRN* gene, which codes for an enzyme that has multiple roles in DNA maintenance and repair, while Hutchinson-Gilford syndrome (a more extreme form of progeria) is associated with mutation in the *LMNA* gene coding for a component of the external envelope of the cell nucleus.

Other gene associations with aging are being discovered among genes that regulate the cellular response to damage. When a cell detects that it has suffered damage, particularly to its DNA, it may activate a pathway that leads to programmed cell death (apoptosis)

or another pathway that leads to permanent cell cycle arrest. Which of these routes is taken depends in large part on the risk, posed by the damage, of potentially initiating a tumor. If the cell is a stem cell, it is more likely to undergo apoptosis. Teleologically this appears to make sense, since the cancer transformation risk of preserving a cell that belongs to a highly proliferative tissue compartment is greater, and so it is logical for the cell to be deleted and replaced. On the other hand, if the cell belongs to a more general category, such as a fibroblast, it is less likely that apoptosis will be triggered and the cell instead is subjected to permanent arrest, or senescence. Various genes influence the likelihood of adopting one or another of these alternatives. Furthermore, experimental modulation of these genes or naturally occurring polymorphisms have been found to influence the outcome. For example, if the function of the tumor suppressor p53 is genetically enhanced, apoptosis is more likely, and this is found to be associated with a reduced lifetime risk of cancer. However, this protection comes at a cost, since in mouse models, at least, the process of intrinsic aging, caused by age-dependent tissue loss of cellularity, is accelerated by genetic enhancement of p53 activity. Life span is reduced and various age-dependent pathological changes occur earlier.

In terms of the genetics of specific age-dependent diseases, there is likely to be considerable overlap between the underlying pathways contributing to intrinsic aging generally and to the lesions associated with individual diseases. It is striking that even in the cases where gene polymorphisms have been linked to particular diseases, such as Alzheimer's, the dominant risk factor in sporadic cases, i.e., those not associated with strongly familial, early-onset presentation, is age rather than genotype. Thus, in pursuing the genetics of these kinds of age-dependent conditions, the research question is more likely to be answered if it is formulated in terms of addressing how specific genes affect the underlying pathogenesis of intrinsic aging, rather than driving a pathway that is mechanistically distinct.

## MALLEABILITY OF THE HUMAN AGING PROCESS

One of the striking features of the increase in human life expectancy in recent decades is that, contrary to demographic forecasts of the major national and international agencies, life span has continued to increase steadily. This was initially surprising because it was thought that there was a fixed ceiling on human life expectancy imposed by the intrinsic, programmed nature of the aging process itself. By this logic, once death rates in the early and middle years had been pushed down to the low levels seen in most developed countries, there would be little opportunity for life expectancy to climb further.

The failure of the limited life span paradigm can, however, be understood within the framework for the intrinsic biology of aging outlined previously. If there is no intrinsic genetic program for aging, then the mechanisms that drive the aging process—accumulation of molecular and cellular damage—are amenable to environmental modulation. Aging is the result of a gradual but progressive accumulation of *damage* to cells, tissues, and organs. However, the process is not entirely passive, since the rate of accumulation is strongly resisted by maintenance and repair processes, which are controlled by *genes*. Furthermore, both the incidence of damage and the regulation of these genes may be influenced by extrinsic factors. This picture readily accommodates the roles of at least five major elements

contributing to the individuality of the human aging process: genes, nutrition, lifestyle (e.g., exercise), environment, and chance.

The recognition of this interplay of factors is likely to be crucial for integrating biological, clinical, and social gerontology. For example, environment is often defined by social factors such as housing, transport, and income. Poor environments may adversely affect an individual's opportunities for healthy aging in terms of nutrition, lifestyle, etc. In particular, a poor environment can reinforce a tendency for the older person to suffer social isolation, which in turn can exacerbate psychological and physical deterioration. On the positive side, the understanding that we now have of the biological science of human aging supports the idea that the aging process is much more malleable than has hitherto been recognized. It is likely that the continuing increase in human life expectancy reflects the increasingly favorable conditions of life in most developed countries. This opens the way to a range of interventions that may further improve health in old age and extend quality of life. Conversely, the threat exists that with rising levels of obesity and declining levels of physical activity, the future may see the increase in longevity slow down or even reverse.

# Immunology and Aging

*Birgit Weinberger* ■ *Daniela Weiskopf* ■ *Beatrix Grubeck-Loebenstein*

## GENERAL ASPECTS OF IMMUNOSENESCENCE

The immune system undergoes profound age-related changes, collectively termed immunosenescence. This process affects various cell types including hematopoietic stem cells (HSCs), lymphoid progenitor cells in the bone marrow and in the thymus, the thymus itself, mature lymphocytes in peripheral blood and secondary lymphatic organs and also elements of the innate immune system. These immunological changes contribute to elevated susceptibility to infectious diseases, to more severe symptoms, prolonged duration and poorer prognosis of infections and to decreased protective effects of vaccinations. Reactivation of Varicella-Zoster virus leading to herpes zoster is observed by far more frequently in elderly compared to young adults. Infections with influenza virus are associated with more severe symptoms in elderly patients and with an increased risk for secondary complications. Additionally, risks for many other infections are increased in elderly people. As the elderly population is particularly susceptible to infection and vulnerable in case of disease, vaccination is of special importance. Unfortunately, the efficacy of various vaccines, e.g., influenza, hepatitis A and hepatitis B, is lower in elderly people. New strategies are needed to improve vaccination and to develop vaccines that specifically target and stimulate the aged immune system.

## EFFECT OF AGING ON DIFFERENT CELL TYPES

### Hematopoietic Stem Cells and Lymphoid Progenitor Cells

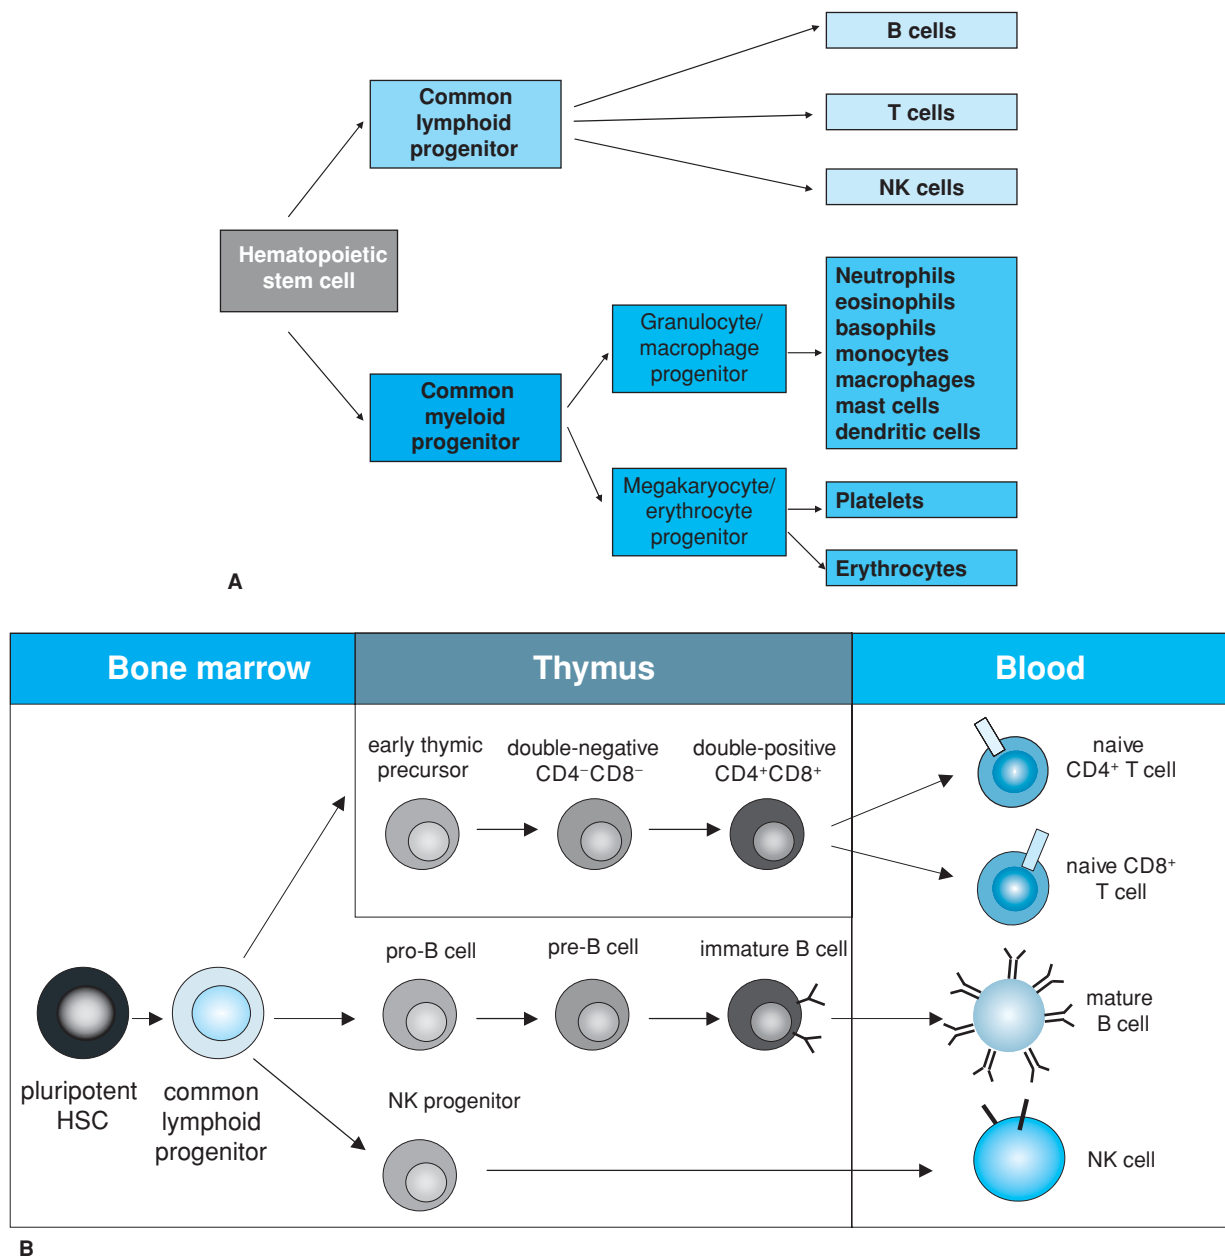

#### Hematopoiesis

All circulating blood cells of an adult individual including immature lymphocytes are generated in the bone marrow. Both liver and

spleen can also be recruited as sites for haematopoiesis in case of increased need for newly generated blood cells or if the bone marrow is injured. All blood cells originate from a common stem cell (HSC) and become committed to develop along particular lineages. The first step of differentiation leads to the separation of myeloid and lymphoid progenitors. Myeloid progenitors further differentiate to become erythrocytes, platelets, basophils, eosinophils, neutrophils, monocytes, macrophages, mast cells, or dendritic cells (DC). Lymphoid progenitors give rise to B lymphocytes, T lymphocytes, and natural killer (NK) cells (Figure 3-1A). Maturation of B cells, which includes rearrangement and expression of immunoglobulin genes as well as selection for cells with functional immunoglobulins and against self-reactive B cells, takes place in the bone marrow. Mature B cells then enter the circulation and lymphoid organs where they encounter their specific antigens. T lymphocytes leave the bone marrow in an immature state and migrate to the thymus where maturation with somatic recombination and expression of the T cell receptor (TCR) genes occur. Additionally, positive selection for functional TCRs and negative selection against self-reactive T cells take place in the thymus. Like B cells, mature T cells finally migrate to lymphoid organs and are also found in the blood stream (Figure 3-1B) (Color Plate 1).

#### Age-Related Changes of Hematopoiesis

The overall amount of hematopoietic tissue in the bone marrow is decreased with age. Changes of the hematopoietic microenvironment and alterations of hormone production disturb self-renewal and lineage commitment of HSCs. HSCs themselves are also affected by aging as indicated, e.g., by shortening of telomeres. In combination, these two effects may lead to fewer and less functional HSCs with increasing age. Interestingly, the lymphoid lineage is far more compromised by age-related changes than the myeloid lineage. Fewer pro-B cells are generated in aging and fewer of these cells transit through the next differentiation steps. As a consequence, the

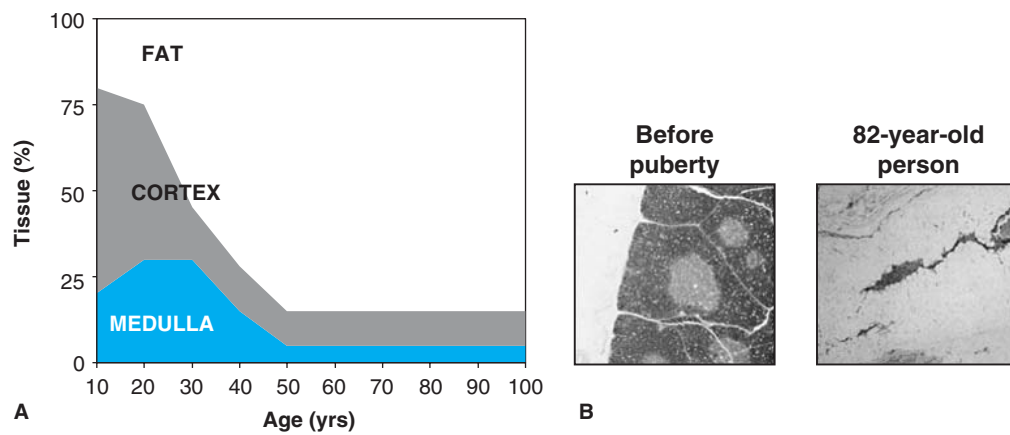

**FIGURE 3-1.** Hematopoiesis and maturation of lymphoid cells. (A) Schematic representation of hematopoiesis. Hematopoietic stem cells differentiate into lymphoid and myeloid progenitors that give rise to the different cell types found in peripheral blood. (B) Maturation of lymphoid cells. Maturation of T cells takes place in the thymus, whereas B cells and NK cells undergo maturation in the bone marrow. All mature lymphocytes migrate into the periphery and can be found in blood.

number of mature B cells leaving the bone marrow is lower. T cell precursors seem to be less affected by aging. However, due in part to dramatic alterations in the thymus, where the maturation of T cells takes place, the T cell compartment undergoes substantial changes with age.

### Involution of the Thymus

Maturation of T cells takes place in the thymus, a bilobed organ situated in the upper anterior thorax, just above the heart. It is divided into multiple lobules that consist of an outer cortex that is densely populated with thymocytes and an inner medulla that is sparsely populated with thymocytes. Other cell types found in the thymus

are nonlymphoid epithelial cells, macrophages, and lymphoid DC. They provide important stimuli (e.g., cytokines and physical interaction via major histocompatibility complex (MHC) molecules) for the development of mature T lymphocytes. Immature T cells enter the thymus where they proliferate and differentiate into mature T lymphocytes. During this differentiation, the T cells migrate from the outer cortex to the medulla from where they exit the thymus and spread to the periphery. The very complex maturation process includes proliferation, recombination of the TCR genes to assure diversity of the T cell repertoire, negative selection, and extensive apoptosis of self-reactive or nonreactive T cells and positive selection of expedient T cells, which recognize foreign antigens presented by MHC complexes. The T cells that exit from the thymus are called

**FIGURE 3-2.** Thymic involution and loss of functional thymic tissue. (A) With increasing age, functional thymic tissues (medulla and cortex) are replaced by fat. Depicted are percentages of thymic tissues and fat tissue against donor age. (B) Histological pictures of human thymic tissue derived from a child or an 82-yr-old person stained with hematoxylin. In the pediatric thymus areas of cortex (outer darker staining) and medulla (inner lighter staining) tissue are prominent. Thymic tissue from elderly individuals shows dramatic reduction of functional tissue and invasion of adipose tissue. Magnification = 120 $\times$ . Reprinted from George AJT, Ritter MA. Thymic involution with ageing: obsolescence or good housekeeping? *Immunol. Today.* 1996;17;267. With permission from Elsevier.

naïve as they have never had contact with their specific antigen. Naïve T cells make up the reservoir of cells that is needed to respond to neoantigens that are encountered throughout life.

One of the hallmarks of immunosenescence is the involution of the thymus, which is characterized by a reduction in the overall size of the organ and by a replacement of the functional cortex and medulla tissue by fat. These changes start early in life and are almost complete by the age of 40 to 50 years. [Figure 3-2](#) illustrates the redistribution of tissues in the thymus with increasing age and depicts histological changes. Involution of the thymus could be caused by both defects in the T cell precursor cells and changes of the thymic stromal cells. This working model postulates that these changes could occur simultaneously in each compartment or one could precede the other. In either case, age-associated degeneration of the one compartment negatively influences the other, leading to progressive loss of thymic function. As a consequence, the number of thymocytes and of naïve T cells exiting the thymus is dramatically decreased with age. The missing output of newly generated naïve T cells leads to crucial changes in the T cell repertoire and the composition of the T cell compartment. However, the overall role of thymus involution in age-related changes of peripheral immune cells remains to be determined.

## Innate Immune System

### Components and Functions of the Innate Immune System

The innate immune system is the first line of defense against infection. It consists of cellular and biochemical defense mechanisms that respond to infectious agents by recognizing common structures shared by pathogens. It is not able to distinguish between fine differences of antigens. The innate immune system reacts faster than the adaptive immune system. However, due to a lack of memory mechanisms, the innate immune system is not able to “remember” antigens. There are therefore no differences between primary and subsequent responses to the same pathogen. The major components of innate immunity are physical barriers (epithelia), phagocytic cells

(neutrophils, macrophages, DCs), NK cells, the complement system, and a variety of cytokines that regulate and coordinate innate immune responses ([Table 3-1](#)). Toll-like receptors (TLR) are highly conserved receptors that are expressed on different cell types of the innate immune system and recognize distinct classes of pathogens. To date, over 20 mammalian TLR have been identified recognizing, for example, lipopolysaccharide (LPS), other bacterial proteoglycans, or unmethylated CpG nucleotides found in bacteria or viruses. Each TLR seems to be crucial in the responses to distinct classes of infectious pathogens. Binding of microbial components to the TLR leads to activation of innate immune cells and induces production of cytokines.

**TABLE 3-1**

### Components and Functions of the Innate Immune System

COMPONENT	FUNCTION
Epithelial barriers	Prevention of microbial entry
Complement	Opsonization of microbes, killing of microbes, activation of leukocytes
Mannose-binding lectin	Opsonization of microbes, activation of complement
Cytokines	Inflammation, activation of phagocytes, stimulation of IFN- $\gamma$ production
Dendritic cells	Antigen uptake in peripheral sites, antigen presentation in lymph nodes
Neutrophils	Phagocytosis, killing of pathogens
Eosinophils	Killing of antibody-coated parasites
Mast cells and basophils	Release of granules containing histamine and active agents, induction of inflammation and tissue responses
Macrophages	Phagocytosis, killing of pathogens, cytokine release, antigen presentation
Natural killer cells	Release of lytic granules, killing of infected cells and tumor cells

The main function of neutrophils and macrophages is to recognize, internalize, and destroy pathogens. Macrophages also process foreign proteins to peptides that are then presented to T lymphocytes. This link between innate and adaptive immunity will be described in more detail in the next section. DC are of crucial importance for the initiation of an adaptive immune response to new antigens. They are found under the epithelia of many organs where they capture antigens, process them, and present them to naïve T cells after migrating to lymph nodes.

NK cells are able to directly kill target cells by releasing perforin and granzymes. Perforin creates pores in the target cells through which granzymes enter the cells. These enzymes activate caspases and induce apoptosis of the cell. NK cell function is regulated by a balance of activating and inhibiting receptors. Activation is induced by molecules that are expressed on infected or otherwise stressed host cells. NK cells are thus able to identify, for example, virus-infected cells. MHC class I molecules, which are present on all host cells, act as inhibitory signals and prevent killing of healthy cells by NK cells. As a variety of viruses induce down-regulation of MHC class I in order to avoid recognition by the adaptive immune response, the lack of MHC expression indicates viral infection and is also used by NK cells to identify these cells.

Additionally, cells of the innate immune system produce cytokines that cause inflammation, induce the release of inflammatory plasma proteins, and activate innate and adaptive immune cells, which are recruited to the site of infection (see Chapter 4).

### Age-Related Changes of the Innate Immune System (Table 3-2)

While most humoral components of the innate immune system such as the complement system are not affected by the aging process, age-related changes of innate immune cells occur, leading to alterations in cell function and in the production of cytokines and chemokines. The overall number of neutrophils remains constant, but there are characteristic age-related functional changes. Both their phagocytic capacity as well as their efficiency of killing internalized microbes is

decreased in old age. This leads to an overall reduction of bactericidal activity. A decreased ability to kill pathogens has also been observed in aged macrophages. Additionally, their antigen-presenting function is impaired due to a decreased expression of MHC class II molecules, leading to defects in the activation of CD4<sup>+</sup> T cells. Alterations in the expression and function of TLRs also add to age-related impairments within the innate immune system.

NK cell numbers increase with age, but their cytotoxic potential and the production of cytokines decrease on a per cell basis. Proliferation of aged NK cells in response to stimulatory cytokines like IL-2 is reduced. How DC are affected by age is still not fully understood. In aged mice and humans, the number of DC in the skin is decreased and the capacity of DC to migrate to lymph nodes after antigen contact is impaired. Little is known about age-related functional changes of human DC. Animal models suggest that antigen presentation is decreased in old age; however, so far this has not been confirmed in humans. DC differentiated in vitro from monocytes derived from aged humans are indistinguishable from their young counterparts.

Subclinical inflammatory processes gradually increase with age in a variety of species (see Chapter 4). Elevated plasma concentrations of interleukin-6 (IL-6), IL-1 $\beta$ , and tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) have been described in elderly populations and were postulated as predictive markers of functional disability and mortality. This progressive proinflammatory state in elderly persons has been referred to as “inflamm-aging.” Such chronic inflammatory processes may support the development and progression of age-related diseases, such as osteoporosis, neurodegeneration, and atherosclerosis. At first sight, “inflamm-aging” seems to contradict the functional defects observed in innate immune cells. However, it is believed that chronic subclinical inflammation is caused by chronic stimulation of the innate immune system by products of degradation processes and/or by the partial inability of the aged immune system to eliminate certain pathogens. This could lead to chronic, yet inefficient innate immune responses.

Genetic factors, like polymorphisms in genes encoding for cytokines like IFN- $\gamma$ , IL-6, and IL-10 can also influence the severity of inflammatory responses in old age. Chemokines, which direct the movement of circulating lymphocytes to sites of injury or infection, play a crucial role in initiating adaptive immune responses and in directing movement of immune cells through the body. Approximately 50 human chemokines have been described. Alterations in serum concentrations of some of them have been reported in elderly people. However, for most of the proteins studied, conflicting results have been obtained. Some reports show increased concentrations of the proinflammatory, IFN- $\gamma$  inducible chemokines MIG (CXCL9) and IP-10 (CXCL10). Elevated levels of MCP-1 (CCL2), which also acts proinflammatory by regulating T cell and monocyte recruitment toward sites of inflammation, have been described in elderly people; however, other studies were not able to confirm these findings.

## Adaptive Immune System

### Components and Principal Functions of the Adaptive Immune System

The adaptive immune system consists of lymphocytes, namely, T and B cells, and antibodies, which are produced by B cells. Both

**TABLE 3-2**

**Age-Related Changes of Innate Immune Cells**

	AGE-RELATED DECREASE	AGE-RELATED INCREASE
Neutrophils	Phagocytic capacity Oxidative burst Bactericidal activity	Membrane viscosity

**FIGURE 3-3.** Primary and secondary immune response. The upper panel shows a schematic depiction of the strength of the immune response as measured, e.g. by antibody titers or numbers of effector T cells. The secondary immune response after repeated encounter with the same antigen is faster and more pronounced compared to the primary immune response. After repeated stimulation with the same antigen immune responses are sustained at a higher level. The lower panel depicts the expansion and differentiation of lymphocytes in the course of primary and secondary immune responses. Naïve cells differentiate into effector cells after encountering their antigen. Most effector cells are eliminated by apoptosis after clearance of the pathogens. Few cells remain in the body as long-lived memory cells and are able to quickly and efficiently differentiate into effector cells in case of a second contact with the same antigen. After clearance of the pathogens, most effector cells are again eliminated; however, more long-lived memory cells are generated.

B and T lymphocytes can be divided into naïve, memory, and effector cells with regard to their differentiation status. Lymphocytes that have not yet encountered their specific antigen are called naïve. Upon contact with their antigen, these cells proliferate and differentiate into memory and effector lymphocytes. This antigen-triggered response increases in magnitude and effectiveness with each encounter of a particular infectious agent (Figure 3-3) (Color Plate 2). After the first encounter with the antigen, it takes several days for the adaptive immune response to fully respond and activate effector cells. Once the pathogen is cleared, most of the activated effector cells are eliminated. However, long-lived memory cells remain in the body and ensure that the response to a second contact with the same antigen is faster and more pronounced compared to the primary response. Both T and B lymphocytes recognize their antigens via highly diverse surface molecules called T cell receptor (TCR) or B cell receptor (BCR), respectively. The diversity of these molecules is due to extensive somatic recombination of the genes encoding the TCR or BCR during the maturation of lymphocytes. The total

number of specificities of the lymphocytes in an individual, called the immunological repertoire, is estimated to be  $10^7$  to  $10^9$ .

### T Lymphocytes

T cells can be divided into  $CD4^+$  and  $CD8^+$  T cells.  $CD4^+$  T cells are called T-helper cells and are required for stimulation of B cells and activation of macrophages.  $CD8^+$  T cells or cytotoxic T lymphocytes (CTL) directly interact with virally infected and tumor cells and kill these target cells. T cells are not able to directly recognize foreign antigens. Their highly diverse T cell receptors interact with molecules of the MHC that are associated with peptides derived from antigenic proteins. MHC class I molecules are present in all nucleated cells. All proteins that are synthesized within a cell are processed into peptides and presented via MHC class I on the surface of the cells.  $CD8^+$  T cells interact with the MHC-peptide complexes and distinguish between self and nonself peptides. Cells presenting foreign peptides, e.g. viral components on infected cells, are targeted for

**FIGURE 3-4.** Processing and presentation of antigens via MHC class I or class II. (A) Synthesized proteins are degraded via proteasomes and presented on MHC class I molecules.  $CD8^+$  cytotoxic T cells recognize foreign peptides and mediate killing of infected cells. (B) Pathogens are internalized by antigen presenting cells; proteins are degraded in endocytic vesicles and presented on MHC class II molecules.  $CD4^+$  helper T cells recognize foreign peptides and stimulate B cells and macrophages.

killing (Figure 3-4A).  $CD4^+$  T-helper cells recognize peptides in the context of MHC class II molecules. These proteins are present only on specialized antigen-presenting cells of the innate immune system (monocytes, macrophages, DC) and on B cells. Antigen-presenting cells recognize foreign antigens, internalize them, and process them into peptides, which are presented in the context of MHC class II molecules. Interaction of antigen-presenting cells with specific T-helper cells induces cytokine production in T cells and stimulates B cells to produce antibodies (Figure 3-4B) (Color Plate 3).

When naïve T cells (both  $CD4^+$  and  $CD8^+$ ) make contact with cells presenting their specific antigen via MHC molecules, they proliferate and differentiate into memory and effector T cells. This process is called clonal expansion. As mentioned above,  $CD8^+$  and  $CD4^+$  T cells exert distinct effector functions. As described above for NK cells, effector  $CD8^+$  T cells also release perforin and granzymes to induce apoptosis in infected or tumor cells.  $CD4^+$  effector cells stimulate phagocytes of the innate immune system. NK cells induce cytokine production in T cells to enhance immune responses and are required for efficient antibody production by B cells (Figure 3-5A) (Color Plate 4). On the basis of their cytokine profile and effector functions,  $T_{H1}$  and  $T_{H2}$  subpopulations have been characterized within the T-helper cells. Both subsets differentiate from the same precursors, namely naïve  $CD4^+$  T cells. The  $T_{H1}$  differentiation pathway is mainly triggered by the cytokine IL-12, which is produced by innate immune cells in response to microbes that infect or activate macrophages and DC.  $T_{H1}$  cells produce proinflammatory cytokines, such as IFN- $\gamma$  and TNF- $\alpha$ . These cytokines stimulate the microbicidal activity of phagocytes and the production of opsonizing and complement-fixing IgG antibodies. Microbes can then be efficiently phagocytosed and eliminated by phagocytes.

$T_{H2}$  responses mainly occur in response to helminths and allergens, which cause chronic T cell stimulation, often in the absence of macrophage activation or pronounced innate immune responses.  $T_{H2}$  differentiation is induced by IL-4, which is produced mainly by the  $T_{H2}$  cells themselves.  $T_{H2}$  cells produce IL-4, IL-5, IL-10, and IL-13, stimulate B cells, and antagonize the phagocyte-stimulating effect of IFN- $\gamma$ . As both differentiation pathways are self-enhancing, immune responses are often polarized in either the one or the other direction. However, T cells with a  $T_{H0}$  phenotype, which are able to produce  $T_{H1}$  and  $T_{H2}$  cytokines, have also been described.

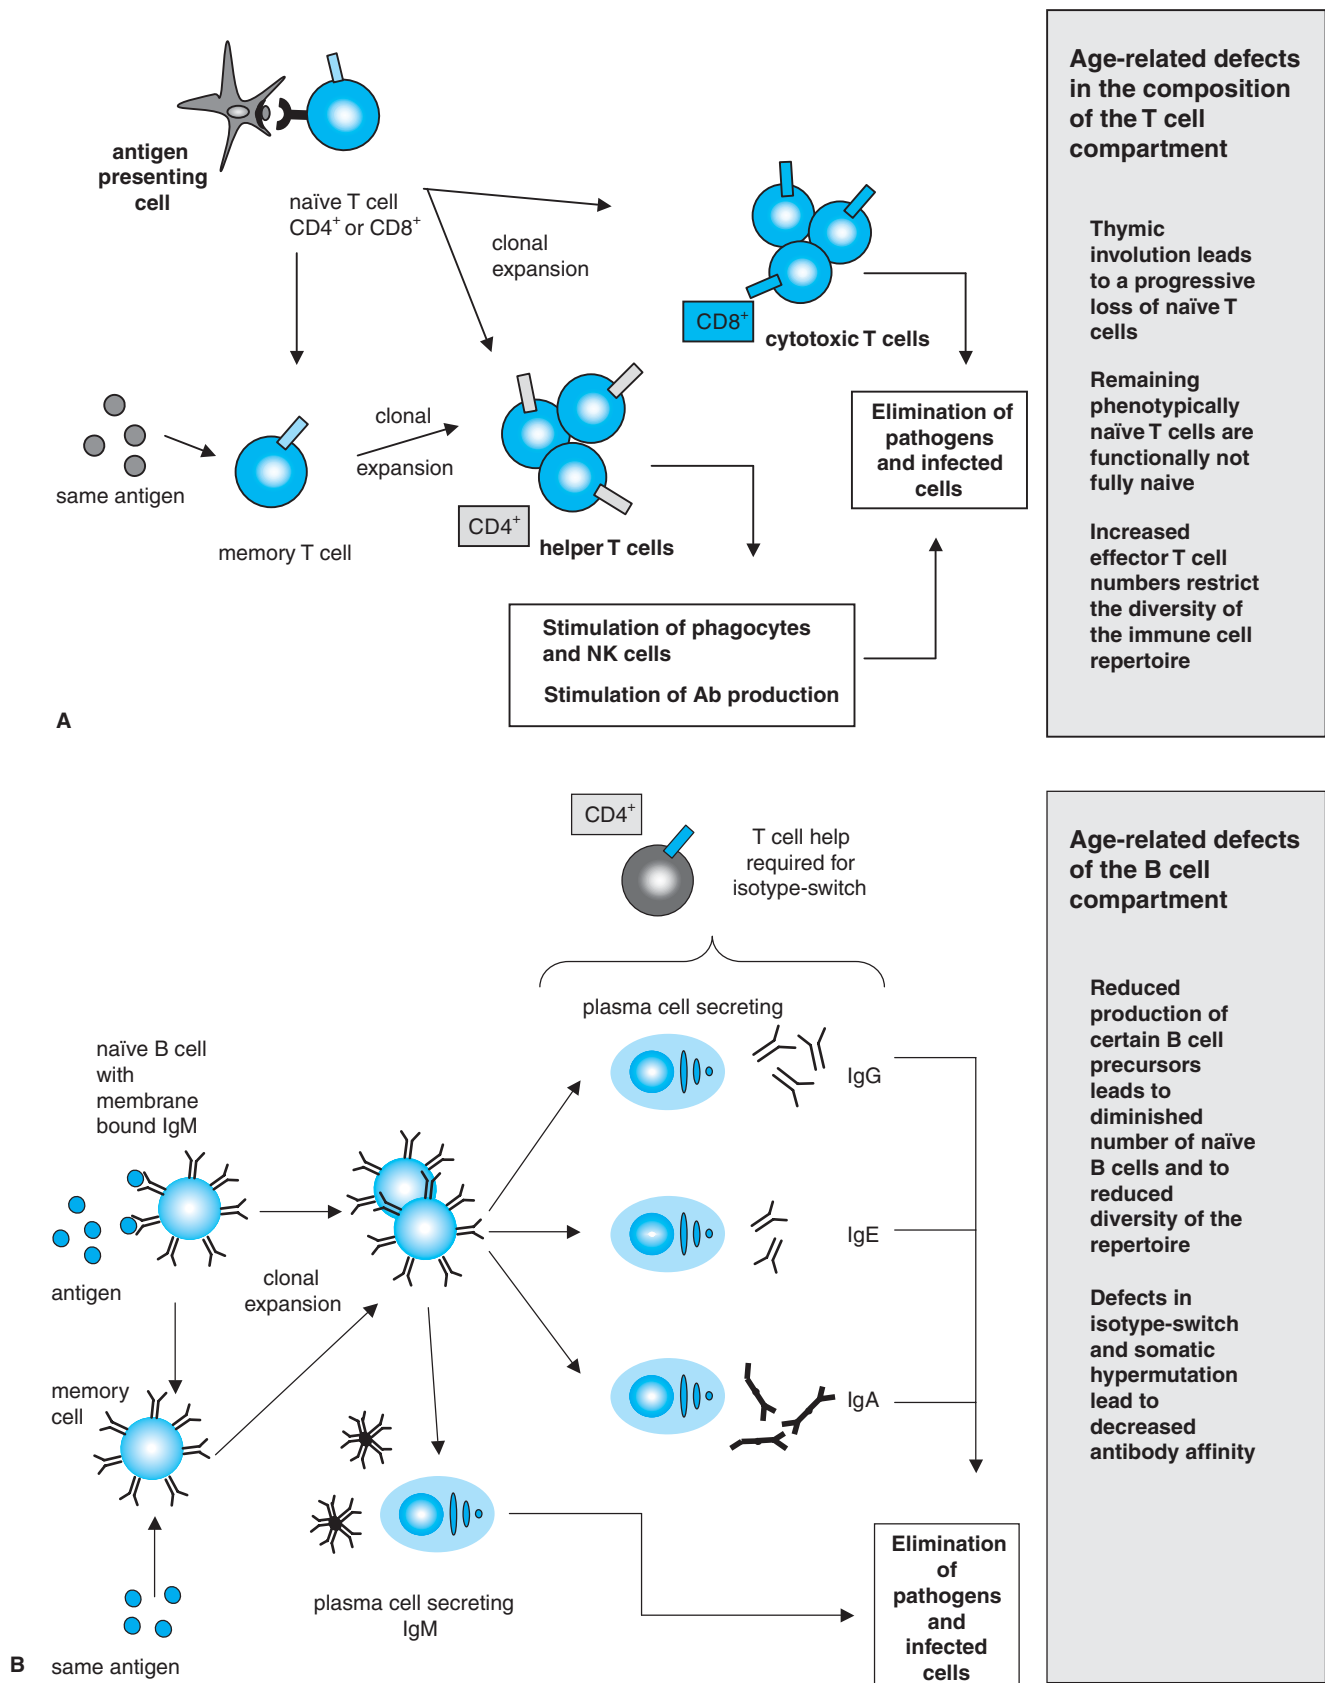

A third population of T helper cells referred to as  $T_{H17}$  cells has been described in mice and humans. These cells are generated in response to signals different from the ones needed for the induction of  $T_{H1}$  and  $T_{H2}$  responses and secrete IL-17.  $T_{H17}$  cells have been detected in the blood and tissues from patients suffering from a variety of diseases such as multiple sclerosis, rheumatoid arthritis, systemic lupus erythematosus, and Crohn's disease. The role of  $T_{H17}$  cells in host defense is not yet fully understood, but many studies suggest that they may trigger autoreactive responses and autoimmune diseases. Additionally, the so-called "regulatory" T cells have recently attracted much attention. Several subtypes of regulatory T cells, which downregulate immune responses, have been characterized. An important current research focus in the field is on  $CD4^+$  TREGs ("naturally occurring" regulatory T cells). These cells express high levels of the  $\alpha$ -chain of the IL-2 receptor CD25 and of the transcription factor forkhead box P3 (FOXP3). Autoimmune diseases, chronic infections, and cancer have been linked to quantitative and/or qualitative defects of TREGs.

For in vitro analysis and isolation, different cells of the immune system can be characterized and identified by expression of particular surface proteins. These markers are used to distinguish between different cell types and cell subsets especially in the T cell compartment. Table 3-3 summarizes frequently used surface markers and gives an overview about their expression on different cell types.

### Age-Related Changes in the T Cell Compartment

The size of the mature T cell pool remains stable over the lifetime of an individual. However, the proportionate representation of different T cell subsets, namely, of naïve, memory, and effector cells, undergoes substantial changes with increasing age (Figure 3-5A). Figure 3-6 (Color Plate 5) illustrates the phenotype and functional properties of naïve, memory, and effector T cells.

Aging leads to a decrease of naïve T cells, while memory and effector cells accumulate (Figure 3-7A). Generally, the changes are more pronounced in the  $CD8^+$  than in the  $CD4^+$  compartment. A relatively diverse naïve  $CD4^+$  T cell compartment is maintained for decades despite decreasing thymic output. However, after the age of 70 years, a dramatic decline of diversity occurs, resulting in a severely contracted repertoire. Similar changes within the  $CD8^+$

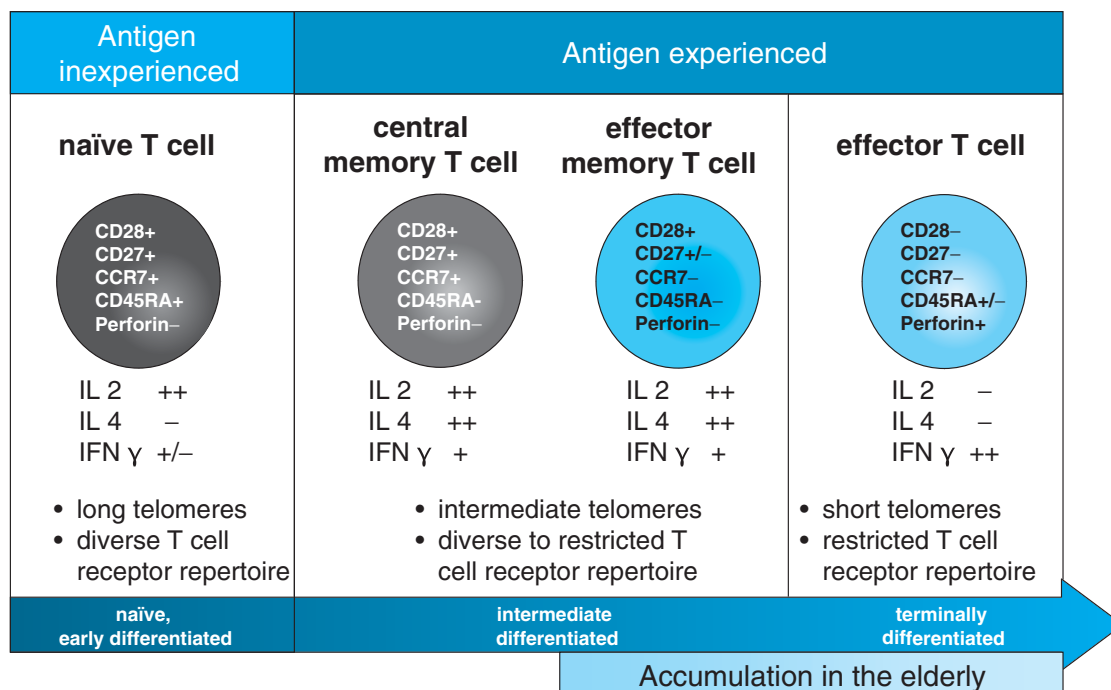

**FIGURE 3-5.** Schematic representation of adaptive immune responses and age-related changes. (A) Antigen presenting cells present foreign peptides to naïve T cells, which expand and differentiate into memory and effector T cells.  $CD8^+$  cytotoxic T cells directly eliminate infected cells.  $CD4^+$  helper T cells stimulate phagocytes and NK cells and are crucial for the induction of antibody production. Thus they indirectly contribute to elimination of pathogens and infected cells. (B) Antigens bind to the membrane-bound antibodies on naïve B cells which expand and differentiate into memory and effector B cells, which are called plasma cells and secrete antibodies. Contact with T helper cells and stimulation by cytokines leads to recombination events in the genes encoding for heavy chains of antibodies. Depending on the stimulus IgG, IgE or IgA antibodies are generated and secreted in order to eliminate pathogens.

**TABLE 3-3****Surface Markers Used for Definition of Cell Types and T Cell Subsets**

	<b>SURFACE MARKER</b>	<b>CELLULAR EXPRESSION</b>	<b>FUNCTION</b>
T cells	CD3	T cells	Required for cell-surface expression and signal transduction of the T cell receptor
	CD4	T helper cells	Coreceptor, binds to MHC class II molecule
	CD8	Cytotoxic T cells	Coreceptor, binds to MHC class I molecule
	CD27	Subsets of T cells	Receptor for costimulatory signal
	CD28	Subsets of T cells	Receptor for costimulatory signal
	CD45RA	Subsets of T cells	Tyrosine phosphatase, involved in antigen-receptor mediated signaling
	CD62L	Subsets of T cells	Homing to peripheral lymph nodes, adhesion to endothelial cells
	CD25	Activated T cells Regulatory T cells	IL-2 receptor $\alpha$ -chain
	CCR7	Subsets of T cells	Chemokine receptor
B cells	CD19	B cells	Coreceptor for B cell activation
	CD20	B cells	B cell activation
	CD22	Mature B cells	Regulation of B cell activation
NK cells	CD16	NK cells	Receptor for Fc part of IgG antibodies
	CD56	NK cells	Homotypic adhesion
	CD158	NK cells	Killer Ig-like receptor (KIR), inhibition or activation of NK cells
Dendritic cells	CD1a	DC	Nonpeptide antigen presentation
Monocytes	CD14	Myelomonocytic cells	Lipopolysaccharide (LPS) receptor

T cell pool occur even earlier in life. As naïve T cells are required to adequately respond to new antigens that have not been encountered before, the loss of diversity within the naïve T cell compartment may be one factor that contributes to diminution of the host's ability to cope with new pathogens. Effector cells are characterized by the occurrence of a limited number of large, expanded clones. CD8<sup>+</sup> ef-

factor cells frequently exhibit specificity for persistent viruses, mainly for cytomegalovirus (CMV) but also for Epstein–Barr virus (EBV) or hepatitis C virus (HCV). CMV-specific CD8<sup>+</sup> T cells from elderly donors exhibit a terminally differentiated effector phenotype and occur as few largely expanded clones. Expanded CD4<sup>+</sup> T cell clonotypes appear to be less frequent.

**FIGURE 3-6.** Characteristics of different T cell subsets upon differentiation. Antigen inexperienced (naïve) and antigen experienced (memory and effector) T cells are shown with respect to their surface marker expression, telomere length, and T cell receptor repertoire. Central memory and effector memory T cells can be distinguished within the memory compartment. Effector memory and effector T cells accumulate in the elderly.

**FIGURE 3-7.** Age-related changes of the composition of the T cell compartment and influence of latent CMV-infection. (A) Schematic representation of changes in the quantitative distribution of naive (blue), memory (black), and effector (gray) T cells in peripheral blood. (B) Representative FACS data are shown for young and old CMV-negative and CMV-positive donors. Naive, memory, and effector CD8<sup>+</sup> T cells are defined by expression of CD45RA and CD28 and are highlighted in blue, black, or gray respectively. Percentages of the individual subsets are depicted in the upper right corner. With increasing age the percentage of naive cells decreases, whereas effector T cells accumulate. CMV-seropositivity significantly enhances these changes. *Reprinted with modifications from Almanzar G, et al. Long-term cytomegalovirus infection leads to significant changes in the composition of the CD8<sup>+</sup> T cell repertoire, which may be the basis for an imbalance in the cytokine production profile in elderly persons J Virol. 2005;79:3675. With permission from the American Society for Microbiology.*

Age-related changes in the composition of the T cell pool are accompanied by alterations in the cytokine production profile. Cytokines are crucial for communication processes among immune cells and for the regulation of immunological responses. Murine studies suggest an age-related shift from a T<sub>H1</sub>-like to a T<sub>H2</sub>-like response with decreased levels of IL-2 and IFN- $\gamma$  and an increase in the production of IL-4, IL-6, and IL-10. This shift, however, could not be confirmed in humans, in whom a polarization toward type 1 responses has been shown. This discrepancy may reflect different response patterns in different species, but also differences in experimental protocols.

The influence of aging on T<sub>H17</sub> cells and their potential role in immunosenescence has not yet been analyzed. A possible role for

regulatory T cells (TREGs) in aging has been discussed, but so far no consensus has been reached about if and how this specific T cell type changes with aging.

#### Age-Related Changes of T Cells on the Single Cell Level (Table 3-4)

Age-related defects also occur at the single cell level. Both signaling deficiencies and changes of immunological synapses that are formed upon interaction of T cells with antigen presenting cells contribute to the altered activation potential of some aged T cells. Hyporesponsiveness to antigenic challenge has been especially observed in CD4<sup>+</sup> T cells. This may be due to cell-type-specific changes in the

**TABLE 3-4****Age-Related Changes of Adaptive Immune Cells**

	<b>AGE-RELATED DECREASE</b>	<b>AGE-RELATED INCREASE</b>
T cells	Number of naïve cells Diversity of the T cell repertoire Expression of co-stimulatory molecules (CD28, CD27, CD40L) Proliferative capacity T cell signaling Activation potential of naïve cells	Numbers of memory and effector cells Expression of senescence-associated molecules (CD57, KLRG-1) Expanded clones of effector cells
B cells	Generation of B cell precursors Diversity of the B cell repertoire Size and number of germinal centers Expression of costimulatory molecules (CD27, CD40) Antibody affinity Isotype switch Serum antibody response to specific foreign antigens	Number of B1 cells Autoreactive serum antibodies

plasma membrane. Lipid raft formation is essential for T cell signalling and may play a role in the regulation of T cell activation and other immunological processes. Lipid rafts are dynamic structures of the plasma membrane where signaling molecules are organized and recruited/excluded in a time-dependent manner. Due to an age-dependent increase of the cholesterol content of plasma membranes, the dynamics of lipid rafts are altered in aged cells. The expression of molecules that are prototypic markers for NK cells, for example, CD57 and killer cell lectin-like receptor G 1 (KLRG-1), is elevated on effector T cells from elderly persons.

### Factors That Accelerate Age-Related Changes in the T Cell Pool

Aging is not only a risk factor for infection, but pathogens themselves may contribute to immunosenescence, as repeated exposure to antigens directly shapes the T cell compartment in the aging individual. CMV, a herpes virus that infects the majority of the adult population and establishes lifelong latency in the host, is one example that has been studied in the context of immunosenescence. Infection with CMV induces characteristic changes in the CD4<sup>+</sup> as well as in the CD8<sup>+</sup> compartment. The age-related decrease of naïve T cells and the accumulation of terminally differentiated effector T cells are enhanced in persons infected with CMV compared to CMV-seronegative elderly persons (Figure 3-7B). Longitudinal studies of individuals above the age of 86 years with a follow-up of up to 8 years found that 2-year mortality could be predicted using the so-called “immune risk phenotype” (IRP) defined by immunological parameters like a low CD8<sup>+</sup>/CD4<sup>+</sup> ratio and a poor response of T cells after stimulation with mitogens. The IRP was also associated with CMV seropositivity.

Chronic infection with CMV appears to affect the capacity of the immune system to respond to other pathogens. For example, the immune response to EBV is also impaired, as the number of

EBV-specific cells increases with age only in CMV-negative but not in CMV-positive persons. These observations have led to the hypothesis that the accumulation of CMV-specific cells leads to a shrunken repertoire of other specificities. The effects of CMV on the aging immune system raise questions about the role of other persistent pathogens. For example, HIV infection may accelerate certain aspects of aging of the immune system. Thus, persistent or recurrent pathogens might be involved in the complex process of immunosenescence.

### B Lymphocytes

Generally, B cells can be divided into three subsets: follicular (B2), marginal zone (MZ), and B1 B cells. Follicular B cells originate from primary follicles, which are areas within the lymph nodes where naïve B cells reside. Upon antigenic stimulation, germinal centers develop in the lymph node. In these germinal centers, B cells proliferate, are selected for high-affinity binding to antigen, and develop into memory B cells and antibody-producing plasma cells. The peripheral blood B cell pool consists mainly of follicular B cells. In contrast, MZ B cells do not contribute significantly to the germinal center reaction but instead act as a first line of defense against pathogens, particularly encapsulated bacteria, which enter the blood stream. The subset of B cells known as B1 cells differs from the majority of B cells. Generally only 5% to 10% of the total B cell pool in the periphery and the secondary lymphoid organs are B1 cells. They express a relatively restricted repertoire of immunoglobulins mainly recognizing common bacterial antigens.

Resting B cells express membrane-bound immunoglobulin M (IgM), also referred to as BCR. Upon contact with their antigen, B cells secrete IgM, which is the first class of antibodies produced after stimulation. In response to cytokines and direct contact with T helper cells, a fraction of activated B cells undergoes the process of heavy chain isotype switching, which is mediated by recombination of the genes encoding for immunoglobulins and leads to the secretion of antibodies with heavy chains of different classes such as IgG, IgA, or IgE (Figure 3-5B). These antibody classes perform distinct effector functions. IgG antibodies block the entry of pathogens into cells and mediate phagocytosis by macrophages. These antibodies are needed for effective defense against most viral and bacterial pathogens. IgA antibodies are mainly produced by B cells in mucosal tissues, as these antibodies are most efficiently transported into mucosal secretions where they eliminate microbes entering through the epithelia. IgE antibodies are generated in response to helminths and also mediate allergic reactions. In a further step of maturation, somatic recombination occurs in the variable region of the genes encoding for immunoglobulins in order to generate antibodies with higher affinity. Long-lived memory B cells and plasma cells reside in the body for up to several decades and ensure efficient “recall” responses in the case of subsequent encounter of the same pathogen.

### Age-Related Changes of the B Cell Compartment

Primary antibody responses in aged humans are often weaker, antibody levels drop faster, and the antibodies bind their antigen with lower affinity compared to young adults. These responses have been studied in detail in the context of vaccination and it has been concluded that the protective effect of vaccinations against *Streptococcus pneumoniae*, influenza, hepatitis B, and tetanus is decreased with age.

Additionally, aging is also associated with an increased prevalence of autoantibodies. These antibodies are in the majority of cases present in low concentrations and are frequently directed against cellular components such as nuclei or mitochondria. They rarely contribute to autoimmune diseases, which classically occur earlier in life.

The impact of aging on peripheral B cells is complex and involves a variety of changes of single cells as well as of the repertoire. The number of B2 cells is reduced in elderly people. In contrast, there are more B1 cells, which means that fewer of the classical, antibody-producing B cells that are essential for defense against pathogens are present. Some of the changes observed in the B cell compartment seem to parallel the ones observed in the T cell pool. Thus the number of naïve B cells decreases in some elderly people while memory cells accumulate, leading to clonal expansions of certain B cell specificities. These expansions may limit the diversity of the repertoire.

As mentioned above, isotype switching is required to produce high-affinity IgG antibodies that eliminate pathogens. Defects in isotype switching lead to the accumulation of B cells producing IgM and a concomitant lack of IgG-secreting cells. IgM antibodies have a lower affinity to antigens. Age-related defects in somatic mutation also lead to a reduced affinity of antibodies from aged individuals (Table 3-4).

#### Age-Related Defects in Interactions Between T and B Cells

As interactions with T cells are essential for B cell activation and antibody production, it is difficult to attribute defects in the humoral immune response exclusively to intrinsic alterations of B cells. Low-level and transient production of specific antibodies in elderly persons is frequently due to a combination of age-related defects in the generation and maturation of B cells and dysregulated or defective T cell help.

Aged CD4<sup>+</sup> T cells produce less IL-2 and as a consequence express less CD40L, which is a crucial molecule in the interaction of B and T cells. Less efficient T cell help leads to a reduced antigen-specific B cell expansion and differentiation as well as to decreased IgG production and germinal center formation. T helper cells also play a crucial role in isotype switching and the affinity maturation of antibodies. A defective T helper function thus contributes to diminished high-affinity B cell responses in old age. In fact, in mouse models, there is little evidence of intrinsic age-dependent defects in B cell function. Rather, age-related loss of B cell function is a result of poor T cell stimulation.

#### Cutaneous Immune System

The specialized immune system that is found in the skin is called the cutaneous immune system and consists of lymphocytes and antigen-presenting cells. The epidermis is composed of keratinocytes, melanocytes, Langerhans cells (LC), and intraepidermal T cells. Keratinocytes and melanocytes play no role for the adaptive immune response; however, keratinocytes are capable of producing cytokines that contribute to innate immune responses and local inflammation. Langerhans cells are immature DC and are specialized for capturing antigens that enter the body through the skin. After contact with the antigen, they mature, migrate into the dermis, and via lymphatic vessels to the lymph nodes, where they act as antigen-presenting cells and stimulate T cells. Only a small frac-

tion of the skin-associated lymphocytes reside in the epidermis, and most of them are CD8<sup>+</sup> T cells. The majority of cutaneous T cells (both CD4<sup>+</sup> and CD8<sup>+</sup>) are found in the dermis. Most of these T cells show an activated or memory phenotype. However, it is unclear whether these cells permanently populate the skin compartment or are circulating between blood, lymphatic vessels, and tissues. Macrophages are also present in the dermis.

Age-associated changes of T cells and macrophages as described above also affect these cell types in the skin and contribute to the impaired immunological properties of aged skin. Langerhans cells, which are found exclusively in the epidermis, also undergo age-related alterations. The number of Langerhans cells decreases with age. Morphological changes like reduced formation of dendrites have been observed in LC from aged individuals. In animal models, the capability of LC to trap antigen, present it to T cells, and stimulate T cell proliferation decreases with age. However, these functional defects have not been confirmed in humans. Migration of LC from the epidermis to local lymph nodes is essential for antigen presentation and activation of adaptive immune responses. Migration of LC following administration of TNF- $\alpha$  is impaired with aging. However IL-1 $\beta$ -induced mobilization of LC seems to be intact in aged individuals.

Keratinocytes produce a variety of pro- and anti-inflammatory cytokines like interleukins, interferons, growth factors, and chemokines upon stimulation by UV light, allergens, or infectious agents. Only a few cytokines have been analyzed in the context of skin aging. As an example, keratinocytes of elderly persons produce less IL-1 and more of the antagonist of the IL-1 receptor, reducing the overall IL-1 activity. Therefore local inflammation and activation of innate immune responses could be reduced at the site of infection.

In addition to age-related changes of ubiquitous immune cells and of skin-specific immunologically active cells like keratinocytes and Langerhans cells, morphological and structural changes of the aged skin contribute to the increased incidence of skin infections in elderly people.

#### Mucosal Immune System

The mucosal surfaces of the gastrointestinal and respiratory tracts are colonized by lymphocytes and antigen-presenting cells that initiate immune responses against ingested or inhaled antigens. However, little is known about age-related changes of the immune function of the respiratory mucosa. More is known about aging effects on the gastrointestinal tract. Lymphocytes are found within the epithelial layer as well as in the lamina propria and in organized structures called Peyer's patches with distinct cell populations at the different sites. Like lymph nodes and lymphoid follicles in the spleen, the Peyer's patches contain B cell-rich areas, which contain germinal centers that are essential for initiation of immune responses. The gastrointestinal tract is permanently colonized by the gut flora. The mucosal immune system on the one hand establishes tolerance to the indigenous microflora and to food proteins and on the other hand fights pathogens by the production of IgA antibodies and the activation of T cells. Total IgA levels are unchanged or even elevated in elderly people, whereas the response to specific antigens as measured by specific IgA is lower in aged animals. Aged mice also exhibit decreased susceptibility to oral tolerance induction. The precise cellular and molecular regulatory mechanisms in the induction of mucosal tolerance and immunity and their alterations in aging

are currently not fully understood. However, it seems reasonable to argue that increased susceptibility to infectious agents that enter the body through mucosal surfaces is at least partly due to age-related defects in mucosal immunity.

## CLINICAL IMPLICATIONS OF IMMUNOSENESCENCE

### Infectious Diseases

A thorough review of “Infections in Older Adults” can be found in Chapter 124, and individual chapters throughout this textbook. The high rate of infection-related hospitalization in elderly people is not only due to increased incidence of infection but also because of more severe symptoms and underlying comorbidity. Most common infections have a poorer prognosis in elderly patients, partially due to decreased immune function. In addition, underlying diseases that cause tissue damage and age-related changes (e.g. of the epithelium) facilitate infection. Fever is generally less common in elderly patients. Less than 50% of frail, very elderly patients with infection will develop temperatures high enough to be considered fever.

### Immunosenescence and Cancer

The immune system plays a crucial role in controlling cancer and protecting the individual. As immune function declines with age, it seems reasonable to hypothesize that immunosenescence might be involved in the dramatic age-related increase of many cancers (see Chapter 94). However, despite provocative findings described below, the relevance of immunosenescence to tumor development and immune evasion remains controversial.

Enhanced inflammatory responses may contribute to tumor development in the elderly people. Genetic polymorphisms, resulting in distinct expression levels of cytokines like IL-6 and IL-10, could theoretically affect tumor incidence and progression. Additionally, the limited pool of naïve T cells and the impaired processing and presentation of antigens might contribute to a decreased recognition of emerging tumor antigens and to the increased incidence of tumors with aging. Some evidence suggests that at least some of the mechanisms that are used by tumor cells to escape immune surveillance are more effective in elderly people. Tumors often express Fas ligand (FasL), which interacts with its receptor (FasR) on the surface of lymphocytes and induces apoptosis in the T cells that attack the tumor. As the expression of FasR is elevated on aged cells, T cells infiltrating the tumor might be killed more effectively in elderly people, allowing tumor growth. Several tumors release immunosuppressive cytokines to suppress antitumor immune responses. This immunosuppressive strategy of the tumor could be more effective in the already proinflammatory milieu of the aged immune system. Other factors involved in cancer-induced immunosuppression are prostaglandins that are produced by tumor cells. Aged lymphocytes may be more sensitive to prostaglandins, which inhibit activation of antitumor lymphocytes.

Thus, a variety of links may connect immunosenescence, tumor incidence, and tumor growth. However, more research is required to elucidate the interplay of immunosenescence, age-related changes of

other body systems, environmental influences, and stochastic events in tumorigenesis.

## IMMUNOLOGICAL INTERVENTIONS

### Vaccines

Vaccination is the most cost-effective measure to prevent infection-related disease. More than 25 different infectious diseases can be prevented by vaccination. Large-scale vaccination programs have led to the eradication of smallpox and to a dramatic reduction of diseases like poliomyelitis, diphtheria, tetanus, measles, mumps, and many more. However, vaccination efficacy is generally lower in the elderly population, and this particularly vulnerable cohort may not be fully protected following immunization. For some vaccines such as tetanus, diphtheria, and pertussis, vaccination induces lower concentrations of antibodies in the elderly people. Additionally, antibody titers decline more rapidly in aged individuals compared to young adults. The quality and specific type of antibody may also be important in determining the effectiveness of vaccination in an elderly patient.

### Recommendations for Vaccination

Several vaccinations are specifically recommended for elderly people in various developed countries. Vaccination against influenza is recommended for everybody above the age of 60 or 65 years as influenza is associated with a high risk of severe disease and death in this age group. Due to the occurrence of various viral subtypes and a high rate of mutation, the influenza vaccine is matched with circulating strains every year. Thus, annual vaccination with the new vaccine is required to obtain protection. Vaccination rates have increased since the 1990s, but depending on the region they still only range from 30% to 60% of the elderly population. Although influenza vaccination efficacy decreases with advancing age, hospitalization and death due to influenza are reduced by vaccination (see Chapter 130 for additional details on influenza vaccine and other preventive measures).

Another vaccine that is generally recommended for elderly individuals is the 23-valent polysaccharide vaccine directed against *Streptococcus pneumoniae*. Case-control studies suggest that the incidence of invasive pneumococcal disease is reduced by 65% in vaccinated elderly people. However, protection of high-risk groups with underlying comorbidities is lower. Vaccine efficacy with regard to pneumonia is generally low. The poor efficacy of the vaccine for preventing pneumonia and the associated apathy of patients and providers accounts for some of the relatively low vaccination coverage in elderly populations (see Chapter 126 for additional information on preventing pneumonia and pneumococcal vaccination).

Reactivation of Varicella-Zoster virus, which manifests as herpes zoster, occurs in old age, in part because the immune response established after primary infection weakens with time. However, individuals who frequently come in contact with the virus, e.g. via children with varicella, have a reduced risk of herpes zoster. Vaccination to prevent herpes zoster has now been approved in the United States and in Europe for use in elderly people. The attenuated live vaccine contains a higher dose of the same virus strain that is also

used for vaccination of infants. The vaccination is recommended for individuals over the age of 60 years. Incidence of herpes zoster and postherpetic neuralgia is reduced by approximately 50% and 67%, respectively. Currently, the maximum follow-up of the first large clinical trials is 3 years, which means that it is not yet clear how long the protective effect will last and whether booster vaccinations will be necessary (see Chapter 129 for details on herpes zoster and its prevention).

As the number of elderly individuals vaccinated against yellow fever has increased in recent years, it has become apparent that this age group might be at a higher risk of developing severe adverse effects. It has been postulated that the aged immune system might be failing to control the attenuated vaccine virus, leading to systemic infection.

### Improving Vaccination Efficacy

It is now apparent that specific vaccination strategies and vaccines are needed for elderly people. Most vaccines currently used aim to induce serum antibodies. For efficient induction of antibody production, B cells need to be stimulated by CD4<sup>+</sup> T helper cells. Thus, vaccines specifically targeting enhanced CD4<sup>+</sup> T cell responses might also be successful in increasing antibody production. This strategy could lead to more efficient vaccines that are able to raise protective antibody levels in the elderly people. However, conjugation of polysaccharides to protein (e.g., pneumococcal and meningococcal polysaccharide conjugate vaccines) that significantly enhances CD4<sup>+</sup> T cell responses and vaccine efficacy in very young children has not markedly improved responses in older adults. The reasons for this remain uncertain. Possible explanations could be the nature of the protein conjugate, prior immunity, or age-related defects of the innate immune system.

For various pathogens like influenza, tuberculosis, hepatitis B, and herpes zoster, CD8<sup>+</sup> cytotoxic T cells play a key role in the control of infection as they eliminate infected cells and prevent further spread of the infection. Vaccinations against these pathogens could be designed to induce not only specific antibodies but also long-lasting CD8<sup>+</sup> T cell memory.

Several approaches are currently being investigated in order to improve vaccination efficacy for elderly people. Attenuated live vaccines are highly immunogenic and induce strong T and B cell responses. However, as observed for vaccination against yellow fever, live vaccines in old age might be associated with an increased risk of side effects. The use of live-attenuated vaccines early in life and/or during young adulthood followed by booster vaccination with inactivated vaccines in old age could be one possible strategy to overcome this problem. It has been shown, for example, that previous vaccination with polio live vaccine enhances the effect of booster with the inactivated vaccine later in life.

In order to increase immunogenicity of inactivated vaccines, they can be supplemented with adjuvants, which facilitate an effective immune response. Different classes of adjuvants improve processing and presentation of the antigen, stimulate components of the innate immune response, or provide the appropriate cytokine environment to elicit T and B cell responses. However, very few adjuvants are currently approved for use in humans. Many vaccines are supplemented with aluminum salts, which enhance antibody production but have little effect on cellular immunity. MF59<sup>®</sup> is an oil-in-water emulsion that is used as an adjuvant in influenza vaccines. The adju-

vanted vaccine seems to be more efficient in elderly people, leading to higher rates of seroconversion compared to conventional vaccines. Numerous adjuvants are currently being tested in animal studies or in early clinical trials. Of particular interest are immunomodulatory adjuvants that might overcome the specific deficits of the aging immune system.

The effect of booster vaccinations is dependent on the time since the last vaccination and particularly on the antibody titer before booster. It is therefore of crucial importance to increase public awareness that regular booster vaccinations during adulthood are essential to maintain the ability to respond to recall antigens in old age. Shortened intervals of booster vaccinations for individuals above 60 years might also be a possible strategy to ensure protective antibody levels.

Unfortunately, it is necessary to emphasize that vaccination coverage remains suboptimal in elderly populations. Only 60% of elderly people are vaccinated against influenza or pneumococcal infection despite clear efficacy of these vaccines. Regular boosters and increased vaccination coverage could be efficient short-term tools to increase protection of the vulnerable aged population.

### Caloric Restriction

For several decades, experiments have been performed in different model organisms in which caloric intake was reduced. When supplemented with vitamins and essential elements to avoid malnutrition, caloric restriction of ~30% increases life span of invertebrates (*Coenorhabditis elegans*, *Drosophila melanogaster*), rodents (mice, rats, hamsters), and other vertebrates (birds, zebra fish) significantly (see Chapter 1). Various mechanisms have been postulated to be responsible for this effect, including the delay of immunosenescence. Generally, dietary restriction is particularly effective when applied long-term and before the onset of aging. Trials conducted with non-human primates (*Macacus rhesus*) in which CR was applied for 10 to 17 years have confirmed physiological and immunological effects that were observed in dietary-restricted smaller animals. CR prevented the loss of naïve T cells and preserved the diversity of the T cell repertoire. Additionally, T cell function was improved and less inflammatory cytokines were produced by memory T cells. Primate studies are still ongoing and aim to eventually elucidate the influence of caloric restriction on life span.

### Additional Measures to Improve Immune Function

In order to overcome age-related defects of the immune system, several interesting approaches to delay or even reverse immunosenescence are being investigated using animal models. As described above, involution of the thymus and the resulting loss of newly generated naïve T cells may contribute to the deterioration of immune function with age. For this reason, thymic regeneration might reduce immunosenescence. Some experiments with mice have shown that it is possible to partially restore thymopoiesis and to stimulate regrowth of the thymus to a certain extent. However, other studies have been less compelling and full rejuvenation of the thymus and regeneration to its previous size has not yet been achieved.

Another driving force for age-related changes of the immune system is chronic stimulation by immunodominant pathogens that favor the accumulation of highly differentiated T cell clones,

replacing naïve and functional memory T cells. It has been suggested that a reduction of antigenic stimulation by eradication of chronic subclinical infections as they are found in the oral cavity, the gastrointestinal tract, and the urinary tract could improve the immune status in old age. As described above latent infection with CMV may accelerate immunosenescence and accumulation of senescent effector T cells. Whether early life vaccination to prevent CMV infection could affect CMV-associated immunological changes in old age has not been tested.

Alternatively, the highly differentiated, clonally expanded T cells that result from chronic antigenic stimulation could be depleted in order to give room for more “useful” T cells. However, it would be essential to remove only dysfunctional T cells without interfering with functionally intact, less differentiated T cells. It has also been proposed to isolate T cells early in adulthood and to store them in vitro until a person needs “fresh” T cells in old age. With this approach, it would theoretically be possible to manipulate the cells before reperfusion, for example, by expanding selected T cell subpopulations or T cells of certain specificities that promise the greatest benefit for the recipient.

## CONCLUSION

One major challenge of the future will be to prolong healthy life in which quality of life is maintained. Overcoming the detrimental effects of immunosenescence may be one important step in achieving this goal. Infectious diseases harbor a substantial risk for illness, loss of independence, disabilities, and death for elderly people. Whereas vaccinations constitute an effective measure to prevent infection, age-related defects of the immune system impede protection following vaccination of older adults. New vaccines and vaccination strategies that specifically target the aged immune system may help ensure protection of the vulnerable elderly population. Deeper insight into and an even better understanding of the immunological changes that occur with age will without doubt help to delay or even reverse the deleterious effects of immune dysfunction in the elderly people.

# Inflammation and Aging

*Jeremy D. Walston*

In recent years, multiple studies of older adults have identified strong relationships between serum markers of inflammation and frailty, worsening chronic disease, disability, and mortality. Although these studies are not proof that the chronic activation of inflammatory pathways causes these adverse health care outcomes, recent biological evidence supports that chronic exposure to inflammatory mediators leads to alterations in multiple physiological systems. These in turn contribute to the older adult's vulnerability to adverse health outcomes. Because the activation of inflammatory pathways appear to be so intricately linked to many aging systems, some investigators have propagated use of the term "inflammaging" as a summary of the physiological and molecular changes consistent with the aging process that are known to be associated with chronic activation of inflammatory pathways. Other investigators now utilize "chronic inflammation" as a descriptor for the ongoing activation of the innate immune system that has been observed in some older individuals. The rising use of these terms in aging research and in clinical practice signifies the emerging importance of inflammation as an important contribution, adverse health outcomes in older adults. The study of the clinical utility of relevant inflammatory biomarkers, the understanding of the specific age-related mechanisms that activate and sustain chronic inflammation in older adults, and exploration of the impact that inflammatory mediators and pathway activation have on specific physiological systems and on the overall vulnerability observed in older adults are certain to impact both research and clinical agendas for older adults in the coming years. Given this crucial focus and the importance of understanding this emerging area of investigation for those who care for older adults, and the high likelihood that both investigators and clinicians will likely encounter this important and evolving area of aging research in the coming years, this chapter will (1) describe evolving definitions of inflammation used in the context of aging research and clinical practice, (2) provide a review of the robust relationships between activation of inflammatory pathways and adverse health outcomes previously identified in older adults, (3) describe the pertinent areas of the molecular biology

of inflammation necessary to understand how and why older adults are more vulnerable to inflammatory pathway activation, (4) characterize the relationships between inflammatory pathway activation, multisystem decline, and the biological vulnerability observed in older adults, and (5) highlight the current and potential future clinical relevance of inflammation in older adults.

## INFLAMMATION IN THE CONTEXT OF AGING AND ADVERSE HEALTH OUTCOMES

Inflammation, often referred to as the activation of the innate immune system, is a complex and important physiological response to external threats. In general, it is a critical housekeeping function that acts to fight acute infections and repair wounds through common biological pathways that in turn activate hormonal, thrombotic, and cytokine pathways (Figure 4-1). These pathways function throughout the life span to attenuate or eliminate countless infections and injuries from becoming life-threatening events. This inflammatory signaling is in general a self-limiting process that ends when the infection or injury is resolved and the local and systemic inflammatory pathways return to a state of inactivation. Common clinical examples that lead to the activation of inflammatory pathways and that are attenuated by inflammatory processes at any age include responses to localized superficial injuries such as skin lacerations, localized infections such as urinary tract infections or small abscesses, systemic bacterial infections, and major trauma such as bone fractures or organ injury. In the most superficial processes, inflammation is localized and does not usually result in a measurable systemic response. However, in major infections or injuries, systemic activation of inflammatory pathways result in measurable elevations in circulating inflammatory cytokines and other acute-phase reactant proteins, cortisol, and sympathetic nervous system activation.

In most cases, these small or large innate immune system responses are largely self-limited by negative feedback mechanisms

**FIGURE 4-1.** Normal inflammatory response to injury or infection, with activation of multiple physiological pathways and ultimately resolution of response.

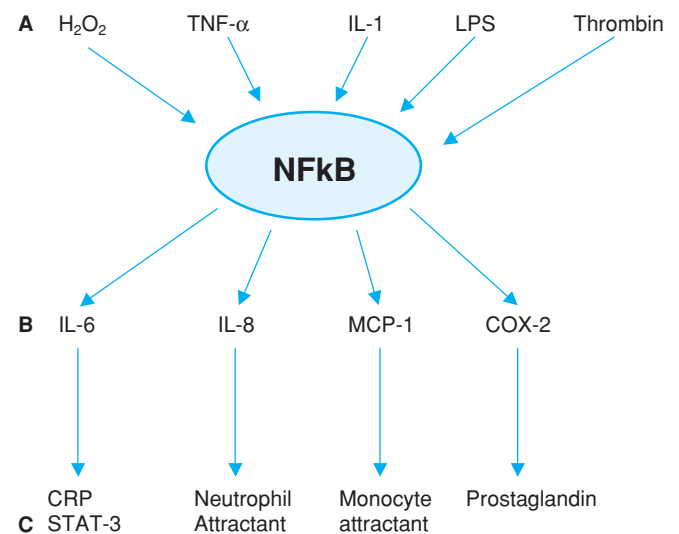

and by the resolution of initial injury or infection (Figure 4-1). However, recent evidence from population studies of older adults suggests that many older individuals who have no obvious injury or infection have ongoing activation of inflammatory processes even when multiple acute and chronic conditions are accounted for. The inflammatory measurements of total white blood cells, neutrophils, and inflammatory cytokines, even after adjustment for disease states, are usually highly correlated with each other. These studies also provide important evidence of a link between inflammatory pathway activation and adverse health outcomes as detailed below.

Part of the evidence that the chronic activation of inflammatory pathways in older adults may be pathological comes from dozens of well-performed association studies that have identified significant inverse relationships between the common adverse health outcomes of disability, frailty, and mortality and elevated serum interleukin-6 (IL-6) and/or C-reactive protein (CRP). A study by Ferrucci et al. demonstrated a 76% increased risk of developing mobility disability over 4 years in previously nondisabled participants of the Established Populations for Epidemiologic Studies of the Elderly who were in the highest tertile of IL-6 compared to those in the lowest tertile. This study identified a serum IL-6 level of 2.5 pg/mL as an important threshold point beyond which the risk for developing disability rises exponentially. In the Cardiovascular Health Study, investigators identified an odds ratio for being frail of 2.80 in those older adults with a CRP level above 5.77  $\mu\text{g}/\text{mL}$  even after excluding those participants with cardiovascular disease and diabetes. In a later study, Puts et al. identified an odds ratio of 1.69 for incident frailty in older adults with a CRP level between 3 and 10 mg/mL. Other investigators have identified strong inverse relationships between inflammatory mediators and mortality in older adults. In the study of osteoporotic fractures, Tice et al. identified an eightfold risk for cardiovascular mortality over 6 years in those with CRP levels above 3.0 mg/mL. Harris et al. identified a 1.9-fold increased relative risk for death over 4.6 years in those participants in the Iowa 65+ Rural Health Study with IL-6 levels greater than 3.19 pg/mL compared to those with low IL-6 levels. Similarly, CRP levels over 2.78 mg/mL also predicted a relative risk for death of 1.6 over the same period of time. Importantly, combining IL-6 and CRP in the analysis increased the sensitivity of identifying those at increased risk of all-cause mortality by identifying a 2.6-fold risk of dying over the same period if both inflammatory markers were elevated compared to the group with neither elevated. Interestingly, many of these studies either excluded participants with severe or chronic disease states known to activate inflammatory pathways, or at least adjusted for them in statistical models, suggesting that this elevation is not purely a result of chronic disease. Although it is not possible to conclude that the activation of inflammatory pathways is causal in these adverse health outcomes for these mostly cross-sectional

association studies, their consistency suggests an important connection between chronic inflammatory pathway activation and adverse health outcomes. Further support for the importance of the connection between inflammation and adverse clinical outcomes has come from the many clinical and basic biological studies that have helped to better elucidate the mechanisms by which inflammatory pathways and adverse health outcomes are connected as described below.

## MOLECULAR BIOLOGY OF INFLAMMATION

Clues to etiology logically extend from recently developed knowledge about age-related physiological and molecular changes and from improved understanding of the signal transduction pathways that activate or deactivate the inflammatory process. Although triggers for inflammation may vary, the key gateway molecular signal transduction system centers around the nuclear transcription factor nuclear factor kappa B (NF $\kappa$ B) (Figure 4-2). NF $\kappa$ B, when activated by specific stress or inflammatory signals, facilitates the expression of multiple inflammatory mediators and in general leads to a cascade

**FIGURE 4-2.** Schematic of the inflammatory gateway nuclear transcription factor NF $\kappa$ B (center circle), along with inflammatory triggers (row A), and inflammatory outflow (rows B and C). Row A shows specific inflammatory stimuli that lead to NF $\kappa$ B activation via specific cell receptors and specific signal transduction pathways (not shown). Activated subunits of NF $\kappa$ B (center circle) in turn leads to the expression of proteins that provide negative feedback for inflammation (not shown) or that propagate inflammatory message (row B) and influence the activation of other pathways (row C) that influence inflammatory response, thrombosis, and the expression of other proteins.

of molecular messages that in sum represents an inflammation (Figure 4-2, row B). Embedded in this response are connections to other important signals that provide negative feedback necessary to attenuate inflammatory responses, and to other signals that provide connections toward or away from apoptosis. Because of the complexity of this signal transduction pathway, a detailed discussion of this biology is well beyond the scope of this chapter. However, because this biology will likely be relevant to the future clinical care of older adults, it is important to understand how and why these pathways may be chronically active in some older adults, and how their downstream effects contribute to many of the pathophysiological changes and even symptoms that older adults experience. Understanding these molecular pathways also helps to facilitate the understanding of the biology that makes older adults more vulnerable to a host of diseases and adverse outcomes, and may provide some future specificity as investigators begin to target these pathways in pharmaceutical interventions for older adults.

### Inflammatory Signal

A set of cell surface receptors (Figure 4-2A) act through cell signal transduction pathways to activate NF $\kappa$ B. This links the message of “stress” to the cell nucleus, where inflammatory mediators are in turn generated (Figure 4-2, row B). One of the more important triggers of NF $\kappa$ B-induced inflammatory pathway activators include the tumor necrosis factor alpha (TNF- $\alpha$ ). TNF- $\alpha$  is secreted very early in the inflammatory process, usually from immune system cells in response to infections. TNF- $\alpha$ , originally discovered as a serum factor related to cancer, is also secreted in high amounts from the connective tissue surrounding malignancies, and from adipocytes. It has several subtypes of specific cell surface receptors that act to transmit the message of inflammation, which in turn activates NF $\kappa$ B and leads to the expression of a host of inflammatory mediators as described below. Interleukin-1 (IL-1) is most often secreted in response to infections and injury, and activates and amplifies inflammatory signaling through its own cell surface receptor. In addition, IL-1 has recently been identified as a major cytokine that is secreted from senescent cells, providing support that may play an important role in late life activation of inflammatory pathways.<sup>7</sup> In addition to these early inflammatory cytokine signals, the bacterial surface antigen lipopolysaccharide (LPS) and some viral particles bind to a family of cell surface toll-like receptors (TLR), which in turn set off a separate signal transduction pathway that in turn amplifies NF $\kappa$ B-related inflammatory signaling. This pathway to inflammatory activation is certainly crucial for the protection of the organism against acute infections, and likely also helps in organized defense against chronic infections. Recent evidence suggests that thrombin, a clotting component, may also activate inflammatory pathways through its own receptor. This provides a link between injury and inflammation. Finally, and potentially very important for aging-related activation of inflammatory systems, the free radicals superoxide and hydrogen peroxide activate inflammatory pathways via signal transduction pathways that facilitate NF $\kappa$ B-mediated inflammatory gene production (Figure 4-2, row A). In sum, all of these specific activating molecules, cell surface receptors, and signal transduction pathways, no matter what the ultimate triggering mechanisms is, transmit the message of stress to the nucleus of the cell, where NF $\kappa$ B-related activity induces the expression of inflammatory mediators that act to either amplify the inflammatory message or exert nega-

tive feedback that brakes inflammatory signaling as described below (Figure 4-2).

### Inflammatory Message

The molecules that are generated by inflammatory signaling give specificity to the inflammatory message that in sum activates inflammatory pathways or leads to an attenuation of that signal (Figure 4-2, rows B and C). The complexity of these pathways and the limited understanding of what drives inflammatory specificity limits the following discussion to a general overview relevant to previously published aging studies. The molecules that are most known for being elevated in older adults that make up the most easily measurable systemic inflammatory response include IL-6 and CRP. IL-6 is a pleiotropic cytokine that in combination with cell-bound and circulating IL-6 receptor plays a crucial role in both inflammatory and anti-inflammatory balancing in acute inflammation. Chronic IL-6 production also leads to the expression of CRP, a commonly measured inflammatory mediator that likely functions at the interface between inflammation and thrombosis and is therefore an increasingly important marker of cardiovascular disease risk. Both of these NF $\kappa$ B pathway-induced molecules have been repeatedly shown to associate with adverse outcomes in older adults. Other potent inflammatory mediators produced by NF $\kappa$ B activation include (1) cyclooxygenase 2 (COX 2), best known for its role in joint inflammation and its key role in prostaglandin production, (2) interleukin-8 (IL-8), a potent neutrophil attractant factor, and (3) monocyte chemoattractant protein 1 (MCP-1), a protein that amplifies monocyte inflammatory response. Each of these factors, and multiple others known to be stimulated by NF $\kappa$ B-related activation, serve to amplify inflammatory signaling both locally and systemically, and provide some specificity in response.

In addition to these inflammation-specific functions, NF $\kappa$ B signaling also leads to the expression of proteins that provide negative feedback to NF $\kappa$ B. NF $\kappa$ B-related signal transduction also plays an important role at the interface between inflammatory signaling, apoptosis, and the development of cellular senescence. Although the details of these pathways are beyond the scope of this chapter, more detailed understanding of the balance between inflammation, apoptosis, and cell senescence may help elucidate many of the important questions underlying late life declines in multiple physiological systems.

### WHY ARE OLDER ADULTS MORE LIKELY TO HAVE HIGHER LEVELS OF INFLAMMATORY CYTOKINES?

Several NF $\kappa$ B pathway triggering mechanisms intrinsic to the aging process lead to the production of inflammatory mediators including: (1) increased numbers of dysfunctional, cytokine secreting senescent cells, (2) increases in TNF- $\alpha$ - and IL-6-producing adipocytes related to increased body fat in older adults, (3) age-related increases in free radicals of oxygen, which are known to directly trigger NF $\kappa$ B activity and lead to the increased generation of inflammatory mediators, and (4) age-related declines in levels of hormones known to attenuate NF $\kappa$ B activity. In addition, multiple chronic disease states can contribute to increased serum levels of inflammatory cytokines and variation in inflammation-related genes that are unmarked in the face of disease states of increased cytokine levels. These reasons are

**Feeding the Fire of Inflammation in Older Adults**

**FIGURE 4-3.** Feeding the fire of inflammation: Multiple age-related molecular and physical alterations account for the increased propensity toward higher levels of inflammatory pathway activation in older adults.

likely additive, and at least are hypothesized to activate a fire of inflammation (Figure 4-3).

With increasing age and increasing numbers of cell cycle passage, many cell types take on senescent characteristics that include inability to undergo apoptosis or reproduction, altered gene expression that results in altered cell function (or dysfunction), and increased tendency to secrete inflammatory cytokines. These senescent characteristics have been observed in multiple cell types, including endothelial cells, adipocytes, fibroblasts, and immune system cells. Next, body composition changes associated with aging are also likely to contribute to increased cytokine production, especially related to the increase in the less metabolically active adipocytes that often take the place of more metabolically active muscle or fibrous tissue. These fat cells are much more likely to secrete both  $\text{TNF-}\alpha$  and IL-6, both of which amplify inflammatory signaling. Levels of free radicals of oxygen also tend to increase with increasing age, which is due to both age-related declines in enzymes that suppress free radical production and increased production. These free radical molecules such as hydrogen peroxide and superoxide are potent stimulators of the  $\text{NF}\kappa\text{B}$  signal transduction cascade, leading to production of inflammatory mediators. These factors can either activate inflammation, which makes it more likely that older adults will have chronically increased levels of circulating inflammatory mediators such as IL-6. Finally, age-related declines of dehydroepiandrosterone-sulfate (DHEA-S), testosterone, and estrogen also likely play an important role in the activation of inflammation. DHEA-S works in part by blocking  $\text{NF}\kappa\text{B}$  activation, while the sex steroid normally binds gene transcription sites for inflammatory cytokines such as IL-6. This braking action gradually declines as these hormones subside late in life.

In addition to these purely age-related changes that result in chronic activation of inflammatory pathways, many chronic disease states common in older adults are known to activate inflammatory pathways. These chronic diseases include those with known inflammatory components such as active rheumatoid arthritis, polymyalgia rheumatica, and most types of cancer. Many chronic disease states not traditionally thought to be inflammatory diseases, including renal failure, congestive heart failure, and atherosclerotic vascular disease trigger the production of inflammatory mediators such as IL-6 and  $\text{TNF-}\alpha$ . These disease states, along with the aging-related

alterations in cell type and oxidative stress, are likely an important trigger for the elevated levels of inflammatory mediators detectable in the serum of many older adults. These mediators, especially if they include IL-1 or  $\text{TNF-}\alpha$ , act to further ramp up inflammatory system activation and lead to the more chronic production of the more stable molecules IL-6 and CRP, two molecules that have most often been associated with adverse health outcomes and disease states in older adults. These age- and disease-related triggers of inflammation help to explain the increasing late-life inflammatory burden, and increase the vulnerability in late life to inflammatory changes. Finally, variation in genes that code for inflammatory mediators have been shown to be increasingly relevant late in life. This appears to be in part related to chronic and acute disease states that trigger inflammatory mediators, which in turn worsen disease states. For example, at least two studies show that older men with myocardial infarction (MI) and IL-6 gene promoter variant were much more likely to die of MI-related complications than those without the promoter variant.

### CHRONIC INFLAMMATION CONTRIBUTES DIRECTLY TO PATHOPHYSIOLOGICAL CHANGES IN OLDER ADULTS

Although multiple studies now demonstrate strong associations between the activation of inflammatory pathways, chronic disease states, and adverse health care outcomes, there is no one clear mechanism that connects inflammation to the vulnerability to decline frequently observed in older adults with chronic activation of inflammatory pathways. Recent evidence from multiple molecular biological studies suggest that many of the inflammatory mediators found to be associated with adverse health outcomes actually contribute directly to the decline in multiple physiological systems. Furthermore, there is increasing evidence that chronically activated inflammatory pathways actually contribute to the development and exacerbation of other disease states, hence further contributing to the vulnerability to adverse health outcomes of disability, frailty, and mortality.

Evidence for inflammatory activation playing a role in multiple system decline in late life comes from both from association studies

in populations of older adults and from molecular studies. For example, one of the most critical physiological systems for preserving function and well being in older adults is skeletal muscle. Declines in skeletal muscle strength, an important contributor to disability and frailty, is strongly associated with elevated inflammatory markers. In a recent manuscript by Schaap et al., older Dutch participants in a longitudinal study of aging were found to have a two- to threefold increased risk of losing 40% of their grip strength over 3 years if their IL-6 level was greater than 5 pg/mL and their CRP was greater than 6 mg/mL. Cesari et al. demonstrated a significant decline in strength over 3 years in older participants in those InCHIANTI participants with the highest levels of IL-6, CRP, and IL-1 receptor antagonist (IL-1RA). IL-1 RA production is stimulated by IL-6 and it is utilized as a surrogate measure for the strongly proinflammatory cytokine IL-1. For molecular evidence, consider a study of IL-6<sup>-/-</sup> mice injected with IL-6, where marked gastrocnemius muscle atrophy and protein degradation by cathepsin L and B was demonstrated. Other molecular studies directly link NFκB activation to the down-regulation of MyoD, a critical factor in skeletal muscle differentiation and repair.

Chronic exposure to inflammatory mediators also influences other critical physiological systems, which in turn influences late-life vulnerability. One in vivo study performed in young rhesus monkeys helps to illustrate multisystemic influence of the inflammatory cytokines. These monkeys were injected with low doses of human recombinant the IL-6 for 30 days. During this period, those injected lost 10% lean body mass, developed depression, mild anemia, osteopenia, and increased levels of CRP. Many other studies focused on individual systems have also demonstrated direct effects of inflammatory mediators on systems that impact late-life vulnerability. For example, osteoclastogenesis, which is an important component of osteoporosis, is directly upregulated by IL-6 neurologic damage in Alzheimer's disease and other neurodegenerative conditions have been directly linked to both Cox-2 and IL-6 expression. TNF-α has been demonstrated to alter iron absorption and utilization in red blood cells, which in turn decreases red blood cell production. In immune system cells, chronic IL-6 signaling activates the STAT 3 pathway and the expression of antiapoptotic factors such as BCL-2 that in turn lead to the accumulation of inflammation-reinforcing T-cells. Chronic IL-6 expression also stimulates the anorexic proteins including leptin, neuropeptide Y, melanocortin, and orexin that suppress hunger. These studies and many others provide substantial evidence that NFκB pathway activation and its downstream products can induce profound tissue changes and can facilitate the pathogenesis of many common disease states.

### CHRONIC INFLAMMATION CONTRIBUTES TO CHRONIC DISEASE IN OLDER ADULTS

While it is increasingly clear that elevated serum levels of inflammatory mediators strongly associate with many disease states and adverse health outcomes common in older adults, clues as to causality or even directionality of the activation of inflammatory pathways have not been identified in these mainly cross-sectional studies. However, recent evidence supports that inflammatory mediators per se, even if they are generated by chronic disease states, go on to have a potent biological impact on the exacerbation of chronic diseases and con-

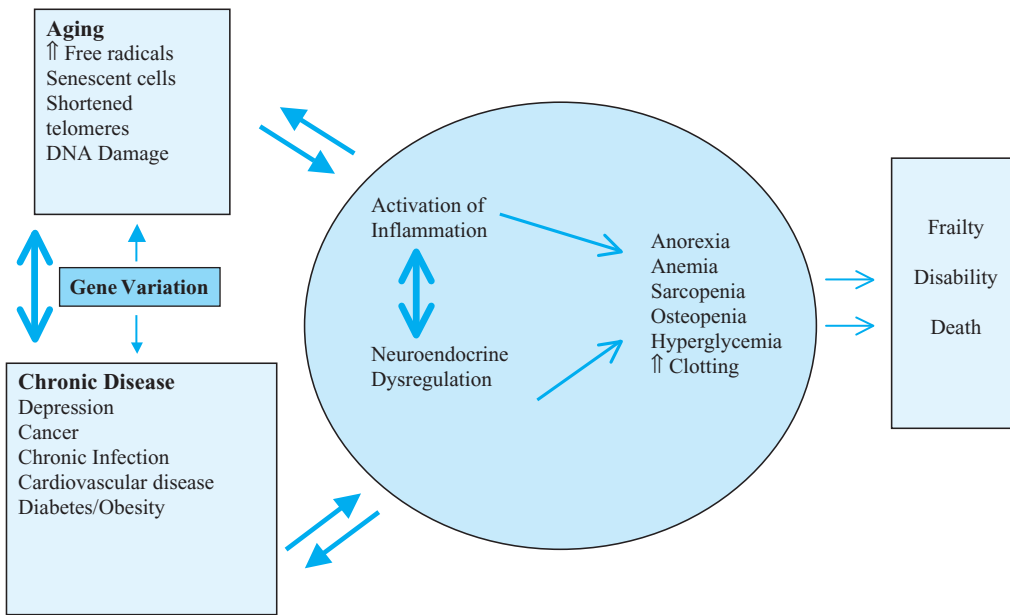

tribute to the development of new disease states. For example, recent laboratory evidence demonstrates that NFκB-related inflammatory mediators contributes directly to malignancy promotion. Furthermore, other studies suggest that inflammation is an integral part of the development of both vascular lesions that lead to chronic blockages in blood vessels, and to the acute process that results in infarctions through activation of thrombotic pathways. These studies and many others provide substantial evidence that inflammatory mediators can induce pathophysiologic change in multiple physiologic systems, and can and do contribute to multiple disease states and distal outcomes of frailty, disability, and mortality in older adults.

### POTENTIAL CLINICAL UTILITY OF INFLAMMATORY MARKERS AND ANTI-INFLAMMATORY INTERVENTIONS

As more and more studies are published that document the increased risk for adverse health outcomes associated with the elevation in serum-based inflammatory mediators, increased interest has developed to utilize these markers as part of clinical practice. Despite the fact that mild IL-6 and CRP elevations are associated with adverse health outcomes, no studies have demonstrated the clinical utility of such measurements. This is in part because there is no known way to prove that lowering inflammatory activation will attenuate inflammation in older adults, especially when it is not related to a specific inflammatory condition. As measurement of individual inflammatory mediators become easier and cheaper, as more specificity is assigned to these markers, and as specific, targeted, and safe interventions targeting inflammatory pathways are developed, serum inflammatory markers may well evolve into a more useful clinical tool that can help identify the most vulnerable older adults and guide therapeutic or preventive interventions.

To date, anti-inflammatory medications, including aspirin (ASA) and nonsteroidal anti-inflammatory drugs (NSAIDs), have mostly been used as over-the-counter pain medications. ASA has certainly been shown to reduce the incidence of clotting-related conditions, and is therefore frequently used in older adults as a safe and effective medication. However, it has not yet been demonstrated to have an impact on function or frailty or other nonspecific adverse health outcome frequently measured in older adults. Epidemiological studies of NSAIDs in relationship to cognition have shown mixed evidence related to long-term impact on slowing cognitive decline. However, there is little doubt that these agents are important components of shorter-term pain management for geriatric conditions such as osteoarthritis.

Over the past several years, many other more specific anti-inflammatory medications have been utilized to treat other geriatric conditions such as anorexia and weight loss, usually in a specific disease state rather than aging or frailty per se. For example, pentoxifylline, an agent that blocks TNF-α RNA transcription, was tested in a group of cancer patients and in human immunodeficiency virus (HIV) patients. There was no evidence that it provided a clear weight gain or appetite benefit, and there was a suggestion that the agent may increase the risk for infection. Thalidomide, a drug that degrades TNF-α RNA and hence blocks inflammatory signal propagation, has shown more promise in clinical trials of

**FIGURE 4-4.** Integrated model representing connections between aging, gene variation, and chronic disease and the activation of inflammation and neuroendocrine changes, which ultimately alters physiologic systems and adverse health outcomes in older adults. The left and in the middle of the figure represent a platform of altered biology from which age-related vulnerability to adverse health outcomes evolve.

patients with pancreatic cancer. In clinical trials, it appears to be well tolerated and may influence weight gain in HIV and in pancreatic cancer, despite the fact that it offered no survival advantage. Megestrol, a hormonal agent known to block IL-6 transcription, has also been shown to be beneficial in HIV and cancer-related cachexia. It has been tolerated with minimal side effects, and is probably safe but not clearly effective at stimulating appetite in most geriatric populations.

As more and more disease specific and cytokine specific blocking agents are developed in the coming years, extreme caution must be taken in any future use in older populations given the increased risk and vulnerability to life-threatening infections or sepsis that is inherent in agents that target key components of the inflammatory cascade such as TNF- $\alpha$  or IL-6. Future studies of agents or activities that modulate or attenuate inflammation rather than block the inflammation, or perhaps agents that treat the underlying cause of the chronic activation of inflammation may be safer and more effective than agents that block these pathways.

### SUMMARY: DOES CHRONIC INFLAMMATION CONTRIBUTE TO AN ALTERED BIOLOGICAL PLATFORM FOR LATE-LIFE VULNERABILITY?

This chapter has presented an overview of studies that connect elevated levels of inflammatory mediators with a range of adverse health outcomes, and an overview of the biological reasons that older adults are more likely to develop chronic inflammation than younger adults. In addition, emerging evidence that inflammatory mediators themselves directly impact multiple physiological systems and acute and chronic disease states has been reviewed. Developed with this background in mind, Figure 4-4 shows inflammatory triggers, pathophysiologic change related to inflammation, and related adverse health outcomes in one comprehensive overview model. The underlying molecular changes, the disease states, and the altered physiology on the left side of the figure represents a platform from which the increased vulnerability to adverse health outcomes

observed in older adults with increased levels of inflammatory mediators can develop (Figure 4-4). Future studies of this vulnerability would benefit from a better understanding of the interface between molecular change and disease development, and how interventions may attenuate inflammation without adverse outcomes.

## INTRODUCTION

Over the past century, there have been truly remarkable changes in the numbers and characteristics of older persons throughout the world. The growth of the older population has resulted from a general increase in the overall population size but has been particularly affected by major declines in several of the leading causes of mortality. The increased survival of older persons has also been accompanied by declining birth rates; so the proportion of the population aged 65 years and older has increased dramatically and will continue to increase for the next 50 years. These demographic transformations have an effect on society that reverberates well beyond the increased medical care needs associated with an older population.

As more people live to advanced old age, it is important to gain a greater understanding of more than just the individual diseases that affect them. It is critical to appreciate the global picture of older persons who may have multiple chronic conditions, decrements in functional abilities, and social and psychological problems that may have an impact on many facets of their health and quality of life. In contrast to the previous stereotype, older people become more heterogeneous, not more alike, as they age, and understanding this process is a key challenge of geriatric medicine. Adding to the clinical perspective on single patients or small samples of patients, geriatric epidemiology has provided a useful tool with which to approach these challenges by studying representative populations of older persons. Going beyond the demographic focus of counting and projecting the number of older people in the population, epidemiology has made additional contributions to our understanding of the health status and functional trajectory of the older population. Since the 1980s, epidemiologic researchers either have utilized previously initiated cohort studies that include persons who have aged during the study or have begun new cohorts focusing on older people. These epidemiologic studies have assessed the distribution and determinants of specific diseases and have evaluated issues of relevance to an aging population, such as quality of life, geriatric

syndromes, comorbidity, functional status, and end-of-life issues. Many of the chapters in this book refer to epidemiologic research on specific diseases and conditions. This chapter focuses on the more general or “geriatric” outcomes, particularly disability, that have also been the subject of much epidemiologic investigation.

The chapter begins by documenting the rapid growth and impressive increases in the number of older persons in the United States and other countries. It then examines improvements in survival and life expectancy. Selected demographic characteristics are then considered, including living situation and labor force participation across many developed countries.

The second section, on mortality, depicts current causes of death in the older population in the United States and considers the change in death rates with increasing age. Data on overall and disease-specific changes in mortality rates from 1950 through 2004 show the dramatic changes in these rates. The third section addresses chronic disease in the older population by using data from national surveys on self-reporting of chronic conditions, ambulatory medical visits, and hospital discharges. Data are then presented for two conditions, cancer and dementia, as examples of conditions where the use of only mortality data would provide an incomplete picture. The fourth section presents epidemiologic data on disability in older persons. This section describes the prevalence of disability, its causes and consequences, individual transitions in functional status, population changes in disability prevalence, and measurement issues. Finally, the chapter provides a description of important behavioral risk factors for chronic disease, injury, and disability and the prevalence rates of these risk factors in the older population.

## DEMOGRAPHICS

### Aging of the Population in the United States

One-hundred-fifty years of aging in America are summarized in [Table 5-1](#), beginning with 1900 and including projections till 2050.

**TABLE 5-1****Actual and Projected Growth of the Older U.S. Population, 1900–2050 (Millions)**

	TOTAL POPULATION (ALL AGES)	≥65 YEARS		≥85 YEARS	
		Number	% of Total	Number	% of ≥65
1900	76.1	3.1	4.1	0.1	3.2
1950	152.3	12.3	8.2	0.6	4.9
2000	276.1	34.9	12.6	4.4	12.6
2050	403.7	82.0	20.3	19.4	23.7

Source: Population Division, U.S. Census Bureau, Washington, DC, 20233.

This table demonstrates how the older population has grown, as well as how the oldest segment of the older population has grown even more rapidly. In 1900, only 4.1% of the 76 million persons in the United States were aged 65 years and older, and among those in this age group only 3.2% were aged 85 years and older. By 1950, more than 8% of the total population was aged 65 years and older, and by 2000, this percentage had increased to 12.6%. The U.S. Census Bureau creates several alternative mortality scenarios when developing population projections, and according to their middle mortality assumption, there will be 82 million persons aged 65 years and older in the United States in 2050. If mortality declines faster than projected under this assumption, the number of older people will be even higher. In 2050, one in five Americans will be aged 65 years or older. The growth of the 85 years and older population, termed by some the oldest old, will be even more dramatic. By 2050, when the current baby boom generation will be in this age group, it is projected that over 19 million persons, representing nearly a quarter of all persons aged 65 years and older, will be 85 years and older. There will be more than four times as many people in the 85 years and older age group as there are now, and almost 200 times as many as there were in 1900. Thus, the number of older people is rising dramatically; the proportion of the total population aged 65 years and older is increasing; and the older population itself is

getting older, with increasing proportions in the 85 years and older subgroup.

### Aging of the Population and Life Expectancy Around the World

Population aging is taking place throughout the world. Figure 5-1 presents data on the current and projected percentage of the population aged 65 years and older for six regions of the world. Change in the proportion of a population that is elderly depends on changes both in the survival of older persons and in the birthrate. Improved survival at older ages and a low birthrate have resulted in European countries having the oldest populations in the world. In fact, the Population Research Bureau estimates that of the world's 25 countries with the oldest populations (not including small island countries), 24 are in Europe. Italy and Germany are estimated to have the oldest populations in Europe and the second and third oldest in the world at approximately 19% each. Sometime around 2004, Japan surpassed Italy to become the oldest major country in the world, with 20% of its population being 65 years or older. Japan remains the only major country not in Europe on the list of the oldest 25 populations. Considering countries of all sizes, the tiny country of Monaco surpasses Japan to become the country with the highest proportion of the population aged 65 years and older, at approximately 22%. Europe will continue to have the oldest populations in the world in the twenty-first century, with almost one in four Europeans projected to be aged 65 years or older by 2030. The current percentage aged 65 years and older in Latin America, the Caribbean, Asia, the Near East, and North Africa is low, ranging from about 4% to 6%. However, growth of the older population will be rapid in these countries, and it is projected that in 2030, the proportion of the population in this age range will double. Sub-Saharan Africa has few older persons, and it is expected that the percentage of older people in the general population will not grow substantially in the future.

Populations have aged at different speeds and during different time periods throughout the world. Figure 5-2 shows the number of years it took, or is projected to take, for specific countries to

**FIGURE 5-1.** Percent of population age 65 yrs and older, 2000 and projected for 2030. U.S. Census Bureau, 2004, "Life Tables," International Data Base, at <http://www.census.gov/ipc/www/idbnew.html> Accessed on February 21, 2007.

**FIGURE 5-2.** Speed of aging: number of years and time period in which percent of population aged 65 and over doubled or will double from 7% to 14%. Reprinted with permission from Kinsella K, Velkoff VA. *An Aging World: 2001*. U.S. Census Bureau, Series P95/01-1. Washington, DC: US Government Printing Office; 2001.

progress from having 7% of the population aged 65 years and older to having 14% of the population in this age range. The United States is expected to reach 14% in 2013 and will have taken 69 years to make the transition. Sweden and the United Kingdom reached the 14% level in 1975, with Sweden taking 85 years to go from 7% to 14% and the United Kingdom taking about half that time. Japan has already reached the 14% mark and took only 26 years to do so.

A particularly clear message about the speed of aging in developing countries is presented in Figure 5-2. Although the developing countries shown will generally not reach the 14% mark until the third decade of this century, they will have spent less than 27 years making the transition. The rapid aging of these countries will certainly have a large societal impact, with less ability to adapt than in countries that have aged more slowly.

### Life Expectancy at Different Ages

Better survival at all ages has had a major impact on the size and age distribution of the older population. Figure 5-3 depicts survival curves for the total U.S. population over the course of the twentieth century and into the twenty-first century. In 1900, there was substantial mortality in infancy and early childhood, with the survival curve in midlife being somewhat steeper than at the end of the twentieth century. By 1950, a large proportion of early-life mortality had

been removed, although survival in this age range was still improving by the end of the century. By 1990, a large proportion of persons were living to age 60 years, and only at age 70 years did the survival curve start to fall rapidly. The survival curve continued to shift to the right through 2003. The change observed in the shape of survival

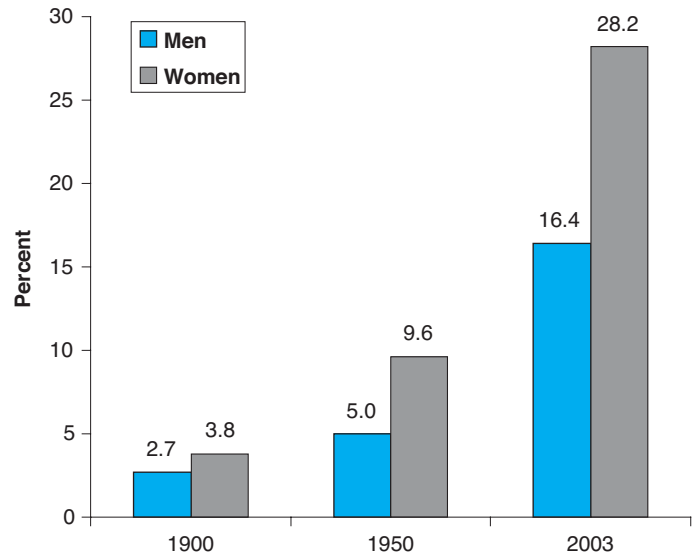

**FIGURE 5-3.** Survival curves for U.S. population. Arias E. *United States Life Tables, 2003*. National Vital Statistics Reports, vol. 54, no. 14. Hyattsville, MD: National Center for Health Statistics; 2006.

curves has been termed the rectangularization of survival, and it has been proposed that at some point in time full rectangularization will be reached, with no further increases in life expectancy. When this will occur is not yet clear, but the U.S. Census Bureau and Social Security Administration are projecting continued increases in survival for at least the next 50 years.

Life expectancy at age  $x$  is defined as the average number of years remaining to be lived by a member of a survivorship group who is exactly age  $x$ . Most life expectancy estimates use current life tables, meaning that they use the age-specific mortality experience of the current population. With this approach, life expectancy at birth gives an estimate of the average length of life of a cohort of children who are born now and then experience today's age-specific mortality rates as they proceed through life. This is an artificial construct, but it provides a way to represent the overall mortality experience of a current population and allows us to compare this experience across countries and over time. If mortality rates continue to decline, as is expected, the average child born today will live considerably longer than the estimate shown on a current life table. Given these caveats, it is nonetheless useful to examine changes in life expectancy over the last century and life expectancy at specific ages. Life expectancy at birth was only 47.3 years in 1900 and rose to 68.2 years by 1950, affected to a large extent by improvements in infant and child mortality. Life expectancy continued to rise through the second half of the twentieth century, driven mainly by increases in survival in middle and old age. Table 5-2 shows life expectancy at birth and at ages 65, 75, and 85 years for the year 2003. At every age, females have a higher life expectancy than males, with the differential at birth being 5.3 years. The gender differential for blacks (7.1 years) is greater than for whites (5.2 years). Blacks have a lower life expectancy than whites through age 75 years and then have a higher life expectancy at age 85 years. The observations of importance to geriatric medicine in these estimates are that the average 75-year-old man will live about 10 more years and the average 75-year-old woman will live more than 12 additional years. At age 85, the average person can still expect to live another 6 to 7 years.

The estimates shown in Table 5-2 do not include Hispanics. Although the National Center for Health Statistics does publish data on Hispanic mortality rates, these data come with warnings of problems associated with their accuracy. The denominator for Hispanic rates comes from the U.S. Census, where Hispanic ethnicity is self-reported. At the time of death, Hispanic ethnicity is reported by the person completing the death certificate, and there is likely a large amount of underreporting. It is also known that a not insignificant number of Hispanic persons return to their native countries to spend

**FIGURE 5-4.** Probability of 50-year-old living to 90 yrs, 1900 to 2003. Computed from U.S. life tables in Arias E. *United States Life Tables, 2003. National Vital Statistics Reports, vol. 54, no. 14.* Hyattsville, MD: National Center for Health Statistics; 2006.

the last years of their lives, and so their deaths are not enumerated as deaths in the United States. Thus, there is substantial underascertainment of the numerator for Hispanic death rate calculations, leading to an underestimation of the true rates.

The improvements in survival over the last century are relevant to the field of geriatric medicine, as the decline in mortality rates throughout life has resulted in a population with a large proportion of individuals who will survive to advanced old age. This point is made compellingly by the data shown in Figure 5-4. This figure was generated using data from 1900, 1950, and 2003 life tables and illustrates the proportion of 50-year-old men and women who can expect to live to age 90 years or older. Only about 3% of 50-year-olds could expect to live to this age in 1900. By 1950, this proportion had hardly risen at all in men but had gone up to nearly 10% in women. The large decreases in old-age mortality in the second half of the century led to large changes by 2003, when over 16% of 50-year-old men and more than 28% of 50-year-old women could expect to reach the age of 90 years or older. All these estimates are derived from current life tables; so if mortality continues to decline, these percentages will be even higher in the current cohort of 50-year-olds. The consequence of these changes is that an unprecedented proportion of the current middle-aged population will live to very old age.

### Extreme Longevity

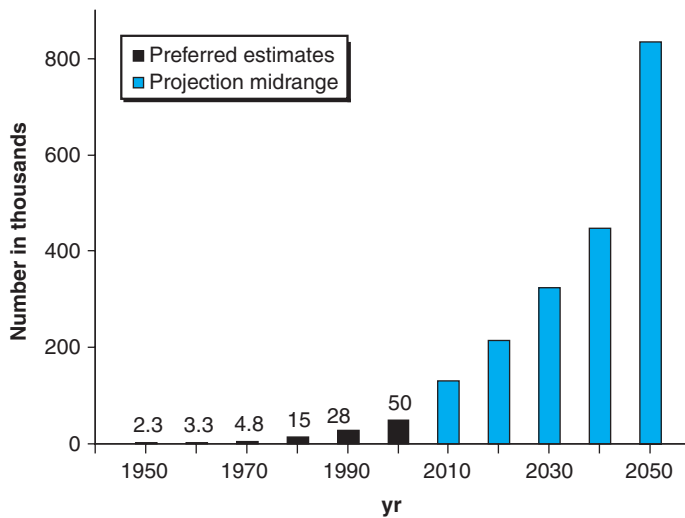

There has always been a fascination with extreme longevity, but the demographics of very long life have been formally studied only in recent years. Examples of persons who lived to 100 years are mentioned at the time of the Imperial Rome and, although these reports cannot be directly validated, there is no reason to believe that a few rare individuals might not have reached extreme longevity. However, as the percentage of centenarians has risen, especially in the last century, centenarians are no longer rare and virtually all geriatricians have dealt with a centenarian patient. Studying centenarians

**TABLE 5-2**

#### Life Expectancy in 2003 (Years)

AGE	MALE			FEMALE		
	All	White	Black	All	White	Black
At birth	74.8	75.3	69.0	80.1	80.5	76.1
At 65 yrs	16.8	16.9	14.9	19.8	19.8	18.5
At 75 yrs	10.5	10.5	9.8	12.6	12.6	12.4
At 85 yrs	6.0	5.9	6.4	7.2	7.1	7.8

Washington, DC: U.S. Government Printing Office; 1996. Preferred estimates for 1950–2000 acquired from He W, Sungupta M, Velkoff VA, DeBarros KA. U.S. Census Bureau, Current Population Reports, P23-209, 65+ in the United States, 2005. Washington, DC: U.S. Government Printing Office; 2005.

provides a magnified view of the aging process, but the study of long-lived individuals can also provide results that are important in geriatric practice. In fact, little is known about the factors that predict decline in health status, disability, and mortality in individuals in their nineties.

Previous claims for the world record for longevity were often unsubstantiated, and pockets of the world where claims were made for general high longevity usually turned out to be no different than other parts of the world. However, recent data from places like Sardinia, Italy, have identified areas of increased longevity that have been meticulously validated. There is currently no solid explanation about why centenarians are concentrated in these geographical areas.

Better age documentation has made it possible to be more confident about the numbers of centenarians and changes in these numbers. It has been estimated that the number of centenarians in western Europe has doubled every decade since 1950, and estimates for the United States also show a doubling between 1980 and 1990 and again from 1990 to 2000, when the total number of centenarians rose from 28,000 to more than 50,000 (Figure 5-5). In 2005, the United States had 55,000 centenarians, more than any other country in the world and about 12% of the estimated living world centenarians. In comparison, the population of the United States represents only 4.6% of the world population. However, future increases will be spectacular. It has been estimated that between 2000 and 2050, the number of centenarians will increase more than 16-fold, with a projected 850,000 centenarians in the United States in 2050.

In 1990, 78% of U.S. centenarians were non-Hispanic whites. However, since then, the Hispanic and black population have expanded much faster than the white population. Thus, centenarians in the future are expected to be much more ethnically diverse. In all reported series, with the single exception of Sardinia, there are fewer male than female centenarians. However, men reaching this age are

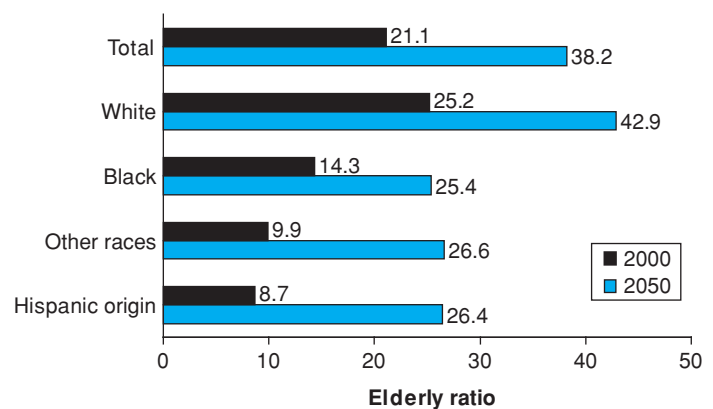

considerably less likely to have significant mental and cognitive disability than women.

Although family and twin studies suggest a strong genetic predisposition to extreme longevity and candidate genes have been described, the full mechanism is not understood. The secret is probably a combination of favorable genetic background and environmental factors that exert their influence in critical periods over the life span. In fact, many centenarians report that they were completely independent in self-care activities of daily living and free of disabling condition up to their late nineties. In addition, a sizable proportion of centenarian “escapers” are totally independent and free of major medical condition. Super-centenarians, individuals 110 years old or older, appeared around 200 years ago and their number is currently estimated at about 300 to 400. However, age has been validated in less than 100 of these people. In spite of many claims, only two persons have been clearly documented to have lived to 120 years.

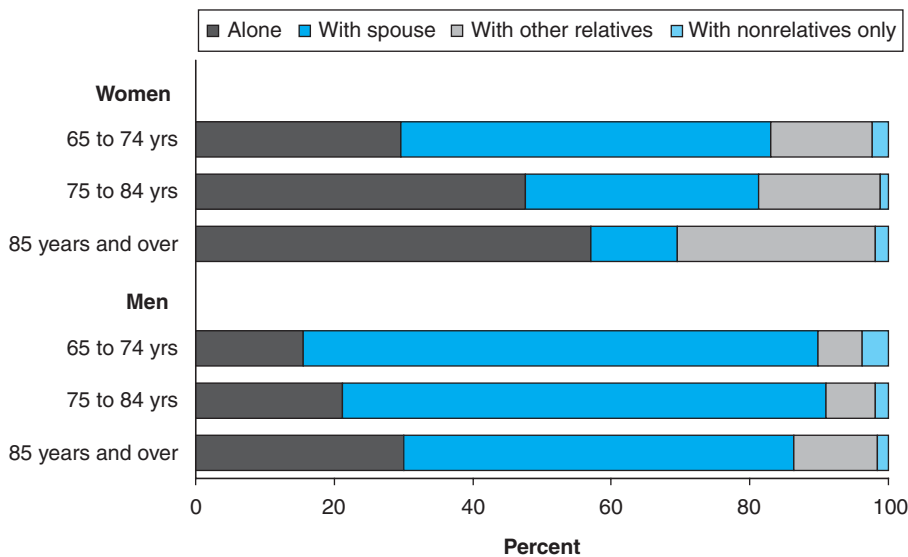

### Demographic Characteristics of the Aging Population

Further demographic characteristics relevant to the social environment in which older persons find themselves living are shown in Figures 5-6 and 5-7. In Figure 5-6, the elderly ratio, defined as the number of persons aged 65 years and older divided by the number of persons aged 20 to 64 years, multiplied by 100, is shown for the total population and racial and ethnic subgroups in 2000 and projected to 2050. With the faster growth of the older population and the less rapid increase in the younger population, this ratio will rise dramatically in the future. Currently there are about 21 older people for every 100 persons aged 20 to 64 years. By 2050, there will be 38 older people for every 100 persons in the younger age group, the group who will be called on to care for older parents and grandparents and whose Social Security payments will be used to provide for retirees. Now and in the future, the elderly ratio is highest in whites. Blacks currently have a higher ratio than Hispanics, but by 2050 there will be about 26 elderly blacks, Hispanics, and persons of other races for every 100 people aged 20 to 64 years.

Living situation is determined by health, financial factors, and widowhood and varies considerably by gender and age, as seen in Figure 5-7. Among community-living persons in the United States, women are much more likely to live alone, with almost 60% of

**FIGURE 5-6.** Elderly ratio: number of persons aged 65 yrs and older divided by number of persons aged 20 to 64, times 100. He W, Sungupta M, Velkoff VA, DeBarros KA. U.S. Census Bureau, Current Population Reports, P23-209, 65+ in the United States, 2005. Washington, DC: U.S. Government Printing Office; 2005.

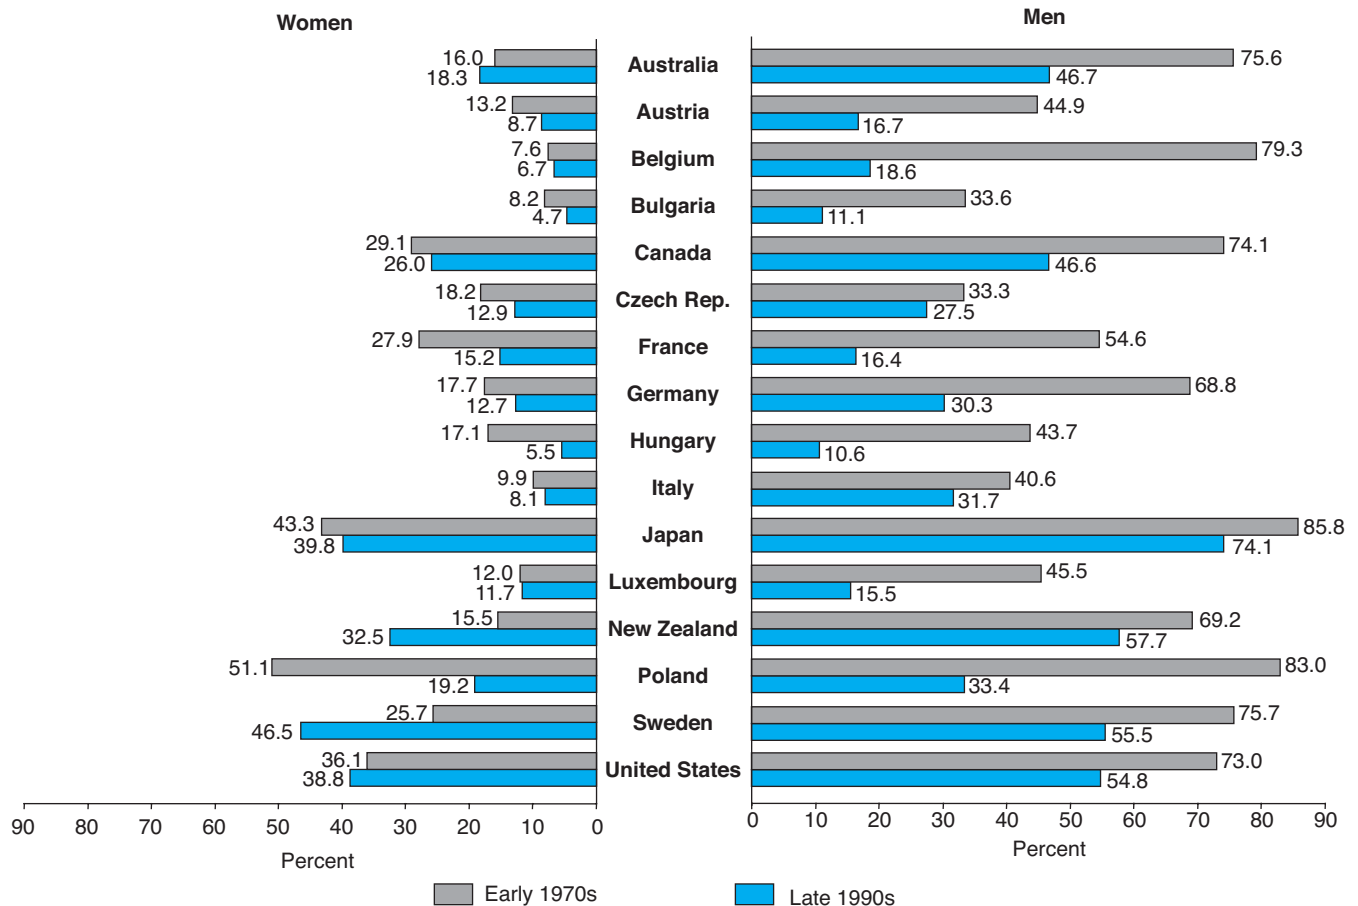

**FIGURE 5-7.** Living arrangements of community-dwelling persons 65 yrs and over United States, 2003. U.S. Census Bureau, 2003a, Current Population Survey, Annual Social and Economic Supplement, detailed tables.

women aged 85 years and older living alone. A large proportion of men live with their spouses. Women are more likely to outlive their husbands not only because they live longer but also because they tend to marry older men. Modest percentages of older persons live with other relatives, and a very small proportion live with nonrelatives.

### Employment

In recent years, the percentage of older people who work and the average age of retirement have fallen throughout the developed countries. In Figure 5-8, the percentage of persons working is shown for the early 1970s and the late 1990s for the 60 to 64-year age group,

**FIGURE 5-8.** Labor force participation rates for men and women aged 60-64 yrs in developed countries, early 1970s and late 1990s. the group that was traditionally preretirement. Overall, women work less than men, but in a few countries, including the United States, the percentage of women working rose during this time. In many countries, there have been extremely large declines in the percentage of men in this age group who work. For example, the percentage of men 60 to 64 years old who were employed declined over this 25-year period from 76% to 47% in Australia, from 79% to 19% in Belgium, from 55% to 16% in France, and from 69% to 30% in Germany. An increase in societal wealth has been the main driving force for decreased workforce participation, but other factors include obsolescence of the skills of older workers, pressure for older workers to leave their jobs to make room for younger workers in countries with high unemployment, and the growth of financial incentives for early retirement. The percentage of persons in the 65 years and older age group who work has also declined. For example, in the United States, the percentage of men in this age group who work dropped from 24.8% in the early 1970s to 16.9% in the late 1990s. The corresponding percentages for men in Germany were 16% and 4.5%, in France 10.7% and 2.3%, and in Japan 54.5% and 35.5%. With earlier retirement and longer life expectancy, the number of years people live after retirement has increased greatly. The Organization for Economic Cooperation and Development (OECD) has estimated that in 1960 men in developed countries could expect to spend 46 years in the labor force and a little more than 1 year in retirement. By 1995, years in the labor force had decreased to 37, whereas years in retirement had increased to 12.

## MORTALITY

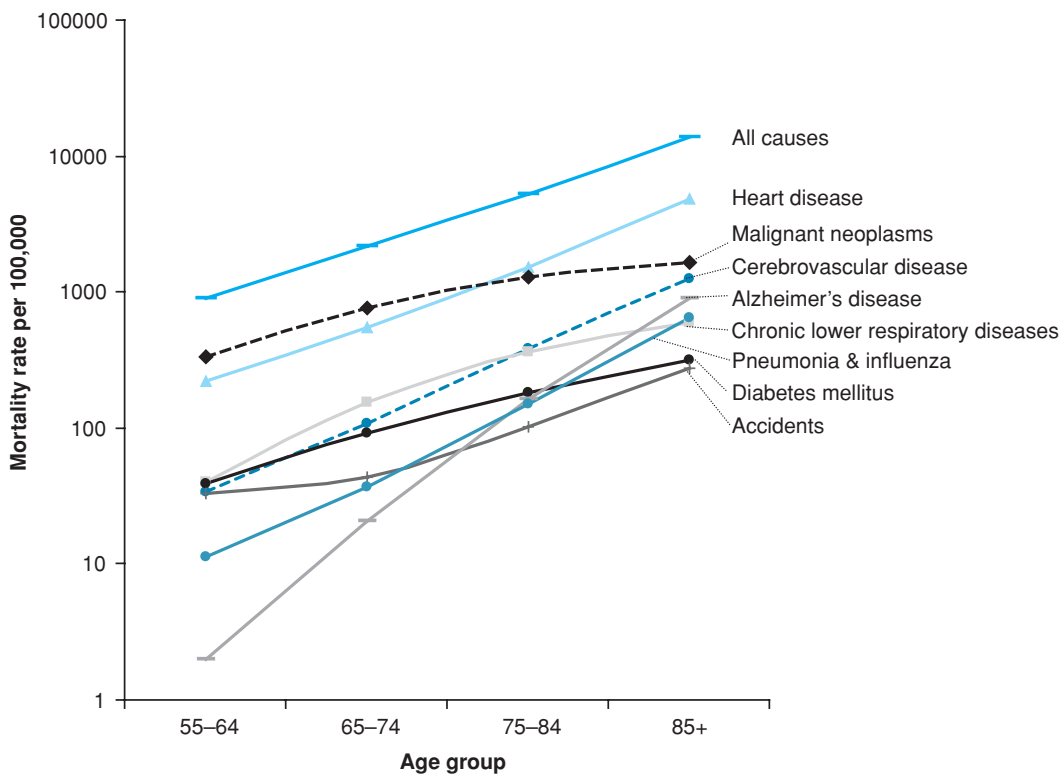

### Leading Causes of Death

The increasingly greater life expectancy of the population has been driven in part by reduced mortality at older ages. It is instructive to review the U.S. vital statistics data on causes of death in the older population, changes in these rates with increasing age, and trends in

overall and disease-specific mortality over time. Table 5-3 lists the leading causes of death in the population age 65 years and older in 2004. It employs the ICD-10 classification system, which was first used for national data in 1999. As in younger individuals, heart disease is by far the most common cause of death, followed by cancer. The five leading causes of death—heart disease, cancer, stroke, chronic lower respiratory tract disease, and Alzheimer's disease account for 69.5% of all deaths. Alzheimer's disease, which in the past was rarely assigned as the underlying cause of death and was not on the list of leading causes of death, was the seventh leading cause of death in older persons in 2000 and in 2003 rose to the fifth leading cause of death, responsible for 3.7% of deaths. This is still likely a gross underestimation. The contribution of Alzheimer's disease in the future will probably grow substantially. It is well recognized that assigning a single underlying cause of death is fraught with problems when an individual dies in advanced old age and has multiple chronic conditions. What is surprising is that despite this difficulty the distribution of causes of death in the United States remains quite stable from year to year.

Age-specific mortality rates for selected leading causes of death are depicted in Figure 5-9. On this logarithmic scale, a straight-line increase indicates an exponential increase in mortality rate with age. An exponential increase is present for all causes of death and parallel increases are seen for heart disease, cerebrovascular disease, and pneumonia and influenza. The exponential rise with age for Alzheimer's disease mortality is substantially steeper. The mortality rates for cancer and lower respiratory tract disease do not maintain as steep a rise with increasing age, perhaps because the people who contribute in large part to these categories are smokers, who die at younger ages and are less represented in the oldest segment of the population. Diabetes mortality rates also do not show an exponential increase with advancing age, again because diabetic patients may die disproportionately at younger ages. The one condition in this figure for which the mortality rate slope becomes steeper with advancing age is accidents. Although motor vehicle accidents are an issue of real concern in older persons, it is important to note, as shown in Table 5-3, that there are four times as many deaths from other types of accidents, primarily falls, as from motor vehicle accidents.

**FIGURE 5-9.** Age-specific death rates for leading cause of death in the older population, United States, 2004. Centers for Disease Control and Prevention, National Center for Health Statistics, National Vital Statistics System; Vital statistics of the United States, 2004 annual mortality file.

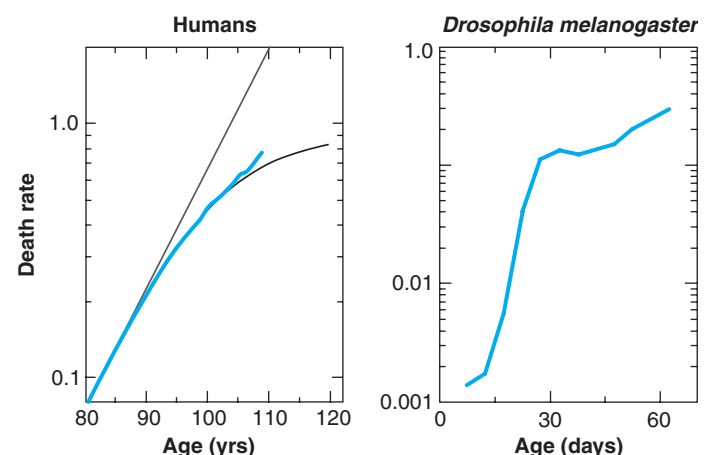

## Mortality Rates

The graph of the exponential rise in mortality with increasing age, which has been described for many species, has been termed the Gompertz curve. It has been difficult to evaluate whether the exponential increase is maintained to the very end of life, as the numbers of extremely old individuals available for study have traditionally been quite small. Recently, larger populations of very old humans and other species have been evaluated to examine whether the Gompertz curve continues to describe mortality rates at advanced old age. Figure 5-10 shows death rates for humans and fruit flies at the extremes of old age, and in both these examples the Gompertz function, which is represented as a straight line in the human example, is not consistent with the data. The conclusion from these studies and from studies on a variety of other species is that the force of mortality declines somewhat in individuals who survive to very old age, although the causes of this phenomenon remain unclear.

The first half of the twentieth century saw large declines in mortality in infants and children, but in the second half of the century, there were unprecedented declines in mortality in the older segment of the population. In the total population, mortality rates between 1950 and 2004 fell by 41.9% in males and 45.1% in females (Figure 5-11). What was notable during the latter half of the century was that this magnitude of decline was also seen in men and women in the 65- to 74-year-old and 75- to 84-year-old age groups. Even for people 85 years and older, there was a mortality rate decline that exceeded 30%.

Mortality change over this time period is further explored in Table 5-4, which lists 1950 and 2004 death rates and percentage changes in these rates for heart disease, stroke, and cancer, diseases that account for 60% of deaths in older adults. For the total population, heart disease mortality declined more than 60%, and stroke mortality dropped more than 70%, a truly remarkable decline in

these diseases that reflects major advances in both prevention and treatment as well as a secular trend that is not fully understood. For both these diseases, the declines in the 65- to 74-year-old and 75- to 85-year old age groups generally exceeded the percentage decline seen for the total population. In persons aged 85 years and older, heart disease mortality declined by more than 45%, with stroke mortality dropping by more than 60% in men and more than 55% in women, impressive declines in this very old segment of the population. Unfortunately, the declines in mortality seen for heart disease and stroke were not seen for cancer. In women, the overall population

**FIGURE 5-10.** Death rates at advanced old age in women and from age 0–60 days for a genetically homogeneous line of *Drosophila melanogaster*. Human estimates come from data aggregated from 14 countries for which data were available over the period from 1950 to 1990 for ages 80–109, and to 1997 for ages 110 and over. Data on *Drosophila* are from 6333 flies reared under usual laboratory conditions. Reprinted with permission from Vaupel JW, Carey JR, et al. *Biodemographic trajectories of longevity*. *Science*. 1998;280:855.

**FIGURE 5-11.** Percent change in mortality rates, United States, 1950–2004, for all ages (age-adjusted using yr 2000 standard population) and for older age groups. Calculated from data in National Center for Health Statistics. *Health, United States, 2006 with Chartbook on Trends in the Health of Americans*. Hyattsville, MD: National Center for Health Statistics; 2006.

showed a modest decline in cancer mortality, but the older population had a slight rise in rates. Cancer mortality rates rose in older men, with increases of 25% in men 75 to 84 years and 40% in men 85 years and older. Heavy cigarette smoking in the cohort of men who were in the older age groups at the end of the last century was probably a major contributing factor to this increase in cancer rates. Figure 5-12 depicts change in mortality from cancers of the lung, trachea, and bronchus over the past half century. Mortality in men was much higher than in women and rose very steeply in men 75 to 84 years and 85 years and older until the early 1990s, when it leveled off. Cancer mortality rose less steeply in men 65 to 74 years, leveled off in the late 1980s and is now showing a downturn. Mortality from cancer of the lung, trachea, and bronchus in older women rose slowly after 1960, with a slightly steeper rise in those 75 to 84 years beginning in the 1980s.

Mortality from acquired immunodeficiency syndrome (AIDS) has had a small but not insubstantial impact on older persons compared to the younger population. Figure 5-13 shows trends in age groups beginning at age 45 years. The steep rise and then fall in AIDS mortality in the 45 to 54 years age group is reflected in similar but increasingly less pronounced patterns in each succeeding age group.

## DISEASE STATUS

### Prevalence of Common Diseases

Although there is much useful information to be gained by observing the diseases responsible for mortality, a full picture of disease status in the older population cannot be obtained by looking only at diseases that cause death. A number of ascertainment approaches that work well to characterize morbidity in the general population are used here to give an overview of important diseases prevalent in

**TABLE 5-4**

older persons. This overview is not meant to provide a comprehensive epidemiology of all medical conditions that often develop with aging but to show data that allow for a comparison of rates across the major conditions.

When a medical history is obtained, a clinician begins to construct a profile of disease status from self-reporting by the patient. In extending this approach to surveys of large, representative samples of older persons, it has been found that self-reporting works quite well for most diseases. Table 5-5 lists the most commonly reported chronic conditions among people aged 65 years and older in the United States. The most commonly reported condition is hypertension, reported by nearly half of older persons. Nearly one-quarter of men and 17% of women reported coronary heart disease and stroke history is reported by over 8% of older persons. Arthritis and chronic joint symptoms were reported by a large proportion of older persons and they, like many of the conditions on the list, have a large impact on overall health and quality of life but do not appear on the list of the most common conditions causing death. There

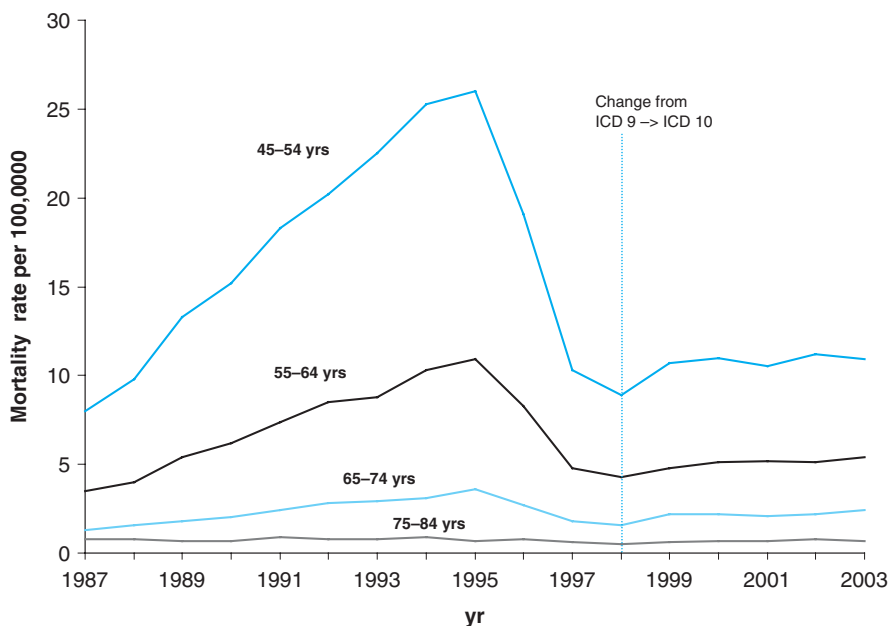

**FIGURE 5-12.** Mortality rate for malignant neoplasms of the trachea, bronchus, and lung by age, sex, and year: United States, 1950–2004. Miniño AM, Heron M, Murphy SL, Kochanek KD. Deaths: Final data for 2004. *Health E-Stats*. Hyattsville, MD: National Center for Health Statistics; 2006.

are some differences in the prevalence rates of chronic conditions according to race and ethnicity. For example, in persons aged 70 years and older, diabetes is more common in non-Hispanic black and Hispanic persons than in non-Hispanic whites. Non-Hispanic blacks have 1.5 times as much hypertension as non-Hispanic whites. Non-Hispanic white men report more heart disease than Hispanic whites or non-Hispanic blacks, whereas non-Hispanic black women report more stroke than non-Hispanic whites or Hispanics.

### Co-occurrence of Multiple Chronic Conditions

An important aspect of disease status that distinguishes the older population from the younger population is the high rate of the co-occurrence of multiple chronic conditions, termed comorbidity or multiple morbidity. Because the risk of developing most diseases increases progressively with age, the increased prevalence and severity of comorbidity is not surprising. However, several lines of research

suggest that the observed prevalence of comorbidity is higher than the prevalence expected based on the rates of individual diseases, implying a clustering of diseases in certain individuals. The concept of comorbidity is a useful one in considering the burden of disease in older people. However, the operationalization of a definition for comorbidity depends on the number of conditions being ascertained and the intensity of the diagnostic effort to identify prevalent diseases. The longer the list of conditions and the harder one works to find prevalent diseases, the greater the prevalence of comorbidity. In a national survey that used self-reporting of nine common conditions, comorbidity was present in almost 50% of persons aged 60 years and older. Among those aged 80 years and older, 70% of women and 53% of men had comorbidity. Although comorbidity is a characteristic of older patients that is dealt with regularly by clinicians, there has been a limited amount of research on the classification of specific patterns of comorbidity and on the impact of comorbidity. In particular, certain combinations of conditions seem to occur at a higher

**FIGURE 5-13.** Mortality rate for HIV/AIDS by age and year in the United States, 1987–2003. Miniño AM, Heron M, Murphy SL, Kochanek KD. Deaths: Final data for 2004. *Health E-Stats*. Hyattsville, MD: National Center for Health Statistics; 2006.

rate than would be expected by chance alone, and certain pairs of conditions may have a synergistic effect on functional loss.

## Health Care Utilization

### Physician and Ambulatory Visits

Data on physician visits and hospitalizations can also provide insight into the disease status of older people. Table 5-6 shows data on medical visits and hospitalizations in 2004 for the full age spectrum.

**TABLE 5-6****Ambulatory Medical Visits, Reasons for the Visit\* and Drug Prescription According To Age Group, and Hospital Discharges By Age Group, U.S., 2004**

AGE GROUP	AVERAGE NUMBER OF VISITS PER PERSON PER YR <sup>†</sup>	PERCENT VISITS FOR ACUTE PROBLEMS	PERCENT VISITS FOR CHRONIC PROBLEMS (ROUTINE OR FLARE-UP)	PERCENT OF VISITS WITH 4+ DRUGS PRESCRIBED OR CONTINUED (1999)	NUMBER OF HOSPITAL DISCHARGES PER 1000 POPULATION

Cherry DK, Burt CW, Woodwell DA. National Ambulatory Medical Care Survey: 1999 summary. Advance data from vital and health statistics; no. 322. Hyattsville, Maryland: National Center for Health Statistics; 2001.

Lolak LJ, DeFrances CJ, Hall MJ. National Hospital Discharge Survey: 2004 Annual Summary with Detailed Diagnosis and Procedure Data. National Center for Health Statistics. Vital Health Stat. 2006;13(151).

With increasing age, the number of physician visits increases steadily, and persons aged 75 years and older make, on average, over seven visits per person per year. The proportion of each age group's visits that are for acute problems and for chronic problems are shown separately, and there is a clear trend in both, with acute problems decreasing steadily with increasing age and chronic problems rising with age and accounting for almost 60% of office visits in persons aged 75 years and older. The percentage of office visits at which four or more drugs are prescribed or continued also rises steeply with age, and one-quarter of ambulatory visits in persons aged 75 years and older involve patients taking this many drugs. Finally, the table lists overall rates of hospital discharge, which go up dramatically with increasing age. For every 1000 persons aged 65 to 74 years there are 259 hospital discharges in a year, and for every 1000 persons aged 75 years and older there are 427 hospital discharges in a year.

Table 5-7 demonstrates data from the National Ambulatory Medical Care Survey on the reasons for ambulatory visits to physicians' offices, hospital outpatient departments and emergency departments in 2001-2002. The three most common reasons for these visits were essential hypertension, diabetes, and arthropathies and related disorders. However, these three conditions accounted for less than 20% of ambulatory visits, with a wide range of problems accounting for the remainder. For all listed reasons, the visit rate per 100 persons is slightly higher in persons 75 years and older compared to the 65 to 74 years age group. Overall, the older group had 828 visits per 100 persons and the younger group 690 visits per 100 persons.

### Causes of Hospitalization

The actual causes of hospitalization in persons aged 65 years and older are represented in Table 5-8, which uses data from the National Hospital Discharge Survey. Heart disease is the most important cause of hospitalization by far, with congestive heart failure a slightly more common cause of hospitalization than other manifestations of heart disease. Other diseases that are frequent causes of death in older adults (pneumonia, stroke and cancer) are also common reasons for

hospitalization, but so are diseases not as strongly associated with mortality, including fractures, osteoarthritis, chronic bronchitis, and psychosis. The presence of septicemia and volume depletion on this list of the leading causes of hospitalization reflects the fact that a portion of the older population is frail and at high risk for these kinds of illnesses.

## Cancer

Cancer mortality rates do not always reflect the incidence rates of newly diagnosed cancers. The latter data are available from the Surveillance, Epidemiology, and End Results (SEER) survey of the National Cancer Institute and other cancer registries. Figure 5-14 depicts the age-specific incidence of the most common cancers that affect men and women. The highest incidence rates in men are seen for prostate, lung, colon and rectum, and bladder cancers, and in women for breast, colon and rectum, lung, and uterine cancers. The incidence of most of these cancers rises steadily with increasing age, but several, including prostate, breast, and lung cancers, begin to drop in incidence at the oldest ages.

## Dementia

Dementia is a condition of aging for which prevalence and incidence rates cannot be validly obtained from either national survey data or registries. Because of the complexities of diagnosing dementia, data on the occurrence of the condition must rely on well-designed epidemiologic studies in local geographic areas. A network of dementia studies in Europe used comparable diagnostic techniques, which allowed for the aggregation of data on both prevalence and incidence (Figure 5-15). These pooled results show that both incidence and prevalence increase with age, with a steep rise in prevalence after age 80 years, when the prevalence in women becomes somewhat higher than in men. The incidence data show a clear rise in women to age 90 years and older, but some leveling off in men after age 85 years. The incidence rates are about 15% to 30% of the prevalence rates. In a condition such as dementia, which cannot be cured, this relationship between incidence and prevalence indicates that mortality

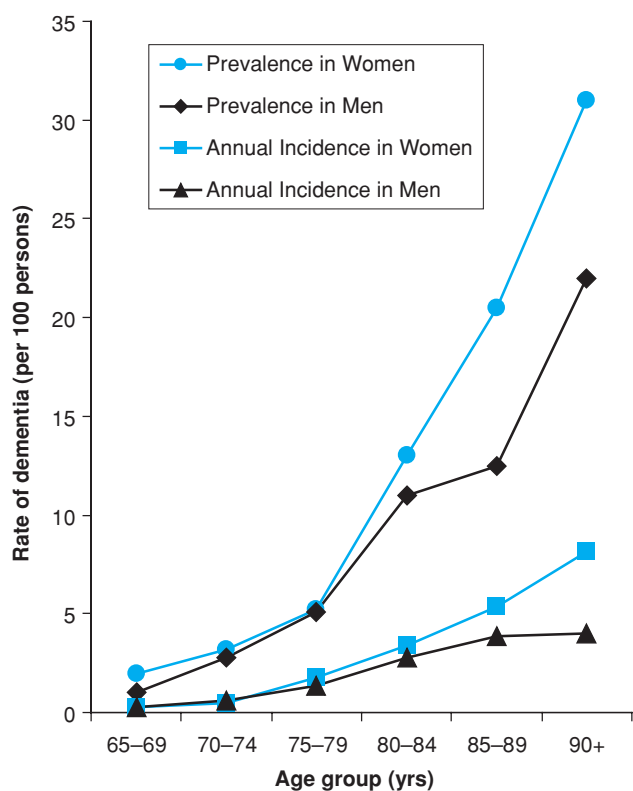

**FIGURE 5-14.** Incidence rates of specific cancers in men (top panel) and women (bottom panel) by age. SEER Cancer Statistics Review 1973–1998. Surveillance, Epidemiology and End Results Program, National Cancer Institute. [http://seer.cancer.gov/csr/1973\\_1998/](http://seer.cancer.gov/csr/1973_1998/) Accessed on March 7, 2007.

occurs about 3 to 5 years after diagnosis. An even larger collection of studies on dementia incidence from around the world supported an exponential increase in dementia with age and demonstrated that rates tend to be lower in East Asia than in Europe and the United States.

## DISABILITY

A hallmark of geriatrics is emphasis on the functional ability of older patients, and this subject is discussed from a clinical point of view in several chapters in this book. This approach recognizes that

although individual diseases are important and that our system of modern medicine is oriented toward the diagnosis and treatment of specific diseases, the consequences of single and multiple diseases can be understood best by evaluating the functional status of the patient. A large body of epidemiologic work undertaken over the past two decades has treated disability as a condition that can be studied in much the same way as if it were a well-defined chronic disease by using epidemiologic tools to assess prevalence, incidence, and a wide range of risk factors. This work has led to a greater understanding of the occurrence, determinants, and consequences of disability in the older population and has provided insights into strategies for the prevention of disability.

**FIGURE 5-15.** Age- and gender-specific prevalence and annual incidence of dementia in persons aged 65 and older. ### Measures of Function and Disability

Measures of disability were originally developed for use in the clinical setting and were aimed at quantifying the impact of severe medi-

cal conditions such as stroke on physical and mental functioning, obtaining standard information on the rate and degree of recovery from these conditions, and assessing work ability and the need for formal and informal care. These assessment tools were gradually applied in clinical research and population-based studies, and almost all research studies in older populations now assess disability status. Federal data collection efforts did not include very old populations as recently as the early 1980's, but these surveys now have no upper age limit and include various instruments to assess disability. This type of assessment is illustrated in Figure 5-16, which is based on data from the Medicare Current Beneficiary Survey. Physical limitations include such basic tasks as standing, reaching, and grasping. These tasks represent the building blocks of functioning but are not specifically measures of disability. Activities of daily living (ADLs) are basic self-care tasks. Instrumental ADL (IADLs) are tasks that are physically and cognitively somewhat more complicated and difficult than self-care tasks and are necessary for independent living in the community. ADL and IADL are measures of disability and reflect how an individual's limitations interact with the demands of the environment. In the youngest age group, physical limitations are present in 40% of men and women and there is a low prevalence difficulty with ADLs. With increasing age, the prevalence of ADL disability increases rapidly and the proportion of persons with no limitations decreases to under 10% in persons 85 years and older. Additionally, the prevalence of disability is higher in women compared to men of the same age.

Disability has been assessed with a wide variety of instruments, and even when instruments contain the same items, they may differ in how they assess specific aspects of performing the task or the severity of limitation in performing the task. For example, it is always debatable whether it is better to ask people whether they actually perform a specific task or whether they should be asked to judge whether they could perform the task even if they have not done it for long time. The former approach gives more concrete information, but respondents could be classified as disabled simply because they have chosen not to do a task that they are perfectly capable of performing. The latter approach allows for classification of people regardless of whether or not they have actually done the

**FIGURE 5-16.** Physical limitations and disability according to age and sex, U.S., 2004. Physical limitations are defined as any difficulty doing one or more of the following: stooping, lifting, reaching, grasping, and walking 1/4 mile. Instrumental activities of daily living (IADLs) are defined as any difficulty doing one or more of the following: using the telephone, doing light housework, doing heavy housework, preparing meals, shopping, and managing money. Activities of daily living (ADLs) are defined as any difficulty doing one or more of the following: bathing or showering, dressing, eating, getting in or out of bed or chair, walking across a room, and using the toilet. Functional limitations of Medicare beneficiaries by age, residence, sex, race, and ethnicity from the Medicare Current Beneficiary Survey, 1992-2004. **FIGURE 5-17.** Disability estimates using three different measurement methods. Reprinted with permission from Jette AM. *How measurement techniques influence estimates of disability in older populations.* *Soc Sci Med.* 1994;38:937.

task recently but is limited because respondents who have not done the task are required to speculate as to their ability. For this and other issues in disability assessment, there is no single best way to perform an assessment, and there is therefore no single instrument that is ideal. The lack of standardization that results from the use of different instruments makes it difficult to compare rates of disability across studies. The differences in prevalence rates that different methods of assessment yield are demonstrated in the methodologic study of ADL disability shown in [Figure 5-17](#). Disability classified as

having any difficulty or being unable to perform a task had a higher prevalence than disability classified as requiring human assistance or being unable to perform. Disability classified as requiring human help or help from an assistive device had a higher prevalence rate than disability requiring human help only and was similar in prevalence to the classification using difficulty. This study found that for individual ADLs the assessments that relied on difficulty produced estimates of disability 1.2 to 5 times greater than assessments that used human assistance as the criterion for disability. Thus, in evaluating research that reports on disability rates, it is critical to examine the way questions are asked and how responses are used to determine the presence of disability.

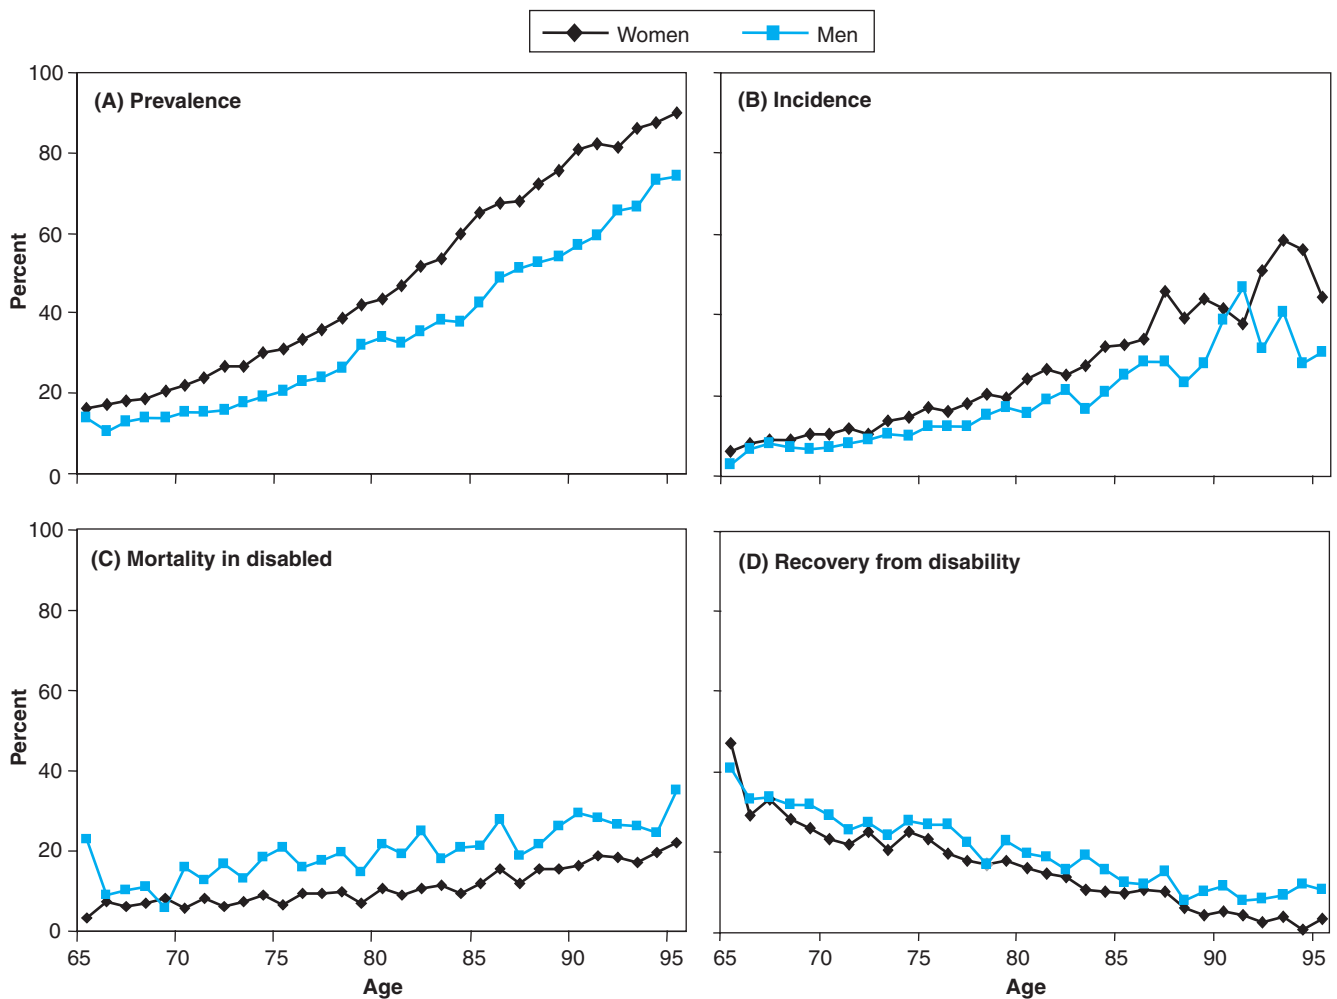

### Disability as an Indicator of Health Status and Prognosis

Disability status has been demonstrated in epidemiologic studies to be one of the most potent of all health status indicators in predicting adverse outcomes. This is probably because disability measures are able to capture the impact of the presence and severity of multiple pathologies, including physical, cognitive, and psychological conditions, as well as the potential synergistic effects of these conditions on overall health status. The powerful prognostic power of disability presence is illustrated in [Figure 5-18](#), which considers a hierarchy of disability statuses that are defined as independent in ADLs, independent but reporting some difficulty with ADLs, and dependent on personal assistance for ADLs. For these three groups, there were different cumulative probabilities over a 4-year follow-up period of the two outcomes shown here—admission to a nursing home and mortality. These results support the discussion in the previous paragraph that different disability criteria can identify population subgroups with different prognoses. They also support the validity of disability

**FIGURE 5-18.** Cumulative probability of admission to a skilled-nursing facility (left) and death (right) for three basic activities of daily living groups. Reprinted with permission from Gill TM, Robison JT, et al. *Difficulty and dependence: Two components of the disability continuum among community-living older persons.* *Ann Intern Med.* 1998;128:96.

**FIGURE 5-19.** Women's and men's prevalence of mobility disability (a), 1-year incidence among nondisabled persons (b), and 1-year mortality (c) and recovery (d) among disabled persons, by age. Established Populations for the Epidemiologic Study of the Elderly. Reprinted with permission from Leveille SG, Penninx BW, et al. Sex differences in the prevalence of mobility disability in old age: the dynamics of incidence, recovery, and mortality. *J Gerontol B Psychol Sci Soc Sci.* 2000;55:S41.

measurement, with level of disability being highly predictive of two important outcomes.

### Prevalence of Disability

The higher prevalence rate of disability in women, shown in Figure 5-16, has been repeatedly demonstrated in many studies and is consistent across a variety of measures and in studies using both self-reporting and objective assessments. Indeed, the fact that women live longer than men in spite of their worse health and higher rate of disability at all ages is one of the most interesting paradoxes in the epidemiology of aging. Another valuable measure of disability that has received increasing attention is mobility disability and is usually evaluated using questions related to walking and climbing stairs. Figure 5-19A shows that one definition of mobility disability—the inability to walk 0.5 mile or climb stairs—increases with age and has a higher prevalence in women than in men at all ages after 65 years. The dynamics of this difference in prevalence are highly instructive. Prevalence is a snapshot at a single point in time and is a function of the flow into and out of the condition being assessed. In the case of mobility disability, women have a higher incidence (new occur-

rence) of disability (Figure 5-19B) and are less likely to exit from the disabled state than men because they have lower mortality than men when they are disabled (Figure 5-19C) and because they are less likely to recover from disability than men (Figure 5-19D). Thus, the prevention of disability and better treatment of women who have become disabled are likely to have a beneficial effect in lowering the disability rates of women to the level of those of men. Reduction in mortality in disabled men would also contribute to reducing gender differences in disability prevalence.

### Risk Factors for Disability

In addition to gender, a wide array of risk factors for disability has been found in longitudinal studies in older populations. Although the disability definitions were not consistent across these studies, the relative risk of disability for many risk factors was found to be consistent across different definitions, providing strong support for the importance of these risk factors. The most commonly and consistently reported risk factors for disability are listed in Table 5-9, which comes from a review of 78 community-based longitudinal studies that assessed factors related to decline in functional status

**TABLE 5-9****Risk Factors for Functional Status Decline***Behavioral Risk Factors and Individual Characteristics*

Low physical activity  
 Smoking  
 High and low body mass index, weight loss  
 Heavy and no alcohol consumption  
 Increased age  
 Lower socioeconomic status (income, education)  
 High medication use  
 Poor self-rated health  
 Reduced social contacts

in older persons. Risk factors are divided into behavioral and individual characteristics, and specific chronic conditions. There is a great deal of interdependence among these risk factors. Behavioral risk factors such as physical inactivity and smoking can promote the development of a variety of diseases, which can then go on to cause disability. It is becoming evident that these behavioral risk factors may also have direct effects of their own. For example, physical inactivity may be a risk factor for the onset of specific diseases, and it also may have a direct negative impact on muscle, bone, and the central and peripheral nervous systems. These changes can move an individual closer to the physiologic and functional threshold beyond which functioning is impaired to the point that disability occurs. Figure 5-20 shows the relative contributions of specific conditions to disability according to age group. These data were obtained by asking persons who reported a limitation in their activities (work limitation or need for assistance in ADLs or IADLs) to specify the health condition that they thought was responsible for that limitation. Arthritis and heart or other circulatory diseases were by far the most commonly reported conditions contributing to physical limitations but it is notable that sensory limitations are also reported to make large contributions. Dementia is reported by proxies to be a substantial contributor to activity limitations in those age 85 years and older.

The role that cognitive impairment plays in physical disability has been generally underappreciated in epidemiologic studies. For clinicians attending to severely disabled persons in nursing homes,

however, it is evident that dementia itself prevents these individuals from being independent. Figure 5-21, based on data from population-based studies in Tuscany, Italy, shows estimates of the numbers of men and women with ADL disability in 1999 according to age. It also separates these people into those with and without dementia. There is an overall increase in the number of disabled persons through the mid-eighties in men and through the late eighties in women, with a drop-off in the numbers after that because of the decline in the total number of persons in the population at these advanced ages. The obvious gap in these otherwise smooth curves is a result of the low birthrate during and just after World War I, which translated into a smaller population 80 years later. In both men and women, most ADL disability before age 75 years is not associated with dementia. From age 75 to 90 years, about half of ADL disability is accompanied by dementia, and after age 90 years, the majority of persons with ADL disability have dementia. It should be noted that these data do not prove that dementia is what caused the disability in these individuals. Serious physical impairments and diseases co-occur with dementia, and it may not be possible to always understand just what the cause of disability is. Nevertheless, it is impressive that such a large proportion of disabled persons have dementia, and it is clear that cognitive functioning must be considered when developing interventions to prevent or treat disability.

### Recovery from Disability

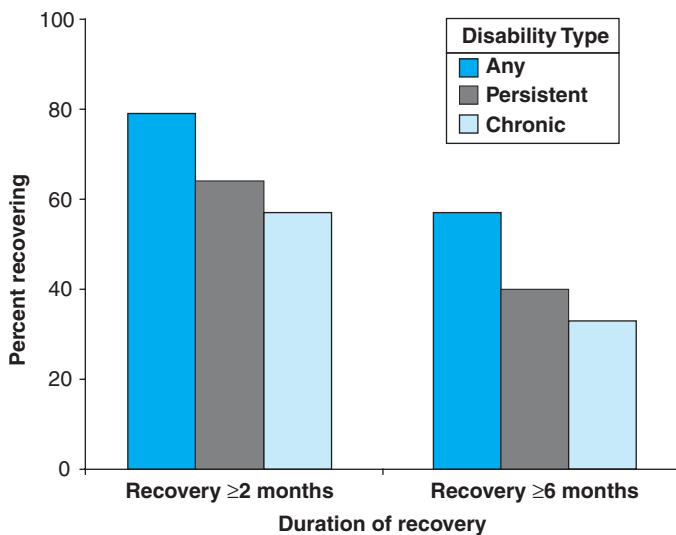

Longitudinal epidemiologic studies have revealed much about the dynamics of disability onset and progression. It has been found that, contrary to previous belief, a substantial proportion of individuals who are disabled report improvement on subsequent assessments. In effect, disability is a product of the disease or diseases from which an individual suffers, sedentary lifestyle or disuse, and physiologic declines that may be the result of aging or pathologic processes that are not specific diseases but result from factors such as inflammation or endocrine changes. As these predisposing conditions change, they have an impact on the initiation of disability and on changes in the status of already established disability. Figure 5-22 shows data on recovery from a study that assessed community-dwelling persons age 70 years and over on a monthly basis. Results are shown for the percent with disability who recovered for 2 or more months and 6 or more months according to the pattern of disability they initially reported. For persons with any disability, recovery rates were high and long-term recovery was also quite common. Recovery rates were also high in persons who had disability reported for 2 or more consecutive months (persistent disability) and 3 or more consecutive months (chronic disability). Other studies have observed high rates of improvement in disability status over intervals ranging from 1 to 3 years. These studies are conservative in their estimates of recovery because they are missing transient improvement due to the long time interval between assessments. Observed improvement in function could result from inaccurate self-reporting of disability over time (unreliability of instrument), a true change in disability status, or both. There is some evidence that both these explanations play a role, but there is consistent evidence that there is a certain amount of real improvement in disability. Both community-based studies and studies on persons hospitalized after an acute event have evaluated factors that predict recovery from disability. Age less than 85 years, good cognitive function, remaining physically mobile, absence of

**FIGURE 5-20.** Reported chronic conditions responsible for self-reported activity limitation by age group: NHIS, 2003–2004. Activity limitation defined as work limitations or need for assistance with ADLs (eating, bathing, dressing, and getting around inside the home) or IADLs (household chores, doing necessary business, and shopping or running errands). If any limitations are identified, the respondent is asked to specify the health condition(s) causing the limitation(s) and indicate how long he or she has had each specified condition. U.S. Census Bureau 2004, National Health Interview Survey, 1997–2000, Prevalence of selected chronic conditions by age, sex, race, and Hispanic origin: United States, Data Warehouse on Trends in Health and Aging, NHICO1c, National Center for Health Statistics. Accessed on February 21, 2007.

**FIGURE 5-21.** Estimated number of men and women with activities of daily living disability (need for help of another person) with and without an additional diagnosis of dementia according to age, Tuscany, Italy, 1999. The figure was obtained by applying estimates from three large population-based epidemiologic studies in the Tuscany population, the Italian Longitudinal Study on Aging, JCARE Dicomano, and InCHIANTI. The original analyses and population estimates are from Istituto Nazionale di Statistica: National Statistical Institute of Italy, 1999. Internet address [www.istat.it](http://www.istat.it). Accessed February 21, 2007.

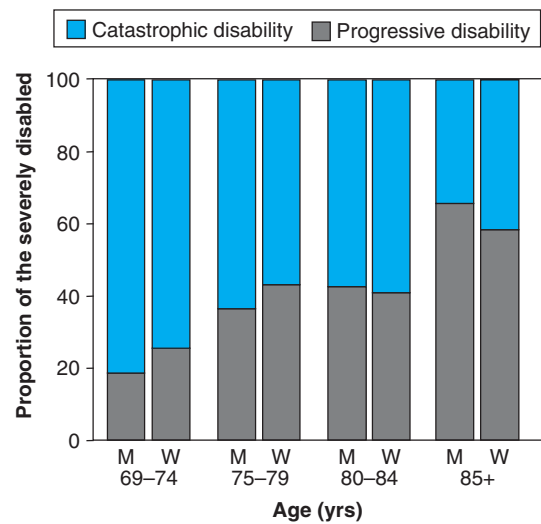

**FIGURE 5-22.** Percent recovering function after 2 months and after 6 months according to disability type. Any disability is defined at monthly visits as any new need for help or inability to perform one or more of the following ADLs: bathing, dressing, walking, and transferring. “Persistent” disability is defined as a new disability that was present for at least two consecutive months. “Chronic” disability is defined as a new disability that was present for at least 3 consecutive months. Adapted from Hardy SE, Gill TM. Recovery from disability among community-dwelling older persons. *JAMA*. 2004;291:1596–1602.

depression, and good social support have all been associated with a greater probability of recovery.

### Types of Disability Progression

In understanding the dynamics of disability progression, it is useful to consider the pace at which disability develops. The terms “progressive disability” and “catastrophic disability” have been used, indicating a slow downhill course and a very rapid decline, respectively. Progressive disability results from one or more ongoing chronic conditions and causes disability over months or years, whereas catastrophic disability can occur in moments as a result of a stroke or a hip fracture. The prevalence of both progressive and catastrophic severe ADL disability, defined as needing help with three or more ADLs, increases with increasing age, although progressive disability rises faster than catastrophic disability. Among older persons with severe ADL disability, the proportion that has catastrophic ADL disability is much higher at younger ages, and the proportion that has progressive ADL disability is much higher at the oldest ages (Figure 5-23). A similar age pattern has been found for onset of severe mobility disability (inability to walk across a room), where it has been demonstrated that progressive disability is much more common in people who have three or more chronic conditions.

The dynamics of disability can also be approached by studying the pathologic changes that precede its onset. Different theoretical pathways have been proposed to describe the changes that occur as a person proceeds from disease to disability. The theoretical pathway that has received substantial empirical support in aging research is that proposed by Nagi and endorsed by the Institute of Medicine. In this pathway, two intermediate steps, impairment and functional limitation, follow disease and lead to disability (see Verbrugge and Jette, 1994). Impairment describes the dysfunction and structural abnormalities in specific body systems that result from pathology.

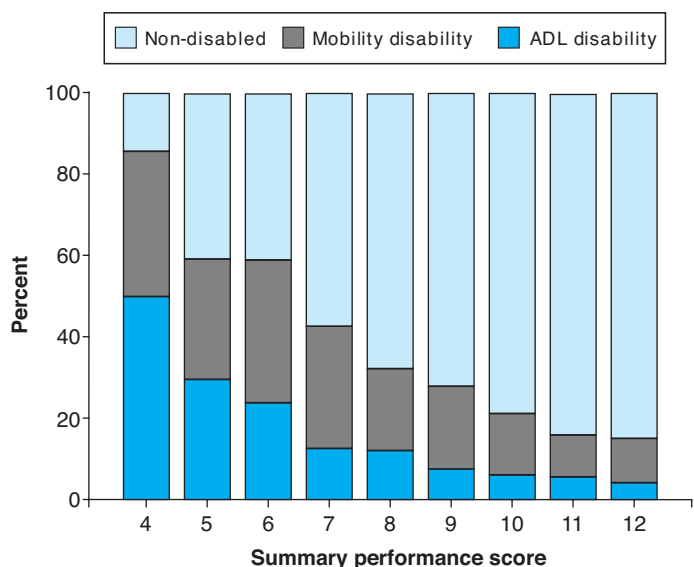

**FIGURE 5-23.** Proportion of population needing help with three or more activities of daily living (ADL) who have catastrophic disability (no ADL disability in preceding year) and progressive disability (need for help with one or two ADL in previous year), by age and gender. Reprinted with permission from Ferrucci L, et al. Progressive versus catastrophic disability: a longitudinal view of the disablement process. *J Gerontol A Biol Sci Med Sci*. 1996;51:M123.

Functional limitation describes restrictions in basic physical and mental actions that result from impairments. Functional limitations are the basic building blocks of functioning, and the interaction of these components of functioning with the environmental demands faced by an individual determines whether that person is disabled (see Guralnik and Ferrucci, 2003). Conventional study of the consequences of disease describes the physiologic organ impairments that result from specific conditions. More recent work in aging has gone on to describe further steps in the pathway. The impacts of impairments such as poor balance, muscle weakness, and visual deficits on functional limitations and disability have been demonstrated. Furthermore, the relationship between functional limitations, such as reduced gait speed, and subsequent disability also supports the pathway.

### Physical Performance Measures

Objective measures of physical performance have received increasing attention as assessments that can measure functioning in a standardized manner in both research and clinical settings. These measures can be used to represent impairments, functional limitations, or actual disability, but most are indicators of functional limitations. The standardized Short Physical Performance Battery (SPPB) was administered to a large number of participants in the Established Populations for the Epidemiologic Study of the Elderly (EPESE). This battery, which included gait speed, time required to rise from a chair and sit down five times, and hierarchic measures of balance, was used to create a summary score of lower extremity performance that ranged from 0 to 12 (see Guralnik et al., 1995). This measure has been found to predict mortality, the need for nursing home admission, and health care utilization in the overall older population. Furthermore, in a population that had no disability at the time the performance battery was administered, the score was found to be highly predictive of who developed ADL and mobility disability 1 and 4 years later (Figure 5-24). These findings have been replicated in other

**FIGURE 5-24.** Disability status at four years according to baseline summary performance score in persons age 71 and older with no disability at baseline. Reprinted with permission from Guralnik JM, Ferrucci L, et al. Lower extremity function in persons over the age of 70 yrs as a predictor of subsequent disability. *N Engl J Med.* 1995;332:556.

populations and with other, similar performance measures and indicate that there is a state of preclinical disability, expressed as impairments and functional limitations, that indicates a high risk of proceeding to full-blown disability. This finding also provides a way of identifying high-risk older persons for whom preventive interventions may be highly effective.

Objective performance measures also provide a means of comparing functional status over time or across countries or cultures, where disability measures may lose comparability because of environmental differences or differential access to assistive devices.

**FIGURE 5-25.** Percent of men and women with Short Physical Performance Battery score  $\leq 8$  and gait speed  $\leq 0.5$  m/s: England, 2002–2003. Institute for Fiscal Studies. Retirement, health, and relationships of the older population in England. The 2004 English Longitudinal Study of Aging (Wave 2). Tunbridge Well: Petersons, 2006. [http://www.ifs.org.uk/elsa/report\\_wave2.php](http://www.ifs.org.uk/elsa/report_wave2.php) Accessed on February 21, 2007.

Figure 5-25 shows results from the English Longitudinal Study on Aging, a nationally representative sample of older persons in England. It demonstrates the prevalence according to age and sex of poor physical performance, documented as an SPPB score of  $\leq 8$  and gait speed of  $< 0.5$  m/s. Performance below these cut-off points has been demonstrated in longitudinal studies to be strongly associated with multiple adverse outcomes. Poor performance affects only about 10% of persons in their sixties but the prevalence rises rapidly in the seventies and attains very high levels in persons above age 80 years. Women have higher rates of poor performance than men at all ages.

### Trends in Disability

Because disability status is a good way of representing overall health status in older persons with complex patterns of disease, and because disability also has direct implications for the long-term care

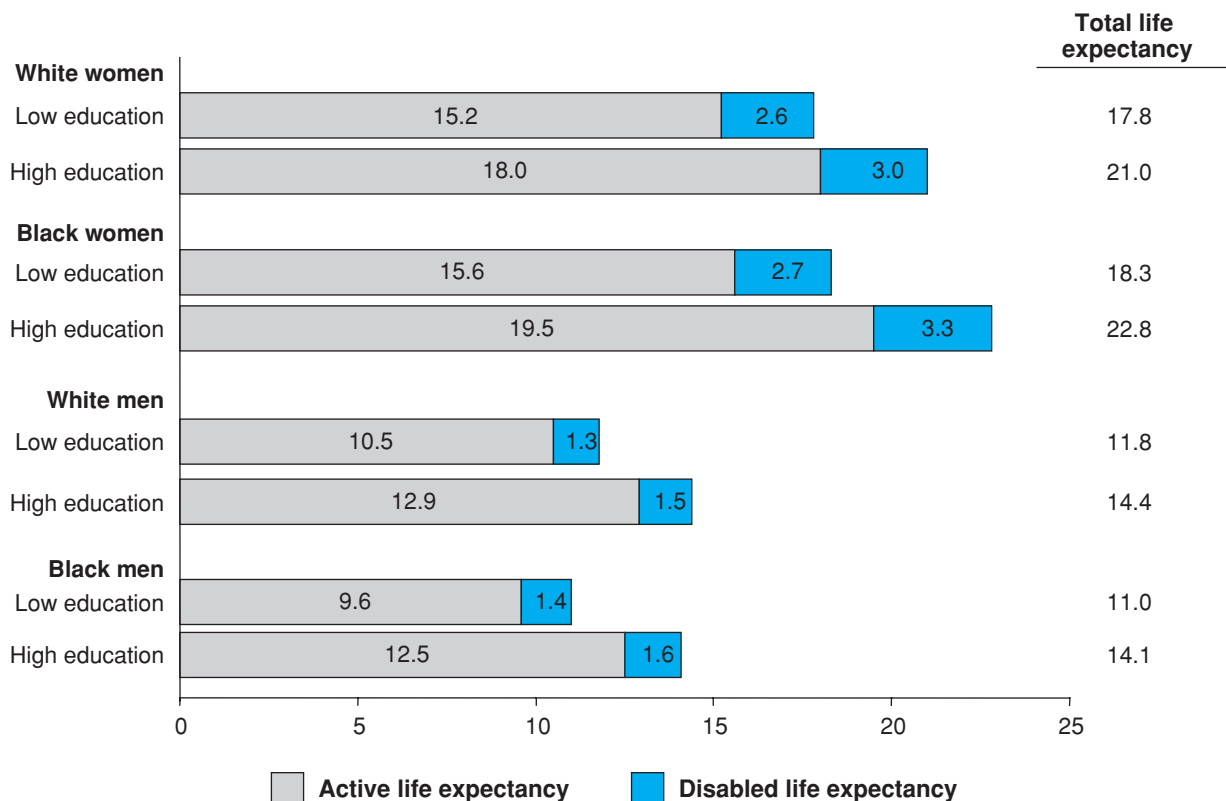

**FIGURE 5-26.** Prevalence of functional limitations, United States, 1984 and 1993. Data from Freedman VA, Martin LG. Understanding trends in functional limitations among older Americans. *Am J Public Health.* 1998; 88:1457.

needs of an older person, there has been much interest in evaluating disability trends over time. Although a number of national surveys now assess disability, uniform disability assessment done over time has been available only since the mid-1980s in just a few studies with nationally representative samples. Although these studies use different assessment instruments, a convincing decline in age- and gender-specific rates of disability was observed from the mid-1980s through the 1990s. The National Long Term Care Survey has similar assessments of ADL and IADL disability available from 1982 through 2005, and recent findings indicate that the decline in disability observed for the first 12 years of the study continued and actually accelerated from 1994 through 2005 (see Manton et al., 2006). In another study that utilized reports of functional limitations, including lifting and carrying 10 lb, climbing stairs, walking 1/4 mile, and seeing words in a newspaper, changes in prevalence were evaluated between 1984 and 1993. Declines were seen in the inability to perform all four of these tasks in the 65 years and older population and as well as the 80 years and older population (Figure 5-26). The functional limitations evaluated in this study, which assess more basic tasks than disability, are an excellent way to follow trends over time because they are influenced less by changing roles that can affect disability assessment (more men cooking in more recent surveys and more women managing money). The observed declines in disability and functional limitations can be attributed to a number of factors. Educational status is strongly associated with disability, and it has been estimated that anywhere from 25% to 75% of the observed functional declines are related to a higher educational level in more recent cohorts. Other factors proposed as

explanations for the decline in disability include reductions in the prevalence of several chronic diseases, changes in nutrition and public health at the time when these cohorts were young, and improved health promotion and medical therapy.

The interplay among time of disability onset, duration of disability, and time of death determines the number of years that older individuals live in the disability-free state, termed active life expectancy, and the number of years spent in the disabled state. Life table approaches have been used to calculate active and disabled life expectancy, utilizing data from population-based longitudinal studies on transitions from the nondisabled state to disability and death and from the disabled state to nondisability and death. Using this approach may provide insight into the mechanisms and risk factors that affect the quality of aging and suggest potential targets for intervention. In Figure 5-27, an example is shown using data from the EPESE study on the impact of race and educational status on total, active, and disabled life expectancy. This demonstrates that low education (less than 12 years) is associated with shorter total life expectancy and shorter active life expectancy in both black and white women and men but that, comparing persons with the same educational status, there are only small differences between blacks and whites. Alternative methods have been developed to estimate active life expectancy that utilize mortality data and prevalence of disability, which is easier to obtain in a national survey than 1-year transition probabilities. As more data become available to estimate both active and disabled life expectancy, we will gain more insight into the prospects for a compression of morbidity, which is the reduction in disabled life expectancy that results from compressing

**FIGURE 5-27.** Total life expectancy, active (nondisabled) life expectancy, and disabled life expectancy at age 65 yrs according to gender, race, and educational status. Lower education defined as less than 12 yrs of school, and higher education as 12 or more years of school. Data from Guralnik JM, Land KC, et al. Educational status and active life expectancy in older blacks and whites. *N Engl J Med.* 1993;329:110.

TABLE 5-10

## Behavioral Risk Factors in Middle-Aged and Older Persons, United States, 2004–2005

	PERCENT OF AGE GROUP			
	35–44 (yr)	45–54 (yr)	55–64 (yr)	65+ (yr)
Alcoholic beverages				
≥ One drink within the past 30 days	60.9	58.3	53.0	39.3
Men >2/day Women >1/day	5.1	4.7	4.2	2.9
5+ at one time	16.1	11.9	7.9	3.0
Cholesterol check				
Past 5 yrs	72.1	82.9	90.2	92.9
Never	21.7	11.6	6.5	4.9
BMI				
Overweight (25.0–29.9)	37.7	39.2	41.7	40.0
Obese (≥30.0)	25.3	27.0	29.3	20.3
Physical activities				
30+ moderate (5×) or 20+ vigor (3×)	49.7	51.5	55.3	61.0
20+ vigorous (3×)	29.9	56.6	21.1	14.1
Past month	78.6	76.9	73.4	65.9
Fruits and vegetables				
5 or more times per day	20.1	22.4	24.8	31.0
Dental visit in last year	72.4	74.4	72.5	66.1
Smoking status				
Everyday	17.7	17.2	14.6	6.6
Some days	5.4	5.0	3.8	2.2
Former	18.7	26.1	36.1	41.6
Never	57.9	49.8	46.1	48.8
Immunization				
Flu in past year	—	—	—	65.5

chronic disease and disability into a smaller number of years between disease and/or disability onset and mortality (see Fries, 1980).

### Aging of Individuals with Life-Long Disabilities

In addition to the large number of persons who will develop disabilities in old age, there is a smaller cohort of persons with lifelong disabilities who will enter old age with these disabilities. Persons with developmental disabilities represent a heterogeneous population with varying abilities, and their disabilities may result from a variety of conditions such as cerebral palsy, mental retardation, learning disorders, autism, and epilepsy. It is estimated that in 2000, there were over 600,000 people in the United States with mental retardation and other developmental disabilities. Their numbers will double to 1.2 million by 2030 when all of the post–World War II “baby boom” generation will be in their sixties. Life expectancy of many persons with mental retardation and developmental disabilities has risen dramatically and many people with these disorders will live into advanced old age. Down’s syndrome is an exception to this, however, with signs of accelerated aging and development of Alzheimer’s disease at early ages. A further consideration related to the growing number of older persons with developmental disabilities is the continuation of their care when their own parents reach old age. Nearly two-thirds of persons with developmental disabilities live with their families and in one-quarter of these households the primary caregiver is 60 years or older. Over the next 30 years, there will be a considerable increase in the number of families where parents more than 80 years old are caring for an older child with a developmental disability.

### BEHAVIORAL RISK FACTORS (see Chapter 28)

An important role for epidemiology is to elucidate risk factors for disease, injury, and disability. Many risk factors have been shown to have a large impact in older persons. Although certain risk factors that are potent predictors of major diseases in middle age may have less or no impact at old age, most behavioral risk factors continue to be important throughout old age (see Chapter 28). Cigarette smoking, for example, continues to predict mortality even in smokers who have survived past age 65 years, and stopping smoking even in old age is associated with better outcomes. The Centers for Disease Control and Prevention perform national surveys on a wide range of behavioral risk factors and include the older population in these assessments. Table 5-10 demonstrates the prevalence of risk factors

and protective factors across four age groups, from 35 to 44 years through 65 years and older. For almost all these health practices, older persons have similar or somewhat better rates than younger individuals.

These results are compatible with findings that adherence to physicians’ recommendations and medication schedules is better in older than in younger persons. Thus, this is a population that faces increasing risk of disease and disability with increasing age but one that cares about its health, has a positive risk factor profile, and is willing to comply with interventions to prevent or improve adverse health outcomes. Applying what has been learned in epidemiologic studies on older populations so that effective prevention and treatment strategies will be available to older persons is a continuing challenge for the field.

## IMPLICATIONS OF GLOBAL POPULATION AGING FOR HEALTH AND HEALTH CARE

### Overview

Population aging is a pervasive, unprecedented global phenomenon. The trend is expected to continue into the twenty-first century. The older population is itself aging; the fastest growing age group is the oldest-old, those aged 80 years or older.

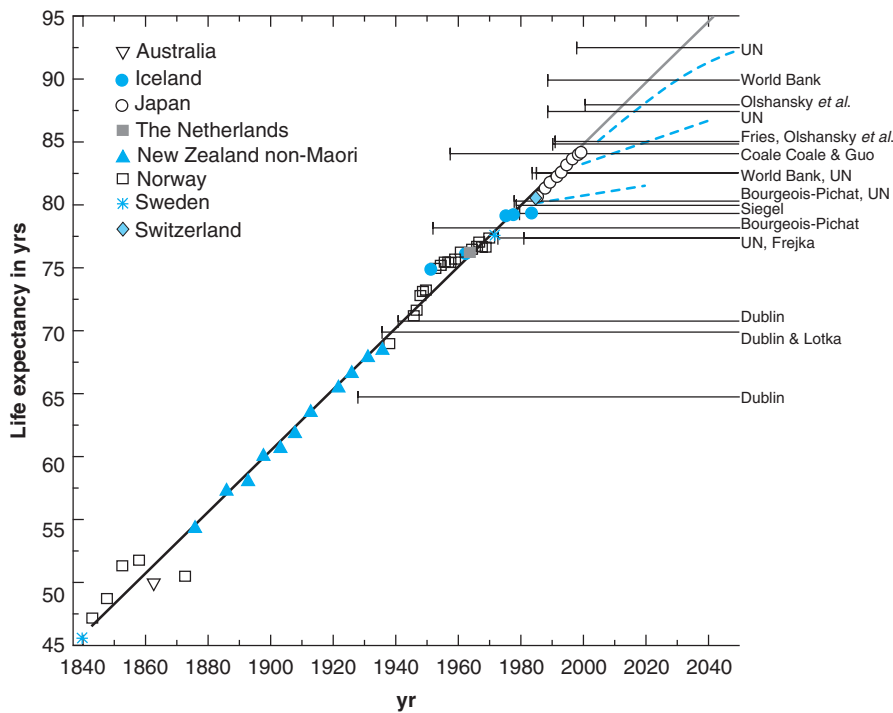

The chapter begins by highlighting the consequences and implications of the global aging of the population. In the economic area, population aging will have an impact on economic growth, savings, investments, and consumption, labor markets, pensions, and taxation. Also, this phenomenon will have a direct bearing on the intergenerational and intragenerational equity and solidarity that are the foundations of our societies. In the social sphere, population aging will affect health and health care, family composition and living arrangements, housing, and migration. Some of the inadequacies of health professional education and health care delivery systems in meeting the chronic health care needs of aging populations around the world are discussed.

The second section of the chapter describes how health care systems around the world are preparing to deal with patients with multiple chronic, degenerative diseases. Information is provided about developed countries in four continents including Canada and United States for North America; Iceland, Norway, United Kingdom, France, and Italy for Europe; Japan for Asia; and Australia for Oceania. The current situation in China is discussed as an example of the preparedness of the more densely populated developing countries and those with the fastest growing economies. For each country, the following information is presented: the principal char-

acteristics of the health care system; the organizational approaches and the services available for older adults; and positive aspects, weaknesses, and specific peculiarities. Each nation's description ends with a description of what would happen in a hypothetical example of an 87-year-old widow hoping to return home after suffering a stroke with motor and speech deficits.

The third section of the chapter illustrates the difficulty in addressing these epidemiological changes without a global, standard way of assessing the needs of older individuals. The chapter describes the development of a minimum data set of information that can be applied, independent of nationality, language, and culture, to any health care setting. Data are presented to suggest that this global assessment is one strategy for capturing the essential aspects, variables, and solutions that make a local or a national health care system work more efficiently by responding to the needs of their older clients. Also, the chapter summarizes the results of the real-world application of such instruments by governmental mandate in the Canadian province of Ontario and in health services research conducted in Europe.

Finally, the chapter discusses the evidence that the unprecedented demographic changes, which had their origins in the nineteenth and twentieth centuries, are continuing well into the twenty-first century. The number of older persons has tripled over the last 50 years but it will more than triple again over the next 50 years. In contrast with the slow process of population aging experienced by the more developed countries, the aging process in most of the less developed countries is taking place in a much shorter period of time, and is occurring on larger population bases. Such rapid growth will require far-reaching economic and social adjustments in most countries. Effective and efficient health care for the chronic health problems facing this growing population of older adults will be a daunting challenge for all countries.

**FIGURE 6-1.** Increase in female life expectancy (in years) observed in selected countries since 1840 (solid lines) and extrapolated to 2040 (dashed lines). The horizontal black lines show asserted ceilings on life expectancy, with a short vertical line indicating the year of publication. (Reprinted with permission from Oeppen J and Vaupel JW. *Science* 2002;296:1029–1031.)

### Demography of the Aging Global Population (see also Chapter 5)

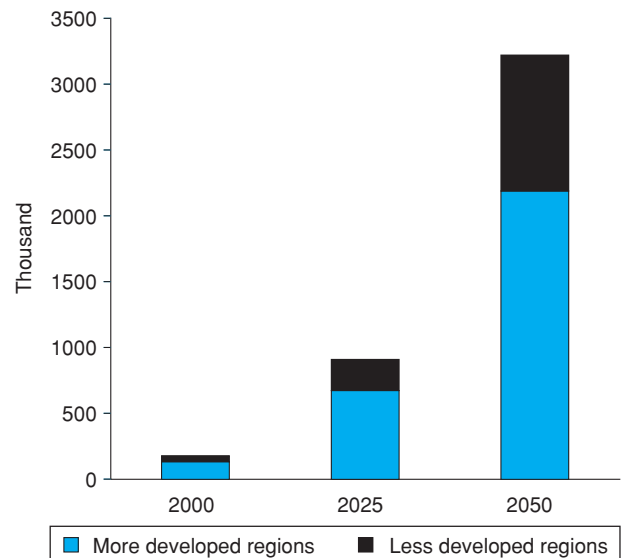

Notwithstanding some heterogeneity, life expectancy is increasing across the globe. In most industrialized countries, this increase in life expectancy has mostly occurred over the last century. However, in the most recent decades, its pace has progressed at an unprecedented speed, reaching estimates far beyond those predicted by most international organizations such as the United Nations. The increase in life expectancy, seen in many countries throughout the world, does not seem to be levelling off (Figure 6-1).

The increase of life expectancy has resulted in increased proportion of individuals reaching the eight and ninth decade of life.

Individuals 80 years+ are consistently found to be the fastest growing segment of the population. Similarly, there is an unprecedented and increasing appearance of centenarians and supercentenarians (Figure 6-2).

The disproportionate life advantage favoring women over men has created a progressive feminization of the older population. Among individuals 85 years+, there are, on average, 55 men for every 100 women.

The increase in life expectancy has been paralleled—especially in the western world—by declining fertility rates. In most countries, the fertility rate is much below the mortality rate and below what is considered the minimum for population replacement and conservation. The concomitance of an increased life expectancy with a

**FIGURE 6-2.** Population aged 80 yrs or older (in millions) in the period 1950 to 2050 (left panel); Distribution of world centenarians by development regions (2000–2050) (right panel). (Reprinted with permission from *World Population Aging 1950–2050*, United Nations.)

**FIGURE 6-3.** Potential support ratio: world, 1950–2050. (Reprinted with permission from *World Population Aging 1950–2050*, United Nations.)

reduced fertility rate has produced profound effects on the labor market, the financial resources, and other societal factors. One example is the potential support ratio, i.e., the number of persons aged 15 to 64 years per one older person aged 65 years and over. Between 1950 and 2000, the potential support ratio fell from 12 to 9 people per each person 65 years or older. By midcentury, the potential support ratio is projected to fall to 4 working-age persons for each person 65 years or older. Potential support ratios have important implications for social security schemes, particularly traditional systems in which current workers pay for the benefits of current retirees (Figure 6-3).

### Effect of Population Aging on Health and Health Care

Epidemiological evidence shows that as age increases, there is a progressive, exponential increase in the occurrence of most chronic, degenerative, and progressive diseases, including cardiovascular disease, cancer, chronic obstructive pulmonary disease, dementia, and other degenerative conditions. Furthermore, there is an increase in the cooccurrence of these diseases, resulting in comorbidity.

Health care systems around the world have been modeled around the ideology of the disease model. Diagnosis and treatment is focused on eliminating or ameliorating the underlying pathology; health outcomes are determined by the disease. Also, functional impairment and quality of life are assumed to be improved by treating the “causative” disease. The disease model has resulted in the creation of health systems centered on acute care hospitals and disease-based specialists. This model has informed the way we have developed and accrued knowledge. For example, evidence-based medicine (EBM) has been promoted as the best approach to improving health and health care. The randomized, controlled trials on which EBM recommendations are based typically provide evidence of modest reductions in the relative risk of the disease-specific outcomes that are associated with the use of various interventions such as medications. Older patients and patients with multiple health conditions and therapies have been excluded from many evidence-generating randomized, controlled trials. Arguments have been made for extrapolating the evidence from such trials to subpopulations of elderly patients, but the generalizability of the results to these patients remains unknown.

Consequently, physicians and health personnel are facing a “new” type of patient who presents with an array of concomitant clinical conditions. These combinations of conditions result in varying degrees of functional deficits, cognitive deterioration, nutritional problems, and geriatric syndromes (delirium, falls, incontinence), often in the face of inadequate social support and financial resources.

This “new” complex, older patient presents a degree of complexity not previously considered by the traditional understanding of medicine and its role. The traditionally envisioned health care system, whether operating under universal coverage or private mechanisms, is challenged by this complex patient.

The response to the challenge of the complex older patient has been heterogeneous around over the world; differences in resource availability and economical and cultural issues have resulted in different organizations of health care systems. In addition, the methodological approaches adopted by systems to evaluate the needs of such complex patients have been highly variable and not standardized. In particular, the organization of services to care for geriatric patients, including geriatric assessment and management, remains highly variable. This variation is seen among nurses, physicians, therapists, nursing homes, home care services, and health systems.

To display this intercountry variability, each country’s section will end with the description of likely sequences of events in a clinical case scenario. The clinical scenario is an 87-year-old widow who was independent in activities of daily living, cognitively intact, and living in her own house albeit with few social supports prior to suffering a stroke with resultant motor, speech, and swallowing deficits. Despite these deficits and lack of supports, she strongly wishes to return home. The types of treatments and services offered to her in each country will be presented.

### INTERNATIONAL COMPARISONS

In order to illustrate the way countries in the most developed world have prepared to cope with population aging we have selected nine countries in four continents with large percentages of persons older than age 65, including Canada and the United States for North America, Iceland, Norway, United Kingdom, France, and Italy for Europe, Japan for Asia, and Australia for Oceania (Figure 6-4).

These countries have among the highest life expectancy at birth, well over 80 years for all but the United States and United Kingdom. The percentage of the population in that is aged 65 years and older ranges from 11% in Iceland to approximately 20% in Italy and Japan (Table 6-1). In the next 50 years, the percentage of older adults will

**FIGURE 6-4.** Percentage of population 65 yrs and older in nine Organization for Economic Cooperation and Development (OECD) countries compared with the mean OECD in the year 2005. (Adapted from *OECD Factbook 2007: Economic, Environmental and Social Statistics*.)

- Proportion 65+—7.7%
- Health expenditures—5.6% of GDP

almost double in each country, estimated to reach over a third of the population in Italy and Japan (Table 6-2).

More alarming, the dependency ratio (ratio of inactive population aged 65 years and older to the labor force) is projected to be close to 50% in France, Italy, and Japan by 2020. This means that, for every older adult, there will be only two persons in the labor force. Iceland will be characterized by the lowest dependency ratio. Regardless, all countries will experience a further increase in the dependency ratio over the period 2020 to 2050. By that time in Italy, for every retired older adult, there will only one person in the labor force (Figure 6-5).

In most nine Organization for Economic Cooperation and Development (OECD) countries, expenditures on health are a large and growing share of both public and private expenditures (see

Table 6-1). The level of health spending varies widely across countries, reflecting different market and social factors as well as the different financing and organizational structures of the health system in each country. In terms of total health spending per capita, the United States is well ahead of the next highest spending countries, including Norway, and well over double the unweighted average of all OECD countries (Figure 6-6).

Since 1990, health spending has grown faster than gross domestic product in every OECD country except Finland, although this growth has not been constant. In most OECD countries, the bulk of health care costs are financed through taxes, with 73% of health spending, on average, being publicly funded in 2004.

The strategy and the organizational approach to deal with complex patients with multiple chronic conditions differ substantially across countries. In part, these differences are historical, cultural, demographic, and financial, and societal. For each country, we present key characteristics of the health care system, and organizational approaches and services available for older adults.

## America: United States

### Type of Health Care System

At the time this chapter is being written, the United States does not have universal health care. In the year 2007, as many as 50 000 000 Americans are uninsured. Nonetheless almost the entire older population is covered for some health care services under a federal insurance program known as Medicare (see Chapter 15).

### Overall Organization and Services Available for Older Adults (see Chapter 15)

To be eligible to receive benefits, either the individual or the person's spouse must have worked for 10 years or more in a Medicare-covered capacity and be at least 65 years of age and a citizen or a legal resident of the country. Under most circumstances, enrolment in the program is automatic at age 65 years. Medicare Part A pays for most acute hospital level care services and many postacute care inpatient services for a limited period of time as well as some skilled home care and hospice services. For individuals who meet economic criteria, non skilled home care services are provided by the states, using either Medicaid or state funds; their availability differs dramatically across the states.

Unlike Part A, the older person must request and pay for Medicare Part B insurance. This is the major payer for most physician services as well as ambulatory care. In 2007, it cost the individual about \$100 per month, the exact amount being determined by the age at which the individual signs up for the plan.

Medicare Part D is an elective insurance plan that pays for pharmaceuticals. The individual desiring this insurance program usually must choose from among a large number of plans offered by different insurance companies, each of which may cost a different amount and have a somewhat different formulary.

Long-term care is not covered under Medicare. Multiple plans are offered by the insurance industry, each of which may differ with respect to the cost, waiting period for eligibility, and duration of coverage. Medicaid provides for long-term institutional care and many other health care services for the indigent population. However, the eligibility requirements and the exact services available vary from

TABLE 6-2

Australia	12.4	13.1	14.3	18.3	22.2	24.5	25.7

OECD, Organization for Economic Cooperation and Development.

state to state as Medicaid is a joint federal and state program of insurance.

The number of residential nursing home beds varies by state from a low of 21 beds per 1000 people older than 65 years to a high of 80 beds. The median is 49 beds. There are now more long-term care beds than there are acute care beds in the country. The percent of people aged 65 years and older with long-term care needs who do and do not reside in institutions and the proportion of the older Americans who reside in institutions are displayed in Figure 6-7.

An entirely separate health care system is provided by the Veterans Administration for military veterans who have limited assets. It has its own hospitals and ambulatory settings and employs its own physicians. Many of these facilities are attached to a varying degree to academic institutions.

There have been some important developments in the availability of physician services for older adults in the last 20 years. In 1988, geriatric medicine was recognized as an area of “Added Competence”

by both the American Board of Internal Medicine and the American Board of Family Medicine. Training programs in geriatric medicine for graduates of these two primary boards were designed and approved by the national accrediting body, the Accrediting Council for Graduate Medical Education. Similarly, geriatric psychiatry programs were established. In 2006, the American Board of Internal Medicine “upgraded” the field by making geriatric medicine a full specialty equivalent to, for example, cardiology and gastroenterology.

Nonetheless in the United States, geriatric medicine has recruited few physicians to its ranks with perhaps as few as 200 physicians entering the specialty annually. Likely, in no small part, this is a consequence of the marked difference in reimbursement for different types of services. For example, a comprehensive assessment of an older person is reimbursed at a far lesser amount than most any procedure that lasts a half an hour or more.

In the United States, most medical students have a limited geriatric experience, perhaps in part because of the inability of medical

FIGURE 6-5. Ratio (percentage) of the retired population aged 65 yrs and older to the labor force, 2000–2050. (Adapted from OECD Factbook 2007: Economic, Environmental and Social Statistics.)

**FIGURE 6-6.** Public and private expenditure on health (U.S. dollars per capita, 2004 or latest available year.) (Adapted from OECD Factbook 2007: Economic, Environmental and Social Statistics.)

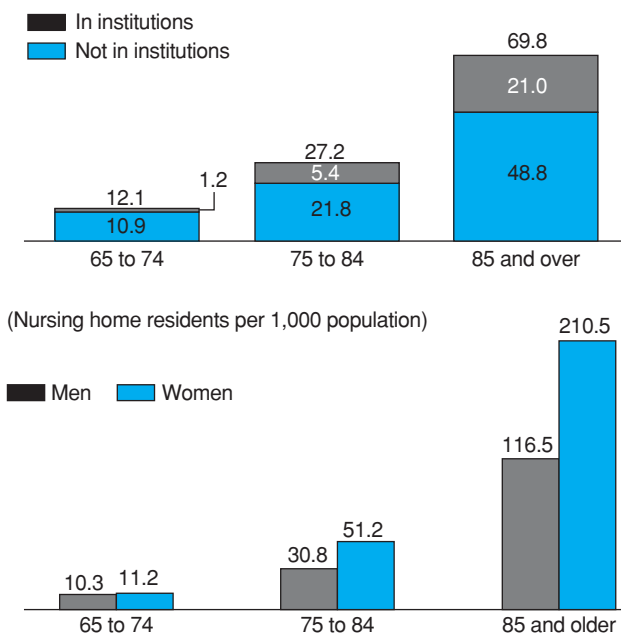

schools to be able to recruit sufficient numbers of faculty. In addition, elders usually have a multiplicity of chronic conditions whereas the traditional emphasis in the medical curriculum has been on acute medical issues in a hospital setting, and more recently but still to a lesser extent, on ambulatory medicine. Most medical students have little or no exposure to such concepts as functional status or to such sites of care as the home or the nursing home. Modest efforts are underway to encourage specialists who care for large numbers of elders, such as gynaecologists and urologists, to have exposure to geriatrics.

The perception remains that the care of elders is not viewed as glamorously by either the public or the health profession as most other medical specialties. As elders tend to have multiple chronic conditions, multiple consultations may be viewed as necessary with the geriatrician serving in a lesser role, merely orchestrating the visits to specialists.

**Peculiarities**

The extraordinary cost of the health care system in the United States, as compared to other developed nations, has become increasingly visible to American industry, which traditionally has funded the health care insurance programs for its workers, to the American people, and to the politicians. Yet large numbers of citizens remain uninsured; the aging population is likely to need more care, increasing the per capita costs in the years ahead (Figure 6-8).

As a consequence of escalating costs, the health care system in the United States is changing. For example, under a pay-for-performance program, the Center for Medicare and Medicaid Services (CMS), the federal agency that oversees Medicare and Medicaid, has begun to offer financial incentives to improve the quality of medical care. This agency began by focusing attention on conditions such as an acute myocardial infarction and pneumonia in the hospital setting. There is some, albeit limited, evidence that such a program will improve the care of the older person requiring hospitalization for an acute illness. Symptoms and geriatric syndromes, rather than discrete diseases, however, are often the most concerning health problems for older adults in many settings (Figure 6-9). Pay-for-performance programs have just begun addressing geriatric syndromes such as falls and urinary incontinence. Functional deficits have not yet been a focus of pay-for-performance efforts. Only recently has there been an interest in beginning to consider quality in other settings, such as ambulatory care and postacute, nursing home care. CMS has at its disposal a wide variety of quality indicators that could be applied to persons in postacute and nursing home settings. Yet, long-term care and home care remain the stepchildren within the health care

**FIGURE 6-7.** Percent of people aged 65 yrs and older with long-term care needs by age and place of residence: 1995 (upper panel); Nursing home residents among people aged 65 yrs and older by age and sex (lower panel). (Reprinted with permission from US Census Bureau, Current Population Reports: 65+ in the United States.)

**FIGURE 6-8.** Cumulative percent change in health care per capita costs due to aging in the United States: 2000–2050. (Martini EM, et al. *Health Services Res.* 2007;42:201–218.)

system. Because Medicare does not pay for long-term care needs, it is not clear how this might change.

### Difficulties and Solutions for a Typical Geriatric Patient

What type of treatment and services would likely be offered to an 87-year-old widow who was independent in activities of daily living (ADL) functioning, cognitively intact, and living in her own house but with few social supports who suffers a stroke with motor deficits and speech and swallowing troubles?

An 87-year-old widow who was living at home independently and presented to an Emergency Department with signs of an acute stroke would be evaluated immediately.

If seen within three hours of the onset of the symptoms she would undergo a computed tomography scan of her brain and likely a magnetic resonance imaging scan to determine if the stroke was due to a thrombosis or a bleed. If there was a thrombosis and if the elder did not have a contraindication, she might be treated with a drug intravenously with an eye to dissolving the thrombosis although few people get to the Emergency Department in time and few older persons are offered this treatment. She would have appropriate studies to rule out marked carotid artery stenosis as well as a myocardial infarction and a cardiac arrhythmia.

If no immediate intervention was indicated, she would be managed at an acute level of care for about 3 or 4 days. If she had a hemiplegia, she would be evaluated by a physical therapist, and possibly, an occupational therapist. She might also be evaluated for speech deficits and aphasia and likely would undergo a swallowing evaluation.

Most such individuals would then be transferred to an acute rehabilitation facility or perhaps to a subacute level of care for rehabilitation. If the individual was transferred to a subacute facility, she would first have had to spend three days (i.e., midnights) at an acute level of care before Medicare would pay for the service. If she were transferred directly to rehabilitation facility, this duration of acute care would not be necessary.

If the woman wished to return home and had no informal support, it would be necessary to determine her functional status. If it was felt that she could manage at home independently, then some home care services, such as nursing and physical therapy, and perhaps a home health aide, would be available for a limited period of time. However no long-term support services, such as assistance with bathing, shopping, or house cleaning, would be available unless the individual paid for them herself or was indigent and eligible for Medicaid. There are charitable organizations in some locations, but not all, that might offer to provide a very limited degree of support. But in all likelihood, these could not be counted on when arranging for discharge from a facility.

If she could not manage reasonably independently at home, it would be necessary for her to go to a long-stay nursing facility or, if she had a significant measure of functional ability, to an assisted living facility. Both would be quite expensive and only the former would be paid for by Medicaid if she had insufficient assets of her own.

### America: Canada

#### Type of Health Care System

Health care in Canada is a joint federal–provincial responsibility. It is delivered and managed at the provincial–territorial level, with the majority of funding provided by provinces. The federal government transfers funds to the provinces and territories to pay for a portion of

**FIGURE 6-9.** Persons in Home care and Nursing home care are compared on four types of symptoms. Data were collected with InterRAI-LTCF and InterRAI-HC instruments, which have these common identical assessment items.

public expenditures in health care, and sets national standards that govern the delivery of hospital and physician services. The federal government is also responsible for health protection related to product safety and pharmaceuticals, and it provides funding for research and health promotion at the national level.

Hospital and physician services have been publicly funded under a “single-payer” system in Canada since the 1957 Hospital Insurance and Diagnostic Services Act and the 1966 Medical Care Act established a shared approach to payment between the two layers of government. The Canada Health Act (CHA) of 1984 represented a major development in defining health care in Canada, by establishing five principles that would govern the delivery of services:

1. Public administration—provincial health care insurance must be operated and administered publicly on a not-for-profit basis.
2. Universality—all citizens must be covered equally with the same benefits and entitlements, irrespective of ability to pay.
3. Accessibility—no financial or other barriers (e.g., user fees) are permitted to ensure equity of access among citizens.
4. Portability—provides funding for Canadians visiting or moving to other parts of the country or travelling outside of Canada.
5. Comprehensiveness—ensures full coverage for “medically necessary services” provided by physicians or in hospitals (including dental surgery).

Following a protracted debate between federal and provincial governments, the Romanow Commission on the Future of Health Care in Canada was assembled to address issues such as the share of federal contributions to health expenditures and the scope of the Canada Health Act. The commission made numerous recommendations, but two that had the potential for a direct impact on the older persons were (1) expansion of the Canada Health Act to include home care and (2) addition of “accountability” to the Canada Health Act as a new principle governing health care in Canada. Ultimately, both recommendations were only partially implemented. Although almost every province provides substantial public funding for home care, there was tremendous resistance to its inclusion under the Canada Health Act. Following a meeting of the Prime Minister and provincial premiers, an agreement was reached that additional federal funds would flow to the provinces to expand existing home care services in targeted areas (mental health, postacute care, rehabilitation, and palliative care) without bringing it under the Canada Health Act. The Canadian Health Quality Council was established as a vehicle to improving accountability in health care, but it has not achieved full participation by all provinces and the Canada Health Act was not modified to include “accountability” as a new principle. Many provinces have launched their own accountability initiatives over the last 5 years, but there is no national consensus on what should be done to ensure quality, appropriateness, and cost-effectiveness of health care.

Another major development in the Canadian health care system has been the move toward regional management of health services. Provincial governments have played a diminishing role in the actual delivery of health care, with most organizational decision-making and resource allocation made at the local levels. The role of provincial ministries of health has changed to a stewardship function instead of direct management and oversight. While this model may mean that health care is delivered and managed in a way that is tailored to needs at the local level, it is increasingly difficult to speak of a “Canadian”

health care system. While the Canada Health Act does provide some national standards for certain services and there are many commonalities in models of care, the specific services available and the terms under which they are provided vary substantially between about 50 health authorities managing services in 10 provinces and three territories.

### Overall Organization and Services Available for Older Adults

As noted above, there is no singular model of Canadian health care. Rather, health policy and service delivery in Canada are best understood as multiple variants on a set of common, high-level principles. With that caveat in mind, it can be said that health care for older adults in Canada involves several common services and care settings—home care, nursing homes, and hospitals are the constants across provinces, but the precise function of these services, payment systems, and eligibility criteria vary from province to province.

There is no exact estimate of the size of the home care population in Canada, in part because there are widely divergent definitions of home care. If one considers services such as nursing, personal support, home health aides, and rehabilitation, it would be reasonable to estimate that between 11% and 15% of older adults receive home care services. However, this value will generally be much higher if one expands the definition to include services such as transportation, meals on wheels, and other community supports offered by social service agencies.

A distinctive feature of home care in many provinces is the use of the case management approach to assessing needs, allocating resources, and managing community based services for frail older adults. For example, in Ontario, Community Care Access Centres (CCACs) use case managers to complete an assessment of long-stay home care clients (using the Resident Assessment Instrument for Home Care, the RAI-HC). Case managers use the assessment information to prioritize clients for access to community- and facility-based services and to establish a care plan based on the clinical findings of the assessment. They then contract with home care companies (both for-profit and not-for-profit) to provide the services needed by the client. Typical services include nursing for wound care and intravenous management, personal support for bathing and home-making, and physical or occupational therapy; social work, speech language pathology, nutrition, and mental health services are only provided infrequently. A common concern in Ontario, however, is that caps on home care expenditures may limit the capacity of case managers to allocate services that would fully address clients’ needs. In contrast, preliminary evidence from the Province of Manitoba suggests that if case managers have more resources for home care and they are better able to calibrate them to client needs, then a lower rate of nursing home admissions results.

Definitional problems also plague any estimates of nursing home utilization in Canada. Different provinces refer to nursing homes with different names. There is also substantial variation across Canada in how nursing home stays are paid. Several provinces employ a copayment system where the resident pays a share of the costs of the stay, while other provinces require the person to pay for all costs of nursing home care until they have spent down their income and assets.

An important change underway in Canada is the introduction of assisted living as a lower cost alternative to nursing home care for a population with lighter care needs. However, in some provinces, the

movement toward assisted living appears to be driven by an interest in replacing regulated nursing home care with unregulated care.

As in other countries, acute hospitals in some Canadian provinces have employed a DRG-like system to manage hospital resources. Over the last two decades, this has resulted in dramatic reductions in average length of stay. However, in some provinces, a major concern has arisen with respect to alternative level of care (ALC) patients—those who no longer have acute care needs and are now in the hospital awaiting placement in a less intensive care setting. Frail older adults make up the vast majority of ALC; the size of this population has grown with the ongoing pressures to reduce hospital length of stay and the limited availability of long-term care beds or supportive housing options. This is further complicated by current case-mix systems for nursing homes that are not responsive to clinical complexity, resulting in a financial disincentive for these homes to accept heavy care residents.

Mental health services for older adults are provided in a variety of ways. In the community, home care services often exclude persons with severe mental illness. Instead, these individuals receive support from community mental health agencies that may or may not work in concert with home care. In addition, community mental health agencies often provide consultation services to nursing homes to assist them in meeting the needs of residents with complex psychiatric issues or high levels of behavior disturbance. However, it is not uncommon for nursing homes to discharge residents with frequent and severe behavior disturbance to inpatient geriatric psychiatry units because they do not have the expertise or resources to cope with these residents. Hence, there is a growing awareness in Canada of the need to find more cost-effective methods to respond to the mental health needs of nursing home residents.

### Peculiarities

About 80% of the population lives in urban settings, mainly in the southern regions of the country near the U.S. border. However, the rest of the population lives in rural settings, sometimes covering vast geographic areas that make it difficult to offer home care programs or nearby primary care services. About one-third (12.2 million) of the population of Canada lives in the province of Ontario. Toronto (the capital city of the province) has 2.5 million residents living in a 630 km<sup>2</sup> area with a population density of 3972 persons/km<sup>2</sup>. In contrast, the 10 000 residents of Yukon Territory who live outside its capital city (Whitehorse) in the northwest region of Canada are dispersed over a 474 000 km<sup>2</sup> area with a density of 0.1 persons per km<sup>2</sup>.

A further consideration is that many residents of remote regions of the country are aboriginal peoples with unique cultural needs and health concerns. Persons with an aboriginal identity comprise 0.5% of the population of the city of Toronto and 1.7% of the Ontario population; however, they represent 15.9% and 36.8% of the population of Whitehorse and rural Yukon, respectively. Health care for aboriginal people on reserves is the responsibility of federal government, and off-reserve care is typically provided for by the provincial government. For most health indicators, persons of aboriginal origin are at disadvantage compared with general population. Although life expectancy has been improving, the gap between aboriginal and nonaboriginal people is 7.4 and 5.2 years for males and females, respectively. Morbidity rates are also notably higher in the aboriginal population for conditions like diabetes, heart disease, and tuberculosis.

### Difficulties/Solutions for a Typical Geriatric Patient

What type of treatment and services would likely be offered to an 87-year-old widow who was independent in ADL functioning, cognitively intact, and living in her own house but with few social supports who suffers a stroke with motor deficits and speech and swallowing troubles?

An 87-year-old widow with an acute stroke and few comorbidities would typically receive care in a general medical ward of acute hospital ward. According to a 1999 study, only 4% of Ontario acute hospitals have a dedicated stroke unit. Rehabilitation in the post-acute phase may be provided in a rehabilitation hospital or unit, or in a complex continuing care hospital (Ontario only). Depending on the patient's functional ability, medical condition, and access to informal support (in this case probably children), she may be transferred home with home care. Rehabilitation may be provided by the home care program or by community-based clinics. The home care program will also offer personal care, homemaking services, and nursing, if needed. If the patient's medical needs exceed the ability of family members to provide adequate support, then she may be placed in a long-term care home or an assisted living setting depending on the severity of impairment.

### Europe: Iceland

#### Type of Health Care System

Iceland's health care system is nationalized, though there are private sector providers. On the purchaser side of the system, two structures fund services: (1) the National Institute of Social Security, which is financed through the central government's budget and through employers' and employees' contributions and (2) the central government's annual appropriation, financed through general taxation, which directly allocates financial resources to hospitals and primary care services. The rich and the less well-off use the same system, contributing copayments of 25% to 30% of the cost (with a limit on maximum expenditure). However, the copayments of older adults amount only to one-third of what actively working citizens pay; no copayments are required for hospitalization or rehabilitation or home nursing care for older adults.

Care of older adults has two components: health care and social services. Health care is organized regionally, through primary health care centers, and is paid for by the state, funded through the central government's budget. Social services are also organized regionally (albeit differently than health care) and are paid for by county councils, which are funded by local governments. Social services include assistance with home care and daycare. Geriatric hospital care, which has developed rapidly during the last 20 years, is financed by the state.

Nursing home placement costs the older person up to US\$2000 per month (if their pensions are generous enough) and Iceland's national health insurance both pays the balance of about US\$5000 per month (2006) and covers whatever portion of the cost is not covered by a resident's pension. Older adults do not have to spend down assets other than their pension fund to pay for their care.

The aim of the health care system is that every citizen should have one primary care provider, located at a primary health care center. However, the primary care providers do not have a gate-keeping function and all citizens can access ambulatory care specialists of their

choice, although with slightly higher copayment than if a person was to seek primary care services. Hospital care has become increasingly specialized with the merging of hospitals, particularly in the Reykjavík area. Similarly, geriatric hospital care has been strengthened with consolidation of services at the University Hospital in Reykjavík. There are now 16 geriatricians and seven junior physician positions covering a population of 180 000. The geriatricians have all been trained abroad, in the United States, United Kingdom, and Sweden. The junior positions are both part of an internship year and residencies in internal and family medicine. The Department of Geriatrics is sectioned into acute geriatrics, consultation service, falls clinic, rehabilitation and respite care (four units), memory clinic and dementia units, palliative care unit, day hospital, and general outpatient unit. Geriatricians participate in nursing home care delivery along with family practitioners.

### Overall Organization and Services Available for the Elderly

Until 25 years ago, the development of elderly care in Iceland was haphazard. In 1982, Iceland passed laws dealing specifically with issues relating to older adults, which were revised in 1989 and again in 1999. The law's underlying principle is that the autonomy of older adults shall be respected. Elderly persons have a legal entitlement to required services and the state must meet their needs in a way that is relevant and economically feasible. Elderly persons must be supported in their homes for as long as possible and have access to a nursing home when the need arises. A dedicated tax of about US\$40 per person per year facilitates the development of care for older adults.

The laws mandated that a Nursing Home Preadmission Assessment (NHPA) be performed on anyone applying for nursing home placement to confirm and grade the need for long-term care. A multidisciplinary team performs the NHPA; the team consists of a physician, a nurse, a social worker, a representative of the municipality, and a representative of the Association of Elderly Citizens (this last team member participates only in planning decisions, not in the clinical assessment). The assessment is standard in form and content. It remains valid for up to 18 months, though it is supposed to be revised if the applicant's condition or situation changes during this time. The NHPA system generates national and regional waiting lists for the 3700 beds currently available. Although "home-made," this system opened the eyes of policymakers to the value of objective assessment and data gathering, and the NHPA had definite consequences on the further development of nursing home care in Iceland.

The content and quality of nursing home care were almost completely unknown in the early 1990s. Costs were considerable and the financing of nursing home care was variable. This began to change with implementation of the International Resident Assessment Instrument (InterRAI) system for nursing home care. Now all nursing home care is being financed based on case-mix or resource utilization groups derived from the assessment data. Other spin-off effects, which are being developed, include the monitoring of quality of care and the generation of clinical guidelines for identified problematic areas, working from a database accumulated through use of the standardized assessment instrument.

Nationwide, 13% of Iceland's elderly reside in nursing homes, although the figure is lower (9.7%) in Reykjavik. The average length of stay is slightly more than 3.5 years. About half of all nursing home

residents in Iceland have dementia, but that figure rises to 80% in skilled nursing homes.

Other aspects of elderly care, however, remain as incompletely understood as nursing home care was. Health care policy allows older persons to stay at home as long as possible and supports them in doing so, but the needs of those in home care are not well-defined. There had long been interest in studying other forms of elderly care when such opportunities would arise, and so in 1997, when the InterRAI instrument for home care became available, such a study was performed. Collecting data at four community health centers in Reykjavik quickly raised questions about the quality of home care services. For example, older persons living in their own homes seem to have more untreated physical symptoms than similar residents of nursing homes. This may be due to the fact that there is less teamwork in the home care setting. The typical home care recipient may go for long periods of time without seeing a physician. That so many elderly persons are lonely and never get out of doors leads to question the wisdom of the policy of having people stay at home as long as possible. Regardless, the home care system should attend more carefully to issues of loneliness, depression, and mobility out of doors, perhaps by organizing elderly volunteers who could support their less-healthy peers and bring in the family practitioner in closer cooperation with home nurses. Home visits by family practitioners are all but extinct, except in emergencies, when it is just the on-call family practitioner who attends to the person and the primary care provider of that person is rarely involved.

Progress is also being made toward the eventual implementation of the other instruments in the InterRAI family. Thus in the year 2007, the InterRAI instruments for home care, mental health, and postacute care are being implemented. An acute care instrument is under study and thus Iceland may realize a seamless systematic and coordinated system of information on elderly care that brings information from one setting to the next electronically.

### Peculiarities

Iceland's response to the need for elder care has been both empirical and somewhat chaotic. The philosophy of elder care is in many ways clear, but the system lacks comprehensive administration and is therefore fragmented (as is the health care system in general). The system's major drawbacks include:

1. Health care and social services within communities are not coordinated, in part because they are funded by different sources.
2. Nursing homes have autonomy regarding the admission of new residents and are not officially obliged either to accept first those persons on the waiting list who are in greatest need or those persons in hospitals who are waiting for nursing home beds. In areas where the need for nursing home beds exceeds the supply, some nursing homes admit applicants still living in the community before those persons in greater need who are waiting in hospitals.
3. Because of limited availability, primary health and home care services are insufficient to care adequately for elderly people living at home. This factor, combined with nursing homes' selection process, leads to the "bed blocking" of elderly persons in hospitals—an inefficient use of resources.
4. The quality of care received by Iceland's elderly persons is largely unknown.

### Difficulties/Solutions for a Typical Geriatric Patient

What type of treatment and services would likely be offered to an 87-year-old widow who was independent in ADL functioning, cognitively intact, and living in her own house but with few social supports who suffers a stroke with motor deficits and speech and swallowing troubles?

An 87-year-old woman with acute stroke would most likely be admitted first to an inpatient neurology service, particularly if she is without cognitive problems and with limited comorbidities. If she had preexisting cognitive problems or several comorbid conditions, she would more likely be admitted to acute geriatrics.

If the woman was admitted to neurology, she would be transferred in a few days to either rehabilitation or postacute geriatric care. Occupational therapists could help reconfigure her apartment, if that would make it possible for her to return home. Physical therapists could go to her home to provide maintenance therapy; respite care could be organized. She could get meals-on-wheels, help with cleaning of the house, and home nursing care up to two times a day. Each professional would still make only very short visits. It is conceivable that she could go to a daycare center a few times of the week. The issue would be how she would feel being mostly alone. She would in any case get rehabilitation commensurate with her potential for recovery. With great determination, this person could possibly go home, but the situation would be precarious and with even minor additional insults or problems, it is likely that she would be admitted again to the hospital, where she might block a bed for months while awaiting nursing home placement. That would also be the case if she was not motivated to go home, in spite of her being cognitively intact.

## Europe: Norway

### Type of Health Care System

Norway has a national health service with universal coverage for medical care in hospitals, medications for chronic diseases, and also coverage for consultations with general practitioners (GPs), outpatient services, and physiotherapy when the yearly costs for the patients are over a certain limit (approximately €200). Home care services are partly covered by the municipalities, but patients have to pay a minimal fee. In some municipalities, the caring services are given by private organizations as a supplement to public care services. Long-term care in nursing home is covered for the first 3 months. For longer stays, the patient has to pay 85% of their income.

### Overall Organization and Services Available for Older Persons

Generally, the health and caring services for elderly persons are viewed as satisfactory although services generally lack resources. The present government has declared the care of elderly persons a national priority.

**Hospital Services** In a National Survey in medical departments (1998), 35% of the patients were 75+ years and 11% had geriatric syndromes such as falls, cognitive impairment, and incontinence. Later figures show that 40% to 45% of patients in medical departments are 75+ years old.

Geriatric medicine is a subspecialty of internal medicine and most of the 70 practicing geriatricians are working in hospitals. The Universities in Oslo, Bergen, Trondheim, and Tromsø have faculties of medicine, and all of them have geriatric medicine on their curriculum and university hospitals with geriatric departments. Most general hospitals have geriatric specialist services organized as geriatric departments in the larger hospitals (more than 4 to 500 beds) and geriatric sections in medical departments in middle sized hospitals (<200 beds). Some smaller hospitals have a geriatrician and geriatric outpatient services, but usually no dedicated beds for geriatric patients. Geriatric outpatient clinics in the hospitals are responsible for assessment of cognitive impairment and dementia, falls, urinary incontinence, and functional impairment. They have an interdisciplinary approach with specially trained nurses, physiotherapists, and occupational therapists.

Elderly units have been the preferred way to organize acute hospital care for the elderly. All stroke patients, independent of age, are recommended to be treated in acute stroke units, where internists or neurologists, and rarely geriatricians, are usually responsible. Despite these recommendations, there are still several hospitals where the acute geriatric patients are treated without geriatric expertise. In some places, the patients are transferred to a geriatric unit for rehabilitation after acute care, but many geriatric patients in the hospitals do not get access to geriatric specialist services at all.

**Community Services** Community care is the cornerstone in the care for elderly persons. All inhabitants have their own GP, responsible for the continuation and coordination of medical care.

Overall, 20% of elderly persons are receiving home care services, 5% are living in sheltered housing with care services, and 6% are living in nursing homes. Among persons 80+ years old, 10% are living in sheltered homes, and 14% in nursing homes. The municipalities also provide daycare centers for persons with dementia and physiotherapists and occupational therapists for assessment and rehabilitation.

Home-nursing and home-help services meet nursing needs and need for assistance in ADL and instrumental activities of daily living (IADL) and are received by more than half of persons 80+ years old. As in many other countries, the demands for services are higher than the supply. To allocate services to best meet the needs, many municipalities are using an “order and supply” model. Applications for home-care services (by letter, telephone, or personal contact) can be given from patients, proxies, and GPs to a public office in the municipality. The decision is detailed to type and objective of service and for how much time, and should give the patient a guarantee. The model is criticized for not being flexible and adaptable to the highly variable needs of frail elderly person.

During the last 20 years, retirement homes have been closed and sheltered housing with care services have been developed. They are suitable for elderly persons without major medical problems or great need for nursing care.

In some cities, it is possible to choose between public services and private agencies with the same coverage of the costs. Families with the necessary economic resources tend to organize private services as a supplement to the public services. Some nursing homes are run by private organizations, but with public financing.

Nursing homes are also part of community care. GPs or nursing home physicians are responsible for the medical services, rarely geriatricians. A survey of medical care in nursing homes in 2004 showed

that doctors' hours per patient were low and the quality often insufficient. Nursing homes have three main functions; long-term care, respite care, and rehabilitation. Some nursing homes have special units for dementia care. The average age of the patients is 83 years and 70% to 80% suffer from dementia.

### Peculiarities

Norway has the highest incidence of hip fractures worldwide. To organize a better care for these numerous patients, orthogeriatric units with comprehensive geriatric assessment and an interdisciplinary approach have been organized in some hospitals. The evidence of benefit from organizing such units is still sparse, but the practical experience is good.

### Difficulties/Solutions for a Typical Geriatric Patient

What type of treatment and services would likely be offered to an 87-year-old widow who was independent in ADL functioning, cognitively intact, and living in her own house but with few social supports who suffers a stroke with motor deficits and speech and swallowing troubles?

An 87-year-old patient with a stroke should be treated in an acute stroke unit. If this happens, she will receive excellent care. However, often the stroke unit is full in which case she will be admitted to another medical ward where interdisciplinary care is lacking. At discharge, if she still has residual hemiparesis, she will get home care services and home rehabilitation. A nurse will come three times a day to give help with personal care and medication. During the first week, it is possible that four different nurses and nursing aids will visit. Every time the patient will have to tell her story and how she wants things to be done. Always the nurse is too busy to give more than basic nursing, and she never has the time to sit down for a chat. A home helper will come once per month to clean the flat. Our patient would receive home rehabilitation by a physiotherapist who will visit twice per week.

## Europe: United Kingdom

### Type of Health Care System

Organization and access to health care for older people is (in principle) no different from that available to the rest of the population. The predominant health care models are:

- a comprehensive National Health Service (NHS), funded from taxation and (mainly) free at the point of delivery and
- a system strongly based on primary care, both as provider of first-line medical management, and as gatekeeper to secondary care.

Since the foundation of the NHS in 1948, there have been frequent major reorganizations, as often as every 2 years. We have therefore seen repeated, and largely politically driven, changes of service. Currently health care is commissioned by Primary Care Trusts, in which GPs have a major leadership role. Commissioning is on the basis of a diagnosis-related group (DRG) model and a national tariff with funding allocated to commissioners by central government. Having been largely based on historical patterns of resource allocation, and central government direction on priorities (for example, various access targets, and the use of expensive drugs), funding is in-

creasingly on a weighted capitation system to allow for regional variations in population and health profiles. At least five types of health care provider can be identified, including GPs, hospitals, newer NHS models, private providers, and local government.

### Overall Organization and Services for Elderly Persons

**General Medical Practices** These practices are mostly partnerships (with 1 to 12 medical partners), being self-employed contractors to the NHS, operating from locality-based premises. More recently, some practitioners are directly employed by the NHS. Practices employ their own nursing, counseling, and other staff. They undertake routine medical care for acute and chronic illnesses, including most immunization, vascular prevention, and screening of those older than 75-year-olds (once, but no longer, mandatory). The GPs are responsible for long-term prescribing and medication review. They provide the primary medical care for all care home residents. GPs undertake a 3-year training programme, 2 years of which is spent in hospital specialities, but only some GPs will have training experience in geriatric medicine.

**Hospitals** These are relatively large, and provide secondary and tertiary care for populations of about 200 000 to 600 000 persons. Emergency admissions are via GPs, or open-access emergency departments. Geriatric medicine is a well-established specialty, second in size only to anaesthesia. Geriatric training involves 5 years of higher specialist training following 3 years of junior hospital posts. Most geriatricians also practice general internal medicine, in particular for unselected medical emergency admissions. Some subspecialization occurs, including falls, movement disorders, continence, orthopedic, and old-age psychiatric liaison. All-age stroke medicine has emerged as a separate subspecialty, with the majority of stroke physicians being geriatricians (not neurologists). The majority of older persons will not be admitted to hospital under a geriatrician, however, and a lively debate continues about how to define the most appropriate specialist for a given patient. A variety of models exist (needs based, age-related, integrated with internal medicine). Geriatricians operate in multidisciplinary teams including nurses and various therapists. Some have duties outside hospital (community geriatricians) including care home and intermediate care support.

Acute medical emergencies are usually admitted to a single admissions ward under the care of a general physician, pending triage to specialty-based wards (including specialist acute geriatric medicine). Most older people will be discharged home from these wards, but postacute rehabilitation facilities (sometimes away from the main hospital site) are common.

Elective surgical patients will usually be "preassessed" and admitted on the day of operation. Those suffering complications or requiring prolonged rehabilitation will often be referred to geriatricians. In recent years, the UK government has made a major effort to reduce waiting times for elective surgery, which are rarely more than 3 to 6 months now, mostly benefiting older people.

Old-age psychiatry is also well established, but usually provided by separate psychiatric NHS organizations, with variable levels of integration with geriatric medicine. Over recent decades, they have concentrated on community-based services and have few in-patient beds. Older people with dementia who suffer a crisis are more likely to be admitted under physicians or geriatricians.

There is virtually no remaining hospital-based long-term care.

**Newer Models of NHS Provision** These models include a telephone consultation and triage service (NHS Direct), and nurse-led, open-access minor illness facilities (walk-in centres). Two notable developments have been intermediate care and community case management. Both aim to minimize acute hospital admission rates (increasing at 5% to 10% per year over recent decades) and reduce length of stay. Several intermediate care models exist, the most successful being home rehabilitation, sometimes supporting early hospital discharge. The other main model is rehabilitation provided in care homes, with medical oversight by GPs. Community case management, for older people with complex medical needs, provided by senior nurses, provides a surveillance and coordination function, with the aim of preventing escalation of medical crises.

**Private Providers** Traditional private provision (up to about 2000) accounted for 5% of total UK healthcare expenditure, mainly for elective surgery. For some procedures, such as joint replacement or cataract surgery, private sector providers undertook up to 30% of operations, encouraged by long NHS waiting times.

Since the 1980s, private providers have supplied the majority of care home places, divided between residential homes (board, lodging, and personal care) and nursing homes. Such care is classified as “social care” rather than “health care,” and as such attracts user charges, albeit abated or subsidized depending on income. Private agencies also supply most home personal and domestic care.

Recently, the government has promoted a mixed-economy of provision with the introduction of commercial providers for NHS-funded outpatient clinic and elective surgical procedures, in part to increase capacity and reduce waiting times. Most dentistry and optometry is privately provided.

**Local Government Authorities** Local authorities are commissioners of “social care,” but this includes domestic and personal home care (provided either directly or through private agencies), including meals at home, and daycare, and funding for care home placements, including respite care. Intermediate care schemes are mostly joint initiatives between primary health care and local authorities. Some home-based social care schemes are very intensive and sophisticated, such as specialist intensive home support for people with dementia. Local authorities employ social workers, some of whom are hospital-based, and are responsible for arranging home care and care home placements. However, resources are limited, and response times are often slow, causing prolonged hospital stays. For patients assessed as responsible for funding their own care, delays in finding care home places (usually the responsibility of their relatives) are common, however, there is wide regional variation.

### Peculiarities

Peculiarities include the development of intermediate care rehabilitation schemes to reduce avoidable disability postacute illness intended to extend provision of multidisciplinary rehabilitation. However, usually there is no provision for specialist geriatrician input, medical care being the responsibility of GPs. Implementation has been widespread. Not all models have a strong evidence base to support their effectiveness, and their success in practice has been mixed. For example, some supported hospital early discharge schemes have worked very well. On the other hand, services are often reluctant to accept patients with cognitive impairment. Moreover the service

has a strict 6-week timeframe, and concentrates more on restorative rehabilitation than the adaptive model that is more appropriate to chronic or progressive disabilities.

Community case management by specialist nurses intends to provide preemptive care to people living in their own homes at high risk of hospital admission in a crisis. The model of care is still evolving, in particular the means of selecting those to target, and also the extent to which links have been made with specialist geriatrician support (the main medical responsibility being with GPs). Case loads are about 50 per nurse. The service is popular, but evaluations of effectiveness have been equivocal.

The large number of geriatricians, long tradition of rehabilitation, relatively low level of reliance on care homes, emphasis on primary and out-of-hospital care, and the artificial division between “health” and “social” care, are all also peculiar features of United Kingdom.

### Difficulties/Solutions for a Typical Geriatric Patient

What type of treatment and services would likely be offered to an 87-year-old widow who was independent in ADL functioning, cognitively intact, and living in her own house but with few social supports who suffers a stroke with motor deficits and speech and swallowing troubles?

UK policy is that elderly people should return to, and be maintained in, their own homes for as long as possible, although, in practice, patients or relatives may not agree with this. Requests for care home placements are rarely challenged (although the patient may be responsible for funding). Moreover, very intensive (and therefore expensive) home-based social care packages may not always be available. There has long been a rehabilitation culture, but there are also strong pressures to reduce hospital length of stay, and intermediate care rehabilitation often shuns more difficult cases (risking overreliance on potentially inappropriate care home discharges).

An 87-year-old with acute stroke, residual disabilities and social problems, and the will to return home, would almost certainly be able to return home. The policy is for her to be admitted under a specialist stroke service, although in some places, she may be admitted under a general geriatric service. Most stroke services provide comprehensive acute and rehabilitation care and are staffed by geriatricians, so the pattern of care would be very similar. Initial care would be multidisciplinary, with early medical, nursing, physiotherapy, and occupational therapy (and, if necessary, speech and language for communication or swallowing problems, and dietetics). Best practice would include early contact and information gathering from relatives, prior caregivers, and GP. Adherence to these guidelines is variable. However, the general standard of care for elderly people (typically those aged older than 75 years) in acute hospitals varies from hospital to hospital, with some having suboptimal staffing levels, and high rates of hospital-acquired infections compared with care for younger people. After medical stabilization, and when it had become clear that more prolonged rehabilitation would be required (probably after 1 to 2 weeks), she would be moved to a rehabilitation ward, either on the same hospital site or elsewhere. Depending on the local facilities available, she may move on to an intermediate care rehabilitation scheme. For someone living alone, typically this would be toward the end of rehabilitation, when specialized physiotherapy was no longer required, but when independent toileting was achieved. This would often be supported by a social care package providing up to four visits a day, for personal care, domestic tasks,

shopping, and meals. Additional follow-up facilities might include hospital-based day hospitals, although many of these have lost their rehabilitation role to home-based intermediate care, and some have closed. Common difficulties will include timely access to the most appropriate admissions ward, delay in transfer to a rehabilitation ward, poor staffing of these wards, and delays in instituting social care (or care home if that is what she chose).

## Europe: France

### Type of Health Care System

The health care system provides universal care for all legal residents, choice of providers, free health programs for the poor and disabled, and significant cost reimbursement. The national health care system combines elements of public and private sectors, and Social Security consists of several public organizations, distinct from the state government, with separate budgets that refunds to patients the cost of care in both private and public facilities. It generally refunds patients 70% of most health care costs and 100% in case of costly or long-term ailments. Supplemental coverage may be bought from private insurers, most of them nonprofit, and from mutual insurers. Until recently, social security coverage was restricted to those who contributed to social security (generally, workers or retirees), excluding some poor segments of the population; only in recent years, has the government put into place universal health coverage.

### Overall Organization and Services Available for Elderly Persons

Older persons seeking ambulatory care can elect to consult the general medical practitioner they have chosen. In the case of an emergency, patients are referred to the emergency department of a nearby local public hospital. When hospital care is required, the person has the freedom to choose the hospital. About 80% of beds are in public or nonprofit hospitals with physicians paid for by the government. The patient pays a daily flat rate (15 euros in 2006). The remaining 20% of beds are for-profit clinics with fee-for-service physicians paid entirely by patients. About 25% of beds are in rehabilitation wards and primarily used by older persons.

Since the mid-1980s, responsibility for organizing residential and home care has been decentralized at the level of the 100 local councils, assisted by the municipalities. There are various kinds of long-term care institutions for the elderly. Long-term care hospitals with full-time physicians are specifically intended for older persons who have lost their physical independence, regardless of the cause. In addition, there are nursing homes for dependent elderly people, public or nonprofit retirement homes, and private commercial residences with services. All these may have a part-time physician, but his or her responsibilities are not clear as residents usually have their own private physician. All together, in 2003, there were 51.2 long-term care beds per 1000 people aged 65 years and older.

Sheltered housing, providing a studio apartment with kitchen and bath room for one or two elderly persons has been progressively adapted to the needs of increasingly old occupants, with the installation of new technical equipment and the provision of some forms of care beside community services. Therefore such facilities may be considered as part of long-term care; they represent an additional 15.3 beds per 1000 aged 65 years and older.

Since the 1960s, the government has laid down a living-at-home policy that claims to be universal. Services implementation, however, has not achieved intended levels. The family still plays a major role in supporting and caring for older people. A national survey on impairment, disability, and handicap conducted in the year 2000 showed that family help represented more than 75% of all assistance.

Home-help services and home nursing services have been designed specifically for older people. The former have been in existence for 50 years. The latter were created in 1981 and have been developing slowly. A nurse coordinates and organizes the various interventions by either registered or auxiliary nurses. The services most frequently carried out include help with activities of daily living, mobility, and the prevention of pressure sores. Since 1992, in order to facilitate employment, new home help services have been designed for domestic help and assistance to handicapped persons.

In 2002, an autonomy allowance was created, specifically for dependent elderly persons living at home or in an institution. Responsibility for this allowance has been given to the local councils although eligibility and the amount of allowance are related to disability assessment by a medicosocial team using a national scale. This team proposes a personalized care program of required interventions and appliances for those living at home. The person's copayment (15% on average, but up to 90%) is related to the person's income.

Public authorities have laid down a medicosocial policy for elderly persons that claims to be universal, but they have not provided the means for its development, especially for home care. Such development has been hindered by the seemingly impossible task of integrating policies from health sector and the scarcity of funds. The result today is that a distinction has been made between systems of care for handicapped adults and for dependent older people. Both are fragmented and usually characterized by numerous dysfunctions and inadequate responses to the complex care needs of these vulnerable populations. In the care sector for older persons, there are important geographical inequalities in accessibility to care. The lack of domiciliary care results in an overconsumption of acute hospital care. Moreover, there are inequalities in terms of quality of care due to differences in caregivers' qualification and the copayment amount relates to the status of care giver rather than the needs of the recipient.

The main issues at the present time are paying for long-term care insurance, integrating health and social care; increasing quantity and quality of care in both the residential and domiciliary settings; and increasing empowerment of older person in the determining their needs and how care will be provided.

**Paying For Long-Term Care** Less than 10% of the health care expenditure is used for long-term care provided to older persons. In contrast, three times more resources are provided for the long-term care of handicapped young adults.

There is currently a debate about creating long-term care insurance for handicapped persons, independent of their age. This should merge the different sources of financing in a national scheme, which includes long-term health and social care. The local responsibility for its implementation is still under discussion.

**Integrating Health and Social Care** Fragmentation of responsibilities for financing, organizing, and providing health and social long-term care, and poor coordination with acute care are particularly marked. The existing care system does not match the complex

needs of older people with numerous, simultaneous, chronic, and disabling conditions. Integration of care may lead to more rational care processes, and would allow a more elaborate and flexible combination of interventions. It also may correct the insufficiencies in the supportive network and the housing condition of vulnerable older persons. During the last 20 years, demonstration projects have been undertaken to overcome the fragmentation of services and to reach a more coordinated care package for elderly persons. Newly promoted organizational models of care include improving case management programs within a multidisciplinary team, performing initial geriatric assessment and follow-up, linking primary health and social care givers together with geriatric team.

**Increasing Quantity and Quality of Services** Home care suffers from the lack of staff and of sufficient economic resources. Those obtained from the autonomy allowance are usually not sufficient to meet the needs of the most severely disabled. Therefore, those who can afford it will employ several unskilled persons. Persons unable to afford extra help will usually end up being admitted to an institution. Increasing the number of professional caregivers and giving them better training to improve their professional skill are priorities, which are regularly recognized but not fully implemented.

**Increasing Empowerment of Older Persons** On the whole, the wishes of the oldest old are not well represented. Rather, professionals and managers speak or decide for elderly persons. But some local programs now aim to take into account the users' viewpoint and the needs expressed by the oldest old persons in the definition of their needs and care.

### Peculiarities

Several measures have been taken to help informal caregivers of disabled older adults. Respite care enables the older person living at home with family to be institutionalized periodically or to attend daycare several days a week. This allows a period of relief for a spouse or relatives who normally care for elderly persons. Financial measures, such as a tax relief, have been taken to encourage and maintain the ability of families to provide care.

### Difficulties/Solutions for a Typical Geriatric Patient

What type of treatment and services would likely be offered to an 87-year-old widow who was independent in ADL functioning, cognitively intact, and living in her own house but with few social supports who suffers a stroke with motor deficits and speech and swallowing troubles?

In the best case scenario, a patient with a stroke will be admitted to a stroke unit and then discharged to a rehabilitation unit. Most often an elderly patient sustaining a stroke with moderate to severe disability would be admitted to an acute hospital. After a period of medical treatment (from 10 to 20 days), she will be transferred to a rehabilitation service, provided there is some prospect of returning to the community. Rehabilitation will be offered for up to 3 months, provided that functional gains continue and the prospect of returning home remains. At discharge, a home visit would be conducted and autonomy allowance may be provided. This allowance will provide a social life auxiliary to assist the elderly patient for personal care and domestic tasks. The amount of the allowance will

be determined by the patient's disability level and a copayment percentage for which she will be responsible will depend on her income (up to 80%). Rehabilitation would be provided for several weeks or months, as required, by an independent physiotherapist paid on a fee-for-service basis. Severely disabled patients, particularly those without a coresident carer, will often be referred directly for permanent residential care in long-term care hospital or nursing home.

## Europe: Italy

### Type of Health Care System

Since 1978, Italy has a National Health Service, the Servizio Sanitario Nazionale (SSN), based on the principle of universal entitlement, with the central government providing free and equal access to preventive and medical care and to rehabilitation services to all residents. Citizens have a basically unlimited coverage, although they are asked to contribute minimal fees. These fees apply mainly to drug prescriptions (with the exception of so-called life-saving medications), laboratory tests, diagnostic investigations, and Emergency Room visits. Pressured by the economical outlook, the government has recently completed an unprecedented reform. Italy is adopting a semifederal organization of health care delivery. Each of the 20 regions, into which the country is divided, has now the responsibility to autonomously organize the services they feel appropriate based on the population needs. A national budget for health is set by the government each year (approximately 1000 euros per citizen) and then divided among the regions. In turn, the regions are required to allocate the necessary financial resources to each of nearly 300 local health agencies based on standard health-related indicators.

### Overall Organization and Services Available for Elderly Persons

In the early-mid 1990s, Italy accounted for the lowest number of residential beds for elderly persons among western countries: 25 beds per 1000 people older than 65 years, while no other country had fewer than 60 beds. The numbers of elderly persons cared at home were even lower, less than 1% among those older than 65 years old, with a few exceptions in some northern regions.

The low number of nursing home beds and the shortage of home care services were due both to family structure and to the use of acute care hospitals. Italians have a family structure that—either because of choice or lack of availability—traditionally takes responsibility for the care of elderly persons, even when they become disabled. In southern Italy, this tradition is central to a culture that views care of elderly persons a natural responsibility of the family.

The other cause appears to be the use of acute hospital beds, which numbered 7 per 1000 inhabitants in the early 1990s, although there were marked differences between northern and southern regions. People relied upon acute care hospitals to solve a wide range of problems related to the assistance of elderly persons. As a result, the length of stay in internal medicine wards averaged 18 days in 1992, mostly because of delayed discharge. In 1993, a reform dramatically changed the approach to frail elderly patients needing long-term care; hospital reimbursement shifted from a fee-for-service to a prospective system based on the DRGs.

The aging of the population, with the rising number of older "clients" of the health agencies and the new prospective payment

**FIGURE 6-10.** Number of persons 65 yrs or older/1000 in home care (panel A) and in long-term care (panel B) in 20 Italian regions in 2003. Data on home care are from CENSIS ([www.censis.it](http://www.censis.it)) and data on long-term care are from ISTAT ([www.istat.it](http://www.istat.it)). Datum on one region was not available for home care.

system, all led to redesign of the long-term care system and to the shift of resources from acute care hospitals to community services. Regional health authorities assign available resources based on central government's directives, local, and political needs. As a consequence, the availability of long-term care and home care services is highly different among the 20 Italian regions, which further widen already existing inequalities (Figure 6-10).

To guide and to coordinate the work of local health agencies, the Italian parliament promulgated a document in 1992 about frail elderly people needing continuing care. The "Progetto Obiettivo Salute dell'Anziano" (POSA), was not a law, but simply a series of suggestions and recommendations to health agencies.

The POSA identified the integration between health and social services as the key to satisfying the needs of these patients, delivering individualized and, at the same time, comprehensive care services. The POSA determined that the community-based geriatric evaluation unit (GEU) was the appropriate approach and that the GEU should include registered nurses, social workers, physiotherapists, and patient's GPs, and be coordinated by a geriatrician. Integrated home care (Assistenza Domiciliare Integrata [ADI]) and skilled nurs-

ing facility (Residenza Sanitaria Assistenziale [RSA]) were identified as the two major services.

Difficulties soon became evident. Health and social programs have been implemented irregularly in varying forms, mostly in northern regions and in rare, spotted areas of central Italy. In addition, community services are usually limited to social needs and the shift of health resources from hospital to community is not underway. Overall, the implementation of the POSA guidelines has been slow. Presently, 2% of persons aged 65 years or older are receiving home care and 2.4% are in a nursing home.

### Peculiarities

Italy has traditionally emphasized family care giving, particularly by female members. Elderly persons in need of long-term care often prefer to live at home, rather than in an institution. This choice is rooted in cultural and religious values. It also depends on the very limited availability of long-term care beds on the one hand, and on the fact that more than 80% of elderly Italians own the house where they live, on the other hand.

In recent decades, triggered by societal forces, Italian women have been increasingly entering the labor market, limiting the time they can spend home caring for their loved ones. As a result, the need for in-home caregivers has quickly increased; this void has been filled by foreign-born caregivers (the *badanti*), paid either by elderly persons or by their families.

The high number of foreign-born caregivers is considered to be a panacea for the nationwide shortage of aides and services in general. Currently, there is an estimated 800 000 *badanti* and they cost Italian families about €8 billion each year. However, these caregivers are not licensed, they work outside the oversight of regulatory bodies, and nurture the “gray economy.”

### The Difficulties/Solutions for a Typical Geriatric Patient

What type of treatment and services would likely be offered to an 87-year-old widow who was independent in ADL functioning, cognitively intact, and living in her own house but with few social supports who suffers a stroke with motor deficits and speech and swallowing troubles?

Difficulties for a typical frail elderly person, having suffered a stroke but wishing to stay at home, are related to the limited availability of home care services. Only 2% of older adults in Italy receive home care services. Home care services are completely free, but given the paucity of resources, only young adults with cancer and/or disability or very frail and/or severely disabled older adults can be entitled to them. Therefore, older adults who are not admitted to home care and wishing to stay at home, the great majority, rely almost entirely (both socially and economically) on their families or on their own resources. Either members of the family, or more commonly, foreign caregivers (paid by the patient or by their family) care for the older adult at home.

Rehabilitation services provided by the National Health Service (and therefore free of charge) are also very limited, and preferentially reserved for young adults or healthy older adults without severe comorbidities. Private rehabilitation services are also available and easy to access if the patient or their family pay for it.

In cases in which she and her family cannot afford the social and economical costs needed to stay at home, long-term care may be the most reasonable solution. Long-term care is also paid for by the National Health Service, with a minimal copayment. However, due to the limited availability of beds, admission to long-term care may require a long wait (up to 6 months). Less than 3% of older adults aged 65 years or older in Italy are in long-term care.

## Asia: Japan

### Type of Health Care System

Since 1961, there has been universal coverage by a form of social insurance. Virtually all residents are compulsorily covered either by a health plan provided by the employer, or by the municipality where they reside if self-employed or retired. There is no choice of plans and all provide the same benefits including medications, dental care, and preventive services. The copayment is usually set at 10% for those 70 years and older. Copayment reaches 30% for those with incomes above the average worker. This affects about 10% of elderly persons. If copayment exceeds US \$300 per month, then the rate for any additional payment is reduced to 1%. Although providers

are reimbursed on a fee-for-service basis, service fees and drug prices are set and have been tightly controlled by the government. The percentage of the gross domestic product spent on health care is 8.0% and ranks 17th among the OECD countries. There is no gate-keeping, so patients may directly access virtually any provider in Japan. The delivery system is dominated by the private sector except for the high-tech medical centers that receive subsidies for their capital expenditures. Waiting lists are not a problem in acute care but are in long-term care (LTC) facilities. LTC is provided by the public LTC insurance, which was implemented in the year 2000.

### Overall Organization and Services Available for Elderly Persons

Health care is highly accessible. A national survey showed that 11.5% of the population aged 65 years or older visited a health facility as outpatients on the day surveyed; the average interval between two visits was 9.6 days. Japan is unique among developed countries because most of the institutional LTC continues to be provided by hospitals. Almost 4% of the elderly population is currently hospitalized. This heavy reliance on hospitals was an unintended effect of making health care free for elders 70 years and older in 1973. Until that time, copayment rate was 50%. The fact that hospitals are reimbursed on an open-ended fee-for-service basis by health insurance combined with the fact that the majority of small- to medium-size hospitals are owned by doctors who could exercise their professional discretion on admission, led to rapid increment in the number of elderly inpatients. From the family's point of view, hospital care has the advantage that costs are covered by insurance and that it is socially acceptable. The establishment in 1986 of a new type of intermediate care facility, the Health Facilities for Elders (HFE), led to a decline in the proportion of older adults staying in acute care hospital, but to an increment in the absolute number of elderly inpatients.

Developments in social services generally lagged behind health care because they were financed entirely by taxes and limited by the budget. However, services began to improve after the government embarked on a 10-year plan to increase funding of local governments for developing LTC services in 1989 (referred to as the “Gold Plan”). By completion in 1999, the goal of increasing the number of full-time equivalent home-helpers from the 1990 level of 38 945 to 170 000 and the number of adult daycare centres from 1615 to 17 000 were met. However, access to services continued to be controlled by the local government welfare department, to be means-tested and to offer no choice of providers by the individual. Although restrictions based on income and availability of family support had officially been removed, the institutional culture of the social welfare agencies and budget limitations led to priority given to indigent elders living alone or with spouse.

These structural problems led to the implementation of the public LTC insurance that provides defined benefits as a universal entitlement for all elders 65 years and older who meet the eligibility criteria. For those 40 to 64 years old, benefits are limited to those having disabilities as a result of designated age-related diseases, such as stroke or Alzheimer's disease. Health and social LTC services have become integrated and coordinated by a care manager. Home-helpers for personal care (ADL support) and domestic tasks (IADL support), bathing service, loan of devices like wheelchairs, home reconstruction (putting in ramps and hand-bars etc.), and nursing homes were transferred from social services to the LTC insurance. Some hospital

LTC beds, all HFE beds, most visiting nurse and visiting rehabilitation services, and “medical management” (supervision of care by doctors) were transferred from health insurance to the LTC insurance. Adult daycare and temporary “respite” stays in institutional settings, which had been available from both sectors, were transferred but not unified and continued to maintain different staffing requirements. Doctors’ services continue to be paid in the same way as before by health insurance. There are no cash benefits for family carers, partly because they were opposed by groups who claimed that their provision would further increase the social pressure to provide care for in-laws.

Eligibility is determined by the process shown in **Figure 6-11**: (1) completing a 79-item form on physical and mental status by a local government employee (usually a public health nurse) or individual under contract, (2) putting the results into a computer, which groups the individual into the seven levels of eligibility or ineligibility according to the algorithm, and (3) review by a local expert committee. This committee changes the level calculated by the computer, usually to a more severe level, based on the information in the forms written by the assessor and the attending physician. Income levels and the amount of informal care available are not taken into consideration. After eligibility has been determined, the individual can go to a certified care management agency of her choice for community care and be covered for LTC services up to the amount set for each level (from 49 700 Yen [US \$200] to 358 300 Yen [US \$3000] per month), or ask to be admitted to any LTC facility. There is a 10% copayment, with a ceiling for those with low incomes.

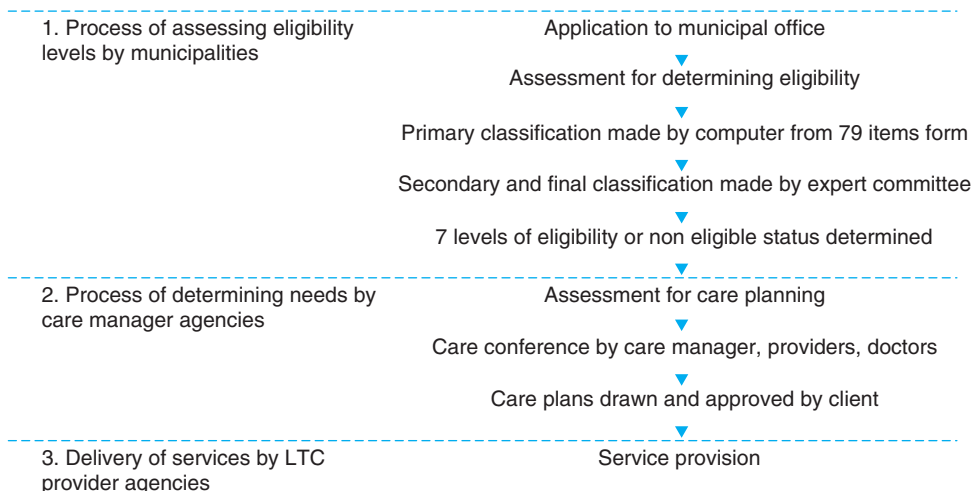

The LTC insurance is managed by the municipalities and financed by a combination of social insurance premiums and taxes. A method was devised to make the municipalities fiscally responsible for their LTC insurance programmes, while taking into account the differences in their income and demographic structure. The premiums of individuals aged 65 years and older reflect the LTC insurance expenditure levels of their municipality and are of six levels according to the individual’s income. These premiums finance approximately one-sixth of the total expenditures. About twice this amount, one-third, is financed by premiums from those aged 40 to 64 years that are collected at the national level and redistributed to the municipalities, after adjusting for their income level and age distribution. The remaining half is financed by national and local taxes. Thus, although elderly persons who reside in municipalities

using more services pay higher premiums (the maximum difference being threefold), their contributions compose only one-sixth of the total costs.

The implementation of the LTC insurance has led to dramatic increases in the number of elderly persons receiving services. The percentage of persons aged 65 years and older certified as being eligible increased from 10% in 2000 to 16% in 2005. In absolute terms, the number certified nearly doubled to 4.3 million in 2005, with the increase greater for the lighter eligibility levels and community care. Waiting lists for community care services have disappeared. Thus, the objectives were more than met, but expenditures increased more than projected. Instead of increasing from 4.3 trillion Yen in 2000 to 5.5 trillion Yen in 2005, expenditures increased to 6.8 trillion Yen (1.4% of GDP). In order to contain costs, service fees were cut in 2003 and 2006, partial payment of “hotel costs” was introduced in 2005, and benefits limited to preventive services (mainly light exercise in day care centres) for the two lightest eligibility levels in 2006. In addition, the 130 000 LTCI hospital beds will be phased out and converted to either a HFE or care home by the year 2012.

### Peculiarities

The Japanese system is unique in that little reliance is placed on geriatricians or social workers. Geriatrics is not officially recognized as a specialty and only about one-quarter of the medical schools have such a department. Nor is general practice or family medicine recognized as a specialty. Although clinic-based physicians do not have access to hospital facilities and their patients are, for most part, primary care, they are usually trained in and have worked as specialists in hospitals before going into private practice. Consequently, social aspects of care tend to be neglected. Professionalism has also been lacking in social work, which was one reason why eligibility levels came to be determined by a computer program. Care managers were hastily created for the LTC insurance by allowing anyone who had worked for more than 5 years in a health or social care field to sit for the multiple-choice examination and, having passed, to participate in a 72-hour training program in order to obtain the license. By the year 2006, 370 000 individuals have cleared the examination and training, but there is little monitoring of their quality. No patient databases exist for quality monitoring purpose.

**FIGURE 6-11.** Flow chart for receiving LTC services in Japan.

### Difficulties/Solutions for a Typical Geriatric Patient

What type of treatment and services would likely be offered to an 87-year-old widow who was independent in ADL functioning, cognitively intact, and living in her own house but with few social supports who suffers a stroke with motor deficits and speech and swallowing troubles?

Under the best case scenario, the patient would be admitted to an acute stroke unit and then discharged to a rehabilitation unit, where the LTC insurance care manager would come and work with the hospital staff to draw the care plan: a weekly schedule for care workers to provide her with IADL and ADL support, and for visits by a nurse and a physiotherapist. If needed, ramps would be placed in her apartment before discharge. Her attending physician would visit her on a monthly basis to provide medical supervision and feedback the information to the care manager.

Under a more likely scenario, the patient would be admitted to the nearest hospital where the treatment and rehabilitation may not be up to standard. She would then be transferred to any LTC facility that has an empty bed. She would probably stay in the facility and may come to prefer it to her own home because of the security it provides and the lower costs. Her monthly out-of-pocket expenditures, assuming she has an average income, would be about US \$200 in the case of the former, and about US \$700 in the case of the latter.

## Oceania: Australia

### Type of Health Care System

The organization of the health care system in Australia is a complex blend of administrative and service provider arrangements. General community-based medical practice is provided largely by independent “private” practitioners. However, the fees are heavily subsidized by the national government through the “Medicare” scheme. Personal contributions by older and less well-off citizens are minimized. The scheme also subsidizes medical costs in private hospitals and the provision of pharmaceuticals (through the Pharmaceutical Benefits Scheme in the community and private hospital settings).

Hospital care is provided by public and private hospitals. Around 60% of admissions and 70% of bed days are provided in the public sector. Public hospitals are administered by state governments (there are nine states and territories, which comprise Australia), and are jointly funded by the national and state governments. Public hospital care is provided free of charge, regardless of financial status.

Citizens access private hospitals through the support of private health insurance which approximately 43% of the population elects to purchase from independent health insurance agencies. Persons holding private health insurance, however, can elect to use public hospitals and, when doing so, may elect to be admitted either as a “public” or “private” patient. In the latter instance, they may have some choice of their treating physician and access to slightly better physical facilities.

GPs act as “gate-keepers” to specialists, including geriatricians. Medicare subsidizes only specialist consultations that are referred by GPs.

Overall, the Australian government funds around two-thirds (68%) of total health expenditure. The remainder is sourced either directly from individuals at the point of service or indirectly

through private health insurance. Hospital services account for 35% of all recurrent health expenditure.

In spite of the level of complexity, the overall impression of the Australian health care system is one of good accessibility and equity. By international standards, Australians enjoy good health status. Life expectancy at birth has risen significantly in recent decades to be among the highest in the world. Life expectancy at age 65 years is second only to Japan for males and third to Japan and France for females.

### Overall Organization and Services Available for Elderly Persons

Specific services for elderly persons exhibit a similar level of complexity of administrative and service arrangements to those of the general health system. Long-term residential care is fully administered by the national government, whereas home care is a complex array of programs, some jointly administered by state and national governments and others administered by one or the other.

Long-term care is provided by a mixture of government, for-profit and not-for-profit organizations. Funding is provided on the basis of a locally developed dependency based system. User contributions are based on assets and means testing, and are netted off against the government funding. This results in the levels of funding available for care being approximately the same regardless of the resident’s ability to pay.

The level of provision of services is governed in a variety of ways. Long-term residential care is tightly controlled by the national government according to a planning formula, which stipulates the ratio of beds to aged population (70+ years) at a state and regional level. Since this strategy was introduced in 1986, there has been increasing equity of provision across the nation. Certain aspects of community care are similarly regulated. So-called “packaged care” is made available on a places-per-aged population basis. These programs (entitled community-aged care packages) attract a subsidy-linked loosely to the equivalent cost to government of low level residential care. The other major community care program (the Home and Community Care program) provides a wide array of services but generally at a lower level of intensity than the packages referred to above. In both programs, the user contribution is modest, making home care highly affordable. Access can be limited, however, because service demand often exceeds supply.

Over the past 20 years, the national government policy has promoted a shift away from institutional to community care, although the level of provision of the former remains comparable to other developed nations. Government investment in community care is expanding considerably in real terms.

Eligibility for residential care is controlled through a national Aged Care Assessment Program, which comprises regionally based multidisciplinary teams of nurses, allied health personnel, and usually geriatricians. These services typically present themselves as services to individuals and families, offering advice and short-term case management in addition to their gate-keeping role for residential care and packaged community care.

Postacute community service provision is more complex with varying levels and types of services being provided across jurisdictions. In 2006, a national “transition care” program was established to provide short-term therapy and personal care services following hospital admission.

Specialist hospital-based geriatric services vary widely in availability across jurisdictions. They are state funded, but in some states, the establishment of such services is unplanned and often left to the discretion of individual hospitals. In other states, real attempts to plan services are made. Regardless, the majority of large hospitals operate some form of inpatient geriatric service. Predominantly these operate a “postacute” service model, accepting patients from acute hospital wards. Postacute care is rarely provided in long-term care institutions.

Inpatient rehabilitation services are widely available, although the lack of any planning framework results in some areas of poor availability. Rehabilitation is generally provided in the public hospitals but rehabilitation units also are common in the private sector. Many rehabilitation wards admit a mix of older and younger patients. Some hospital geriatric units provide a blend of acute and postacute geriatric assessment and rehabilitation services. Respite care is provided mainly in long-term care institutions.

Geriatric medicine is a rapidly expanding specialty, with geriatricians representing the second largest group after cardiology within specialist internal medicine. Geriatric practice is predominantly hospital-based, although many are linked to community assessment teams, ambulatory clinics, and day hospitals. Specialist geriatricians undergo training under the auspices of the Royal Australasian College of Physicians, the program comprising general or “basic” training followed by 3 years of “advanced” training within the specialty. Medical services for residents of long-term care facilities are provided by GPs.

#### Difficulties/Solutions for a Typical Geriatric Patient

What type of treatment and services would likely be offered to an 87-year-old widow who was independent in ADL functioning, cognitively intact, and living in her own house but with few social

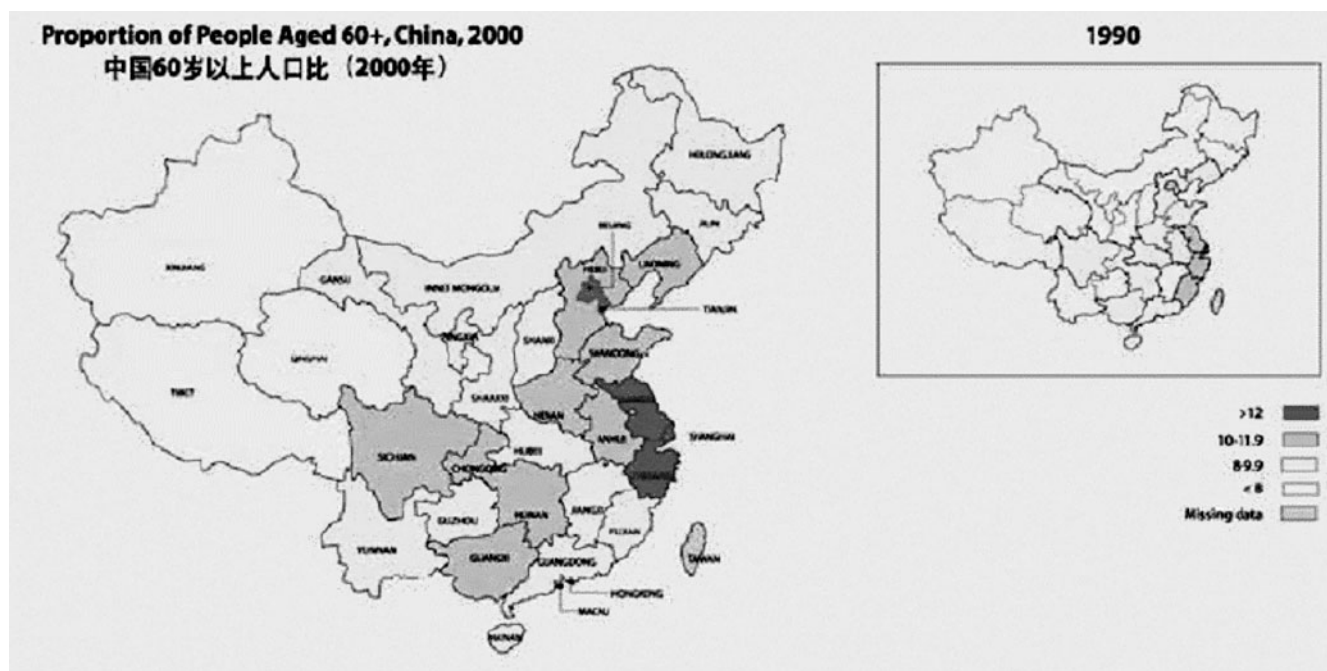

supports who suffers a stroke with motor deficits and speech and swallowing troubles?

An elderly patient sustaining a stroke with moderate to severe impairments would almost always be admitted to an acute hospital. After a period of medical treatment, around 10 to 20 days, transfer to a rehabilitation service would be typical, provided there was some prospect of returning to the community. Severely disabled patients, particularly those without a coresident carer, will often be referred directly for permanent residential care. Rehabilitation is offered for up to several months, provided functional gains continue and the prospect of returning home remains. A home visit would be conducted, with aids and appliances provided as needed. At discharge, a blend of in-home and centre-based rehabilitation would be offered, for at least 3 months if required. Subsequently, daycare, personal care assistance, and general home-maker services typically would be available.

#### Developing Countries: China

China is an excellent example of the future prospects for countries of the third and fourth world. In China, fertility rate dropped from 5.8 to 2.4 in just 10 years, from 1970 and 1980, and life expectancy increased almost 30 years, from 35 to 64 years, between 1950 and 1980. Thus, the transition, which took around 150 years in more developed countries, took 50 years in less developed countries, and only 10 to 20 years in China. Today, China’s average is equal to that of the world in terms of the proportion of people aged 60+ years (10%) (Figure 6-12). However, by 2050, this proportion is expected to rise to 30%; in absolute numbers, this is an increase from 130 to 430 million people.

If current demographic rates in China are similar to those of developed countries, its economy and social welfare institutions are more similar to less developed countries. China plans to quadruple

**FIGURE 6-12.** Proportion of people aged 60 yrs+ in China, by regions, 1990–2000. (Reprinted with permission from *Population ageing in China—facts and figures*, UNPFA 2006.)

its GDP per capita by 2020 but if the projections are correct, China will become old before it gets rich.

### Type of Health Care System

The health care system in China is funded by a combination of state, social insurance, and private payments. In general, costs of primary health care are covered only in part by the state. Employees of the industrialized sectors are covered in part by the social medical insurance, financed by contributions by both the employee and the employer, and subsidized by the state. Farmers, who account for 60% of the total population, are covered in part by a cooperative medical insurance subsidized by the government at both the state and local levels. These insurances cover both medical and drug costs up to 50% to 100%, depending on the types of care received and sectors in which the care receiver is employed or was employed before retirement. As a result of the rising health care costs and limited coverage of the existing social medical insurance, health care cost increasingly becomes a burden to the majority of aged persons.

### Overall Organization and Services Available for Elderly Persons

Care for elderly persons in China is administratively divided into two categories—medical services and residential care—which are supervised, respectively, by the Ministry of Health and the Ministry of Civil Affairs. Hospital care is the most frequently sought by aged persons. China's medical system was not originally designed to meet the chronic illnesses of elderly persons and there is a lack of well-trained professionals such as geriatricians and geriatric nurses. Although general hospitals in large cities currently tend to have geriatric wards to meet the needs of a rapidly growing aged population, physicians are usually not systematically trained as geriatricians. Indeed, few medical schools currently provide such training. Nevertheless, the annual hospitalization rate for those aged 65 years is around 8%. A somewhat good opinion about the quality of services in general hospitals and a lack of other options make the elderly population rely on acute care when they have to deal with health issues.

To reduce overuse of acute care resources and provide more appropriate care to aged persons, the Chinese government has made substantial effort over the last decade to develop community medical

services. By 2004, 14 153 community health centers were operating in the urban areas. To attract elderly people away from large hospitals, most of the costs of community health care were reimbursed from social insurance. As a result, access to primary health care, which is one of the major concerns of aged community dwellers, has been improved.

Along with the declining overuse of acute care by aged patients, there has been a growth of a variety of services targeting the older population in the community, including rehabilitation and nursing care. An elderly patient being discharged from the hospital could receive home care, which would be delivered by health care workers from community health centers. Community health services are still at their early stage of development, and only present in urban areas, nevertheless, they provide elderly persons with a new alternative to family care.

The narrow coverage of the existing insurance programs, which only cover approximately 60% of elderly persons living in urban areas and less than 10% of those in rural areas, is a serious barrier for elderly persons needing access to health care. A considerable proportion of the urban elderly population and the majority of the rural elderly population have to rely totally on themselves and their family to pay for medical services. The sources of financial support for older adults in China by age are shown in Figure 6-13.

Another problem of the health care system in China is the lack of coordination between medical care and social care in terms of service organization and finance. When an elderly patient is discharged from hospital, it is likely that they will find it difficult to locate appropriate intermediate care between hospital and home. Long-term care facilities are confined to providing residential services under the regulations of the local bureaus of civil affairs. Very few facilities have qualified nursing staff to provide professional nursing care. For those who benefit from the social medical insurance, expenses related to long-term care are not covered by the program. There is currently no long-term care insurance, though the need for such insurance is growing rapidly.

In the country, there is a long tradition of family members caring for their elders at home. However, recent demographic changes have resulted in older persons living longer and have led to a decline in the availability of care by their families. By the year of 2001, the number of long-term care institutions reached 39 338. There were 893 000 persons, less than 1% of the aged population, residing in

Source: National Population Sample Survey in China, 2004

**FIGURE 6-13.** Primary financial sources for the elderly by age in China in 2004. (Reprinted with permission from *Population ageing in China—facts and figures*, UNPFA 2006.)

these facilities. Long-term care institutions for elderly persons can be categorized by sources of funding as follows: (1) municipal institutions where funding for investment and operation directly comes from the local bureaus of civil affairs as public expenditures on social welfare and these institutions are owned by the city governments; (2) institutions funded by state enterprises in the urban areas or by township government in the rural areas and these institutions are owned by collectives; and (3) institutions funded and owned by private investors.

Three types of elderly persons become residents in the long-term care institutions: those who have no income and family, those who either themselves or their direct family members made publicly recognized contributions to the state, and all others who need care. For the first two types of elderly residents, the institutional services are paid for by the government agencies of civil affairs. For the last category, services are charged to the care receivers and their families. By the year of 2001, less than 25% of residents in urban facilities and about 6% of those in rural facilities were paying for services out-of-pocket.

Institutional long-term care for elderly persons is still underdeveloped, with currently insufficient capacity to meet the demand. Various empirical surveys have reported the significant proportions of elderly persons who need nursing care and assistance in daily life. On the other hand, the average occupancy rate of the existing facilities is only around 70%. Lack of funding for services, shortage of professional trained providers, and inadequacy in regulations to control the quality of care in these facilities are currently the major concerns about the development of elderly care services in China.

### Peculiarities

Due to the cultural tradition of family care for the elderly and the scarcity of institutional long-term care resources, the overwhelming majority of the aged remain at their own homes when they are in need of care. However, the high rate of women's labor force participation and the reduction in the nation's birth rate has seriously challenged this tradition. With 78% of women aged 16 to 55 years employed outside the home, there has been a serious shortage of formal caregivers. In addition, since 1970s, China has implemented a family planning policy, which has dramatically reduced the average number of children per family. An unexpected consequence of such a policy is that more and more people grow old in an "empty nest."

To meet the need of elderly persons while keeping the tradition of family care, families in urban areas have started to look for in-home caregivers. As there is an oversupply of labourers in rural China and many migrate to urban areas seeking a job, there is a reservoir of potential in-home caregivers, most of whom are women. They have been introduced by commercial home service agencies or simply by friends to the families seeking care. They take daily care of the elderly persons and are paid by the client or family members.

There is no statistics about the number of in-home caregivers and the cost borne by the families, though it is now typical of elderly care in urban China. The practice of family care by nonfamily members is well accepted by the state as a way to absorb the surplus labourers from the rural areas and is sustained by the affordable cost of the services. As caregivers only have limited education and skills, they can only bargain for a wage much lower than the average income

of urban residents. On the other hand, there is a lack of training, license, and supervision over the care provided.

### Difficulties/Solutions for a Typical Geriatric Patient

What type of treatment and services would likely be offered to an 87-year-old widow who was independent in ADL functioning, cognitively intact, and living in her own house but with few social supports who suffers a stroke with motor deficits and speech and swallowing troubles?

A typical frail older woman discharged from the hospital after a stroke is most likely to go home directly as a result of difficulties in access to rehabilitation or nursing care. The number of rehabilitation facilities is limited and there is a lack of public funding to support the use of health care services other than hospital services. Once back home, she would have the problem of finding someone who could provide care to meet her health and daily living needs. She may find that her children are not always available even if she lives together with one of them unless this son or daughter is retired. She may also find that she cannot afford to seek long-term care without the financial support from her children, since few facilities are public funded and means-testing is required to be admitted to those facilities. Even if she could afford to fund her long-term care through private sources, she would soon find that most facilities are not prepared for people with comorbidities or hemiparesis.

In addition, she would have limited options to cope with the difficulties of resource scarcity and service inadequacy. She could hire an in-home caregiver to help when the family members are not available, an option that would be more affordable than institutional long-term care. Community services such as home beds or day care have been organized in recent years with the support of some local governments. Whether the elderly person in need could receive these services would depend on the availability of the services in the community where she resides. As these services are only available in large cities such as Beijing or Shanghai at present, only a small segment of elderly persons actually benefit from them.

## NEED FOR STANDARD ASSESSMENT OF HEALTH NEEDS AND SERVICES ACROSS COUNTRIES

Health care systems in different countries worldwide have elected to confront the same demographic changes with a heterogeneous array of schemes and possible solutions. In the introduction to *Home Care for Older People in Europe*, Raymond Ilesley noted in 1991 that it was impossible to compare systems of different countries and to identify a model of health care organization and delivery that could be considered a reference. He wrote: "We were surprised at how little experts on these services in their own countries knew about practices, or even principles, pursued in other countries. Services had emerged nationally, not through cross-country observation and learning. Because systems have developed in response to local circumstances, it is impossible to pick and choose and put together a mosaic of the best bits."

Over 15 years later, there is still little information about the effectiveness or efficiency of health care systems. Hence, health care providers and policy makers continue to find "local" solutions, but these remain limited and nonreproducible experiences. In the field

of geriatric medicine and health services organization for older people, there is no evidence on which to base efficient models of care. Currently, few data are available on health care organization; comparisons across different approaches in terms of patient outcomes and resources utilization have rarely been performed. A major obstacle to a systematic approach to evidence-based practice has been the use of different, noncomparable, assessment instruments, protocols, and procedures.

Comprehensive assessment (CGA) is considered the “technology” of geriatrics and its application is thought to result in a better quality of care by providing information on comorbidities, syndromes, socioeconomic problems, and functional and cognitive deficits. CGA facilitates development of specific and sensible care plans for individual patients. CGA typically is performed with variable measures and scales according to individual geriatrician’s knowledge and access, limiting the ability to measure cross-population health and functional status. Health services are even less well studied. Thus, what constitutes best practices in terms of geriatric services remains largely unknown.

Standardized assessments that consider systematically several relevant areas appropriate to specific settings can provide evidence of health and health service needs across settings and locations. One such suite of comprehensive assessments has been developed by an international group of researchers gathered in a not-for-profit corporation, InterRAI.

## InterRAI

InterRAI is a crossnational collaboration of geriatricians, researchers, and policy-makers, primarily experts in long-term care issues, dedicated to developing assessment systems. Its members come from 26 nations (Figure 6-14). InterRAI, since 1990, has worked to design second generation assessment systems characterized by comprehensiveness and health care setting specificity. Also, following their implementation, InterRAI has used the experiences of one nation to inform others, and to develop innovative research approaches using the data generated by these assessments. In 2006, InterRAI released a “suite,” covering all of the major health care sectors devoted to elder

care, thus creating the third generation of instruments. In particular, there are assessment systems that address the following populations: frail elderly persons in the community, home care, assisted living, nursing homes, postacute care, palliative care, acute care, and inpatient and community-based mental health.

These instruments use the same major items in common, facilitating clinical communication both between different caregiving professionals and across acute, postacute and long-term care settings. Thus, they can enhance multidisciplinary care planning and continuity of care, and provide the most effective use of information technology (Figures 6-15 and 6-16). These standardized instruments offer the opportunity to doctors, nurses, families, advocates, administrators, and public payers to track changes in the older adults’ status across settings and over time. Each of these instruments has been developed to be rooted in care planning through a triggering system that enables the identification of the person’s problems, but also to provide quality measures, case-mix systems, and eligibility screeners. Pre- versus postimplementation comparisons have suggested an impact on the quality of care being delivered. After the implementation of the Resident Assessment Instrument for nursing home patients (now called InterRAI-LTCF) for example, evidence of advanced directives increased by 60%, the use of restraints dropped by 40% particularly among cognitively intact residents, the use of indwelling catheter dropped significantly, while there was a dramatic increase in the use of preventive skin programs. The prevalence of pressure ulcers, dehydration, and poor nutrition declined. Finally, in the postimplementation phase, the hospitalization rate declined by 25% with no increase in mortality.

The instruments have also been adopted by 11 states in the United States, primarily for their home- and community-based (waiver) programs, where compatibility with the nursing home system has been crucial. When systematically collected in large databases, data from these standardized assessment instruments can help identify both individual and organizational level predictors of patients’ outcomes and to evaluate the overall system of care.

InterRAI systems have been adopted nationwide in Iceland, Finland, and Estonia (both home care and nursing home); Switzerland and Hong Kong (home care), Japan (one of three recommended home care systems), and a major trial of the new suite is scheduled for a pilot in China, to name a few.

## Experiences with InterRAI

**Ontario’s Experience** Canada is the nation most advanced in adopting InterRAI instruments. It has designated three of the InterRAI instruments as national standards (home care, nursing home care, mental health) and is testing others in several communities (Figure 6-17). The province of Ontario, Canada, has made several steps forward in establishing an integrated health information system based on the InterRAI instruments. Complex continuing care hospitals/units were mandated in 1996 to use the Resident Assessment Instrument (now InterRAI-LTCF). By 2002, the RAI-Home Care (now InterRAI-HC) was mandated for all home care clients expected to be on service for 60 days or more. Case managers in single point entry agencies known as Community Care Access Centers (CCACs) now use the RAI-HC to assess needs and to contract services for home care clients. In 2005, the RAI-Mental Health (InterRAI-MH) was mandated for use in all adult in-patient beds in psychiatric hospitals/units, including acute, long stay, forensic, and

geriatric psychiatry. Implementation of the Resident Assessment Instrument is currently underway for all long-term care facilities in the province, including for-profit and not-for-profit homes. Implementation of the InterRAI Contact Assessment (InterRAI CA) began in 2006, and it currently is used to determine (1) the need for comprehensive assessment with the RAI-HC; (2) urgency for initiation of services such as nursing or personal support, and (3) need for a referral for rehabilitation. The InterRAI CA will also be used as the basic assessment for short-stay home care clients with relatively uncomplicated care needs.

The use of InterRAI assessment instruments for each of these sectors has brought Ontario closer than many jurisdictions to the possibility of an integrated health information system, linking the major providers of health services to frail elderly people. The Canadian Institute for Health Information has established three national reporting systems to provide comparative reports on continuing care, home care, and mental health (see, for example, report on facility-based continuing care).

Many factors have contributed to the progress that Ontario has made to date, including strong leadership at all levels of the health care system; effective collaboration between key stakeholders; a clear commitment to standardization based on psychometrically sound

data and the establishment of an infrastructure to capture, compile, and report on the gathered data.

**European Union Experience** The “Aged in Home Care” (ADHOC) study (funded with a large grant from the European Union) was aimed at analyzing and comparing different models of home care for older persons in 11 European countries: the Czech Republic, Denmark, England, Finland, France, Germany, Iceland, Italy, the Netherlands, Norway, and Sweden. In each country, distinct municipalities providing formal home care services that were considered representative of the nation’s urban areas were selected. The cities chosen were Amsterdam (the Netherlands), Copenhagen (Denmark), Helsinki (Finland), Oslo (Norway), Prague (Czech Republic), Reykjavik (Iceland), Stockholm (Sweden), Amiens (France), Ashford and Maidstone (UK), Monza (Italy), and Nuremberg and Bayreuth (Germany) (Figure 6-18).

Thousands of home care clients were assessed three times in one year in the 11 cities with the InterRAI Home Care instrument and a structured questionnaire on services’ characteristics (the European-Home Care Service [EU-HCS]) was created to capture basic structural characteristics and delivery of these different home care services.

**SECTION F. PSYCHOSOCIAL WELL-BEING**

**1. SOCIAL RELATIONSHIPS**  
*[Note: Ask person, direct care staff, and family, if available]*  
 0. Never  
 1. More than 30 days ago  
 2. 8 to 30 days ago  
 3. 4 to 7 days ago  
 4. In last 3 days  
 8. Unable to determine

a. Participation in social activities of long-standing interest

b. Visit with a long-standing social relation or family member

c. Other interaction with long-standing social relation or family member—e.g., telephone, e-mail

**2. SENSE OF INVOLVEMENT**  
 0. Not present  
 1. Present but not exhibited in last 3 days  
 2. Exhibited on 1-2 of last 3 days  
 3. Exhibited daily in last 3 days

a. At ease interacting with others

b. At ease doing planned or structured activities

c. Accepts invitations into most group activities

d. Pursues involvement in life of facility—e.g., makes or keeps friends; involved in group activities; responds positively to new activities; assists at religious services

e. Initiates interaction(s) with others

f. Reacts positively to interactions initiated by others

g. Adjusts easily to change in routine

**3. UNSETTLED RELATIONSHIPS**  
 0. No 1. Yes

a. Conflict with or repeated criticism of other care recipients

b. Conflict with or repeated criticism of staff

c. Staff report persistent frustration in dealing with person

d. Family or close friends report feeling overwhelmed by person's illness

e. Says or indicates that he/she feels lonely

**4. MAJOR LIFE STRESSORS IN LAST 90 DAYS—**  
*e.g., episode of severe personal illness; death or severe illness of close family member / friend; loss of home; major loss of income/assets; victim of a crime such as robbery or assault; loss of driving license/car*

**SECTION F. PSYCHOSOCIAL WELL-BEING**

**1. SOCIAL RELATIONSHIPS**  
*[Note: Whenever possible, ask person]*  
 0. Never  
 1. More than 30 days ago  
 2. 8 to 30 days ago  
 3. 4 to 7 days ago  
 4. In last 3 days  
 8. Unable to determine

a. Participation in social activities of long-standing interest

b. Visit with a long-standing social relation or family member

c. Other interaction with long-standing social relation or family member—e.g., telephone, e-mail

d. Openly expresses conflict or anger with family or friends

e. Fearful of a family member or close acquaintance

f. Neglected, abused, or mistreated

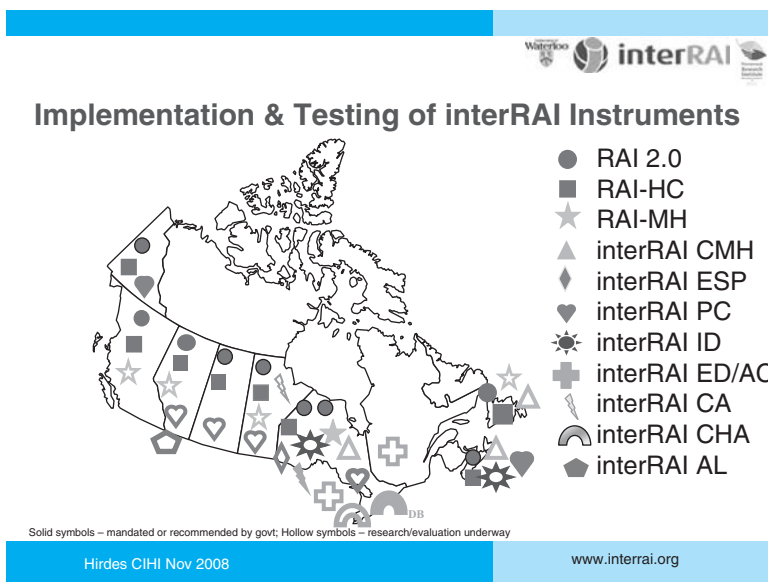

**2. LONELY**  
*Says or indicates that he / she feels lonely*  
 0. No 1. Yes

**3. CHANGE IN SOCIAL ACTIVITIES IN LAST 90 DAYS (OR SINCE LAST ASSESSMENT IF LESS THAN 90 DAYS AGO)**  
*Decline in level of participation in social, religious, occupational or other preferred activities*  
**IF THERE WAS A DECLINE, person distressed by this fact**  
 0. No decline  
 1. Decline, not distressed  
 2. Decline, distressed

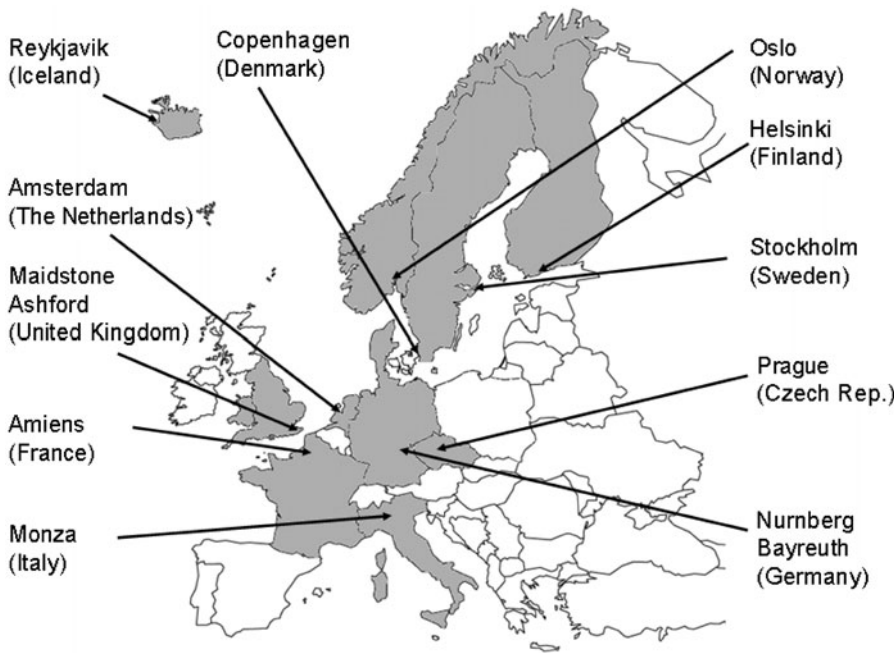

**4. LENGTH OF TIME ALONE DURING THE DAY (MORNING AND AFTERNOON)**  
 0. Less than 1 hour  
 1. 1-2 hours  
 2. More than 2 hours but less than 8 hours  
 3. 8 hours or more

**5. MAJOR LIFE STRESSORS IN LAST 90 DAYS—**  
*e.g., episode of severe personal illness; death or severe illness of close family member / friend; loss of home; major loss of income / assets; victim of a crime such as robbery or assault; loss of driving license/car*  
 0. No 1. Yes

**FIGURE 6-16.** Distinctions across InterRAI instruments: assessment of psychosocial well-being in InterRAI-LTCF and InterRAI-HC. (Source: www.interrai.org.)

**FIGURE 6-17.** Implementation and testing of InterRAI instruments in Canada. (Source: www.interrai.org.)

**FIGURE 6-18.** Geographic distribution of countries participating in the AdHoc Study.

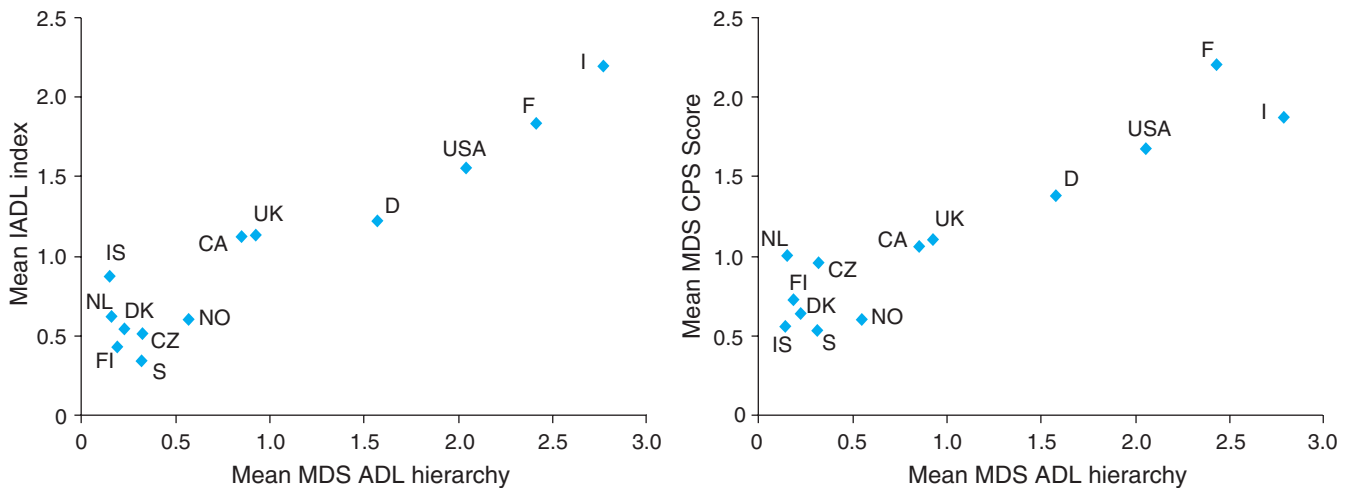

The AdHoc study also offered the opportunity to compare characteristics of care recipients in home care services in countries across Europe. For example, Figure 6-19 shows the functional and cognitive characteristics of patients receiving home care in European countries (participating to the AdHoc study) with those of other countries adopting the same instrument.

Functional status was measured by the seven-point ADL hierarchy and three-point IADL index based on meal preparation, medication management, and phone use (higher scores meaning more severe impairment). Cognitive status was measured using the seven-point Cognitive Performance Scale (CPS) (higher scores meaning more severe impairment). As shown in Figure 6-19, home care patients living in northern Europe present lower rate of functional and cognitive impairment compared to those living in south-

ern Europe (France and Italy), where home care recipients are very dependent. Patients in United States present a level of functional and cognitive impairment that resemble home care recipients in France and Italy much more than the United Kingdom, for example. Conversely, Canada presents a situation that is undistinguishable from that of United Kingdom.

### CONCLUSION

In 1950, there were 205 million persons aged 65 years or over throughout the world. Fifty years later, the number had increased threefold to 606 million. By the year 2050, the number of older persons in the world will exceed the number of persons aged 5 years

**FIGURE 6-19.** Relationship between mean MDS HC IADL index and mean MDS ADL hierarchy score by country (left panel); Relationship between mean MDS cognitive performance scale (CPS) and mean MDS ADL hierarchy by country (right panel). Data for European countries are from the AdHoc study. Data for United States are from Michigan MI Choice Waiver (home- and community-based services) in year 2005. or less for the first time in history to reach nearly 2 billion. The older population is growing faster than the total population in practically all regions of the world, and the difference in growth rates is increasing.

However, the more developed countries are in general in a more advanced stage of the demographic transition. The proportions of older persons in those countries, therefore, will remain significantly

higher than the proportions in the less developed regions well into the twenty-first century (Figure 6-20).

In contrast with the slow process of population aging experienced in the past by most countries in the more developed regions, the aging process in most of the less developed countries is taking place in a much shorter period of time, and it is occurring on relatively larger population bases. As a result, the number of older people is increasingly larger in the less developed countries. Over the last century, the number of older adults increased globally by an average of 8 million persons every year. Of this increase, 66% occurred in the less developed countries. Over the next half century, this trend will intensify. In the more developed countries, the number of older adults will increase by about 70%, from 231 million in 2000 to 395 million in 2050. In contrast, in the less developed countries, the population aging will more than quadruple from 374 million to 1.6 billion. By 2050, nearly four-fifths of the world’s older population will be living in the less developed countries (Figure 6-21).

This chapter has highlighted that even the richest countries in the world found themselves totally unprepared to confront the demographic changes. There is an extreme heterogeneity of the organization that each country has given to their respective health care services, and a substantial fragmentation into an array of services of unproven efficacy and efficiency. If this experience does not inform the policy decisions of the countries where most of the older adults will live in the future, it is highly foreseeable that there will be tremendous challenges for government and private spending in health care and, more generally, for economic growth and welfare.

One possible solution is to develop a more integrated and interdisciplinary care models of elderly services. The transition to this model will require a major reorganization of health care from education through delivery systems. Standardized assessment instruments that allow a cross-talk among different health care services

**FIGURE 6-21.** Population (in millions) aged 65 yrs and older for developed and developing countries by age: 2000–2050. (Reprinted with permission from U.S. Census Bureau, *Current Population Reports: 65+ in the United States*.)

can facilitate this transition to interdisciplinary care models, determine appropriate services based on need, and evaluate effectiveness and efficiency of specific services. Experiences in every country should inform practice and policy in other countries. Aging is a global issue.

# Psychosocial Aspects of Aging

Richard Schulz ■ Steven M. Albert

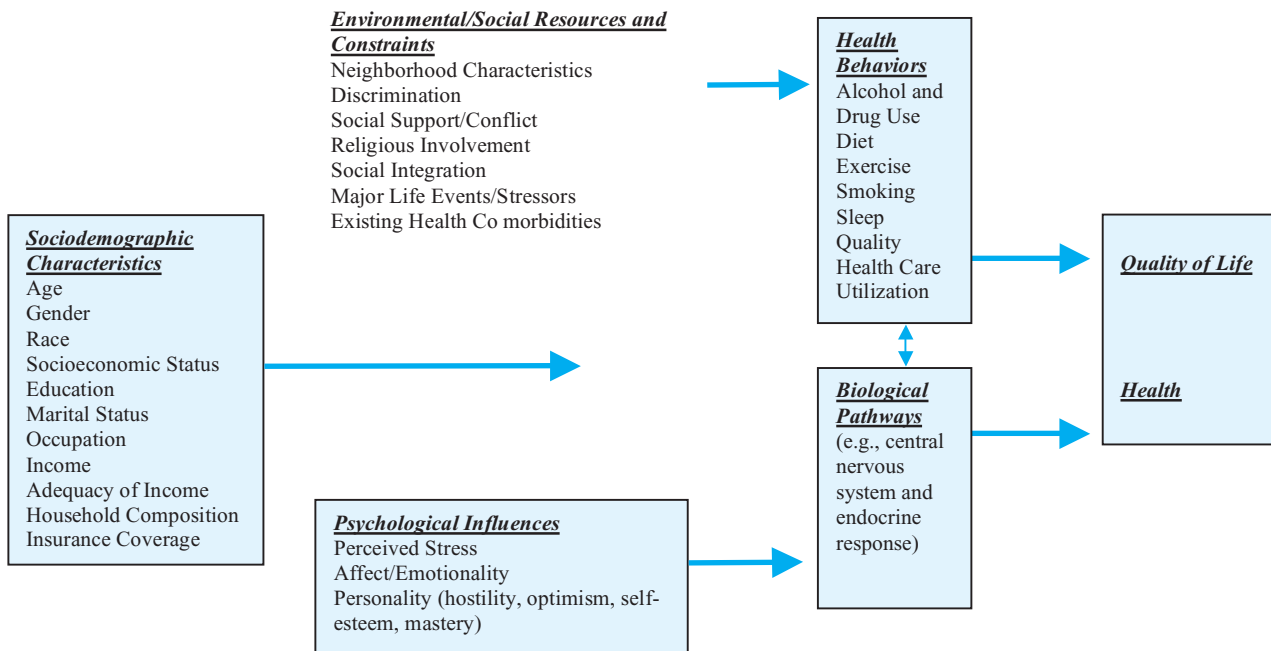

Understanding the role of psychosocial factors in late life requires a high-altitude view of human development to identify the basic biological and social forces that fundamentally shape the development of the person and the ways in which they respond to life challenges. These forces are typically viewed as constraints and can be briefly summarized in four propositions.

1. Biological development follows a sequential pattern. Although there is considerable interindividual variability in biological development, the overall biological resources across the life span resemble an inverted U-function. During childhood and adolescence, cognitive and physical abilities increase and provide the basis for the development of complex motor and cognitive skills. Physical development plateaus during early adulthood and then later declines. In old age, declines in both physical and cognitive functioning are evident.
2. Societies impose age-graded sociostructural constraints on development. Life span psychologists and life course sociologists emphasize that all societies can be characterized as having age-graded systems, which constrain and provide a scaffold for life course patterns. These patterns provide predictability and structure at both individual and societal levels. A prototypical case is childbearing in women, which is shaped by both social institutions and biological constraints.
3. Life is finite. Whatever is to be achieved or experienced in life has to be done in a limited period of time, typically less than 80 years. At any given point in an individual's life, the anticipated amount of time left to live may shape behavior and affect in important ways.
4. Genetic endowment is a limiting factor on the biological and behavioral functioning of the individual. Although the potential behavioral repertoire of humans is vast, the capacity to achieve extraordinary levels of functioning in a given domain is often constrained by the genetic makeup of the individual.

This view of development emphasizes that accumulated resilience or adaptive capacity of individuals will vary as function of the individual's location in the life course. For example, the biological and physical reserves of an individual will generally be greater for persons in young adulthood than for persons in old age. Conversely, behavioral resources and psychological reserves may be greater at older ages because of accumulated life experiences, acquisition of skills, and increased knowledge. In addition, a given stressor will likely activate different psychological and behavioral processes in varying intensities as a function of the individual's location in the life course. Finally, because of fundamental changes in age-related biological functioning, the type and intensity of biological pathways activated by stressful encounters as well as the manifestation of overt disease will vary substantially as a function of the individual's location in the life course.

## PSYCHOSOCIAL FACTORS, HEALTH, AND QUALITY OF LIFE

The number of topics that could legitimately be included in a discussion of psychosocial aspects of aging is vast. Work, retirement, migration, sexuality, stress, widowhood, emotionality, mental health, social support, and friendship are just a few of the domains that might be discussed within a psychosocial framework, and many of these topics are covered in other chapters of this book. The focus here is on psychosocial factors linked to health and quality of life. A broad conceptual framework identifying key psychosocial factors is presented in [Figure 7-1](#). At the far left, the model identifies a broad array of *sociodemographic characteristics*, which directly and indirectly shape individual development, quality of life, and health throughout the life course. For example, many of the health disparities in our society have been linked to socioeconomic status, race, and gender. *Environmental and social resources and constraints* include multiple indicators known to affect health outcomes, including

**FIGURE 7-1.** Psychosocial factors, health, and quality of life.

physical and social characteristics of the environment people live in. Discrimination, negative life events, and existing comorbidities can be major sources of constraint, while religious involvement and social support are often important protective resources (Figure 7-1).

*Psychological influences* include both positive and negative factors, including optimism, self-esteem, mastery, and control. Negative affect, such as depressive symptoms and perceived stress, affect health through their impact on behaviors and through biological pathways. The effects of psychological and social/environmental factors on health are often mediated through *health behaviors* and through *biological pathways* such as the central nervous system and endocrine response. Although there is still considerable debate regarding the causal links between these groups of variables, there is strong consensus that they are important contributors to health and quality of life. A detailed review of all of the variables identified within this model is beyond the scope of this chapter and would be redundant with other chapters in this volume. Thus, the goal here is to highlight core psychosocial factors and mechanisms linked to health and well-being. Specifically, the discussion that follows focuses on four psychosocial domains—social relationships, stress, personality and affect, and quality of life—that are critical to understanding aging and health.

## SOCIAL RELATIONSHIPS

Maintaining social relationships is critical to promoting psychological and physical well-being in late life. Involvement in satisfying social relationships has been linked to decreased risk of cardiovascular disease, functional decline, and mortality. Social interactions and companionship also contribute to emotional well-being, life satisfaction, and happiness. Although the impact of social relationships on well-being is predominantly positive, there are circumstances when social relationships can be detrimental to the older individual. Thus, there is interest in determining which aspects of social relationships

are beneficial (and which are not) as well as the specific mechanisms by which they contribute to positive or negative health outcomes.

Three aspects of social relationships are typically identified: (1) *structural support*, often referred to as social integration or social connectedness, focuses on the quantity and types of social ties an individual has, (2) *social support* refers to the tangible or intangible benefits that people receive through social ties, and (3) *negative support* refers to the detrimental effects of social relationships.

*Structural support* is typically measured by counting the number and types (e.g., spouse, partner, friend, church member) of individuals in one's social network as well as the frequency of contact between members of the network. Numerous studies have shown that older individuals with more network ties are less likely to develop cognitive and physical disability, after controlling for baseline health and functional status characteristics. Other studies have shown slower rates of decline in functioning as well as longer survival among individuals with larger social networks and more frequent contact with network members. Put another way, low levels of social integration (i.e., social isolation) are a major risk factor for mortality, independent of traditional biomedical and other behavioral risk factors. The mechanisms responsible for the beneficial health effects of social integration have not been definitively established. Candidate mechanisms include improved health behaviors resulting from the positive influence of friends and relatives, reduced exposure to external stressors, a stronger sense of coherence and self-esteem, and improved biological resilience.

*Social support* typically identifies perceived support and received support, including four different types of support provided. Perceived support is the perception that support is available if needed, and received support refers to support that has actually been provided. The four types of support are as follows: (1) instrumental support, which refers to tangible goods and services such as financial assistance, help with self-care tasks; (2) informational support, which is defined as the provision of advice, information on how to solve problems, or guidance; (3) emotional support, which

includes the provision of love, caring, and other positive feelings; and (4) appraisal support, which includes feedback given to help individuals evaluate themselves or a particular situation they may be struggling with. Although distinctions among the last three types of support are sometimes difficult to make in practice, they are useful in helping to understand what types of support are more or less beneficial under what circumstances. For example, emotional support has been shown to be particularly beneficial to promoting psychological well-being and cognitive and physical functioning. A number of mechanisms have been proposed to explain the beneficial effects of support including provision of needed material resources and services (instrumental support), reduction of the perceived severity of life stressors (appraisal support), or improvement of coping skills (informational or emotional support).

On the whole, the benefits of social relationships far outweigh their occasional *detrimental effects*. Nevertheless, interactions with network members are not always positive and may include criticism, neglect, demands, and other insensitive behaviors that negatively affect health and well-being. At the extreme, close network members may abuse their elderly relative with threats, economic exploitation, or physical harm. Close friends and relatives may also provide support that is well-intentioned but backfires, resulting in worse, rather than better, health outcomes. For example, receiving help with self-care tasks has been linked to disability onset and progression among originally high functioning older adults. Network members who are overprotective and provide too much support may foster dependency in older adults, leading to reduced physical activity and accelerated physical decline. Overprotection may also erode an older adult's confidence in being able to care for oneself, threaten feelings of autonomy, independence, and overall well-being.

Despite the potential for detrimental effects of social relationships, satisfaction with social relationships tends to be high in late life, even though social networks become somewhat smaller, and interactions with network members become less frequent. One reason is that older adults manage their social relationships to maximize positive support and companionship, and minimize relationships that are conflictual and difficult.

## STRESS AND DISTRESS

Stress is the nonspecific result of a demand upon the body. It is a common pathway for a variety of physical, cognitive, and emotional challenges. The stressed person will experience adverse physiologic effects (primarily in the pituitary–adrenal axis and immune system) but also clinically appreciable effects on decision-making, problem-solving, vigilance, social inference, and perceptual and motor skills. In this case, stress, a normal feature of an individual's interaction with the environment, becomes distress, prolonged stress that overwhelms physiologic and psychologic regulatory mechanisms. Some research suggests that prolonged stress may even affect the rate of aging, as measured by telomeric shortening over successive cell replication cycles.

In older people, stress from health limitations and consequent social losses becomes more common. The rising prevalence of chronic disease and disability, increased awareness of cognitive or physical limitation, loss of valued social roles, and reduction in social networks through widowhood and loss of friendships all act as stressors that increase the risk of negative mental and physical states. The adverse effects of stress are lower for those who have strong social

support systems and greater personal resources, but repeated losses in multiple domains may ultimately lead to the sense that one has lost control generally. Yet a robust finding from a variety of research settings is that older adults are able to maintain a sense of control even in quite challenging health circumstances. The elderly patient unable to leave home or nursing home floor may station herself in a strategic position to retain a view of activity and encourage social interaction. The elderly patient unable to ambulate in his home may sit in a chair by the window that affords the clearest view of what is happening outside the home. In these ways, older people with poor health and threats to autonomy or control may yet retain some command over features of their living space.

## STRESSFUL LIFE EVENTS

Stressful life events have been linked to poor mental and physical health in individuals of all ages. Researchers interested in the relationship between stress and health have generally pursued two strategies to assess life stressors. Major life events such as illness and death of a loved one can be assessed using checklists or interviews to gauge their frequency and intensity. Alternatively, the ordinary hassles of day-to-day living (e.g., cooking, housework, work load, meeting deadlines, home repair, etc.) can be measured with structured self-report or interviewer-administered instruments. Older individuals, when compared to younger persons, experience fewer life events overall, although they experience more loss events, particularly those associated with declining health and loss of friends and loved ones. Younger individuals report more hassles in domains such as finances, work, home maintenance, personal life, and family and friends, whereas older men and women report more hassles in domains reflecting social issues, home maintenance, and health. Overall, for both younger and older individuals, daily hassles are more potent determinants of physical and psychological well-being than major life stressors. Older individuals demonstrate remarkable ability to successfully adapt to major life stressors such as the loss of a loved one. One important exception to this general observation occurs when older individuals are exposed to unrelenting chronic stressors such as having to care for a spouse with Alzheimer's disease. Under such circumstances, the chronicity, intensity, and variety of stressors impinging on the caregiver can exact a high price in terms of physical and psychiatric morbidity.

However, there is considerable variability in individual response to major life stressors. The concept of *resilience*, defined as the ability to recover from or benefit from adversity, has been introduced to account for this variability. Individuals able to overcome adversity are thought to have high levels of resilience, a combination of internal personality traits such as hardiness, high self-efficacy, mastery, and optimism, along with a strong external support system. Although intuitively engaging, the empirical and clinical utility of the concept of resilience remains open to debate.

## BIOLOGICAL CONSEQUENCES OF STRESS

An important advance in recent decades is our increased understanding of the biological pathways through which psychosocial factors modulate changes in health. The field of psychoneuroimmunology focuses on linkages between psychosocial factors and nervous, neuroendocrine, and immune processes, which in turn have been linked

to health. Much of this research has focused on stress, particularly chronic stress, and associated negative affective states such as depression, anxiety, and anger, as disruptors of these biological regulatory systems. Stress may influence immunity either through direct innervation of the central nervous system and immune system or directly through neuroendocrine immune pathways. Behavioral responses to stress may also affect immunity. For example, individuals experiencing stress may smoke more, drink more alcohol, eat poorly, and sleep less, all of which may influence immune response.

Because increasing age is associated with significant alterations in the functioning of many physiological systems, including endocrine and immune systems, old age has become a fertile ground for examining the relation between stress, biological mediators, and disease. For example, family caregiving is a chronic stressor with the ability to disrupt immune and neuroendocrine function. Compared to non-caregiver older adults, older caregivers have higher antibody titers for latent viruses, poor immune control over latent viral infections, reduced responsiveness of natural killer (NK) cells to cytokine signals, slower healing of wounds, poorer antibody responses to vaccination, and higher basal cortisol levels. Physical health effects of caregiving include greater risk of infectious disease, hypertensive changes in blood pressure, increased prevalence of cardiovascular disease, and mortality. Taken together, these findings suggest a strong link between stress, biological mediators, and illness; however, few studies have demonstrated the progression from stress to biological mediators to disease in the same individuals in the same study.

## PERSONALITY, AFFECT, AND HEALTH

Personality is defined as the characteristics and attributes, and their associated behavioral patterns, which differentiate one person from another. Sometimes referred to as traits, dispositional tendencies, or fundamental human qualities, personality has long been of interest with respect to how it develops and may change across the life span. The five-factor model (FFM) of personality has been influential among gerontologists and claims that personality can be defined by five traits—openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism—that remain relatively fixed until well into old age. Other important traits include mastery or control, the belief that important outcomes in life are under one's own control, as well as traits such as optimism and hostility. Despite the relative stability over time of key traits, personality traits may continue to change during midlife and beyond in response to specific goals, opportunities, and constraints. For example, functional declines in late life may erode one's sense of mastery, extraversion, or optimism about the future.

An important emerging area of research is focused on the link between two distinct dispositional attributes and health. Enduring negative affective styles such as anger, depression, and anxiety appear to be linked to greater morbidity and mortality, and conversely positive affect is linked to lower morbidity and decreased symptoms and pain. Positive affect is also associated with increased longevity among community-dwelling elderly. For example, one study coded autobiographical writing samples collected from a group of nuns when they were in their early twenties for positive emotion words and sentences. The greater the positive affect expressed in their writing, the greater the probability of being alive 60 years later (adjusting for age and education).

Multiple mechanisms might account for the relation between dispositional affect and morbidity and mortality, including health practices such as diet, exercise, and sleep quality, biological processes such as cardiovascular reactivity, as well as the stress hormones (such as epinephrine, norepinephrine, and cortisol). Positive affect has been associated with health-relevant hormones, including increases in oxytocin, growth hormone, and endogenous opioids. Inasmuch as individuals with positive affect are typically more pleasant to be around, they may also accrue health benefits through more positive social interactions and more attentive and higher quality health care from health care providers.

An important unresolved question is whether positive and negative affect are opposite sides of the same coin or two independent factors. If positive and negative affect are simple opposites, then being high on one necessarily means being low on the other, making it difficult to know whether salutary health effects are due to the presence of positive or the absence of negative affect. However, if individuals can simultaneously experience high levels of positive and negative affect, the two constructs might be independent and each uniquely contribute to health outcomes.

## PSYCHOSOCIAL ASPECTS OF QUALITY OF LIFE AND VALUATION OF LIFE

Quality of life (QOL) includes two overlapping domains. Health-related quality of life specifies elements of daily function and well-being that change as a result of disease or therapeutic intervention. A satisfactory QOL measure in this sense allows researchers to rank different health conditions (and treatments) according to their impact on domains of health, such as mobility, independence in bathing and dressing, sensory acuity, mood, and absence of pain. The more negative the impact in these areas, the greater the quality of life impact of the health condition. Environment-based quality of life, by contrast, is not a health impact measure but rather registers the effect of personal resources or environmental factors on daily experience. Environment-related QOL domains include features of the natural and built environment (such as economic resources, housing, air and water quality, community stability, access to the arts and entertainment), as well as personal resources (such as the capacity to form friendships, appreciate nature, or find satisfaction in spiritual or religious life).

Maintaining the distinction between the two types of QOL is important. Health-related quality of life domains—patient reports of functional status, discomfort, pain, energy levels, social engagement—will track more closely with clinical measures of disease than environmental indicators. Recognizing this distinction eliminates much of the confusion about the “idiosyncrasy” of QOL ratings. However, the two types of QOL are also related in important ways. An impoverished environment (e.g., poor air quality, noise, lack of social stimulation) may affect health-related QOL. By the same token, health limitations may require environmental changes, such as reliance on assistive devices or personal assistance care, which affect environmental sources of QOL. The older adult with cognitive impairment faces threats to both dimensions of QOL: Dementia directly affects function and well-being and also forces environmental changes that may further reduce opportunities for quality in daily life.

A good test of whether a domain falls within the category of health-related QOL is whether this domain changes with successful medical treatment or change in care environment. Sample domains of this type, recorded in the Sickness Impact Profile (SIP), include ambulation, mobility, body care and movement, communication, alertness behavior, emotional behavior, social interaction, sleep and rest, eating, work, home management, and recreation. The Medical Outcomes Study (MOS SF36) identified a related set of eight domains: health perception, pain, physical function, social function, mental health, role limitation from physical causes, role limitation from mental health causes, and vitality. Others, such as the Health Utilities Index (HUI), stress still different domains, in this case a “within the skin” approach that restricts QOL to domains that are closely connected to clinical conditions.

QOL can be assessed as the difference between a population norm and mean value for patient samples, or more directly as a “utility” rating, that is, a numeric rating of how preferred (and thus how much better) one health state is relative to another. One common way to derive utilities for health states is to ask how many years of life people would be willing to give up to live without a health condition or disability.

The psychological analogue to quality of life is valuation of life. M. Powell Lawton raised this issue directly by examining psychological factors involved in people’s reports of willingness to live in impaired states of health or with poor quality of life. Valuation of life (VOL) is “the extent to which the person is attached to his or her present life, for reasons related to a sense not only of enjoyment and absence of distress, but also hope, futurity, purpose, meaningfulness, persistence, and self-efficacy.” VOL can be measured by reports of hope, the sense that life has meaning, and continued commitment to personal projects, that is, goal-driven activity. Valuation of life is an independent correlate of the wish to live even when we adjust for many factors associated with the wish to live, such as health state, cognitive capacity, mental health, perceived quality of life, and personal mastery. Valuation of life is a significant independent correlate of the wish to live under a great range of severe health limitations, including states of mobility impairment and severe pain, but not in the case of dementia or nursing home residence. It may be that perceived meaningfulness and purpose in life do not lead to the wish to live at any cost.

However it is measured, health-related QOL declines with age. This is a central, inescapable consequence of the increased prevalence of chronic disease with greater age and the effects of senescent changes in many physiologic domains. Older people adjust their daily lives to accommodate these decrements, and adjustment strategies may reduce the effects of such decrements on health-related QOL. Still, cross-sectional studies show strong declines in health-related QOL with increasing age. Valuation of life may not show so clear a pattern, but there is limited data on VOL over the life course. Investigations in this area will be important to help clarify decision-making at the end of life. A key issue is whether the wish for a shorter life is an expression of discouragement based on depression, or whether it is an expression of discouragement based on a judgment that life no longer has intrinsic value because impaired health does not allow meaning, purpose, or desired personal projects.

In contrast to health-related QOL, environment-related QOL may remain high throughout life and may even improve with greater age. With retirement, for example, older people have greater leisure time; and with children gone, houses paid for, and successful invest-

ments, they may have greater disposable income as well. As a result, older people have increased opportunities to develop interests and create satisfying environments. These freedoms and opportunities counterbalance declines in health-related QOL and may be responsible for the great resiliency older people show in the face of declining health.

## CONCLUSION

This chapter has described how psychosocial factors are critical contributors to the health and quality of life of older individuals. The chapter has focused on those factors that appear to be most promising in terms of explaining variability in health outcomes using a broad conceptual model that shows how psychosocial factors sequentially contribute to behaviors and biological processes linked to illness and quality of life. Although there is still much work to be done, one of the significant advances of the last decade is research showing how psychosocial factors get under the skin to affect the physiology and functioning of the organism. Continued advances in mind–body science along these lines will further enhance understating of the relationships between biology and psychology and will provide new opportunities for intervention.

A second theme of this chapter is the remarkable resilience of older individuals. Despite significant declines in multiple functional domains in late life, most older individuals adapt well to the challenges they face and maintain a high quality of life. This strength reflects finely tuned adaptive mechanisms that maximize the ability to cope with major life challenges.

A third and final theme is the importance of viewing aging in a life course context. No one is born old, and to be old means that one has accumulated experience, knowledge, social relationships, as well as physiological vulnerabilities. Understanding old age requires that we pay close attention to these factors in order to unravel the complexities of how life experiences contribute to functioning and development in late life.

# General Principles of Pharmacology

Sarah N. Hilmer ■ Gary A. Ford

## INTRODUCTION

The use of drug therapy in elderly individuals has increased substantially in recent years driven by increased numbers of older adults, the results of clinical trials including older adults, and a less nihilistic approach to therapy in this age group. As a consequence, the majority of drug therapy is prescribed to older adults. An understanding of the principles of pharmacology and appropriate application to the individual older person is necessary for all those who develop, regulate, and prescribe and monitor drug therapies in older adults. A further challenge is the need to optimally individualise drug therapy in older adults who constitute a very heterogeneous group ranging from healthy, fit community dwelling individuals taking no regular medication to frail institutionalized individuals with multiple comorbidities and polypharmacy.

When prescribing for older patients, it is important to consider pharmacokinetic and pharmacodynamic changes observed in normal aging, the likely effects of the individual's genetics and intercurrent disease, as well as evidence for therapeutic efficacy, and safety and the patient's total exposure to medications. In this chapter, we begin by describing the changes in pharmacokinetics and pharmacodynamics associated with aging and frailty. We then discuss adverse drug reactions and relevant issues in drug development, regulation, and pharmacoconomics.

## PHARMACOKINETICS

Pharmacokinetic processes determine the relationship between drug input (dose, dosage form, frequency, route of administration) and the concentration of drug achieved over time. The major components of pharmacokinetics are bioavailability, distribution, and clearance. While changes in many of these parameters have been described with aging, the most consistent and marked change in pharma-

cokinetics in older adults is the increase in interindividual variability.

### Bioavailability

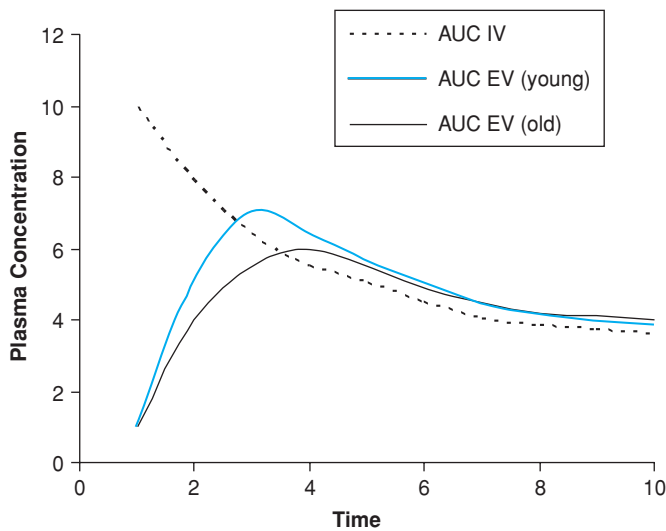

Bioavailability ( $F$ ) is the proportion of drug reaching the systemic circulation after administration. Bioavailability depends on the route of administration, the chemical properties of the drug, the absorption of the drug, and the amount of drug that is cleared (first pass loss) before reaching the systemic circulation. Bioavailability of drugs administered by the intravascular route is 100% by definition, and is not affected by aging. Factors that influence bioavailability of medications for common extravascular routes of administration, and any known changes that occur with aging, are shown in [Table 8-1](#). Bioavailability is the ratio of the area under the concentration–time curve (AUC) when the drug is given extravascularly to that when it is given intravenously ([Figure 8-1](#)). Bioavailability ( $F$ ) is expressed as a fraction or percentage:

$$\text{Bioavailability } (F) = \frac{\text{AUC}_{\text{ev}}}{\text{AUC}_{\text{iv}}}$$

The bioavailability of a drug given extravascularly can vary with age. As shown in [Figure 8-1](#), with aging, absorption is often slower so the maximal plasma concentration is reached later (longer  $T_{\text{max}}$ ) and is lower (lower  $C_{\text{max}}$ ). However, the extent of absorption is usually complete in older adults so the area under the curve (bioavailability) is not affected. Drugs that require an acidic environment for absorption, such as ketoconazole, ampicillin, and iron, may have a reduced extent of absorption in the 5% to 10% of older adults with age-related hypochlorhydria secondary to atrophic gastritis, and in those taking medications that raise gastric pH such as H<sub>2</sub>-antagonists and proton pump inhibitors. In the case of oral administration where the medication undergoes first pass metabolism, which is often decreased in older adults, the area under the curve (bioavailability) may be increased.

**TABLE 8-1****Factors Associated with Bioavailability of Drugs Administered Through Common Extravascular Routes and Description of Age-Related Changes**

ROUTE	PROPERTIES OF DRUG	ABSORPTION		FIRST PASS CLEARANCE	
		Description	Age-Related Changes	Description	Age-Related Changes
Oral	Particle size formulation Lipid solubility Ionization	Gut lumen decomposition	Gastric pH may be less acidic, altering ionisation	Gut wall CYP450 metabolism	Not known
		Passive absorption	Complete but slower – Increased by longer gastrointestinal transit time and possible increase in permeability of epithelium – Decreased by reduced perfusion	Hepatic metabolism	Reduced 30–50%
		Active transport (e.g., iron, vitamin B-12)	Probably decreased		
		Gut wall P-glycoprotein transports drugs back into lumen	Not known		
Sublingual	Particle size Lipid solubility Potency	Rapid into blood vessels at base of tongue	Not known ?Reduced perfusion	Nil	
Rectal (local and systemic action)	Lipid solubility Ionisation	Varies with rectal contents	Not known ?Reduced perfusion	Nil	
Subcutaneous Injection	Particle size (small particles absorbed by capillaries, large particles absorbed by lymphatics) Protein complex pH Use of vasoconstrictors	Slow	Not known ?Reduced perfusion ?Changes to lymphatics	Nil ?Proteolysis of protein drugs in lymph nodes	
Intramuscular Injection	Lipid solubility Particle size (small particles absorbed by capillaries, large particles absorbed by lymphatics)	Slow (faster than subcutaneous due to better perfusion)	Not known ?Reduced perfusion ?Changes to lymphatics	Nil ?Proteolysis of protein drugs in lymph nodes	
Percutaneous	Lipid solubility	Slow Heat dependent	Not known ?Reduced perfusion	Nil	
Intranasal (local and systemic)	Lipid solubility	Variable	Not known ?Reduced perfusion	Nil	
Inhaled (local and systemic)	Particle size – Powders – Aerosol solutions inhaler (type and how used) Gases: gas partition coefficient (blood)	Minimal systemic absorption	Not known ?Effects of reduced alveolar area, low-grade inflammation, ventilation/perfusion mismatch, decreased diffusion and transport across alveolar capillary membrane	Lung metabolism and clearance	Not known
Ophthalmic (topical)	Formulation: drops, suspensions, ointments	Minimal (drainage through nasolacrimal canal)	Not known	Nil	

**FIGURE 8-1.** Theoretical plasma concentration–time curves for the same drug given intravenously (IV) and extravascularly (EV). The bioavailability is the ratio of the area under the curve (AUC) for the EV route to the AUC for the IV route. The intravenous AUC is not affected by age. With aging, the extravascular curve shows delayed and lower maximal plasma concentration and AUC may be increased for drugs that undergo first pass hepatic metabolism.

Bioavailability defines the dose adjustment between intravenous and extravascular drug administration. Lower bioavailability drugs require higher doses when given extravascularly than intravenously. Reduced first pass hepatic metabolism in older adults results in a lower dose requirement for oral active drugs that undergo hepatic clearance. Examples of prodrugs, which are administered as inactive compounds that must be metabolized into the active drug, include codeine, propranolol, enalapril, perindopril, and simvastatin. In older adults, there may be a higher dose requirement for prodrugs to obtain the same AUC for the active drug (metabolite) as in a young person.

The effects of aging on bioavailability of modified release oral formulations are not known. Modified release oral formulations tend to be released for absorption lower in the gastrointestinal tract. In young adults, cytochrome P450 3A4 (CYP 3A4) has the highest content in the duodenum, followed by the jejunum, ileum, and colon. Drugs released lower in the gastrointestinal tract undergo less gut wall metabolism, increasing their bioavailability. Expression of CYP 3A4 in the gut wall has not been studied in aging. The activity of the transporter, P-glycoprotein (P-gp), which pumps drugs from the enterocytes back into the gut lumen, has its highest concentration in the ileum, followed by the colon, jejunum, and duodenum. Therefore, modified release formulations, released lower in the gastrointestinal tract, may undergo less P-gp efflux back into the gut lumen, increasing their absorption. There is no change in expression of P-gp in intestinal microsomes in aged rats; it is not known how intestinal wall transporter activity varies with age in humans. The combination of modified release medications, the possibility of less gut wall metabolism lower in the gastrointestinal tract and slower transit time with aging may increase drug bioavailability in older adults, although the different formulations of modified release medications may be differentially affected by age. Some formulations rely on pH to dissolve an external coat and may be affected by higher gastrointestinal pH in some older adults. Others have a

constant drug delivery rate independent of pH or gastrointestinal motility and may be less affected by changes of aging.

## Distribution

Volume of distribution ( $V_d$ ) is the apparent volume that the drug distributes into to achieve the plasma concentration ( $C_p$ ).  $V_d$  is not a real anatomical volume.  $V_d$  may exceed the total real volume of the human body when there is significant binding to tissues.  $V_d$  is expressed by the equation:

$$V_d = \frac{\text{Amount of drug in body}}{C_p}$$

The amount of drug in the body is known immediately after a known dose of the drug has been given intravenously, before it can be eliminated. Therefore,  $V_d$  can be calculated in humans from the dose given intravenously and the  $C_p$  immediately after administration.

The volume of distribution of a drug depends on plasma protein binding, lipid to water partition coefficient, tissue binding properties, and transporters. The main determinant of volume of distribution is the ratio of the strength of binding to plasma proteins to the strength of binding in tissues. Drugs that are bound more strongly to plasma proteins have a smaller  $V_d$ , and those that are bound more strongly to tissues have a larger  $V_d$ . Some examples include heparin and warfarin, which are highly plasma protein bound, and have  $V_d$  of 5 and 8 L, respectively, similar to blood volume. Digoxin is water-soluble but highly bound to muscle, with a  $V_d$  of 15 L. Imipramine is lipid soluble and has a  $V_d$  of 2100 L, which is far greater than the 42 L real volume of a 70 kg human. Alendronate adheres strongly to the bone surface, and has a  $V_d$  of 2580 L. The major determinants of  $V_d$  and how they are affected by normal aging are shown in Table 8-2.

The immediate volume of distribution is blood volume. Then the drug is distributed from the blood into various tissues at a rate that depends on the perfusion of the tissue, the ease with which the drug can pass through lipid membranes of cells and any active transport. Membrane permeability and passive transport may increase with age and malnutrition. The effects of aging on active transport is not well documented in humans, and in rats, varies between tissues, with an increase in P-glycoprotein expression and activity in the liver and lymphocytes, but not in the intestine or endothelium, with aging. With aging, the volume of distribution of verapamil (a substrate of P-glycoprotein) in the brain increases, consistent with dysfunction of the blood–brain barrier. Tissue perfusion may decrease with aging, which may slow distribution, particularly to less highly perfused tissues such as muscle and fat. The rate of distribution to or from the site of action of a drug may determine the onset or offset of drug effects.

The volume of distribution determines the loading dose of a drug. The loading dose is the dose required to achieve the desired  $C_p$  as soon as possible, and is calculated with the equation:

$$\text{Loading dose} = \text{Desired } C_p \times V_p$$

There may be small changes in loading dose in older adults due to the changes in  $V_d$  described above. For example, the volume of distribution of digoxin decreases from approximately 7 to 6 L/kg with aging, probably due to reduced muscle mass and reduced binding of digoxin to muscle. Therefore, loading dose should decrease by approximately 15%.

**TABLE 8-2****Factors That Determine Volume of Distribution: Effects of Aging**

FACTOR	EFFECT ON $V_d$	AGE-RELATED CHANGES	CLINICAL APPLICATION
Plasma protein binding	Highly protein bound drugs are generally less able to cross membranes and have smaller $V_d$	Decreased albumin which binds acidic drugs, e.g., warfarin, NSAIDs, phenytoin. Increased $\alpha$ 1-acid glycoprotein which binds basic drugs, e.g., verapamil, propranolol.	Not usually clinically significant.
Tissue binding properties	Drugs which are tightly bound to tissues have large $V_d$	Changes in body composition (sarcopenia, increased adiposity) may affect $V_d$ .	Drugs bound to muscle, e.g., digoxin, have decreased $V_d$ with aging. Therefore decreased loading dose required.
Lipid: water coefficient	Lipid soluble drugs can pass through lipid membranes of cells more easily and have higher $V_d$ than water soluble drugs	Relative increase in proportion of body fat and decrease in body water (muscle mass). Therefore, higher $V_d$ for lipid soluble drugs and lower $V_d$ for water soluble drugs with aging.	Loading dose of water soluble drugs, e.g., gentamicin, digoxin, decreased with aging to avoid toxicity from high initial $C_p$ .
Transporters	Passive facilitated diffusion (move drug in same direction as concentration gradient). Active transport (use ATP to move drug against concentration gradient).	Unknown.	Drug interactions may occur at level of transporters. Passive transporters include the Organic Anion Transport Proteins (OAT-P) for benzyl penicillin, digoxin, and pravastatin. Active transporters include MDR1 (P-gp) for many cationic or neutral drugs, e.g., digoxin, macrolide antibiotics, verapamil.

## Clearance

Clearance is the rate of elimination of a drug from the body. Clearance,  $CL$ , from each organ of elimination can be defined by the equation:

$$CL = Q \times E,$$

where  $Q$  is the flow rate to the organ and  $E$  is the extraction ratio. Total body clearance is the sum of the drug clearances by each organ, and can be expressed as

$$CL_{\text{total}} = CL_{\text{hepatic}} + CL_{\text{renal}} + CL_{\text{other}}.$$

Clinically, the clearance affects the maintenance dose of medications.

### Hepatic Drug Clearance

Removal of a drug by the liver depends on portal and arterial hepatic blood flow and elimination by metabolism and/or secretion into the bile. The processes involved in hepatic clearance are shown in Figure 8-2 and changes in normal aging are shown in Table 8-3. Hepatic clearance of highly extracted substrates is determined mostly by hepatic blood flow and is known as flow-limited metabolism. This is consistently reduced in older adults. Hepatic clearance of poorly extracted substrates is described as capacity-limited metabolism because the intrinsic clearance (metabolising capacity) is the rate-limiting step and is less affected by old age. Protein binding may also affect the clearance of poorly extracted substrates. The effects of normal aging on flow-limited and capacity-limited hepatic clearance are shown in Figure 8-3.

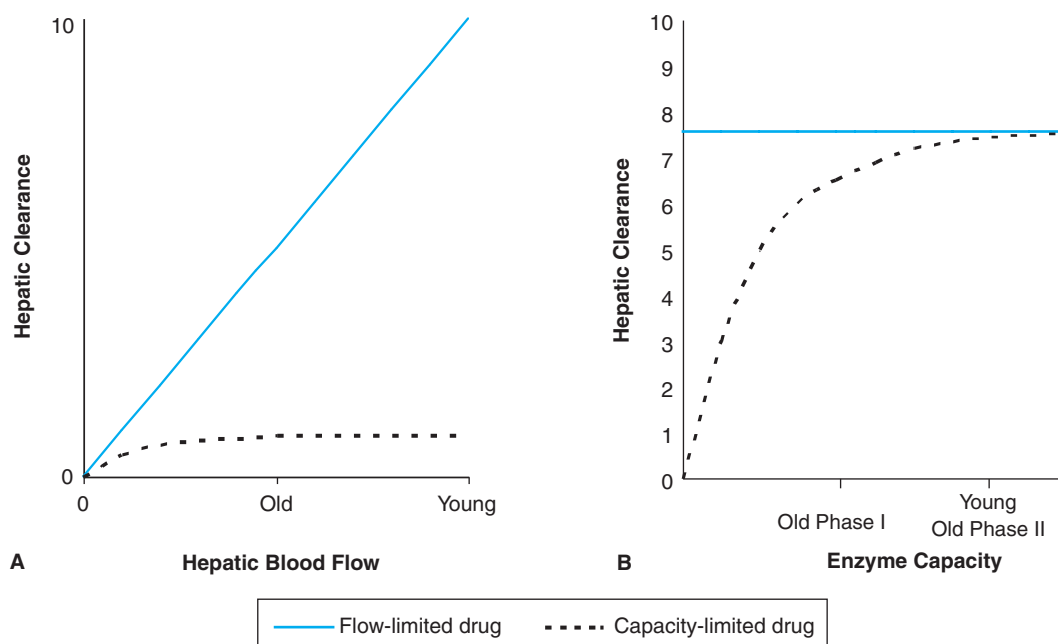

**FIGURE 8-2.** The processes involved in hepatic clearance. A, blood flow; B, protein binding; C, scavenger cells (Kupffer and Liver sinusoidal endothelial cells, LSECs); D, transfer across the LSECs and the hepatocyte apical membrane; E, metabolism; F, transport into bile ductule. Adapted from Tozer TN, Rowland M. *Introduction to Pharmacokinetics and Pharmacodynamics: The Quantitative Basis of Drug Therapy*. Lippincott Williams and Wilkins; 2006, Fig 5-17.

TABLE 8-3

## Changes in Hepatic Clearance with Aging

PROCESS OF HEPATIC CLEARANCE	DESCRIPTION	AGE-RELATED CHANGES	CLINICAL APPLICATION
Hepatic blood flow	Portal venous flow (~80%) and hepatic arterial flow (~20%)	Decreases by 30–50%	Reduced clearance by 30–50% of high extraction ratio drugs, e.g., morphine and verapamil. Less impact on low extraction ratio drugs, e.g., carbamazepine, warfarin, diazepam.
Protein binding	Only free drug is cleared. Protein binding affected by disease and competition from other drugs.	Decreased albumin: acidic drugs have higher fraction unbound and increased hepatic clearance. Increased $\alpha$ 1-acid glycoprotein: basic drugs have lower fraction unbound and decreased hepatic clearance.	Only significant for drugs that are highly protein bound (>90%) with low hepatic extraction ratios, e.g., warfarin, phenytoin, diazepam.
Scavenger cells	Kupffer cells scavenge large protein drugs. Liver sinusoidal endothelial cells (LSECs) may scavenge smaller particles.	Possible reduction in scavenger function (in animal studies).	Not known. May reduce hepatic clearance.
Transfer into hepatocyte	Transfer across the LSECs and the hepatocyte apical membrane by passive or active transport.	Structural changes in LSECs and the space of Disse may reduce transfer. Changes in hepatocyte membrane transport not known.	Not known. May reduce hepatic clearance.
Metabolism	Biotransformation to more hydrophilic metabolites that may be equally, less or more active than parent drug	Reduced phase I metabolism in vivo in normal aging by 30–50%. Phase II metabolism appears to be maintained in healthy aging, reduced in frail aged.	Probably preserved clearance of drugs that undergo capacity-limited phase II metabolism in healthy aging, e.g., temazepam, salicylic acid.
Transfer into bile ductule	Active transport into bile canaliculi. Bile enters small intestine and drug or metabolite reabsorbed (enterohepatic cycle) or excreted in faeces.	Unknown. In aged rodents, increased biliary P-glycoprotein expression and function.	Unknown.

**FIGURE 8-3.** The effects of normal aging on hepatic drug clearance. With aging, hepatic blood flow is reduced by approximately 50%, which is associated with a 50% reduction in clearance of flow-limited drugs, but has little effect on clearance of capacity-limited drugs (A). In normal aging, phase I metabolism is reduced, which reduces hepatic clearance of capacity-limited drugs metabolized by these enzymes, while phase II metabolism is probably preserved, although it may be reduced in frailty. Changes in enzyme capacity do not affect the clearance of flow-limited drugs (B).

TABLE 8-4

## Changes in Renal Drug Clearance with Aging

PROCESS OF RENAL CLEARANCE	EFFECTS OF AGE	CLINICAL APPLICATION	EXAMPLE
Glomerular filtration	Decreased GFR, extent unclear, ~10–40%	Estimates used to adjust maintenance doses of drugs for renal impairment	Gentamicin clearance correlates with Cockcroft-Gault estimates of creatinine clearance.
Tubular secretion (active)	Decreased	Reduction in renal clearance may be greater than reduction in GFR.  With polypharmacy, increase risk of drug-drug interactions through competition for transporters.	Ratio of procainamide clearance to creatinine clearance decreases with aging.  Digoxin excreted by passive glomerular filtration and active tubular secretion. Serum digoxin levels increase with number of concurrent P-gp inhibitors, e.g., verapamil, erythromycin, amiodarone, spironolactone, atorvastatin.
Tubular reabsorption (passive)	Unknown	If impaired, would reduce the effect of reduced glomerular filtration on clearance.	Changes in clearance of lithium, which, like sodium, is freely filtered at glomerulus and 80% reabsorbed in the proximal tubule, consistent with changes in GFR with aging.

Normal aging is only one of many factors that may influence hepatic clearance. For example, the hepatic clearance of flow-limited drugs may be decreased by diseases that reduce hepatic blood flow, such as heart failure, while hepatic clearance of capacity-limited drugs may be altered by other drugs that induce or block hepatic enzymes or by genetic polymorphisms.

### Renal Clearance

The majority of drug elimination occurs through the kidneys. In the kidneys, drugs and their metabolites may undergo glomerular filtration, tubular secretion, and tubular reabsorption. These processes are summarized, with descriptions of any known age-related changes and relevant examples in Table 8-4.

**Glomerular Filtration** At the glomerulus, drugs and their metabolites are passively filtered from the afferent arterioles through the glomerular membrane to produce an ultrafiltrate of plasma within the capsular space of the glomerulus. Plasma proteins and cells are too large to cross the glomerular membrane so only free drug enters the capsular space of the glomerulus. The glomerular filtration rate (GFR) is the total volume of glomerular filtrate produced per unit time by all nephrons, and is approximately 120 mL/min in a young, healthy person (~10% of total renal blood flow). In normal aging, recent estimates suggest that GFR is moderately reduced by 15% to 40%. Effective renal plasma flow (ERPF) decreases proportionally more than GFR, by ~10% per decade from young adulthood to the age of 80 years. Older adults have increased renal vascular resistance, with impaired relaxation in response to vasodilators.

Estimation of renal function in older adults is complicated by confounders. Serum creatinine is not useful because creatinine production is reduced in older adults, due to decreased muscle mass. The Cockcroft-Gault equation [6], which includes age, weight, and serum creatinine, is used clinically to estimate creatinine clearance:

$$\text{Creatinine clearance (mL/min)} = \frac{(140 - \text{age}) \times \text{weight (kg)}}{72 \times \text{serum creatinine (mg/dL)}} \times 0.85 \text{ for females.}$$

Most dosing guidelines use the Cockcroft-Gault equation to adjust doses of renally excreted drugs with narrow therapeutic indices, such as gentamicin and low-molecular weight heparin, for renal function. However, the Cockcroft-Gault equation was derived from observational data from males receiving routine medical care for a range of illnesses, and may underestimate renal function in normal aging. Much of the age-related decline in renal function may be related to disease, particularly hypertension, atherosclerosis, and heart failure, rather than normal aging.

Recently, an equation to estimate the GFR, the modification of diet in renal disease (MDRD) equation, has been introduced to clinical practice. This equation has not been validated for extremes of age or dose adjustment. Unadjusted for body surface area, in the presence of the reduced height and weight observed in normal aging, the MDRD is likely to overestimate renal clearance in older adults. A study of elderly patients in long-term care demonstrated that only one-third of patients were classified in the same stage of renal impairment by both methods, with average MDRD estimates 20 mL/min/1.73 m<sup>2</sup> higher than those determined using Cockcroft-Gault, suggesting that the methods are not interchangeable for determining drug dose. Further validation studies are required to determine the best method for clinically determining renal impairment for the purposes of adjusting drug doses. Recently, it has been suggested that renal function in older adults could be better estimated using methods independent of serum creatinine, such as Cystatin C, an endogenous polypeptide marker of renal function, which is significantly elevated in older adults. The role of this marker in clinical practice is under investigation.

Currently available methods to estimate renal function in older adults are not reliable, particularly in frail or acutely ill older adults. While the Cockcroft-Gault equation can give an estimate of renal function for dose adjustment of renally excreted drugs, the maintenance dose of drugs with narrow therapeutic indices should be guided by therapeutic drug monitoring and clinical response.

**Tubular Secretion** Drugs may also enter the renal tubules through active secretion. The unfiltered fraction of plasma and the particles too large to enter the glomerular filtrate pass through the efferent arterioles to the vessels supplying the renal tubules. The majority

of tubular secretion occurs in the proximal convoluted tubule and relies on active transport by specific pumps for anions and cations. Drugs bound to proteins or cells can undergo tubular secretion, but not glomerular filtration. These pumps are saturable and drugs may compete for transport into the renal tubule. There is a reduction in tubular secretion with aging to a similar and possibly greater extent than GFR.

**Tubular Reabsorption** Drugs that have been filtered at the glomerulus or secreted in the proximal convoluted tubule may be passively reabsorbed down the concentration gradient from the tubular fluid in the proximal and distal tubules. Reabsorption occurs for lipid-soluble drugs that are not ionized, and therefore may be influenced by the pH of the tubular fluid. Reabsorption is inversely related to urine flow rate. Changes in tubular reabsorption with aging are not well described. Proximal tubule functions are generally preserved in healthy aging, with near normal production of erythropoietin and normal sodium reabsorption in the proximal tubules. However, overall tubular function is decreased in the elderly, with impaired ability to concentrate or dilute urine maximally.

### Nonhepatic, Nonrenal Clearance

Drug metabolism through cytochrome P450 and via conjugation can occur at many sites outside the liver. The effect of intestinal cytochrome P450 on bioavailability has been discussed in the section on bioavailability and in [Table 8-1](#). Proteases and peptidases are found throughout the body and metabolise polypeptide drugs such as insulin, erythropoietin, and interferon. Circulating esterases also play a role in drug metabolism, including acetyl cholinesterase and carbonic anhydrase. Age-related changes in clearance outside the liver and kidney are not known.

### Half-Life

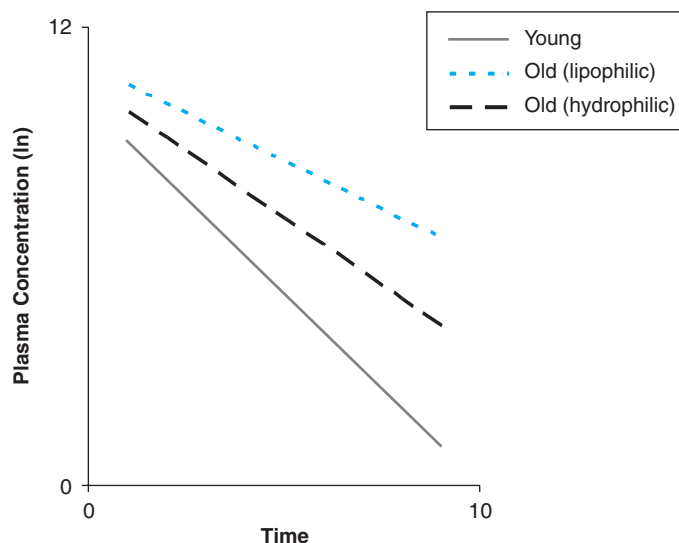

Half-life ( $t_{1/2}$ ) is the time taken to halve the amount of drug in the body (or the plasma concentration of the drug). Half-life depends on volume of distribution ( $V_d$ ) and clearance (CL), and is calculated using the following equation:

$$t_{1/2} = \frac{0.693 \times V_d}{CL}$$

The constant, 0.693, is the natural logarithm of 0.5.

A decrease in clearance, which is seen commonly with aging, results in an increase in half-life. An increase in volume of distribution, which occurs with lipid-soluble drugs with aging, would also result in an increase in half-life. Higher volume of distribution indicates that the drug is more concentrated in the tissues than the blood. Hepatic and renal clearance act on drug in the blood, so a smaller proportion of drug is eliminated with a larger volume of distribution. The theoretical effects of aging on half-life are shown in [Figure 8-4](#).

The half-life determines the time course of drug accumulation and elimination, and the choice of dose interval. When a drug is started, plasma concentration reaches >90% of steady state after approximately four half-lives. When a drug that was at steady state is stopped, plasma concentration reaches <10% of steady state after approximately four half-lives. Dose interval is usually similar to half-life to maintain steady state.

**FIGURE 8-4.** The theoretical effects of aging on half-life. The decrease in clearance with aging prolongs half-life. For lipid-soluble drugs, the increase in volume of distribution prolongs half-life further. For water-soluble drugs, the decrease in volume of distribution reduces half-life, but in most cases, the size of the effect of aging on volume of distribution is smaller than the effect on clearance, resulting in an overall increase in half-life compared to young subjects.

Changes in half-life with age will affect how long the drug takes to accumulate, to be eliminated, and the dosing interval of the drug. The increase in half-life that is observed for many drugs with aging means that it will take longer for drugs to reach steady state, longer to be eliminated after they are ceased, and dosing intervals may need to be increased.

### Summary of Pharmacokinetic Changes with Aging

An increase in interindividual variability is the main change in pharmacokinetics with aging. Of the pharmacokinetic changes seen in normal aging, reduced hepatic and renal clearance are generally the most significant, and these affect maintenance dose and dosing interval. The changes in volume of distribution are smaller, and affect the half-life of drugs (to a lesser extent than the changes in clearance do) and the loading dose. The main changes in bioavailability with aging result from reduced first pass metabolism, with increased bioavailability of drugs that undergo significant first pass hepatic metabolism and decreased activation of prodrugs. Some important examples of age-related changes in pharmacokinetics and pharmacodynamics are shown in [Table 8-5](#).

## PHARMACODYNAMICS

Pharmacodynamics describes the effects of drugs on tissues and organs often described as “what the drug does to the body.” Although the responses to a given weight-adjusted drug dose may be found to be altered in older healthy volunteers and patients, pharmacokinetic changes may account for most of the changes seen. Even when correcting for alterations in plasma drug concentrations, other modulatory neurohumoral influences may account for the altered response rather than any primary age-related sensitivity in cellular response of the relevant drug receptor.

**TABLE 8-5**

**Changes in Pharmacokinetics and Pharmacodynamics with Aging and Suggested Dose Adjustments for Older Patients**

THERAPEUTIC CLASS	MEDICATION	PHARMACOKINETICS							LOADING DOSE ADJUSTMENT	MAINTENANCE DOSE ADJUSTMENT

Most drug actions are mediated through interaction of part of the drug molecule with macromolecular components of the organism referred to as receptors. The majority of drug receptors are proteins involved in the regulation of hormones, neurotransmitters, enzymes, or transport processes. Other cellular components can also be drug targets such as nucleic acids in cancer chemotherapy. Many drug receptors are acted upon by and are highly selective for endogenous hormones or neurotransmitters. Drugs are usually either agonists at such receptors, causing activation of the receptor similar to that produced by the endogenous substance or antagonists, blocking the actions of the endogenous neurotransmitter or hormone. Most drug–receptor interactions involve reversible binding but sometimes if there is covalent binding, the interaction may be irreversible. Drug development seeks to identify target receptors that if activated or inhibited are likely to produce beneficial therapeutic effects, a process referred to as target identification. Target validation is the process where therapeutic efficacy is then demonstrated in preclinical and clinical development. In the last 20 years, a multitude of receptors have been identified through molecular cloning of expressed proteins but the biochemical, physiological, and clinical significance of most of these remains unknown. Receptor expression in cells may be modified by disease, aging, and the effect of drugs or endogenous agonists or antagonists.

The way drugs interact in reversible manner with receptors is described using a number of methods through drug receptor theory, with the maximum effect model ( $E_{\max}$ ) being one of the simplest most commonly used. This model assumes that the receptor when occupied by the drug forms a drug–receptor (DR) complex, which produces an effect and that the effect is proportional to the fraction of occupied receptors. The association and disassociation constants of the DR complex are referred to as  $k_1$  and  $k_2$  in the model and the KD ( $k_2/k_1$ ) describes the equilibrium dissociation constant for the drug–receptor complex:

When the treatment effect is expressed against the drug or agonist concentration, a rectangular hyperbolic relationship is seen. Usually drug or agonist concentration is expressed in log terms and a sigmoidal relationship is seen, which can be described by three parameters:  $EC_{50}$ , the concentration of drug at which 50% maximum drug effect occurs;  $E_{\max}$ , the maximum drug effect, and  $n$  the slope of the curve (Figure 8-5). Understanding the dose–response curve is of critical importance in early development of a drug. A low  $EC_{50}$  identifies a selective agonist, which is preferred for drugs in development as at higher concentrations all drugs become less selective and act on other receptors and proteins. A high  $E_{\max}$  identifies a drug with full agonist actions at the receptor. The steepness of the drug–receptor interaction informs the likely rate of change in response as drug concentration is increased. Depending on the individual variability in responsiveness, very steep or shallow slopes may be problematic in producing drugs for easy use in clinical practice. A key issue in drug development and in the treatment of older adults is that the  $EC_{50}$  and  $E_{\max}$  often differ substantially between individuals. Large interindividual variability in response to a drug is not necessarily a problem for a drug with a high therapeutic index, i.e., a large difference between concentrations that produce efficacy and those that produce toxicity. With such drugs, a dose that produces a high concentration that produces near maximal effect in most subjects can be chosen for clinical use. Some antibiotics fall into this

**FIGURE 8-5.** Sigmoid  $E_{\max}$  dose–response curve showing the relationship between drug concentration in logarithmic units and the effect. The effect is proportional to the number of receptors occupied.  $E_{\max}$  defines the maximal effect of the drug,  $EC_{50}$  the concentration at which half maximal effect occurs and  $n$  the steepness of the slope or response curve.

category. Where there is less margin between a therapeutic and toxic effect, referred to as a low therapeutic index, large interindividual variation make simple dosing regimens problematic as a dose that produces partial efficacy in one patient may produce drug toxicity in another.

### Mechanisms of Aging Pharmacodynamic Changes

The underlying mechanisms of age-associated changes in drug responsiveness are not well understood. The  $\beta$ -adrenoceptor signal transduction system has been studied in some detail. This system is relatively well-characterized and aging changes in  $\beta$ -adrenergic responsiveness are well described. The  $\beta$ -adrenoceptor consists of a membrane-bound seven-loop protein with a receptor recognition site on the cell surface that binds to agonists or antagonists (Figure 8-6). The receptor is coupled to a stimulatory G protein. The G protein has three subunits ( $\alpha$ ,  $\beta$ , and  $\gamma$ ) and exists in an active or inactive state. When the receptor binds to an agonist, the G protein undergoes a conformation change, which results in GTP binding to the  $\alpha$ -subunit to form an  $\alpha$ -GTP complex that activates adenylyl cyclase the catalytic component of the receptor, which converts ATP to cAMP. Increased intracellular cAMP activates protein kinases, which phosphorylate specific substrate proteins that lead to cellular responses such as the opening of ion channels or smooth muscle relaxation.

### Main Pharmacodynamic Changes with Aging

Pharmacodynamic changes with aging are less well-characterized or understood than pharmacokinetic changes. The cardiovascular and central nervous systems are the two organs where the major aging changes have been described.

**FIGURE 8-6.** The  $\beta$ -adrenoceptor adenylyl cyclase complex and signal transduction system. The  $\beta$ -adrenoceptor binds with an agonist drug to undergo conformational change, resulting in the  $\alpha$ -subunit of an associated stimulatory G protein binding to GTP. The  $\alpha$ -GTP complex activates the catalytic moiety of adenylyl cyclase, resulting in conversion of ATP to cAMP, which activates protein kinases that phosphorylate substrate cellular proteins leading to cellular responses.

### Cardiovascular System

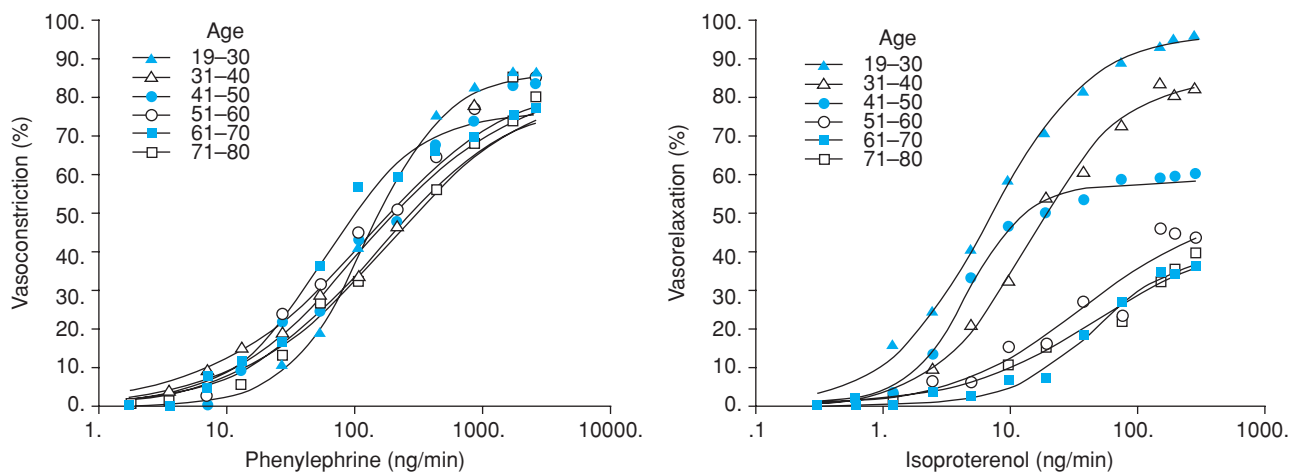

The  $\beta$ -adrenergic system has been extensively studied. Aging is associated with a reduction in cardiac and vascular  $\beta$ -adrenergic responsiveness. The heart rate increase in response to intravenous bolus doses of the nonselective  $\beta$ -adrenoceptor agonist is reduced in older adults. Reduced  $\beta$ -adrenoceptor sensitivity has been observed in a number of animal species. Reduced cAMP second messenger response to  $\beta$ -adrenoceptor agonists has also been seen in *in vitro* studies of isolated human right atrial appendages. The reduced cardiac chronotropic responsiveness of older adults to isoproterenol is only partially due to reduced  $\beta$ -adrenoceptor sensitivity and is an example of the often complex multiple mechanisms underlying altered responsiveness of older adults to drugs. The increased heart rate response to isoproterenol is contributed to by increased efferent cardiac sympathetic activity and reduced parasympathetic activity produced by baroreceptor response to the fall in blood pressure secondary to peripheral vasodilatation mediated by activation of vascular  $\beta_2$ -adrenoceptors. The large age-associated difference in cardiac chronotropic responsiveness disappears when this response is blocked using autonomic blockade with atropine and clonidine. This result can be explained by the well-described reduction in baroreflex sensitivity that occurs with aging.

Older subjects are less sensitive to the hypotensive effect of  $\beta$ -adrenoceptor antagonists. Recent meta-analyses have suggested that  $\beta$ -adrenoceptor antagonists are less effective as initial therapy in the treatment of hypertension in older adults. However, there is little

convincing evidence that this is due to alterations in the affinity of the  $\beta$ -adrenoceptor for antagonists.

The acute blood pressure response to calcium-channel-blockers is more marked in older adults compared to younger adults. This result again can be explained by the reduced baroreflex activation that occurs with aging, rather than any alteration in effects on calcium channels in the peripheral vasculature.

The effect of age on vascular responsiveness has also been extensively studied. The availability of tools such as brachial artery infusion forearm blood flow and hand vein techniques have facilitated detailed study of the vascular system. The age-associated decline in  $\beta$ -adrenergic responsiveness has been demonstrated in both arteries and veins. While impaired  $\beta$ -adrenergic vasodilator responses to infused isoproterenol are seen with age,  $\alpha$ -adrenergic vasoconstrictor responses to  $\alpha$ -adrenergic agonist phenylephrine are preserved (Figure 8-7). The maximal vasodilator responsiveness to isoproterenol is reduced while sensitivity to isoproterenol as measured by the group  $EC_{50}$  is unchanged. This response was shown to be specific and not a generalized reduced impaired response to vasodilatation because responses to some vasodilators including nitroglycerin, an NO donor, and bradykinin are preserved in older adults. An age-associated reduction in responsiveness to histamine, which acts through vascular  $H_2$  receptors, is also found in dorsal hand veins. Both  $\beta$ -adrenergic and histamine vasodilator responses are mediated through activation of adenylyl cyclase. In contrast, responses to prostaglandin  $E_2$ , which also acts by binding to membrane-bound receptors coupled to adenylyl cyclase are preserved. Prostaglandin

**FIGURE 8-7.** Human hand vein responsiveness to  $\alpha_1$ - and  $\beta$ -adrenergic agonists. Vasoconstrictor effects to the  $\alpha_1$ -adrenoceptor agonist phenylephrine and  $\beta$ -adrenoceptor agonist isoproterenol are shown in six healthy volunteer age groups. Age groups (yrs):  $\blacktriangle$  19-30;  $\triangle$  31-40;  $\bullet$  41-50;  $\circ$  51-60;  $\blacksquare$  61-70;  $\square$  71-80. (Reproduced from Pan HYM, Hoffman BB, Pershe RA, Blaschke TF. Decline in  $\beta$ -adrenergic receptor mediated vascular relaxation with aging in man. *J Pharmacol Exp Ther.* 1986;239:802-807.)

E<sub>2</sub> acts through membrane-bound prostanoid receptors to activate adenylyl cyclase and increase cAMP levels. This finding suggests that the reduction in vascular  $\beta$ -adrenergic and histamine responsiveness with aging is due to reduced affinity of the  $\beta$ -adrenoceptor for  $\beta$ -agonists or reduced coupling of the agonist occupied  $\beta$ -adrenoceptor to adenylyl cyclase.

### Central Nervous System

Centrally acting drugs are frequently prescribed to older adults. Older adults are more sensitive to the sedative and respiratory depressant effects of benzodiazepines, for example, requiring lower doses of diazepam to produce adequate sedation for endoscopic procedures.

Older individuals experience more cognitive adverse effects with benzodiazepines than young individuals; older individuals with cognitive impairment are particularly vulnerable to these effects. Many studies have demonstrated that benzodiazepines are associated with falls in older adults. Benzodiazepines and other hypnotic drugs increase postural sway, which may at least partially explain this association. Benzodiazepines have also been reported to produce drops in systolic blood pressure. The increased sensitivity of older adults to benzodiazepines is due to three factors. Drug clearance is reduced; there is increased distribution of benzodiazepines to the older person's brain due to changes in lean body mass; and, finally, in animal models, there is increased pharmacodynamic sensitivity of the brain to any given concentration of benzodiazepine. Benzodiazepines bind to a central type benzodiazepine receptor and enhance affinity of the GABA<sub>A</sub> receptor to GABA, the main inhibitory neurotransmitter.

Older adults have increased sensitivity to narcotic and anesthetic agents. Brainsensitivity to the opiates fentanyl and alfentanil, measured using changes in electroencephalographic (EEG) frequency spectra, is increased in healthy older adults (Figure 8-8). Pharmacokinetics do not differ with age; animal studies suggest that the increased sensitivity may be due to altered expression of opiate receptors. Sensitivity to the anesthetic induction doses of thiopentone

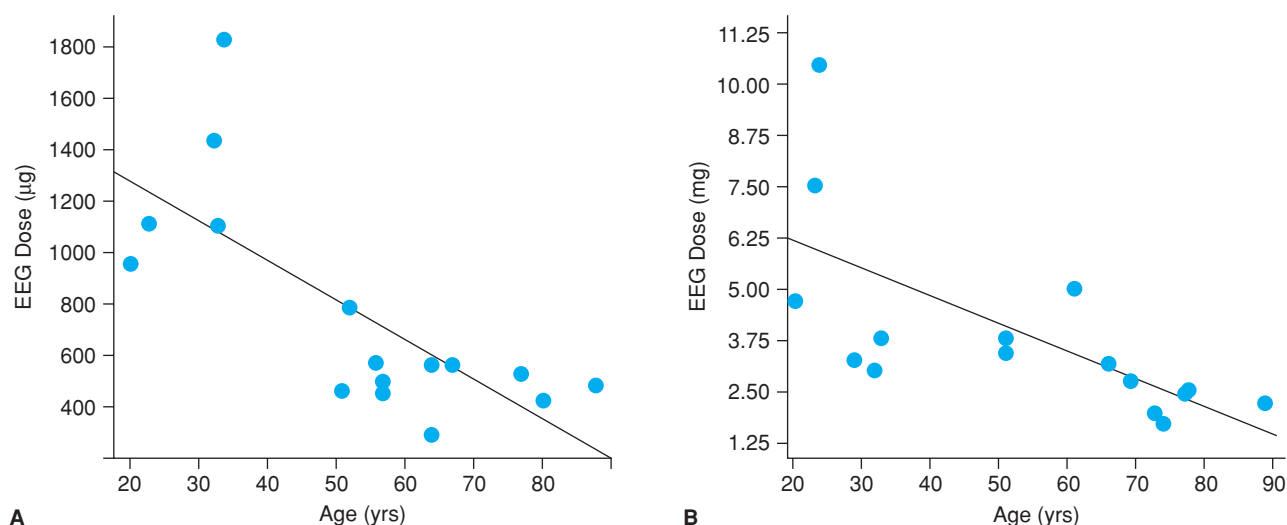

is increased in older adults primarily due to altered drug distribution. Reduced clearance of the drug from the central drug compartment produces higher drug concentrations at the site of action and is responsible for the greater drug effect with no age-associated alteration in receptor sensitivity.

### PHARMACOGENETICS AND PHARMACOGENOMICS

Genetic variation is one of many sources of variability in drug response and may affect any aspect of pharmacology. It is estimated that genetic factors account for between 20% and 95% of variability in drug disposition and drug effects, depending on the individual drug. Inherited sequence variants in genes encoding drug-metabolizing enzymes, drug transporters, or drug targets generally remain stable throughout a person's lifetime. However, gene expression may vary with age and with environmental factors.

Pharmacogenetics is the study of the effects of a drug in relation to a single or defined set of genes. Pharmacogenomics is the study of the effect of a drug in relation to the functions and interactions of all the genes in the genome. Most drug effects are determined by several gene products that modify pharmacokinetics and pharmacodynamics. The aging process itself and the diseases of aging have a variety of complex polygenic causes. Survival to extreme old age may be partly due to genetic variations that affect basic mechanisms of aging, which result in decreased susceptibility to age-associated diseases. Identification of these genetic variations may lead to the discovery of drug targets to enable longevity.

Drug responsiveness in older adults is influenced by genetic factors. Cytochrome P450 2D6 (CYP2D6), which metabolizes many psychoactive, cardiovascular, and analgesic medications, is polymorphic due to autosomal recessive inheritance of CYP2D6-inactivating alleles. Populations can be divided into poor, intermediate, and ultrarapid metabolizers. Age does not appear to affect the population prevalence of genotypes or genetically determined differences between poor, intermediate, and ultrarapid metabolizer phenotypes for

**FIGURE 8-8.** Sensitivity of health subjects to the anesthetic agents (a) fentanyl and (b) alfentanil. The drug dose that produces half the maximal change  $IC_{50}$  in EEG frequency measure is shown with a significant reduction in  $IC_{50}$  with increasing age. (Reproduced from Scott JC, Stanski DR. Decreased fentanyl and alfentanil dose requirements with age. A simultaneous pharmacokinetic and pharmacodynamic evaluation. *J Pharmacol Exp Ther.* 1987;240:159–166.)

CYP2D6. The response to a medication may be altered by polymorphisms in genes that are not responsible for its pharmacokinetics or its direct target. For example, variant alleles for sodium or potassium transporters may predispose to drug-induced long-QT syndrome.

Response to warfarin, an oral anticoagulant increasingly used by older adults, is partly determined by genetic factors that influence both pharmacokinetics and pharmacodynamics. The more active *S*-enantiomer of warfarin is predominantly metabolized by cytochrome P450 2C9 (CYP2C9). The *CYP2C9\*2* and *CYP2C9\*3* variants are associated with decreased metabolic efficiency, reduced *S*-warfarin clearance, and decreased warfarin dose requirements, with an increased risk of over anticoagulation, particularly during initiation of warfarin. Warfarin inhibits synthesis of vitamin-K dependent clotting factors by inhibiting vitamin K epoxide reductase complex 1 (*VCORC1*). Genetic variability in *VCORC1* may account for more variation in warfarin maintenance dose requirements than variability in *CYP2C9*. Age, weight, smoking, exposure to CYP2C9 inducers and inhibitors, INR, and polymorphisms in warfarin metabolizing and drug target genes are all independently associated with warfarin dose, and together explain approximately 50% of the variability in maintenance dose requirements.

Pharmacogenetics currently plays a limited role in individualizing drug therapy. Consideration of pharmacogenetics to guide prescribing is recommended in Food and Drug Administration (FDA) labeling in limited situations to reduce risk of serious adverse drug reactions. Recommendations include considering the roles of CYP2C9 and *VCORC1* in warfarin dosing, genotyping, or phenotyping thiopurine *S*-methyltransferase (TPMT) to guide dosing and reduce myelosuppression from azathioprine and 6-mercaptopurine and genotyping UGT1A1 to guide dosing and reduce neutropenia from irinotecan.

## ADVERSE DRUG REACTIONS

Adverse drug reactions (see also Chapter 24) occur more frequently and are often more severe in older adults compared with younger adults. This increased risk is related to increased comorbidity, altered pharmacokinetics and pharmacodynamics, and polypharmacy. Randomized controlled studies of efficacy do not necessarily provide useful data on safety, particularly in older patients. Pharmacovigilance studies play a major role in this population, particularly those studies that investigate functional impairment as an important adverse drug event.

Adverse drug reactions account for 5% to 10% of hospital admissions among older adults and are the fourth to sixth largest cause of death in hospitalized patients in the United States. The increased risk of adverse drug reactions in older adults occurs with prescribed, over-the-counter, and complementary and alternative medicines. Reports of serious adverse drug events to the FDA are significantly more common in adults aged 65 years and over, controlling for population and medication exposure. The increased risk of adverse drug reactions in older adults has been attributed to increased comorbidity, altered pharmacokinetics and pharmacodynamics, and perhaps most importantly, polypharmacy.

Adverse drug reactions are classified as either Type A, which are related to the pharmacological actions of the drug, dose-related, and predictable, or Type B, which are usually unrelated to the pharmacological actions of the drug and are unpredictable. Type A adverse

drug reactions include dose-related drug toxicity, drug side effects, and drug interactions. Type B adverse reactions include idiosyncratic and immunologic reactions. Most adverse drug reactions causing admission of older adults to hospital are classified as Type A reactions and hence are predictable and potentially preventable. Some type B reactions may also be more common and more severe in older adults.

The majority of type A adverse reactions in older adults are due to pharmacokinetic factors. However, altered pharmacodynamics also contribute to the increased incidence of adverse drug reactions with aging. For example drug-induced aplastic anemia is more frequent in older adults because of increased sensitivity of bone marrow cell lines. Extrapyramidal adverse drug reactions to centrally acting drugs occur more frequently in older adults and are different in nature than in younger adults. Younger subjects experience acute dystonic reactions with metoclopramide and prochlorperazine, whereas dystonic reactions are very unusual in older adults but Parkinsonism and tardive dyskinesia are frequently seen. The age-associated reduction in basal ganglia dopaminergic neurones explains the increased incidence of drug-induced Parkinsonism with aging.

The increased risk of adverse drug events in older adults is often not detected in randomized controlled trials. Older adults, and particularly old frail adults with multiple comorbidities, may be specifically excluded from the trials. The majority of randomized controlled trials may be powered to look at efficacy rather than safety. Meta-analyses may be required to detect significant differences in adverse drug events. For example, a recent meta-analysis of randomized controlled trials in patients with symptomatic left ventricular dysfunction, comparing the combination of angiotensin II receptor blockers plus angiotensin converting enzyme (ACE) inhibitors against control treatment that included ACE inhibitors, found that combination treatment was associated with higher risks of medication discontinuation for adverse drug events, worsening renal function, hyperkalemia, and symptomatic hypotension. These rates may be even higher outside the randomized controlled trial environment, where patients are less well monitored, have more comorbidities, and may be exposed to more polypharmacy with medications such as nonsteroidal anti-inflammatory drugs (NSAIDs) that contribute to renal impairment and hyperkalemia.

Observational pharmacovigilance studies have been used to detect adverse events in these populations. For example, the Randomized Aldactone Evaluation Study (RALES) demonstrated that spironolactone, in addition to ACE inhibitors, significantly improves outcomes in patients with severe heart failure, and only 2% of study patients treated with spironolactone developed hyperkalemia. In contrast, analysis of Canadian linked prescription-claims and hospital-admission data sets for more than 1.3 million adults aged 66 years or older found that among patients treated with ACE inhibitors who had recently been hospitalized for heart failure, the spironolactone-prescription rate increased fourfold after the publication of RALES (34 to 149 per 1000 patients), as did the rate of hospitalization for hyperkalemia (from 2.4 to 11.0 per 1000 patients,  $P < 0.001$ ) and the associated mortality (from 0.3 per 1000 to 2.0 per 1000 patients,  $P < 0.001$ ), without significant decreases in the rates of readmission for heart failure or death from all causes.

Randomized controlled trials are seldom designed to detect increases in falls, functional impairment, and cognitive impairment, among the most important and common adverse drug events in older adults. There is an association between falls and the types and numbers of medications used. Exposure to any psychotropic medication,

regardless of class, is associated with an almost twofold increased risk of falls in older adults. Newer psychotropic medications, such as selective serotonin reuptake inhibitors and atypical antipsychotics have been associated with similar falls risks in older adults compared to the older psychotropics. A randomized placebo-controlled trial of withdrawal of psychotropic medications in older subjects found a 76% reduction in falls over 44 weeks. There is a strong statistical association between polypharmacy and increased falls risk. This association may be explained by increased risk of prescription of specific classes of drugs that increase the risk of falls, such as sedatives, antipsychotics, and cardiovascular medications, with polypharmacy. However, some of the hazards attributed to polypharmacy may be related to the underlying comorbidities for which the medications are prescribed rather than to drug effects.

Drugs frequently play a major or contributory role in confusional states in older adults. Medications have been reported to be the cause of around one-quarter of cases of inpatient delirium. The drug classes most strongly associated with cognitive impairment and delirium are psychotropic and anticholinergic medications. The impairments in physical and cognitive functions associated with psychotropic and anticholinergic medications can be viewed as type A dose-dependent adverse drug reactions. Recent efforts have been made to quantify cumulative psychotropic and/or anticholinergic medication exposure and estimate the effects of this exposure on physical and cognitive functions in older adults, using tools such as the Drug Burden Index.

## FRAILITY AND PHARMACOLOGY

Frailty is a poorly defined but increasingly studied condition characterized by high susceptibility to disease, impending decline in physical function and high risk of death. The most widely used definition of frailty includes measures of mobility (walk time), strength (grip strength), nutrition (weight loss), endurance (exhaustion), and physical activity. Interpretation of studies is limited by inconsistent definitions of frailty, small study size, and the increase in interindividual heterogeneity observed in the frail elderly. A key feature of frailty is loss of lean muscle mass, sarcopenia. Frailty is likely to have a major influence on pharmacokinetics, pharmacodynamics, and the therapeutic ratio of medications.

### Pharmacokinetics and Frailty

Comparison of pharmacokinetics in frail older adults, nonfrail older adults, and young adults is limited to very few studies, most with small numbers of subjects. It appears that bioavailability is not significantly affected by frailty. Volume of distribution is likely to be affected by the increasing sarcopenia and relative adiposity seen in frailty. Hydrophilic drugs would have smaller and lipophilic drugs larger, volumes of distribution in frail older adults than in nonfrail older adults. Changes in hepatic clearance with frailty are varied. It appears that there is no change in phase I hepatic metabolism with frailty. Erythromycin clearance, a measure of CYP3A4 and P-glycoprotein function, is not significantly different in frail and nonfrail older adults. Phase II metabolism is probably maintained in healthy aging but reduced in frailty. Paracetamol and metoclopramide clearance per unit volume of liver, which rely on conjugation, are maintained in fit older adults but significantly reduced in frail adults. Renal clearance has not been well-described in this pop-

ulation, and there is currently no evidence of a further reduction in renal clearance in frailty. Some routes of nonhepatic, nonrenal clearance may be reduced in frailty. Plasma aspirin esterase is maintained in fit, but reduced in frail, older adults.

### Pharmacodynamics and Frailty

There is little information on specific changes in pharmacodynamics in frail older adults. One study found that frail older adults reported more severe and prolonged sedation after intravenous metoclopramide than nonfrail older adults, independent of pharmacokinetic differences. Frailty predicts mortality in older adults with severe coronary artery disease, but it is not clear whether this is related to changes in pharmacologic response. There is some evidence that frailty is associated with a procoagulant state and chronic inflammation, and it is possible that such changes could affect pharmacodynamics, particularly those of anticoagulant and immune-modulating therapies. It is likely that frail older adults will respond differently to drug therapy in view of their reduced physiologic reserve and impaired adaptive responses.

### Adverse Drug Events and Frailty

Frailty is associated with many risk factors for adverse drug events (Table 8-6). However, difficulties with the definition of frailty have limited formal assessment of the association between frailty and adverse events. One study found that one-third of frail elderly persons experience adverse drug reactions after discharge from hospital. For every dollar spent on drugs in nursing facilities, \$1.33 in health care resources is consumed in the treatment of drug-related problems. Frail older adults do not tolerate some medications as well as nonfrail older adults. A study of antidepressants in depressed nursing home residents found that one in eight discontinued sertraline and one-third discontinued venlafaxine due to serious adverse events. These rates are at least four times higher than those observed in a

**TABLE 8-6**

#### Factors That May Increase the Risk of Adverse Drug Events in Frail Older Persons

RISK FACTOR FOR ADVERSE DRUG EVENTS	ASSOCIATION WITH FRAILITY
Pharmacokinetics	Sarcopenia and reduced body weight alter volume of distribution Impaired phase II hepatic metabolism reduces clearance Wide heterogeneity therefore difficult to predict
Pharmacodynamics	Less physiologic reserve Wide heterogeneity so difficult to predict response
Medication Management	
Polypharmacy	Increased number of comorbidities
Compliance	Increased prevalence of cognitive and sensory impairment
Hospital admissions	Frequent admissions due to increased susceptibility to disease

study of treatment of major depression with comparable medications in geriatric outpatients aged over 65 years.

There are likely to be significant changes in pharmacokinetics and pharmacodynamics in frail older adults. Greater understanding of the physiology of frailty and further development of valid tools to recognize frailty in clinical practice are required to allow the study of pharmacologic changes in frail older adults. Understanding such changes will inform therapeutic decisions for frail older adults.

## DRUG DEVELOPMENT AND REGULATION

In the last 50 years, all developed countries have introduced a process of evaluating new drug therapies before they are marketed to ensure safety and efficacy in the target group of patients to be treated. Drug regulation is undertaken by the FDA in the United States and by the European Medicines Evaluation Agency (EMA) in Europe. For a drug to be approved, substantial preclinical and clinical data are required. There is an expectation that clinical studies should include the relevant population that will be treated including older adults (see also Chapter 24).

### Phase I Studies

Clinical drug studies are categorized into four phases (I–IV). Following preclinical model studies to determine toxicity and likely pharmacokinetics in humans, phase I studies are undertaken in healthy volunteers to define tolerability, identify any major toxicity, and establish the drug's pharmacokinetics. Typically, phase I studies are performed in 12 to 20 male subjects with progressive dose escalation with close physiological monitoring and collection of plasma and urine to determine pharmacokinetics. Female subjects are usually excluded from phase I studies because of their childbearing potential and the potential risk of teratogenicity. Healthy older subjects are not usually studied in phase I studies in part because younger subjects are likely to be more resilient to any unanticipated toxicity. For some drug therapies where significant toxicity is anticipated, healthy volunteers are not used and studies to define pharmacokinetics and tolerability are undertaken in the relevant patient group for which it is considered ethically appropriate. For example, initial studies of cytotoxic drugs are usually undertaken in cancer patients with end-stage disease who have received all standard therapy.

There are clear examples in which different responses to drug therapy are seen between young and older subjects (see “Pharmacodynamics” section earlier). Studies in healthy older subjects may provide valuable insight into altered responsiveness or toxicity to inform the design and selected doses for phase II and III studies, which include older patients. For example, the majority of N-Methyl-D-Aspartate (NMDA) antagonists developed for acute stroke never achieved plasma concentrations associated with neuroprotection in phase II studies because of agitation, hallucinations, and confusion, which were particularly problematic in older patients with acute stroke.

Phase I studies had an excellent safety record until the recent incident with TNG 1412, a stimulatory monoclonal antibody being developed to treat rheumatoid arthritis, which led to near-fatal cytokine storm in six healthy volunteers studied in the UK. This has led to closer scrutiny by regulatory bodies of studies using newer

biologic agents and the clinical environment in which such studies are conducted.

### Phase II Studies

Phase II studies are usually placebo-controlled studies with a range of doses thought to produce a therapeutic response without major safety problems in a small group of patients with the target disease. The main aim of phase II studies is to demonstrate “proof of concept” rather than establishing a clinically useful response in a broad range of patients. For example, studies of a reperfusion drug for myocardial infarction or stroke would be designed to determine the extent to which the agent increases reperfusion as measured by angiography of the occluded blood vessel and monitor bleeding rates but not to necessarily demonstrate an improvement in mortality or disability. Prediction of the optimal dose to take forward in phase II studies is recognized to be challenging and maybe further complicated by dose-related differences in efficacy and toxicity between young and old patients. Bayesian adaptive dose design approaches in study design have been used to modify the allocation of doses informed by the response of previously randomized patients and end a study when there is clear evidence of the presence or absence of a predefined response. Phase II studies have proved very problematic for a number of disease areas in older adults particularly central nervous system (CNS) conditions such as acute stroke, pain, and neurodegenerative diseases.

### Phase III Studies

Phase III studies are the key for establishing that a therapy has a benefit relevant to patient outcomes. In most therapy areas, the primary outcome in phase III trials is a clinically relevant disease-specific one that is able to demonstrate a clear benefit to patients in either survival or function and quality of life. In studies of acute stroke treatments, survival without disability is used. In studies of secondary prevention therapy for cardiovascular disease, a combined outcome of cardiovascular death, stroke, or myocardial infarction has been used.

Well-designed phase III trials should include patients who are representative of the population that will be treated if the drug is approved. Until recent years, Phase III trial protocols commonly had upper age limits. For example, many acute stroke studies (ECASS 1 and ECASS 2) had an upper age limit of 80 years and the large Heart Protection Study, which demonstrated the benefits of statins in patients at increased cardiovascular risk had an upper age limit of 75 years. Such age limits appear to have been introduced because of fears that a greater risk of adverse events in older adults might make the trial more likely to fail to achieve a positive outcome. There may be investigators with the view that preventing disease recurrence in older adults was not a worthwhile aim. Even when trials do not have an upper age limit, older adults often are excluded from enrolment in studies because of other protocol exclusion criteria such as comorbidities or concomitant drug therapy. The failure to include older adults in clinical trials leads to problems once the drug is approved. Sometimes the license will have an upper age limit such as alteplase for ischaemic stroke in Europe. Clinicians may be reluctant to treat older adults because of the lack of trial data in this group. Perhaps most importantly, we do not learn the benefits and

harms of this age group, who then are given the medication without this knowledge.

International Guidelines on Drug Development now strongly recommend the inclusion of older adults in phase III trials, emphasizing the importance to seek patients 75 years and older and not excluding unnecessarily patients with concomitant illness. The older the population that is likely to use the drug after marketing the more important it is to include very elderly patients. A minimum of 100 patients is recommended to detect clinically important differences. For diseases such as Alzheimer's disease, it is expected that older patients will constitute the majority of the trial database. Pharmacokinetic studies in older adults and patients with renal impairment are recommended to detect age-associated pharmacokinetic differences.

### Phase IV Studies

Phase IV trials are generally observational studies in large cohorts of patients following licensing and marketing. Well-conducted phase IV trials are larger than phase III trials and include the broad population of patients treated. They are important in detecting rare adverse drug events and in confirming the safety of therapy observed in clinical trials. They may also offer valuable information on drug effects in very elderly patients if these were not included in clinical trials.

## PHARMACOEPIDEMOLOGY

Pharmacoepidemiology uses the science of clinical epidemiology to measure patterns of medication use and outcomes in large populations. Pharmacoepidemiology allows assessment of the safety and efficacy of medications in large populations, which are often more diverse than the participants in randomized trials, over long periods of time.

### Advantages of Pharmacoepidemiologic Studies

The advantages of pharmacoepidemiology over randomized controlled trials include (1) detection of adverse events that are too rare or too delayed to be detected in randomized trials; (2) assessment of efficacy over longer periods in a broader population; (3) correlation of medication use with outcomes that may not have been assessed in randomized trials; (4) assessment of safety and efficacy of medications beyond the stringent monitoring of a randomized trial.

Pharmacoepidemiology is a particularly useful tool to assess medications in older adults. Older adults are often excluded from randomized trials, either on the basis of age alone, or because of comorbidities, comedications, or functional impairment. Observational pharmacoepidemiologic studies can assess patterns of medication use, safety, and efficacy in frail individuals. It is particularly important to understand safety and efficacy over many years when deciding whether to continue or cease medications in older adults who have often been taking their medicines for decades. Many randomized trials only assess disease and mortality outcomes, and pharmacoepidemiologic studies can correlate medication exposure with functional and quality of life measures that may be more relevant to older adults. Pharmacoepidemiology assesses the effects of medications in the presence of medication management issues that occur in real clinical settings, e.g., limited adherence and monitoring.

### Limitations of Pharmacoepidemiologic Studies

Pharmacoepidemiologic studies are limited by confounding and bias. Interpretation of studies is limited by variable prescribing patterns, variable comorbidities, confounding by indication, severity and prognosis, and controlling for the time dependency of drug use. Studies that rely on large epidemiologic data bases often contain very limited clinical information. There are several emerging approaches to manage confounders, including restricting study populations to more homogeneous groups, creating a propensity score to predict the probability of receiving a drug based on baseline covariates, and examining within-patient variability of drug exposure using cross-over designs. Pharmacoepidemiology is likely to do much to inform prescribing for frail older adults.

## PHARMACOECONOMICS

Pharmacoeconomics is the scientific subdiscipline of health economics that compares the value of one drug or drug therapy to another evaluating the cost, expressed in monetary terms, and effects, usually expressed in efficacy or quality of life of a drug. Pharmacoeconomic data can be used to guide optimal healthcare resource allocation. One important consideration in a pharmacoeconomic evaluation is to decide the perspective from which the analysis should be conducted, which may be institutional or societal.

Pharmacoeconomic studies compare two or more alternative courses of action in terms of their financial costs and benefits, usually a generic quality-of-life measure. The underlying aim is to achieve most health benefits across a specified patient population within available resources. The area has expanded in recent years because of the increasing problem of resource limitations in medical care and increasing numbers of often costly drug therapies coming to market. There are a number of different pharmacoeconomic approaches that can be used. Cost minimization analysis assumes or is based on data indicating clinical outcomes are equivalent and that the less costly intervention should be utilized. Cost effectiveness analysis examines outcomes measured in natural units such as life years, i.e. survival. Cost utility analysis examines outcomes measured in quality adjusted life years. Finally cost-benefit analysis examines costs and outcomes using only financial measures. Usually the results of clinical trials and costs of care are used to construct a lifetime model, which determines the cost difference between two treatment strategies and difference in health utility gain.

Cost effectiveness analysis has been used extensively in the United Kingdom by National Institute for Clinical Effectiveness (NICE), which has applied an approximate threshold of around £20,000 to £30,000 per quality adjusted life year gained in deciding whether to recommend therapies should be used in the publicly funded National Health Service. In the United States, managed care funds consider cost-effectiveness when deciding on the availability of drug therapy. There are some concerns that the cost-effectiveness approach may be prejudicial to older adults because their survival time is less than younger patients. However, for most preventative interventions, such as the treatment of cardiovascular risk factors or osteoporosis the greater absolute risk of experiencing an outcome event such as stroke, myocardial infarction, or fracture indicates intervention in older adults is more cost-effective, assuming a life expectancy at least as long as the time required to benefit. Thus

consideration of cost effectiveness can facilitate health care systems appropriately directing resources to the treatment of older adults.

## CONCLUSION

Knowledge of the age-related changes in pharmacokinetics and pharmacodynamics is important for researchers evaluating treatments in older adults and for clinicians treating older patients. Because of the increased risk of adverse drug effects in older adults, optimal prescribing is particularly critical in older patients. Making appropriate decision about drug therapy in the older individual requires careful consideration of the aims of treatment in the individual, risks of treatment from the drug, drugs–disease, and drug–drug interactions and careful review of the effect of treatment once initiated. This remains one of the major challenges of delivering high-quality geriatric care but when successfully delivered highly rewarding for both the physician and the older patient.

# Preventive Gerontology: Strategies for Optimizing Health Across the Life Span

*Elizabeth A. Phelan ■ Miguel A. Paniagua ■ William R. Hazzard*

## INTRODUCTION

In developed societies, the success of disease prevention strategies over the last century, coupled with more effective treatments for many diseases, has resulted in a decline in mortality due to acute disease. However, this has been associated with a rise in chronic illness and attendant morbidity in the form of chronic disability in old age. The sheer magnitude of the elderly population of the near future will place critical demands on existing health care delivery systems. Continued independent functioning of the elderly population has therefore emerged as a major challenge to public health. The ability to perform activities of daily living is essential for ensuring independent living. Thus, preventive gerontology—the study of individual and population health strategies across the life span aimed at maximizing both the quality and quantity of human longevity—must now aim not just to retard chronic disease but also to prevent functional decline.

Aging is a lifelong process in which early- and mid-life events and behaviors can have an important influence on the health and functioning of individuals as they age. Development of chronic disease, functional decline, and loss of independence are not inevitable consequences of aging. Health and function in late life can be seen to a great degree as under one's own personal control. Disability is associated with chronic conditions that are potentially preventable, and changes in behavior and lifestyle will reduce risk factors that lead to many chronic conditions. This is true throughout life, and has been shown to apply even for persons of advanced age.

What should the primary care provider advise his/her young adult and middle-aged patients about how to maintain optimal health and function into their later years? Health promotion efforts at the level of the individual should ideally be established early in life and maintained throughout life. Chronic disease, an avoidable outcome intermediate in the pathway to functional decline or death (Figure 9-1), is unlikely to have a single cause but rather, to be the result of the interactions of multiple factors. Efforts to prevent such dis-

ease require a comprehensive approach that focuses primarily on behavioral modification.

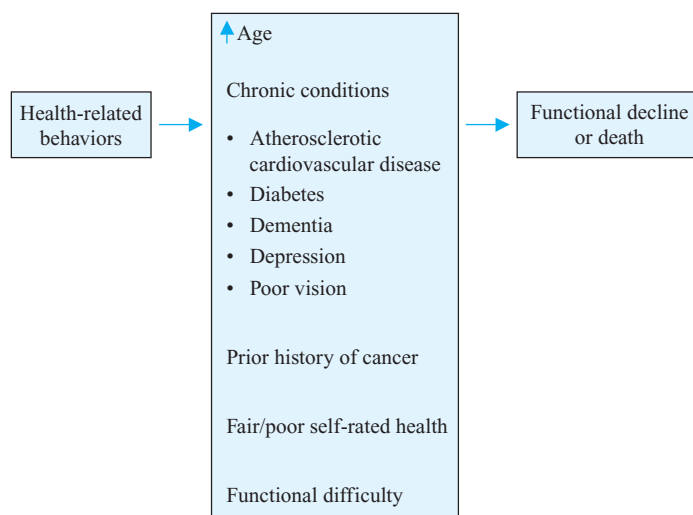

Individuals who pursue a healthy lifestyle have a lower risk of developing a chronic disease. A healthy lifestyle can be conceptualized as one that involves avoidance of health-damaging behaviors along with the adoption of a proactive approach to one's health. This chapter will first examine those behaviors that should be avoided and then focus on those that should be adopted if one is to maximize the time spent in a state of independent functioning.

## BEHAVIORS WITH ADVERSE HEALTH CONSEQUENCES

Achieving and maintaining health and function in advanced years can be aided by a commitment to a lifestyle that involves avoidance of smoking and other behaviors that adversely affect health. The Nurses Health Study found that middle-aged women who did not smoke, drank alcohol in moderate amounts, were not overweight, consumed a healthy diet, and exercised at least one-half hour daily had an 83% reduction in their risk of coronary events as compared with all the other women in the study. Each factor independently and significantly predicted risk, even after adjustment for age, family history, presence or absence of diagnosed hypertension, or diagnosed high cholesterol, and menopausal status. The online publication of Healthy People 2010, at <http://www.healthypeople.gov/>, contains links to reliable information about behavioral risk factors that lead to chronic disease and disability for individuals at every age (click on **Be a Healthy Person** link, and then click the **Online Health Checkups** link). Information on these topics can be found organized by age, race, ethnicity, and gender, and for parents, caregivers, and health professionals by clicking on the **Be a Healthy Person** link and then on **Health Information by Age, Gender, Race...** link.

The Task Force on Community Preventive Services, an independent, nonfederal, multidisciplinary group charged with reviewing

**FIGURE 9-1.** Conceptual model of how health behaviors impact the combined outcome of functional decline or death.

and assessing the quality of available evidence on the effectiveness and cost-effectiveness of essential community preventive health services, publishes reviews in an online document entitled, *The Guide to Community Preventive Services*. Topics coordinate with Healthy People 2010 objectives and address actual causes of death as described by McGinnis et al. in their 1993 JAMA article as well as prevalent risk behaviors. As topic reviews are completed, they are made available at <http://www.thecommunityguide.org> (click on a topic of interest under the heading, **Topics**).

## Tobacco Use

Tobacco use is the largest single preventable cause of illness and premature deaths in the United States. Illnesses related to tobacco use (coronary artery disease (CAD), cancers of the lung, larynx, oral cavity, esophagus, pancreas, and urinary bladder, stroke, chronic obstructive pulmonary disease) account for one in every five deaths in the United States. Evidence from the National Health and Nutrition Examination Survey (NHANES) indicates that tobacco use predicts shorter survival time for middle-aged (45–54 years of age) and older (65–74 years of age) men. Although studies of prevalent cases have suggested that tobacco use either has no effect or is protective against Alzheimer’s dementia, prospective data investigating incident cases found that, quite to the contrary, tobacco use is associated with an increased risk of dementia, including Alzheimer’s dementia. Tobacco use can also multiply the risk associated with other carcinogenic agents: for example, heavy alcohol consumption, associated with esophageal cancer, carries an even greater risk when combined with cigarette smoking. Furthermore, the relative risk of developing lung cancer is at least additive among individuals who smoke and also have history of exposure to certain occupational agents such as arsenic, asbestos, chromium, nickel, and vinyl chloride.

It is increasingly evident that exposure to environmental tobacco smoke may also be a risk factor for lung cancer in lifelong nonsmokers. The adverse health effects of environmental tobacco smoke are far-reaching. In one case study, the attributable risk of death for second-hand smoke was similar to that of melanoma and motor vehicle collisions. A new report summarizing current evidence about second-hand smoke, entitled, *The Health Consequences of Involun-*

*tary Exposure to Tobacco Smoke: A Report of the Surgeon General 2006*, is available at <http://www.ahrq.gov/path/tobacco.htm>.

Tobacco dependence should be viewed as a chronic condition requiring ongoing assessment and repeated intervention. However, effective treatments are available that can lead to long-term, and in some cases, permanent abstinence. Studies have shown that individuals at any age can benefit from quitting the tobacco habit. Benefits include reduction in the risk of CAD, malignancy, stroke, and even hearing loss, along with improved pulmonary function, arterial circulation, and pulmonary perfusion.

Studies have found that only about 35% of adults are routinely asked about their tobacco habits or counseled to quit if they use tobacco. If providers do advise patients not to use tobacco, as many as 25% will quit or reduce the amount they use. Thus, providers should ask all patients at each clinic visit about tobacco use and advise all tobacco users about the importance of quitting, emphasizing factors that have been found to contribute most to successful attempts to quit: health concerns (symptoms); a desire to set an example for children; the expense of the habit; odor of breath, home, and clothing; and loss of taste for food. Providers should then assess a patient’s willingness to attempt to quit. Patients who are unwilling to attempt to quit should be provided with a brief intervention designed to increase their motivation to quit. Patients who are willing to quit should be provided with treatments that have been identified as effective. First-line pharmacotherapies that have been shown to increase long-term smoking abstinence rates include bupropion and nicotine (gum, inhaler, nasal spray, or patch). Second-line therapies include clonidine and nortriptyline, the latter, a tricyclic antidepressant with anticholinergic activity, should be avoided unless there is a compelling contraindication to the other therapies. Additional information about these therapies, as well as descriptions of brief clinical interventions for patients willing and unwilling to make a quit attempt, can be found in the June 2000 guideline, “Treating tobacco use and dependence,” available at <http://www.ahrq.gov/clinic> (click on **Clinical Practice Guidelines** link, then **Treating Tobacco Use and Dependence** box).

## Substance Abuse

The harmful health effects of substance abuse are well documented. Studies have shown that individuals at any age can benefit from quitting these habits, and effective, brief interventions are available. Providers may consider participating in continuing education programs to hone screening and counseling skills.

## Alcohol

Epidemiological studies support a survival benefit associated with moderate (up to two 8-ounce drinks per day) alcohol consumption, primarily through reduction of cardiovascular risk, including elevation of high-density lipoprotein (HDL) cholesterol. Additionally, both epidemiological and experimental studies suggest a protective effect against the development of cardiovascular disease with moderate consumption of red wine. The exact mechanism of the protective effect remains to be established, although it has been attributed to the properties of tannins or phenolic compounds, and to alcohol content, and moderate alcohol intake has been shown to be associated with less coronary atherosclerosis in a high-risk population. Weaker associations with moderate alcohol consumption include

a protective effect against bone loss in older women, Alzheimer's disease, intermittent lower extremity claudication, ischemic stroke, and prevention of hearing loss.

However, consumption of alcohol beyond a moderate level can induce adverse effects on every organ system, including increased risk of hypertension; breast, colon, esophageal, liver, and head and neck cancer; cirrhosis; gastrointestinal bleeding; pancreatitis; cardiomyopathy; seizures; cerebellar degeneration; peripheral neuropathy; cognitive dysfunction; insomnia; depression; and suicide. Counseling about problem drinking following a few screening questions is a high-impact, cost-effective service (see "Priorities Among Effective Clinical Preventive Services: Results of a Systematic Review and Analysis" at <http://www.prevent.org>, under the "Tools and Resources" link). Screening can be accomplished by taking a careful history of alcohol use or by using a standardized screening questionnaire. All adults should be counseled on the health risks associated with excess alcohol consumption as well as the risk of injury (i.e., motor vehicle crashes or other equipment-related injury) after drinking alcohol. Nondependent heavy drinkers as well as those with alcoholism (a chronic illness involving a state of dependency) should be counseled about the benefits of decreasing alcohol intake. Brief counseling by primary care providers can result in a significant reduction in alcohol use. Dependent drinkers should be referred to formal alcohol treatment programs and considered for a trial of naltrexone, an opioid antagonist that reduces the pleasurable effects of alcohol and may reduce relapse to heavy drinking.

## Illicit Drugs

The prevalence of injection drug use among older adults is unknown. Injection drug users typically initiate injection drug use during late adolescence (under age 21); however, a sizable subgroup begins injecting during early and late adulthood. Persons with a history of recreational drug use on only one or a few occasions are unlikely to self-identify; thus, clinicians should probe for such a pattern of usage.

Noninjection drug use (crack smokers, methamphetamine, intranasal heroin or cocaine, etc.) contributes to development of gastroduodenal ulcers, chest pain and myocardial infarction, and increased risk of death. As might be expected, higher levels of drug involvement also were associated with increased age-adjusted mortality. The United States Preventive Services Task Force (USPSTF) is currently updating its 1996 recommendations about screening for substance abuse.

## Prescription Drug Misuse

Prescription drug misuse is poorly described in the medical literature but is a more prevalent problem than illicit drug use among older adults. Misuse of prescription medications may be related to insomnia, chronic pain, depression, and anxiety. The potential misuse of benzodiazepines is well recognized and has led to prescribing recommendations that suggest only short-term use and use only for intended indications. Amphetamine-like stimulants have abuse potential, but addiction to these drugs is seldom documented. Other medications that are often misused are sedative hypnotics, opioid analgesics, and barbiturates. Chronic use of such agents may lead to physical dependency and the development of withdrawal symptoms with attempts to discontinue use. Treatment may require detoxification followed by rehabilitation (see also Chapter 24).

## Behaviors Increasing Risk of Injury

### Head Trauma and Risk for Alzheimer's Disease

A number of case-control studies indicate that, in addition to maximizing one's years of education and minimizing exposure to neurotoxins, avoidance of significant head trauma (which resulted in loss of consciousness or seeking of medical attention) may lower the risk of eventual development of Alzheimer's disease. It therefore stands to reason that with implementation of cranioprotective measures during early life, such as wearing helmets during high-risk activities, and avoidance of high-risk behaviors that may put one at risk for head trauma, the risk of eventual cognitive decline may be reduced.

### Ultraviolet Light and Risk for Skin Cancers and Cataracts

Increased risk of melanoma and nonmelanoma skin cancers as well as cataracts is associated with exposure to ultraviolet B (UV-B, or 280–320 nm) rays. More than five sunburns have been found to double the risk of melanoma, irrespective of the timing in life. Avoiding peak exposures, wearing protective clothing, avoiding artificial tanning devices (tanning lamps and beds) that emit UV radiation, and using sunscreen with a sun protection factor (SPF) of at least 30, indicating protection against UV-B, along with a star rating for Ultraviolet A (UV-A, or 320–400-nm rays) protection of 3 to 4 may reduce the risk of melanoma and other skin cancers. Wearing sunglasses that afford UV-B protection along with hats with brims can reduce the risk of cataracts by lowering eye exposure to UV-B light. Thus, patients should be advised to change behaviors that may increase the risk of skin cancer and cataracts. USPSTF, in its Guide to Clinical Preventive Services (available at <http://www.ahrq.gov/clinic/prevenix.htm>), concluded in 2001 that there is insufficient evidence to recommend for or against a periodic skin examination by clinicians; an update of this topic is in progress.

### Prevention of Age-Related Macular Degeneration

Age-related macular degeneration (ARMD) is the leading cause of blindness in developed countries. The cause of ARMD is unknown; treatment is usually only partially effective, and thus prevention is an active area of investigation. Cigarette smoking appears to be a risk factor for the development and progression of ARMD; other risk factors appear to include hypertension, high cholesterol, high total fat intake, and obesity. The role of sunlight exposure is unclear. A high fish intake (more than four servings per week) may reduce the risk of ARMD. Observational studies examining the association between concentrations of antioxidant vitamins and ARMD development have yielded conflicting results. Published data from randomized controlled trials have thus far shown no clear benefit for vitamin E or beta carotene on the prevention of incident ARMD.

### Excessive Noise and Risk for Hearing Loss

Noise-induced hearing loss ranks second only to presbycusis as a leading cause of sensorineural hearing loss, a well-described disability that is unarguably preventable. Such an insult can occur at any age and can affect one's life for years thereafter. Importantly, progression of cell death at the level of the cochlear cilia can be halted with avoidance of the offending recreational or occupational noise and using hearing

protection, such as earplugs. Patients who have been exposed to excessive noise should be screened for hearing loss. When hearing loss is suspected, a thorough history, physical examination, and audiometry should be performed. If these examinations disclose evidence of hearing loss, referral for full audiologic evaluation is recommended.

### Sleep Deprivation and Motor Vehicle Crash Fatalities

Impaired driving continues to be a considerable cause of morbidity and mortality in the United States. In 1998, alcohol was involved in 38% of all fatal motor vehicle collisions. Acute sleepiness, sleep deprivation, and nocturnal driving are other important risk factors for fatal motor vehicle accidents. Medical (i.e., obstructive sleep apnea, sedating medications) factors may contribute to daytime sleepiness, putting drivers at risk. Sleep deprivation can affect coordination, judgment, and reaction time and has been found to be involved in 16% to 60% of traffic accidents. Drivers' awareness of sleepiness while driving is not sufficient to prevent them from having an accident. Those who drive when sleepy need to be counseled to stop driving and rest before resuming driving.

### Cell Phone Use While Driving and Motor Vehicle Crashes

A growing literature documents the hazards of cell phone use while driving. One study of nearly 500 drivers who had been involved in a motor vehicle crash, resulting in hospitalization showed that use of a cell phone (regardless of whether the phone was a hands-free type or not) up to 10 minutes prior to a crash was associated with a highly significant risk of crashing. Other studies have documented a dose-response relationship, wherein increasing frequency of cell phone use (not duration of use) is associated with a higher likelihood of an accident. Cell phone use may adversely affect driving via several mechanisms, including delaying response time, interfering with attention (e.g., failing to visually scan an intersection for traffic before proceeding through it), and impairing maintenance driving (e.g., staying within a lane).

### Obesity

In adults, obesity is defined as a body mass index (BMI) of 30 kg/m<sup>2</sup> or more; overweight is a BMI of 25 to 29.9 kg/m<sup>2</sup> or more. Despite public health messages that focus on reducing fat intake and increasing energy expenditure, the prevalence of obesity in industrialized countries has reached epidemic proportions, with one in three being obese and another one in three being overweight.

Obesity is a major health hazard. There is strong evidence that obesity is associated with increased cardiovascular risk as well as a higher incidence of hypertension, hyperlipidemia, and type II diabetes mellitus (all associated with insulin resistance and "the metabolic syndrome"). Obesity is one of the factors associated with impaired mobility and other functional limitations, disabling conditions such as osteoarthritis; sleep apnea; gallbladder disease; non-alcoholic fatty liver disease; cancers of the breast, endometrium, and colon; and premature death. Moreover, those who are obese may suffer from social stigmatization, impaired social interaction, depression, and low self-esteem. Excess body weight or weight gain during middle age (especially early middle age, meaning age 25–50 years) contributes to the development of chronic conditions (cardiovascular disease, diabetes mellitus, hypertension, and osteoarthritis) in later years.

Because treatment and reversal of obesity is challenging, primary prevention is warranted. Efforts to maintain a healthy weight should start early in life and continue throughout adulthood, as this is likely to be more successful than efforts to lose substantial amounts of weight and maintain weight loss once obesity has developed. Data from NHANES I suggest that getting adequate rest may be important in obesity prevention. Sleeping less than 7 hours a night was shown to be a risk factor for subsequent obesity. This may be related to altered levels of leptin and ghrelin, two appetite-regulating hormones. Leptin is associated with appetite suppression and ghrelin is an appetite stimulant that is thought to play a role in long-term regulation of body weight. During sleep deprivation, leptin levels fall and ghrelin levels rise.

Adults who are trying to maintain a healthy weight after weight loss are advised to get even more physical activity than the 30 min/d (described below) that is currently recommended; the U.S. Department of Agriculture has recommended at least 60 min/d to manage weight. Weight management leading to a slow, steady weight loss is more beneficial than a pattern of weight cycling, which actually contributes to an elevated risk of mortality. The basal metabolic rate decreases with age, in parallel with a decline in lean body mass, and body fat increases proportionally. Thus, in order to most readily achieve normalization of body weight and body composition, an energy-sufficient (but not excessive) diet should be combined with a program of regular physical activity to permit maintenance of basal metabolic rate.

Obese individuals who are trying to lose a substantial amount of weight should seek the guidance of a health care provider prior to starting a weight-reduction program to ensure appropriate management of obesity as well as other health conditions. Current treatment of obesity involves combining either pharmacologic (e.g., orlistat, a gastrointestinal lipase inhibitor that restricts fat absorption, or sibutramine, a serotonin–norepinephrine reuptake inhibitor that enhances satiety and increases basal energy expenditure) or surgical treatments (e.g., gastric bypass, gastric banding) with dietary modification along with a physical activity program. Surgical intervention is limited to people with class II obesity (BMI  $\geq$  35 kg/m<sup>2</sup>) and severe comorbidity or class III obesity (BMI  $\geq$  40 kg/m<sup>2</sup>). A recent meta-analysis showed that dietary therapy (i.e., a very low calorie diet, less than 1100 kcal/d, or a low-calorie diet, with 1200–1500 kcal/d) provides <5 kg weight loss after 2 to 4 years, pharmacologic therapy provides 5 to 10 kg weight loss after 1 to 2 years, and surgical therapy provides 25 to 75 kg weight loss after 2 to 4 years. The same study showed that weight loss of  $\geq$ 5% baseline weight improves lipids, blood pressure, and glycemic control but mainly among those with cardiovascular risk factors. However, the authors observed the majority of studies of weight loss have methodologic limitations (e.g., inadequate study duration, large proportions of subjects lost to follow-up, a lack of an appropriate usual care group) that limit the applicability of findings to obese persons in everyday clinical practice.

## TAKING A PROACTIVE APPROACH TO PERSONAL HEALTH AND WELL-BEING

Achieving and maintaining health and function in advanced years—successful preventive gerontology—is rooted in a personal commitment to a lifestyle that promotes proper nutrition, physical fitness,

social connections, and use of preventive health care. Whereas the advice and encouragement of the health care provider can facilitate preventive gerontology, it is the acceptance by the individual of primary responsibility in managing his or her health and behavior that is central to the concept.

## Nutrition

A healthy diet can contribute to an increase in life expectancy and better health. Healthy diets have shown the potential to lower blood pressure and blood cholesterol. Optimal diets have also been associated with lower risk of chronic diseases, notably CAD, diabetes, obesity, and some forms of cancer. NHANES III data show potentially important decreases with age in median protein and zinc intakes as well as intakes of calcium, vitamin E, and other nutrients. Subclinical nutrient deficiencies can adversely affect health and physical functioning. Longitudinal studies have shown that caloric intake and macronutrient (fat, protein, and carbohydrate) intake decrease with age.

A diet with adequate calcium and vitamin D reduces the risk of osteoporosis, which is a major cause of fractures and concomitant disability and threatened independence, especially in postmenopausal women. Optimal serum levels of 25-hydroxy vitamin D [25(OH)D] (75–100 nmol/L) appear to not only have a salubrious effect on bone mineral density but may also reduce risk of colon cancer (via less cell proliferation and more cell differentiation), falls (via prevention of muscle weakness), and periodontal disease (independent of bone health). However, the currently recommended daily intakes of vitamin D (200 IU for younger adults, 600 IU for older adults) appear to be insufficient to achieve these optimal serum concentrations.

The traditional Mediterranean diet, dominated by consumption of olive oil, vegetables, nuts, and fruits, meets criteria for a healthy diet. Direct evidence in support of this diet has become available. For example, it has been associated with prevention of progression of cardiovascular disease and reversal of the metabolic syndrome. Such a diet appears to improve endothelial function, reduce serum markers of systemic vascular inflammation (C-reactive protein and the proinflammatory interleukins (IL) IL-6, IL-7, and IL-18), and decrease insulin resistance. A plausible mechanism by which this diet may reduce inflammation may lie in either the antioxidants or the fiber that are common elements in the different components of the diet. Either antioxidants or fiber may effect a reduction in the transient oxidative stress associated with macronutrient intake. The sixth edition of *Nutrition and Your Health: Dietary Guidelines for Americans*, available online at <http://www.health.gov/dietaryguidelines/>, can serve as a reference for providers in counseling adults about healthful eating patterns.

## Physical Activity

Physical activity and physical fitness can help prevent or delay the onset of chronic illnesses such as CAD, type II diabetes, osteoporosis, and obesity; protect against the development of functional decline; improve mood; reduce stress; and, perhaps, increase life expectancy. Physical activities that improve endurance, strength, and flexibility will delay impairments in mobility and may preserve the ability to perform tasks of daily living. Regular, moderate-intensity physical activity increases muscle mass and oxidative capacity, improves immune function, increases antioxidant defense against oxygen free

radicals, and reduces oxidative stress. The current recommendation that every American exercise at least 30 minutes on most, and preferably all days, derives from evidence that even moderate physical activity is associated with a substantial drop in all-cause mortality. The cumulative, lifetime activity pattern may be the most influential factor in terms of providing protection from most diseases, especially those with a long developmental period, as well as mediating secondary disease complications associated with CAD, diabetes, and hypertension. However, despite an enormous amount of information about the positive effects of exercise in preventing disease and increasing life expectancy, the majority of adults do not engage in regular, sufficient physical activity. For example, only 15% of the U.S. adult population met the 30 min/d goal in 1997, and 40% of adults engaged in no leisure-time physical activity. Women are less likely than men to report regular leisure time physical activity; the lowest levels typically are among women of Hispanic or African-American descent. Furthermore, aging appears to be associated with a rise in the prevalence of inactivity, especially among women, such that by age 75 years, one in three men and one in two women engage in *no* regular physical activity. Societal changes over the past 50 years, including increased dependence on cars for transportation, the advent of television and computers, and rise in number of desk jobs, have virtually engineered physical activity out of the daily routines of many Americans. Many mid-life and older adults are unaware of the benefits of physical activity. Thus, encouraging and prescribing physical activity for adults of all ages is imperative and can be viewed as a central tenet of preventive gerontology. Regular participation in activities of moderate intensity (such as brisk walking, climbing stairs, scrubbing floors, yard work), which increase caloric expenditure and maintain muscle strength, is recommended, as it is activity of moderate intensity that appears to allow health benefits to accrue. Current national guidelines suggest at least 30 minutes of moderate intensity exercise on 5 or more days per week (CDC) or vigorous intensity exercise (such as swimming laps, bicycling more than 10 miles per hour, jogging, or running) for 20 or more minutes on 3 or more days per week. The CDC, American College of Sports Medicine, and Surgeon General further state that daily physical activity requirements may be accumulated over the course of the day in short bouts of 10 to 15 minutes. Building activity into one's daily routine (e.g., taking the stairs rather than an elevator) is a practical and efficacious way to achieve a pattern of regular physical activity. Helpful, patient-centered information about how to become more active can be found at the CDC's Physical Activity for Everyone (<http://www.cdc.gov/nccdphp/dnpa/physical/index.htm>) and for overweight and obese adults, the Active at Any Size (<http://www.healthfinder.gov/docs/doc11151.htm>) Web sites.

Several psychological and environmental factors determine physical activity behavior throughout the life span. Self-efficacy, or confidence in one's ability to perform a particular behavior (in this case, regular exercise), is strongly associated with both adoption of and adherence to physical activity among adolescents, young adults, and older adults. Strategies suggested by Bandura to enhance self-efficacy, such as assessing readiness for exercise using a behavior change philosophy, using motivational interviewing techniques, weekly action planning and feedback, collaborative problem-solving, and addressing barriers to exercise may all enhance self-efficacy for exercise. These techniques can be learned and implemented by health care providers. Affective disorders such as depression and anxiety are inversely associated with physical activity participation at any age.

Thus, evaluation for the presence of these conditions and institution of treatment may be necessary before adoption of an exercise program can occur. Social influences on physical activity appear to be strong throughout the life span. Peer reinforcement is particularly important in youth, while social support from spouses and friends is correlated with vigorous activity in younger and older adult populations. Finally, environmental factors, particularly safety and accessibility, influence activity participation across the age span. These latter factors are increasingly becoming a focus of community intervention efforts.

## Social Connections

Ongoing involvement in a social network permits social contact (integration), the provision of social support, and the opportunity for social influence, and is associated with positive health outcomes and self-assessed well-being. Through opportunities for social engagement, such as attending social functions, getting together with friends and family, and going to church, meaningful social roles are defined and reinforced, creating a sense of belonging and identity that is made possible by the network context. Measures of social integration or “connectedness” are powerful predictors of mortality likely because ties give meaning to an individual’s life by enabling and obligating them to be fully involved in their community and thereby to feel attached to it.

In turn, there are several pathways most proximate to health by which social networks are thought to influence health: (1) a health behavioral pathway; (2) a psychological pathway; and (3) a physiologic pathway. Regarding the health behavioral pathway, social ties have been shown to influence the likelihood that certain behaviors will be adopted and that behavior will change (see also Chapter 28). Social influence refers to the way members of a social network obtain normative guidance about health-relevant behaviors (physical activity, smoking, etc.). For example, marriage and friendship ties have been shown in several studies to promote a healthier diet, more regular exercise, less smoking and drinking, and more cancer screening. Spouse pairs demonstrate a concordance in their level of exercise, smoking, and drinking. However, studies have also shown that family and friends carry the potential for encouraging detrimental health behaviors: for example, the presence of a smoker in one’s social network has been associated with greater relapse in efforts to quit. Adherence and nonadherence to medical treatments have each been linked to the presence of more social ties. Thus, the evidence indicates that ties can serve as role models of appropriate or undesirable behavior. Evidence also suggests that social network size, or “connectedness,” is inversely related to risk-related behaviors. Data from Alameda County show a gradient between increasing social disconnection and the prevalence of both health-damaging behaviors and mortality.

A second mechanism by which social networks influence health is via psychological pathways. Evidence suggests that ongoing participation in one’s social network is essential for the maintenance of self-efficacy beliefs throughout life. For example, studies have observed the indirect influence of social support through enhanced self-efficacy in smoking cessation and exercise. In addition, it is generally accepted that social ties have a salutary effect on mental health and psychological well-being, regardless of whether an individual is under stress. Integration in a social network may also directly produce positive psychological states, such as a sense of self-worth,

purpose, and belonging. These positive states, in turn, may benefit mental health due to direct modulation of the neuroendocrine response to stress and may increase the likelihood of social support, protecting against psychological distress (depression and anxiety).

A third mechanism by which social networks influence health is via physiologic pathways. The basic premise is that human physiologic homeostasis is influenced by the social environment. Social relationships may influence health via alteration in immune response, by effects on the hypothalamic–pituitary–adrenal axis, or by cardiovascular reactivity. For example, a low number of contacts with acquaintances is associated with high resting plasma levels of epinephrine, and people with low social support have been found to have higher levels of urinary norepinephrine, regardless of their level of stress. Studies of medical students have shown that those who were lonely had lower levels of natural killer cell activity.

## Cognitive Activity

Continuing cognitive activity has been shown to help maintain cognitive function. Crossword puzzle solving and reading are two examples of activities that can help maintain cognitive skills. Higher levels of education (and cognitive ability, for which education could be a marker) are associated with less age-related loss in cognitive function.

## Napping

New evidence from the Greek European Prospective Investigation into Cancer and Nutrition Cohort, a population-based study involving Greek men and women, suggests that napping may have beneficial effects, particularly for men free of serious illness. Men and women taking midday naps of any duration or frequency had a 34% reduction in coronary mortality. Those who took an occasional nap had a 12% reduction in mortality, while those who napped on average at least 30 minutes, at least three times a week had a 37% reduction in mortality. In analyses stratified by gender, these effects appeared to be significant for men but not for women. The inverse association was significant among men who were currently working but nonsignificant among men who were not currently working (mainly retirees). The putative mechanism for this benefit, as described by the study authors, may be stress reduction.

## Health Care

A primary purpose of health care in an aging society is to help each individual set and achieve personal health-related goals, i.e., goals that will enhance active life expectancy and quality of life. Adults should be instructed to seek medical attention early for bothersome symptoms. They should receive education about self-management of chronic conditions, including the importance of long-term adherence to medications (e.g., for treatment of hypertension or dyslipoproteinemia) prescribed to treat such conditions. Finally, they should be advised to participate fully in the periodic preventive screening and health care activities described below.

## Blood Pressure Evaluations

A recent study supported by the National Heart, Lung, and Blood Institute indicates that middle-aged Americans face a 90% chance

of developing high blood pressure at some time during the rest of their lives. All patients should be counseled that the development of high blood pressure is not an inevitability, and should be educated about the role of abstaining from smoking, following a healthy eating plan that includes low sodium, maintaining a healthy weight, being physically active, and consuming alcohol in moderation in the prevention of hypertension altogether.

The Framingham study showed that men aged 45 to 64 years with blood pressures above 160/95 have two to three times the CAD rate of those with pressures under 140/90. Among those with systolic pressures above 160, strokes are three times as frequent as among those with systolic pressures under 140. Thus, treating high blood pressure with lifestyle modification and medication will reduce the risk of CAD and stroke. There is also reasonably strong evidence that treatment of hypertension will decrease the risk of cognitive impairment.

### Lipid Evaluations

Premature heart disease is unequivocally associated with elevated blood cholesterol levels. Data from the Framingham study indicate that for a 1% rise in cholesterol there is a 2% rise in CAD, while for a 1% rise in high-density lipoprotein (HDL) cholesterol, there is a 2% fall in risk of CAD. Strategies to increase HDL levels while lowering low-density lipoprotein (LDL) cholesterol to the total cholesterol:HDL cholesterol ratio of 3.5 or less are recommended. The USPSTF recommends that all adults (men beginning at age 35 years and women beginning at age 45 years) be screened routinely for lipid disorders to determine whether their cholesterol levels increase their risk for heart disease, and that providers treat abnormal lipids in people who are at increased risk for coronary heart disease. Screening should include total and high-density lipoprotein cholesterol. Providers should counsel all patients about lifestyle changes (reducing saturated fat in the diet, adequate intake of fruits and vegetables, exercising, and losing weight) that can improve their lipid levels. Individuals at highest risk may require medication to control their lipid abnormalities. Prediction tools can help guide treatment decisions; such tools provide a more accurate estimation of cardiovascular risk than does a count of the number of risk factors; see [www.bmj.com/cgi/content/full/320/7236/709](http://www.bmj.com/cgi/content/full/320/7236/709) for an example. An update of these (2001) recommendations is currently underway by the USPSTF.

The Adult Treatment Panel III (ATP III) National Cholesterol Education Program (NCEP) Update 2004: Implications of Recent Clinical Trials for the ATP III Guidelines (see <http://www.nhlbi.nih.gov/guidelines/cholesterol/atp3upd04.htm>) details current cholesterol treatment guidelines, including among others, the recommendations that (1) for very high-risk persons, an LDL-C goal of <70 mg/dL is a therapeutic option; (2) for high-risk persons with high triglycerides or low high-density lipoprotein cholesterol (HDL-C), the combination of a fibrate or nicotinic acid derivative with an LDL-C lowering drug should be considered. These recommendations need to be considered within the context of older adults' life expectancy, comorbidity, and preferences.

### Glucose Monitoring

Diabetes is an important risk factor for CAD. Patients with diabetes tend to have more severe atherosclerosis, two to three times as many myocardial infarctions, and twice as many strokes as persons not

having diabetes at the same age. This is especially germane for women, in whom diabetes appears to negate their relative (5 to 10 years) protection from CAD. In other words, a woman with diabetes is at equal risk of CAD at any given age as a man with diabetes. Current interventions for the prevention of type II diabetes mellitus are those targeted toward modifying risk factors such as reducing obesity and promoting physical activity. Awareness of risk factors for developing type II diabetes (i.e., strong family history of diabetes, age, obesity, physical inactivity, and having a personal history of gestational diabetes or being an offspring of a woman who had gestational diabetes) is important to permit screening, early detection, and treatment in high-risk populations.

Recent evidence suggests that weight reduction (via caloric restriction and increased physical activity) can reduce the risk of developing type II diabetes in overweight adults. This strategy appears to be more effective than pharmacological intervention (with metformin) in reducing insulin resistance (58% reduction in incidence of diabetes with lifestyle modification vs. 31% with metformin, each compared to placebo). Other lines of evidence (chiefly from clinical trials of statins that have included diabetics) underscore the importance and efficacy of CAD risk reduction in diabetics, in whom the risk of CAD events in the absence of clinical CAD is equivalent to that of persons not having diabetes with CAD. This has led to a more ambitious goal for LDL cholesterol reduction in patients with diabetes in the 2001 ATP III NCEP to 100 mg/dL or less, the same as in persons not having diabetes with CAD or other atherosclerotic vascular disease. The NCEP 2001 report can be viewed at <http://www.nhlbi.nih.gov/guidelines/cholesterol/index.htm>. These recommendations did not address older adults specifically and they need to be interpreted in the context of other comorbidities, life expectancy, likelihood of adverse consequences of preventive treatments, and preferences.

### Cancer Screening

Cancers and cancer deaths can be prevented both by limiting exposure to known carcinogens and through early detection and treatment before a cancer has spread. Available screening procedures for colon and cervical cancer, if more widely applied to asymptomatic persons, would likely prevent many deaths from these diseases. For example, The Minnesota Colon Cancer Control Study showed that annual fecal occult-blood testing reduced mortality by 33%. The USPSTF, in its 2002 review, found insufficient evidence that newer screening technologies (e.g., computed tomographic colography) improve health outcomes. A large body of observational studies suggests that early detection through periodic Papanicolaou (Pap) testing lowers mortality from cervical cancer by 20% to 60%. Most organizations recommend discontinuing Pap testing in older women who have multiple negative results and who have been tested regularly.

Mammographic screening for breast cancer remains controversial, given the risks (e.g., low sensitivity and specificity of mammography, false-positive results that generate additional testing and result in anxiety; overdiagnosis and unnecessary treatments) and costs associated with periodic (every 1–2 years beginning at the age of 40 years) screening. Debate continues over whether a survival benefit is derived from mass screening for breast cancer. Clinicians and women should discuss individual risk factors and personal preferences to determine when to have a first mammogram and how often to have them after that. Screening for early detection of prostate cancer also

remains controversial, especially beyond age 70 years. The utility of screening for lung cancer remains an area of active investigation. In 2004, the USPSTF found poor evidence that any screening strategy (chest x-ray, sputum cytology, low-dose computerized tomography) for lung cancer results in decreased mortality. Studies are underway that should provide information about the effectiveness of more modern screening tests, including spiral computed tomography (CT). For more information, see <http://www.cancer.gov/nlst> (the National Lung Screening trial; results expected by 2009) and <http://www.cancer.gov/prevention/plco/> (the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial).

### Depression Screening

Depression is a common and disabling condition. Those with a family history of depression, women, the unemployed, and those with chronic disease are at increased risk of depression. The USPSTF recommends screening adults for depression in clinical practices that have systems in place to ensure accurate diagnosis, effective treatment, and follow-up. This recommendation is comparable to those made by other groups, including the Canadian Task Force on Preventive Health Care (see <http://www.ctfphc.org/>).

### Immunizations for Pneumococcal Pneumonia and Influenza

Both pneumococcal pneumonia and influenza can lead to hospitalization and disability. Vaccinations should be administered to any adult with a chronic condition regardless of age and universally for those over 65 years.

### Aspirin for Primary Prevention of Myocardial Infarction

There is evidence that aspirin decreases the incidence of CAD in middle-aged and older adults who are at increased risk (i.e., a 5-year risk of 3% or more) but have never had a myocardial infarction or a cerebrovascular accident (CVA). Combined data from five clinical trials show that aspirin therapy lowers the risk of CAD by 28%. However, there is no reduction in the risk of CVA with aspirin; the risk of having a hemorrhagic CVA is actually slightly increased. There is also an increased risk of gastrointestinal bleeding with aspirin. Thus, the risk may outweigh the benefits for those who are at average or low risk for CAD. A risk calculator can be found at <http://hin.nhlbi.nih.gov/atp/iii/calculator.asp>.

### Low to Moderate Dose Aspirin for Reduction of All-Cause Mortality in Women

New data from the Nurses' Health Study suggest that use of low to moderate dose aspirin reduces mortality in women, especially for women who have cardiovascular risk factors or who are older. The benefit for cardiovascular mortality was evident within 5 years of use, while the benefit for cancer mortality required prolonged (10 years or more) use.

## CONCLUSION

Adoption and maintenance of a healthy lifestyle should be emphasized from childhood through older adulthood. Sound health habits not only help people survive longer but postpone the onset of disability and compress functional loss into fewer years at the end of life. Among the most important self-care behaviors are those that involve adequate nutrition, avoidance of tobacco use, and regular physical activity. Healthy aging policy should emphasize modification of lifestyle risk factors across the life span and communities that support healthy eating and physical activity. As the population ages, the potential for strain on health care systems will increase, because the greatest use of health services has tended to occur during the last years of life. Thus, in the present health care environment, health promotion is an important focus for providers who care for individuals of any age.

# Evaluation, Management, and Decision Making with the Older Patient

*Sharon E. Strauss* ■ *Mary E. Tinetti*

Clinical decision making, including diagnosis, treatment, and desired outcomes, differs between younger and older adult patients. The primary goal of medical care in younger adult patients usually is diagnosis of the disease causing the presenting symptoms, signs, and/or laboratory abnormalities. Treatment is targeted toward the pathophysiologic mechanisms deemed responsible for the disease. Relevant clinical outcomes are determined by the specific diseases and include cure if the disease is acute, and control or symptom modification if the disease is chronic.

The conventional disease-specific approach is not optimal in older patients for several reasons. First, age-related physiologic changes in most organ systems affect diagnostic test interpretation and response to treatments and may be difficult to differentiate from disease. In addition to age-related physiologic changes, the average 75-year-old suffers from 3.5 chronic diseases. With multiple coexisting chronic diseases, there is a less consistent relationship between pathology and disease or between disease and clinical manifestations. One disease may obscure or change the pathology, manifestations, or accuracy of laboratory evaluation of coexisting diseases. Treatment of one disease may increase the severity of another. With multiple coexisting diseases, it becomes difficult, and often impossible, to assess the severity or manifestations of individual diseases and to ascribe health and/or functional status to specific disease processes.

Second, many distressing symptoms or impairments among older persons, such as pain, dizziness, fatigue, sleep problems, sensory impairments, and gait disorders cannot be ascribed to a single disease; instead, they result from the accumulated effect of physical, psychological, social, environmental, and other factors. A clinical focus solely on diagnosing and treating discrete diseases may lead to expensive diagnostic testing with inconclusive results, to unnecessary, or even harmful, interventions, or, conversely, to ignoring potentially remediable symptoms. While clinicians may be reluctant to treat symptoms in younger and middle-aged patients without a specific diagnosis, treatment focused on improving symptoms in multiply

ill and impaired older patients is often appropriate, because comfort and function are primary goals of health care in this population.

Third, diagnostic test characteristics may be altered by age and comorbidity, making selection and interpretation of tests more complicated than for younger patients. Furthermore, both the benefits and harms of treatment regimens may differ in the face of age-related physiologic changes and coexisting health conditions.

Fourth, older patients vary in the importance they place on potential health outcomes. When asked, older persons are able to prioritize among the often competing goals of increased survival, comfort, cognitive function, and physical function. Optimal clinical decision making in the care of older patients includes the articulation of patient preferences or goals of care; the identification of the diseases, impairments, and nondisease-specific factors affecting the attainment of these preferences and goals; and the selection of treatment options based on the modifiable impediments to individual patient goals. The multiplicity of impairments and diseases; the contribution of psychological, social, and environmental factors to health conditions; the enhanced likelihood of harm as well as benefit from many interventions; and the interindividual variability in patient preference all combine to make clinical decision making in the care of older persons very complex.

Fifth, clinical decision making is further complicated in older patients because other persons, including the spouse, adult children, other relatives, and significant others, are often actively involved, particularly when cognitive impairment is present. Involvement of family and friends is helpful and often crucial, since they may provide additional sources of information, facilitate adherence to treatment recommendations, and offer both emotional and instrumental support. Conflicts may arise, however, when goals of the patient and family differ. Striking a balance between patient confidentiality and family involvement, between independence and support, and between patient and family goals is a constant challenge. When based on an understanding of these factors, however,

the clinical care of older persons is both effective and immensely gratifying.

## PRESENTATION

At least three factors affect clinical presentation in older persons: underreporting of symptoms and impairments, changes in the patterns of presentation of individual illnesses, and an altered spectrum of health conditions. Contrary to a popular perception of older persons as complainers, they tend to underreport significant symptoms. One reason for underreporting is that both older persons and their clinicians often dismiss treatable symptoms and impairments as age-related changes for which nothing can be done. Denial, resulting from fear of economic, social, or functional consequences, is suggested as another reason for underreporting health conditions. Cognitive impairment and depressive symptoms may further limit the ability or desire of some older persons to report symptoms and health conditions. This tendency to underreport means that clinicians must actively inquire about symptoms and concerns.

Altered presentation is a second characteristic of illness in older persons. While both acute and chronic illnesses may, and often do, present with “classic” signs and symptoms, age-related changes and coexisting conditions may combine to obscure these classic presentations in older persons. Symptoms or signs of one condition may exacerbate or mask those of another condition, complicating clinical evaluation. For example, arthritis, if it limits physical activity, may mask the presence of severe cardiovascular disease. Manifestations of clinically important disease may be attenuated in older persons, particularly those who are frail. Chest pain may be absent in older persons presenting with myocardial infarction, as may shortness of breath in persons with congestive heart failure. Another common phenomenon is that symptoms in one organ system may reflect disease in another system. Pneumonia may present as confusion or anorexia; a urinary tract infection may present with behavioral or functional changes. A corollary of these altered presentations is that signs and symptoms are often nonspecific. That is, while suggesting that the older person is experiencing an acute illness or an exacerbation of a chronic condition, the signs and symptoms may offer limited help in determining what the illness or condition might be. These altered presentations mean that the clinician must be particularly diligent in ascertaining all symptoms and signs. She must rely on combinations of findings from the history, physical examination, and ancillary testing to determine the diagnosis, or, as is often the case, to identify the treatable contributors to the illness or health condition.

Third, the spectrum of health conditions in older persons differs from younger patients. Important clinical entities include not only acute and chronic diseases but also geriatric syndromes as well as cognitive and physical disabilities. Geriatric syndromes are health conditions common in older persons that result from the accumulated effect of multiple predisposing factors and that may be precipitated by an acute insult. Examples described in other chapters include delirium, falls, and incontinence. Geriatric syndromes and disabilities are relevant because they may be the presenting manifestation of another underlying illness and because they are treatable causes of morbidity in their own right.

## EVALUATION

### Reason for Performing a Test or Evaluation

The process of establishing a diagnosis is complex for any patient. The goal may be to make a diagnosis in an ill patient, to generate a differential diagnosis for observed signs and symptoms, or to make an early diagnosis of presymptomatic disease among well individuals. Making diagnostic decisions is even more challenging in the older person because many have multiple conditions which can mask, mimic, or increase the symptoms of other diseases. Older persons may present atypically, and with nonspecific signs, symptoms and syndromes such as confusion or falls. Furthermore, contrary to the traditional clinical evaluation that is aimed at identifying the presence of discrete diseases, the aim of the clinical encounter in older patients maybe to identify the impairments, diseases, and other factors impeding the attainment of individual patient preferences and goals, as discussed below.

A clinical evaluation grounded in a clear understanding of these issues can be effective. These factors, however, dictate changes in the conventional clinical encounter in both the content and method of ascertainment for the history, the physical examination, and ancillary testing. It is important for clinicians to understand how to assess, interpret, and use the results of an evaluation.

Before deciding whether to pursue a diagnostic test, clinicians should take into account several issues related to the patient and to the characteristics of the test (Table 10-1). Clinicians should consider what they are going to do with the information obtained from the test and whether its consequences will help patients achieve their goals of care. For example, will the test be used to establish a diagnosis for which there is effective treatment? Is the patient willing to accept the treatment? Are there comorbid conditions or contraindications present that would preclude the patient from receiving the therapy? The diagnostic test is likely unnecessary if the patient is not interested in the therapy or if the therapy would result in significant risk of harm. The diagnostic test could also be done to assist with establishing a prognosis—but does the patient want this information? Will the diagnostic test lead to labeling, which can have

**TABLE 10-1**

### Issues to Consider in Deciding Whether to Perform a Diagnostic Test and How to Interpret Results

- How will the results be used?
  - Establish a diagnosis
    - Is there a safe and effective treatment?
    - Do comorbid conditions preclude treatment or make it ineffective?
    - Will the patient accept the treatment?
  - Establish prognosis
    - Does patient want the information?
  - Monitor disease progression or response to therapy
- Definition and interpretation of normal (see Table 10-2)
- Is the test accurate in the patient for whom it is being considered?
- Can the test distinguish persons with and without the targeted condition?
- Do the potential consequences of the test justify its cost and inconvenience?
- Can the test be performed and interpreted in a competent fashion?

**TABLE 10-2****Six Definitions of Normal**

1. Gaussian: the mean  $\pm$  2 standard deviations—this definition assumes a normal distribution for all tests and results in all “abnormalities” having the same frequency.
2. Percentile: within the range, say, of 5–95%, has the same basic defect as the Gaussian definition.
3. Culturally desirable: when “normal” is that which is preferred by society, the role of medicine gets confused.
4. Risk factor: carrying no additional risk of disease; nicely labels the outliers, but does changing a risk factor necessarily change risk?
5. Diagnostic: range of results beyond which target disorders become highly probable.
6. Therapeutic: range of results beyond which treatment does more good than harm.

disastrous consequences? Diagnostic tests can also provide assistance in monitoring therapy once initiated. Finally, is the test being done for academic curiosity or simply because it is available?

The older population may have multiple target conditions but it may not be necessary or clinically useful to pursue all of these with diagnostic tests. An alternative strategy to consider in the elderly with multiple illnesses and symptoms is to focus on symptom modification.

## Issues in Assessing and Interpreting Evaluation Results

### Definition of Normal in Older Persons

If a diagnostic test is to be performed, then several issues in assessing and interpreting results need to be considered. Results of interview, examination, and ancillary tests typically are reported as “normal” or “abnormal.” What is normal in the older person? There are at least six definitions of normal (Table 10-2) but this chapter will focus on the fifth definition, which refers to a range of results beyond which the target disorder becomes highly probable. The sixth definition is also worthy of consideration and includes the range of results beyond which treatment does more good than harm. This last definition is particularly important in the older population. Consider, for example, how the definition of normal blood pressure has changed over the past few decades as evidence accumulates that treatment of progressively less pronounced elevations in blood pressure does more good than harm.

### Assessing Diagnostic Test Accuracy

Prior to performing a diagnostic test, clinicians should review and understand its accuracy in older patients with a spectrum of comorbidities. When attempting to determine the accuracy of a diagnostic test, three questions must be considered: (1) is the evidence about the accuracy of a diagnostic test valid? (2) Is there evidence that this test can accurately distinguish patients who do and do not have a specific disorder? and (3) How can this valid, accurate diagnostic test be applied to a specific patient? In assessing validity, the three key components to consider are: (1) independent, blind comparison with a reference standard of diagnosis (e.g., auscultation for a heart murmur

should occur independent of results of the echocardiogram; pathological interpretation of a biopsy should be done without knowledge of laboratory tests that precipitated the biopsy); (2) performance of the reference standard regardless of the diagnostic result (e.g., either performance of pulmonary angiography or long-term follow-up in the absence of anticoagulation therapy to determine negative test accuracy for suspected pulmonary embolism); and (3) evaluation of the diagnostic test in a spectrum of patients similar to those in whom it will be used in clinical practice. Methods for assessing validity using these components have been described in several excellent reviews. Of particular relevance is whether the diagnostic test was evaluated in older patients with a spectrum of comorbidities similar to those in whom you plan to apply the test.

### Ability of Tests to Distinguish Patients Who Do and Do Not Have the Disease or Condition

Deciding whether a diagnostic test is important requires consideration of its ability to change the probability of disease prior to test completion (called the pretest probability of the target disorder) to a probability of the disease after test completion (called the posttest probability). Diagnostic tests that produce large changes from pretest to posttest probabilities are important and likely to be useful in clinical practice.

Consider, for example, a 76-year-old woman who is admitted to the hospital with community-acquired pneumonia. She responds nicely to appropriate antibiotics but her hemoglobin remains at 100g/L with a mean cell volume of 80. Her peripheral blood smear shows hypochromia. She is otherwise well and is on no incriminating medications. Her family physician found that her hemoglobin was 105 g/L 6 months prior to admission. She has never been investigated for anemia. A ferritin was ordered and the result is 60 mmol/L. Does this patient have iron-deficiency anemia?

In a systematic review and meta-analysis of the accuracy of ferritin for diagnosing iron-deficiency anemia, displayed in Table 10-3, the prevalence of iron-deficiency anemia was 31%. The posttest probability, also known as the positive predictive value, of iron-deficiency anemia among patients with a serum ferritin  $<65$  mmol/L was 73%. Conversely, for a serum ferritin  $\geq 65$  mmol/L, the posttest probability of iron-deficiency anemia is 5%, meaning that the probability of not having iron-deficiency anemia after a negative test result (serum ferritin  $\geq 65$  mmol/L) is 95%, which is known as the negative predictive value. Thus, the probability of iron-deficiency anemia has shifted from 31% to either 73% or 5% depending on the test result.

But, what if the patient’s pretest probability were greater than that of the population prevalence? A patient’s pretest probability can be estimated from a variety of sources including clinical experience, regional or national prevalence statistics, practice databases, the study used for deciding test accuracy, and studies devoted specifically to determining pretest probabilities (or differential diagnosis). Clinicians might reasonably estimate this patient’s pretest probability to be about 50%. The predictive value could be adjusted for this different pretest probability but it requires a lengthy equation. It is easier instead to calculate other measures of test accuracy such as likelihood ratios, which can be generated using sensitivity and specificity (Table 10-3). Using these two proportions, the patient’s ferritin result would be about six (90%/15%) times as likely to be seen in someone

**TABLE 10-3**

**Results of a Systematic Review of Serum Ferritin as a Diagnostic Test for Iron Deficiency Anemia**

		TARGET DISORDER (IRON-DEFICIENCY ANEMIA)		
		Present	Absent	Total
Diagnostic test result (serum ferritin)	Positive (<65 mmol/L)	731 <i>a</i>	270 <i>b</i>	1001 <i>a + b</i>
	Negative (≥65 mmol/L)	78 <i>c</i>	1500 <i>d</i>	1578 <i>c + d</i>
Total		809 <i>a + c</i>	1770 <i>b + d</i>	2579 <i>a + b + c + d</i>

Prevalence =  $(a + c)/(a + b + c + d) = 809/2579 = 31\%$ .  
 Positive predictive value =  $a/(a + b) = 731/1001 = 73\%$ .  
 Negative predictive value =  $d/(c + d) = 1500/1578 = 95\%$ .  
 Sensitivity =  $a/(a + c) = 731/809 = 90\%$ .  
 Specificity =  $d/(b + d) = 1500/1770 = 85\%$ .  
 Likelihood ratio (LR)<sub>+</sub> =  $sensitivity/(1 - specificity) = 90\%/15\% = 6$ .  
 LR<sub>-</sub> =  $(1 - sensitivity)/specificity = 10\%/85\% = 0.12$ .  
 Study pretest odds =  $prevalence/(1 - prevalence) = 31\%/69\% = 0.45$ .  
 Posttest odds =  $pretest\ odds \times likelihood\ ratio$ .  
 Posttest probability =  $posttest\ odds/(posttest\ odds + 1)$ .  
 Modified with permission from Guyatt GH, Oxman AD, Ali M, et al. Laboratory diagnosis of iron-deficiency anemia: an overview. *J Gen Intern Med.* 1992;7:145–53.

with iron-deficiency anemia as compared to someone without the condition.

Likelihood ratios cannot be combined directly to pretest probabilities. Their use requires converting pretest probability to odds, multiplying the result by the likelihood ratio, and converting the consequent posttest odds into a posttest probability. An easier method is to use the nomogram developed by Fagan (Figure 10-1). For the serum ferritin example, following a positive test result, a pretest probability of 50% results in a posttest probability of 86%.

The likelihood ratio indicates how much a diagnostic test result will raise or lower the pretest probability of the target condition. A likelihood ratio of 1 means that the posttest probability is the same as the pretest probability. Likelihood ratios >1.0 increase the probability that the target disorder is present; and the higher the likelihood ratio, the greater is this increase. Conversely, likelihood ratios <1.0 decrease the probability of the target disorder.

Likelihood ratios are of particular use with multilevel tests, that is, when there is not a single, dichotomous “normal” or “abnormal” result. They also are useful when doing tests sequentially. For example, the posttest probability resulting from a first test becomes the pretest probability for a second, subsequent test. Expressing the accuracy of serum ferritin with level-specific likelihood ratios highlights how restricting a continuous result to just two levels can be misleading (Table 10-4). The likelihood ratio for a serum ferritin <15 mmol/L is an impressive 52, which is sufficient to make a diagnosis of iron-deficiency anemia. Conversely, high levels of ferritin (>95 mmol/L) are sufficient to rule out the diagnosis of iron deficiency. Returning to the clinical scenario, the patient had a pretest probability of 50% and a serum ferritin of 60 mmol/L. This result generates a likelihood ratio of 1, which results in a posttest probability of 50%. This example highlights that the test, which was thought to be useful when considered as a two-level test, really is not been helpful in making a diagnosis.

**FIGURE 10-1.** Nomogram developed by Fagan to calculate posttest probabilities. The left-hand column represents the pretest probability, the middle column represents the likelihood ratio, and the right-hand column shows the posttest probability. The posttest probability is obtained by anchoring a ruler at the pretest probability and shifting it until it lines up with the likelihood ratio for the observed test result.

## Deciding Whether a Diagnostic Test Should Be Performed in a Specific Patient

A test should not be performed unless its potential consequences justify its cost and it can be performed and interpreted in a competent, reproducible fashion. For example, there are many different D-dimer and B-type natriuretic peptide (BNP) assays—all with varying accuracy—resulting in a challenging interpretation for clinicians. Diagnostic tests often behave differently among different subsets of patients, generating higher likelihood ratios in later stages of florid disease and lower likelihood ratios in early, mild stages.

For any target disease, there are probabilities below which a clinician would dismiss a diagnosis and order no further tests to pursue that particular diagnosis. Similarly, there are probabilities above which a clinician would consider the diagnosis confirmed and would stop testing and initiate treatment. When the probability of the target disease lies between the test and treatment thresholds, further testing is considered. The treatment and test thresholds are a matter of judgment and they differ for different conditions depending on the risks of therapy (if risky, clinicians want to be more certain of the diagnosis) and the danger of the disease if left untreated (if the danger of missing the disease is high and effective therapy is available). The test-treatment threshold may not be crossed until several diagnostic tests are performed.

In older persons, there are additional issues to consider including the ability of the patient to complete the test and whether the test does more good than harm. A patient with significant gait impairment, for example, is not going to be able to complete an exercise stress test. And, it may not be appropriate to consider a particular diagnostic test in someone with multiple comorbidities and poor quality of life. For example, a diagnosis of dyslipidemia is not likely to be clinically relevant in someone with terminal cancer.

Establishing whether a test does more good than harm would theoretically require randomizing patients to a diagnostic strategy that includes the test under investigation or to one in which the test is not available and following patients in both groups forward in time to determine the frequency of patient-important outcomes. While such trials are rare, there are a few. Consider for example a recent Cochrane review of studies that evaluated the impact of screening for prostate cancer. Two randomized trials including more than 55 000 patients found no statistically significant difference in prostate cancer mortality between men randomized to prostate cancer screening and controls (RR: 1.01, 95% CI: 0.80–1.29). However, neither study assessed the effect of prostate cancer screening on quality of life, all-cause mortality, or cost effectiveness. Even in this trial, several relevant clinical questions remain unanswered. In the absence of studies that directly assess benefits and harms, we can look for studies assessing test accuracy. The value of an accurate test is then best determined by considering whether the target disorder is dangerous if left undiagnosed, the test has acceptable risks, and effective treatment exists. All three criteria are relevant, particularly in older patients with multiple health conditions and limited life expectancy. Otherwise it will often be the case that tests may be accurate and management may change as a result of their application, but their impact on important patient outcomes may be less certain.

These concerns in selecting, performing, and interpreting tests pertain to the clinical history, physical examination, laboratory testing, imaging, and other components of a clinical evaluation. In the

next section, these and other issues relevant to the evaluation of the older patients are discussed. Illustrative examples are presented.

## History/Interview

### Setting and Source of Information

The clinical interview is an important element of the diagnostic process. It can be used to establish a diagnosis and monitor treatment and prognosis. The setting and sources of information may need to be adapted to the specific impairments of some older persons. Impairments in hearing, visual acuity, and cognition, each prevalent among older persons, mandate a quiet, well-lit, and unhurried setting—not easily obtained in today's health care environment—in order to obtain thorough and accurate information. Multiple encounters may be required to complete the history and to gather the necessary information. While the patient remains the key informant, the history often needs to be supplemented by information obtained from the family, friends, and other care providers, particularly if the older person has cognitive impairment.

### Ascertainment of Goals and Preferences

Patient-centered care dictates that clinical decision making should occur within the context of individual preferences and goals. Ascertainment of these preferences, which are known to vary among older patients and among patients with multiple health conditions, should occur early and often. Older persons rarely volunteer their preferences. Active solicitation of priorities and preferences, therefore, needs to be an integral part of the patient and family interview. Much research attests to the difficulty that patients, especially older patients, have in choosing among a set of treatment options. Rather than having patients make specific treatment choices, which is difficult and often unreliable, encouraging patients to prioritize among different outcome domains allows them to express directly what is most important to them regarding their health care. The elicitation of priorities among general, often competing health outcome domains, including longevity, comfort/symptom relief, cognitive functioning, and physical functioning should drive all evaluation and management decisions. The articulation of specific, feasible goals within these domains then necessitates the identification of underlying diseases, impairments, health conditions, and other factors.

### Components of the History and Interview

The altered, often attenuated, presentation of diseases, the coexistence of multiple processes and the underreporting of symptoms and conditions in older patients mandate a reordering of the importance of various components of the history. The chief complaint, the cornerstone of history-taking in younger patients, has decreased relevance in older persons. Indeed, overreliance on the chief complaint leads to the oft cited, though inaccurate, comment that older persons are “vague or poor historians.” Older patients are not necessarily poor historians. Rather, they may be accurately reporting the often vague, nonspecific manner in which their illnesses present.

**Review of Symptoms and Syndromes** The review of systems takes on greater importance in older persons and is often the vehicle by which treatable health conditions are revealed. Complementary to

the conventional review of systems, physicians should perform a review of syndromes, targeting modifiable multifactorial geriatric syndromes common in older persons including sleep problems, incontinence, pain, dizziness, falls, depressive symptoms, fatigue, anorexia, and weight loss. As noted earlier, these syndromes are both relevant targets of intervention themselves as well as clues to the existence of other acute and chronic illnesses. Difficulty, degree of dependence, and change in ability in both self-care or basic activities of daily living (ADL—eating, dressing, grooming, bathing, walking, and transferring) and instrumental activities of daily living (IADL—taking medication, handling finances, using transportation, preparing meals, housekeeping, communicating outside the home, and shopping) are integral components of the history in older persons constituting the inventory of functional status, as are frequency of participation in social and higher level physical activities. These functional activities often are the primary outcomes targeted in the treatment of older patients. Furthermore, changes in the frequency or difficulty in participating in these activities often herald the onset of a new, or worsening of an existing, illness.

**Assessment of Mood, Affect, and Cognition** The clinical history of older persons should also include assessments of cognitive function, affect, and mood (depressive symptoms), social supports, and economic and environmental factors because problems in these domains are prevalent in older persons, contribute to a wide range of health conditions, and are often modifiable. All patients should undergo quick screens of mood and affect, such as the two-question depressive screen (In the past month, have you been sad, blue, or down in the dumps? Have you lost interest in most things or been unable to enjoy them?) More formal, systematic assessments should be undertaken if there is any question of depression.

While the Mini Mental State Examination (MMSE) has good sensitivity (70%–92%) and specificity (77%–96%), shorter screening tests have been found to perform equally well. The Mini-Cog, for example, combines the three-item recall and the Clock Drawing Test (CDT). In a community-based study, the best performing scoring algorithm for the Mini-Cog was when the participant was judged to have dementia if either the three-item recall score was 0, or the three-item recall score was 1 to 2 and a CDT score was rated between 1 (mild) and 3 (severe). This scoring had a sensitivity of 99%, a specificity of 93%, a positive test likelihood ratio of 14.1, and a negative test likelihood ratio of 0.01. This scoring algorithm had a better sensitivity than the MMSE. The Mini-Cog has several advantages, which makes it a useful screening tool. It takes less than 5 minute to complete, is unaffected by language or education, and can be scored by untrained raters with minimal loss of accuracy. The high likelihood ratio of the best-performing algorithm reflected a population with a diagnosis of dementia and will be lower in populations with a low prevalence of dementia. A positive Mini-Cog should be followed by more comprehensive cognitive testing.

## Physical Examination

The physical examination in older persons differs from younger persons in content and purpose. The purpose of the physical examination in younger persons is primarily to diagnose specific diseases. The physical examination in older persons, however, also serves to identify treatable impairments such as muscle weakness, gait instabil-

ity, or sensory impairments, and to directly observe the performance of key functional tasks.

## Functional Examination

While the technique of physical examination in an older person is often the same as in younger persons, direct observation and functional testing play particularly important roles in older persons. Observing the older patient as they walk down the hall, get on and off the examination table or in and out of bed, and arises from a chair and get dressed and undressed is a valuable and time-efficient way to ascertain relevant information concerning muscle strength, joint range of motion, and gait stability as well as difficulty with daily functional tasks. Similarly, buttoning and unbuttoning a shirt or blouse, taking shoes on and off, and writing a sentence are simple tests of fine-motor coordination, manual dexterity, and motor planning. Reading a prescription bottle or a magazine provides information on visual acuity. Observing a patient's ability to follow multiple-step commands such as during finger-to-nose testing provides valuable information on cognitive, as well as neurological, functioning. Information on nutritional status can be inferred from observations of the face (e.g., temporal wasting) and hands (e.g., interossei atrophy). Recent weight loss can be judged from clothing that is too large, especially at the collar and waist.

## Interpreting Examination Findings

In interpreting physical examination findings, it is important to remember that the coexistence of multiple diseases and the occurrence of nondisease-specific physical impairments in older persons compromise the sensitivity and specificity and, consequently the predictive value of the physical examination in older persons. Abnormal findings may be linked to any of several diseases. Rales, for example, may result from any of congestive heart failure, interstitial fibrosis, or pneumonia, each common and often coexistent in older persons. A decreased neck range of motion may result from arthritis or be a secondary manifestation of voluntarily limiting neck turning because of dizziness caused by vestibular dysfunction. Conversely, the coexistence of multiple diseases may attenuate the physical findings of one or another disease process, such as when the sensitivity of the physical findings of congestive heart failure is compromised by the coexistence of chronic obstructive pulmonary disease.

Physical findings may also have important clinical and functional consequence, even when not linked to any specific disease. Peripheral neuropathy, manifested as decreased vibratory or position sense, for example, may be caused by any number of diseases, including diabetes mellitus, alcohol effect, or vitamin B-12 deficiency, or may occur in the absence of any clinically detectable disease process. Regardless of whether an underlying disease is causative, peripheral neuropathy is an important physical finding in its own right because it leads to gait unsteadiness and a predisposition to falling.

## Selecting Components of the Physical Examination to Perform

While the content of the physical examination will be much the same for older, as for younger patients, given time constraints, high-yield, relevant, but not as yet traditional, examination items should substitute for low-yield items. Low-yield items are those that have low specificity in older persons or that do not provide useful

information concerning diagnosis, prognosis, or treatment. Examples include the Weber and Rinne tests, undilated eye examinations, Papanicolaou (Pap) smear after age 65 years if previous results were normal, and routine testing of patellar reflexes because of the wide variation in “normal range.” Conversely, high-yield items that should become part of the standard physical examination of older persons are defined as findings common in older persons that provide useful diagnostic or prognostic information or suggest the presence of a modifiable condition associated with morbidity. The functional tests described above are examples of high-yield items that should be part of the standard examination. Postural blood pressure, gait examination, inspection of ear canal for cerumen, hearing, visual acuity, and foot examination are other such examples.

### Laboratory and Ancillary Tests

As for the physical examination, the coexistence of diseases and age-related changes may affect the sensitivity, specificity, predictive value, and interpretability of laboratory, imaging, and other ancillary tests. In addition, age-referenced normal values and ranges have been developed for some, albeit, not most laboratory tests.

In deciding whether to perform a laboratory, imaging, or other ancillary test, the clinician should consider the issues outlined in [Table 10-1](#) and the principles described in this chapter. This decision process is illustrated for the example of noninvasive imaging for carotid stenosis, an area for which new technologies are constantly being developed. Consider for example, an 80-year-old patient who presents with a transient ischemic attack. A Carotid Doppler ultrasound is ordered and reveal >70% stenosis of the carotid artery on the affected side. Magnetic resonance angiography (MRA) is ordered and the patient’s family wants to discuss whether to proceed with the test. Before the MRA is done, several issues should be considered in addition to ensuring that surgery is available and effective in your setting. Would the patient consider carotid endarterectomy? If the answer is no, further diagnostic testing is not warranted. Are there significant comorbidities or contraindications to the surgery? For example, if a patient has advanced dementia and poor functional status, the benefits of surgery would be questionable. If surgery might be contemplated, then it is appropriate to determine whether there are accurate and reliable tests for diagnosing carotid stenosis available in your setting.

A recent systematic review of the accuracy of noninvasive imaging tests compared with intra-arterial angiography for significant carotid stenosis in symptomatic patients can help with the last question noted above. Forty-one studies including 2541 patients were included in this review. The accuracy of the four imaging techniques for diagnosing significant carotid stenosis is provided in [Table 10-5](#). For diagnosing 70% to 99% stenosis, the specificity was lowest for MRA and Doppler ultrasonography. Thus, MRA may result in inappropriate surgery in up to one in seven patients. This systematic review suggests that noninvasive testing cannot appropriately be used to recommend carotid endarterectomy. Patients should be made aware that they will likely require intra-arterial angiography, which does carry a small but real risk of complications. Unless the clinician considers patient outcome goals and risk preferences as well as the accuracy of the diagnostic tests, some patients will have surgery who do not need or desire it and some medically treated patients will have preventable strokes.

**TABLE 10-5**

#### Accuracy of Noninvasive Imaging Techniques for Diagnosing 70%-99% Carotid Stenosis Compared with Intra-Arterial Angiography

IMAGING TECHNIQUE	SENSITIVITY (95% CI)	SPECIFICITY (95% CI)	+LR	-LR
CEMRA	95% (88 to 97)	93% (89 to 96)	13	0.06
DUS	89% (85 to 92)	84% (77 to 89)	5.6	0.13
MRA	88% (82 to 92)	84% (76 to 97)	5.5	0.14
CTA	77% (68 to 84)	95% (91 to 97)	15	0.24

## MANAGEMENT

Treatment decisions should be predicated on attaining feasible patient goals, particularly as treatment of one condition may worsen another and as many treatments adversely affect comfort and functioning. The increased chance of harm as well as benefit of most interventions in older persons dictates that a delineation and presentation of risks, benefits, and trade-offs should constitute an initial step in management. Furthermore, the coexistence of multiple conditions and the contribution of multiple factors to individual conditions require a prioritization of possible interventions to maximize adherence and benefit and minimize harm and burden.

Treatment focused on improving symptoms, rather than modifying disease, in multiply ill and impaired older patients is often appropriate, because comfort and function are primary goals of health care in this population. In contrast to a focus on disease management, which aims to reduce interindividual variability in treatment and monitoring, optimal management of older patients with multiple diseases, and variable health preferences and priorities is individualized.

Medication prescribing offers a particular challenge. There is an ever expanding list of medications available for treating chronic diseases and nondisease specific symptoms. Prescribing decisions need to be made within the context of patient preference and with an appreciation of total medication burden not solely the benefit and harm of each individual medication for an individual disease. The cost of medications is another significant medication-related issue in many older patients. Issues related to medication use in older patients are discussed in Chapter 24.

Because many health conditions in older persons result from the accumulated effect of psychological, social, and environmental, as well as purely medical, factors, a multicomponent, integrated treatment plan represents the most effective strategy. The use of nonpharmacologic interventions is one of the most effective ways to minimize medication use. For many health conditions, including diabetes mellitus, arthritis, congestive heart failure, depression, pain, and sleep disorders, treatment should include a combination of pharmacologic, rehabilitative, psychosocial, and environmental interventions. Exercise and physical activity are proven interventions for each of these conditions. Counseling and cognitive behavior therapies are

important treatment components for depression, pain, and sleep disorders. Interdisciplinary teams, as discussed in Chapter 26 are essential to the successful implementation of these multicomponent interventions.

# Principles of Geriatric Assessment

*David B. Reuben* ■ *Sonja Rosen*

Geriatric assessment is a broad term used to describe the health evaluation of the older patient, which emphasizes components and outcomes different from that of the standard medical evaluation. This approach recognizes that the health status of older persons is dependent upon influences beyond the manifestations of their medical conditions. Among these are social, psychological and mental health, and environmental factors. Geriatric assessment also places high value upon functional status, both as a dimension to be evaluated and as an outcome to be improved or maintained.

Although in the strictest sense geriatric assessment is a diagnostic process, many use the term to include both evaluation and management. Moreover, geriatric assessment is sometimes used to refer to evaluation by the individual clinician and at other times is used to refer to a more interdisciplinary process, comprehensive geriatric assessment (CGA). The terminology is further clouded because the latter process has evolved since its inception with respect to sites where the assessment is provided, the participating health professionals, the nature of the assessment, and the amount of follow-up and management that is included. Accordingly, any discussion of geriatric assessment must be precise in its description of the process of interest.

This chapter is divided into four components: (1) geriatric assessment by the individual clinician, with an emphasis on the outpatient setting; (2) a strategic approach to geriatric assessment for the practicing clinician; (3) CGA and evidence for its effectiveness; and (4) lessons learned from geriatric assessment that have been applied to health care delivery of older persons.

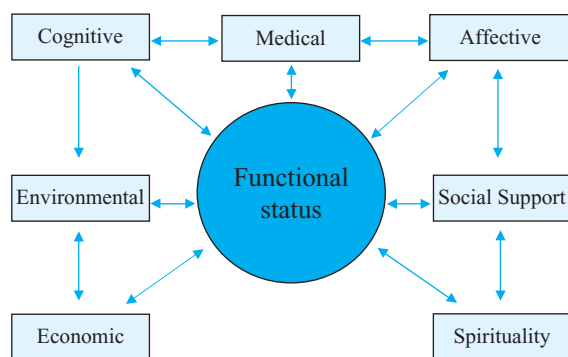

## GERIATRIC ASSESSMENT BY THE INDIVIDUAL CLINICIAN

Geriatric assessment (Figure 11-1) by the individual clinician extends beyond the traditional disease-oriented medical evaluation of older persons' health to include assessment of cognitive, affective,

functional, social, economic, environmental, and spiritual status, as well as a discussion of patient preferences regarding advance directives. Assessment instruments can be used to guide these evaluations but do not substitute for clinical skills and judgment, including the skill of eliciting important items from the patient's history and physical examination. Information obtained from assessment instruments can direct the clinician's attention to issues that are particularly relevant to an individual patient. Systematic assessment of the multiple domains noted above ensures that the evaluation is comprehensive. Some clinicians may prefer to rely on less formal questions to probe into potential problems. Examples of potential open-ended questions are provided later in this chapter.

Geriatric assessment differs according to the setting where the patient is being evaluated. In the hospital setting, the initial assessment is usually directed at the acute medical problem that precipitated the hospitalization. As the patient begins to recover and plans are initiated for discharge, other components (e.g., social support, environment) assume increasing importance in the assessment. The inpatient setting can be problematic for geriatric assessment because of the rapidly changing status of several key dimensions. For example, a patient may temporarily become "dependent" on all measures of functional status when acutely ill and gradually improve prior to discharge. Because patients may overestimate their functional status based on their previous level of functioning, direct observational methods (e.g., by nurses or physical therapists) may provide a more accurate assessment. The patient's full potential to participate in rehabilitation may not be known until near the time of discharge.

Nursing home geriatric assessment requires that attention be directed to selected aspects of assessment such as nutritional status and self-care activities. Other components such as functional status at the instrumental activities of daily living level (e.g., shopping, meal preparation) are less relevant in this setting. Geriatric assessment conducted in the patient's home provides an opportunity for an entirely different type of assessment; environmental factors (e.g., home safety) and insights into functional status (e.g., cleanliness of

**FIGURE 11-1.** Interacting dimensions of geriatric assessment.

the home) can be directly assessed while other aspects of the traditional examination (e.g., the gynecologic examination) are much more difficult.

Because the primary site of most clinicians' practices is the office setting, assessment techniques are described primarily for this setting. When appropriate, differing, or particularly important information about assessment in other settings is added.

### Components of the Geriatric Assessment

In addition to the standard medical history and physical examination, the clinician should systematically search for specific conditions that are common among older persons and that might have considerable impact on function. In the course of the traditional medical evaluation, these problems may go unnoticed because older patients fail to report them spontaneously. For example, they may not recognize that falling is a treatable medical problem. They may also be embarrassed to mention problems with maintaining urinary continence or with sexual function. Finally, they may believe that these symptoms, such as hearing loss, are normal aspects of aging that cannot be helped.

### Visual Impairment

Visual impairment is a common and often under-reported problem in the older population. Each of the four major eye diseases (cataract,

age-related macular degeneration, diabetic retinopathy, and glaucoma) increases in prevalence with age. Moreover, presbyopia is virtually universal and the vast majority of older persons require eyeglasses. Visual impairment has been associated with increased risk of falls, functional and cognitive decline, immobility, and depression. The high rates of vision disorders and their associated sequelae, the brevity of the screening process, and the treatments available for visual impairment justify screening for visual impairment.

The standard method of screening for problems with visual acuity is the Snellen eye chart, which requires the patient to stand 20 ft from the chart and read letters, using corrective lenses. Patients fail the screen if they are unable to read all the letters on the 20/40 line with their eyeglasses (best corrected vision).

Several interviewer and self-administered instruments to detect functional problems caused by visual impairment have been developed, including the "Activities of Daily Vision Scale," VF-14, VFQ-25, and the Cataract Symptom Scale. These are primarily used in research settings, but may hold promise as screening instruments in the future.

### Hearing Impairment

Hearing impairment is among the most common medical conditions reported by older persons, affecting approximately one-third of those 65 years of age or older. Hearing impairment is associated with reduced cognitive, emotional, social, and physical function in older persons and the use of amplification devices has led to improved functional status and quality of life of older persons.

Screening for hearing loss can be accomplished by several methods (Table 11-1). The most accurate of these is the Welch Allyn AudioScope 3 (Welch Allyn, Inc., Skaneateles Falls, NY), a handheld otoscope with a built-in audiometer. The AudioScope 3 can be set at several different levels of intensity, but should be set at 40 dB to evaluate hearing in older persons. A pretone at 60 dB is delivered and then four tones (500, 1000, 2000, and 4000 Hz) at 40 dB are delivered. Patients fail the screen if they are unable to hear either the 1000- or 2000-Hz frequency in both ears or both the 1000- and 2000-Hz frequencies in one ear, indicating the need for formal audiometric testing.

A simple alternative is to rely on patient's own subjective report of hearing loss. A self-reported hearing loss question involves asking

**TABLE 11-1**

#### Simple Tests of Hearing Loss

QUESTION/TEST	TIME TO ADMINISTER	COMMENTS
Audioscope	1–2 minutes	Sensitivity 87–90%, specificity 70–90%
Single question: "Do you feel you have a hearing loss?"	<1 minute	Sensitivity 75–81%, specificity 64–70%
Whisper test	1 minute	Sensitivity 80–100%, specificity 82–89%
Hearing handicap	2 minutes	Sensitivity 48–63%, specificity 75–86% at cutpoint >8
Inventory for the elderly NHANES* battery	<2 minutes	Sensitivity 80%, specificity 80% at cutpoint of >3
Age >70 = 1		
Male sex = 1		
≤12th grade education = 1		
Previously saw doctor about trouble hearing = 1		
Without hearing aid, cannot hear whisper across the room = 1		
Without hearing aid, cannot hear normal voice across the room = 2		

\*National Health and Nutrition Examination Survey.

patients whether they feel they have hearing impairment. An affirmative answer is then considered to be a positive test for hearing loss, and patients should be referred to an audiologist.

Another alternative is the whispered voice test, which is administered by whispering three to six random words (numbers, words, or letters) at a set distance (6, 8, 12, or 24 inches) from the person's ear and then asking the patient to repeat the words. The examiner should be behind the person to prevent speech reading and the opposite ear should be covered or occluded during the examination. Patients fail the screen if they are unable to repeat half of the whispered words correctly.

Similar to vision screening, a self-administered test of emotional and social problems associated with impaired hearing, the Hearing Handicap Inventory for the Elderly—Screening Version (HHIE-S) was developed. Although this questionnaire is brief and easy to administer, its accuracy when compared to audiometry is less than the audiometer. Another screening instrument that uses sociodemographic information coupled with three simple questions (see Table 11-1) about hearing loss has high accuracy in identifying older persons with hearing loss.

### Malnutrition/Weight Loss (See Also Chapter 38)

Malnutrition is a global term that encompasses many different nutritional problems that are associated with diverse health consequences. Both extremes of body weight place older people at risk for subsequent functional impairment, morbidity, and mortality. Among community-dwelling older persons, the most common nutritional disorder is obesity. In addition, a small percentage of community-dwelling older persons have energy or protein energy undernutrition, which places them at higher risk for death and functional decline. Protein energy undernutrition is defined by the presence of clinical (physical signs such as wasting, low body mass index) and biochemical (albumin or other protein) evidence of insufficient intake. Although the importance of low serum albumin and low cholesterol as prognostic factors for mortality in community-dwelling, hospitalized, and institutionalized older persons has been demonstrated, these tests may reflect inflammation rather than malnutrition.

Several methods of nutritional screening can be applied in office settings. On their initial visit, patients should be asked about weight loss within the previous 6 months. All patients should be weighed at every office visit. Height should also be measured on the initial visit to allow calculation of body mass index (weight in kg/[height in meters]<sup>2</sup>). Several self-administered nutritional questionnaires are available, most notably the Nutrition Screening Initiative's 10-item checklist and the Mini-Nutritional Assessment (MNA). The use of the MNA can help detect risk of malnutrition while albumin and BMI are still in the normal range. Although the validity of these instruments has been questioned, they are being increasingly used in community-based screening programs.

In hospitalized older persons, malnutrition has been associated with higher mortality rates, delayed functional recovery, and higher rates of nursing home use. Therefore, energy and protein intake should be monitored closely in this setting. Intake can be measured through formal calorie counts. Laboratory monitoring may also be useful. Although serum albumin levels can drop acutely during inflammatory states, physiologic stress, and in response to trauma or surgical conditions, this protein has a long half-life (approximately 18 days). Accordingly, obtaining serum albumin level at the time of

hospital admission provides an idea of the patient's baseline nutritional status. Prealbumin, which has a much shorter half-life (approximately 2 days) may be a better means of monitoring response to nutritional treatment. Serum cholesterol may also be valuable in monitoring hospitalized patients as falling values have been associated with increased morbidity and mortality.

### Urinary Incontinence

Urinary incontinence is common, especially among older women, and is underrecognized. Women may be embarrassed to raise the issue; they also may regard it as a normal aspect of aging. Urinary incontinence has been associated with depressive symptoms in older adults. Moreover, effective treatments are available for incontinence. As a result, screening for urinary incontinence has increasingly been recognized as an indicator of quality of care.

Asking two questions can screen for incontinence: (1) "In the last year, have you ever lost your urine and gotten wet?" and if so, (2) "Have you lost urine on at least six separate days?" In a research setting, those who answered positive to both questions had high rates (79% for women and 76% for men) of urinary incontinence as determined by a clinician's evaluation (see Chapter 59).

The 3IQ questionnaire is another interviewer-administered instrument that has been developed to distinguish between urinary stress and urge incontinence in primary care settings, (Table 11-2) and will need further validation in clinical settings.

**TABLE 11-2**

#### The Three Incontinence Questions (3IQ)

- During the last 3 months, have you leaked urine (even a small amount)?  
Yes                      No → Questionnaire completed
- During the last 3 months, did you leak urine:  
(Check all that apply.)
  - When you were performing some physical activity, such as coughing, sneezing, lifting, or exercise?
  - When you had the urge or the feeling that you needed to empty your bladder, but you could not get to the toilet fast enough?
  - Without physical activity and without a sense of urgency?
- During the last 3 months, did you leak urine *most often*:  
(Check only one.)
  - When you were performing some physical activity, such as coughing, sneezing, lifting, or exercise?
  - When you had the urge or the feeling that you needed to empty your bladder, but you could not get to the toilet fast enough?
  - Without physical activity and without a sense of urgency?
  - About equally as often with physical activity as with a sense of urgency?

Definitions of type of urinary incontinence are based on response to question 3:

Response to Question 3	Type of Incontinence
a. Most often with physical activity	Stress only or stress predominant
b. Most often with the urge to empty the bladder predominant	Urge only or urge predominant
c. Without physical activity or sense of urgency cause	Other cause only or other predominant
d. About equally with physical activity and sense of urgency	Mixed

### Balance and Gait Impairments and Falling

Over one-third of community-dwelling persons over age 65 years fall every year. Falls are independently associated with functional and mobility decline. Patients who have fallen or have a gait or balance problem are at higher risk of another fall. The risk of falling

can be assessed by asking all older patients if they have fallen in the last year, and then performing a multifactorial falls assessment (Figure 11-2) by testing balance, gait, and lower extremity strength (see Chapter 54). Performing a multifactorial assessment on patients who screen positive for falls, and then treating their risk factors for

**FIGURE 11-2.** Structured visit note to assess persons who have screened positive for falls. The information above dotted line is collected by office staff.

falling can reduce falls by 30% to 40%. Moreover, the assessment of these components may also help identify methods to improve the patient's function beyond reducing the risk of falling. Screening for falls and falls assessment, if the screen is positive, are recognized as indicators of quality of care.

Clinicians should ask their older persons specifically about falls and fear of falling, which should be included in the review of systems at the initial visit and at least annually. The use of a previsit questionnaire can also help elicit this information. The report of any fall should prompt subsequent questions by the clinician to determine the circumstances of the fall. Patients with recurrent falls or falls with any injury should receive a more detailed evaluation, including assessment of gait and balance, orthostatic blood pressure readings, vision testing, and reviewing medications that may contribute to the risk of falling (see Chapter 54).

Observing patients walking and performing balance maneuvers best assesses balance and gait disorders. Once the clinician is trained to assess gait, this evaluation can be performed while the patient is entering or leaving the examining room. Several simple tests of balance and mobility can also be performed quickly in the office setting, including the ability to maintain a side-by-side, semitandem, and full-tandem stance for 10 seconds; resistance to a nudge; and stability during a 360-degree turn (Table 11-3). Quadriceps strength can be briefly assessed by observing an older person arising from a hard armless chair without the use of his or her hands. The timed "up and go" test is a timed measure of the patients ability to rise arm chair, walk 3 m (10 ft), turn, walk back, and sit down again; those who take longer than 20 seconds to complete the test should receive further evaluation. Gait speed is also a helpful marker for recurrent falls. Patients who take more than 13 seconds to walk 10 m are more likely to have recurrent falls.

The Performance-Oriented Assessment of Mobility is a standardized battery that measures gait and balance; it has been widely used in research and in clinical settings, but may take too long to admin-

ister to be practical in most office settings as a screening test. The ability to stretch as measured by functional reach, a test of balance, can predict subsequent recurrent falls.

### Polypharmacy (See Also Chapter 24)

Polypharmacy in older patients is associated with adverse drug reactions, reduced adherence, and inappropriate medication usage. Older persons often receive care from multiple providers and they may fill prescriptions at several pharmacies. Patients should be instructed, therefore, to bring in all current medications—both prescription and nonprescription medications—to each visit. Office personnel can check these against the medication list in the medical record and discrepancies can be brought to the clinician's attention at the time of the patient encounter. Several drug interaction programs are commercially available to check for potential drug–drug interactions. With the introduction of personal digital assistants and drug software programs, clinicians can easily assess the potential for drug–drug interactions at the time of prescribing any new medication. The use of four or more prescription and nonprescription medications should trigger a review and consideration of continued need for each medication given the increased risk of adverse drug effect with increasing number of medications.

### Cognitive Assessment

Because the prevalence of Alzheimer's disease, other dementias, and cognitive impairment, rises considerably with advancing age, the yield of screening for cognitive impairment increases with age. The most commonly used screen is the Mini-Mental State Examination, a 30-item interviewer-administered assessment of several dimensions of cognitive function. However, it is too long for most practitioners to routinely incorporate as a screening test into their clinical practices. Several shorter screens (Table 11-4) have also been validated including recall of three items at 1 minute, the clock drawing test, and the Mini-Cog test, which combines three-item recall and clock drawing. The Time-and-Change test, which employs clock recognition and counting change, is another valid screening test. The clock drawing components of these tests evaluate executive function (which includes higher cognitive processing) and appear to be less influenced by educational level or culture than some other cognitive assessments. Although normal results on these tests vastly reduce the probability of dementia and abnormal results increase the likelihood that the patient has dementia, these tests are neither diagnostic for dementia nor do normal results exclude the possibility of this disorder. Patients who have abnormal findings on a cognitive screening test should receive more in-depth evaluation of memory, language, visual–spatial, and executive function.

Among hospitalized patients, mental status should be assessed at the time of hospital admission and then periodically because older persons are especially prone to develop delirium during the hospital stay. Abnormal findings on the mental status examination in hospitalized patients must be interpreted in the context of change from baseline and the clinical situation. The Confusion Assessment Method provides a guide to interpreting such changes (see Chapter 53).

### Affective Assessment (See Also Chapter 70)

Although major depression is no more common among the elderly than the younger population, depression and other affective

**TABLE 11-3**

#### Simple Tests of Lower Extremities: Strength, Balance, Gait, and Fall Risk

QUESTION/TEST	TIME TO ADMINISTER	COMMENTS
Timed up and go	< 1 minute	Sensitivity 88%, specificity 94% compared to geriatrician's evaluation using cutpoint > 15 s
Gait speed over 10 m	< 30 s	> 13 s predicts recurrent falls (Likelihood ratio: 2.0; 95% CI, 1.5–2.7)
Office-based maneuvers Observed gait Resistance to nudge Tandem/semitandem stand Rising from chair 360° turn	2–3 minutes	Some are part of performance-oriented assessment of mobility
Functional reach	2 minutes	Adjusted odds ratios for > 2 falls within 6 mo 8.1 if unable to reach 4.0 if reach ≤ 6" 2.0 if reach ≥ 6" but < 10"

disorders are common and cause considerable morbidity. Depression in older adults may present atypically, and may be masked in patients with cognitive impairment or other neurologic diseases such as Parkinson's disease. A simple inquiry such as, "Do you often feel sad or depressed?" can be used as a screen. This single question, however, tends to be overly sensitive and may be better used in tandem with a second screen such as the Geriatric Depression Scale, which has 5-, 15-, and 30-item versions. A variety of other screens for depression are available and each has its advantages and disadvantages.

More recently, the Patient Health Questionnaire-9 (PHQ-9) has increasingly been used to detect and monitor depression symptoms. The PHQ-9 is a brief patient-administered depression scale, and provides a reliable and valid measure of depression severity. A score of >10 has a sensitivity of 88% and a specificity of 88% for major depression.

### Assessment of Function

Measurement of functional status is an essential component of the assessment of older persons. The patient's ability to function can be viewed as a summary measure of the overall impact of health conditions in the context of his or her environment and social support system. Moreover, in older persons, the ability to function consistent with their personal lifestyle desires should be an important consideration in all-care planning. Therefore, changes in functional status should prompt further diagnostic evaluation and intervention. An early indicator of impending functional disability is self-perceived difficulty with performing functional tasks. Measurement of functional status is also valuable in monitoring response to treatment and may provide prognostic information that will help plan for long-term care.

Functional status can be assessed at three levels: basic activities of daily living (BADLs), instrumental or intermediate activities of daily living (IADLs), and advanced activities of daily living (AADLs). BADLs refer to self-care tasks such as bathing, dressing, toileting, continence, grooming, feeding, and transferring. Instrumental activities of daily living refer to the ability to maintain an independent household such as shopping for groceries, driving or using public transportation, using the telephone, meal preparation, housework, home repair, laundry, taking medications, and handling finances, whereas AADLs refer to the ability to fulfill societal, community, and family roles as well as participate in recreational or occupational tasks. These advanced activities vary considerably from individual to individual but may be valuable in monitoring functional status prior to the development of disability.

Scales that measure functional status at each of these levels have been developed and validated. Questions that ask about specific BADL and IADL functions have also been incorporated into a variety of more generic health-related quality-of-life instruments (e.g., the Medical Outcomes Study Short-Form 36 and its shorter version, the SF-12). Some AADLs (e.g., exercise and leisure time physical activity) can also be ascertained by using standardized instruments, but open-ended questions about how older persons spend their days might provide a better assessment of function in healthier older persons.

Over the past decade, there has been emerging interest in assessment of physical functioning by directly observing the performance of functional tasks. Instruments have been developed for use in ambulatory, nursing home, and hospital settings, and predictive validity has been demonstrated for many. To date, these instruments are rarely incorporated into clinical practice, but some demonstration projects are in place that are attempting to use performance-based instruments in practice, much like vital signs, to monitor patients. Some recent studies demonstrate that combining self-reported functional with performance-based measures can provide more refined prognostic information than either method alone.

### Assessment of Social Support

The composition of the older patient's social support structure can be assessed by asking a few questions when obtaining the social history. The quality of these relationships should also be determined. For very frail older persons, the availability of assistance from family and friends is frequently the determining factor of whether a functionally dependent older person remains at home or is institutionalized. If dependency is noted during functional assessment, then the clinician should inquire as to who provides help for specific BADL and IADL functions and whether these persons are paid or voluntary help. Even in healthier older persons, it is often valuable to raise the question of who would be available to help if the patient becomes ill. Early identification of problems with social support may prompt planning to develop resources should the necessity arise.

### Economic Assessment

Although some clinicians feel uncomfortable in assessing the economic status of their patients, insurance status is routinely collected by office staff. The patient's income can also be assessed and eligibility for state or local benefits (e.g., In Home Supportive Services through Medicaid) to provide services for the functionally impaired

can be determined. For the frail and functionally impaired, physicians may need to begin discussions of planning to mobilize savings and other resources to provide personal attendant care.

### Environmental Assessment

Environmental assessment encompasses two dimensions, the safety of the home environment and the adequacy of the patient's access to needed personal and medical services. Particularly among frail individuals and those with mobility and balance problems, the home environment should be assessed for safety. Although most physicians do not personally conduct environmental assessments, the National Safety Council has developed a home safety checklist that patients and their families can complete. For those receiving home health services, in-home safety inspections can be performed, including recommendations for installation of adaptive devices such as shower bars and raised toilet seats.

Older persons who begin to develop IADL dependencies should be evaluated for the geographic proximity of necessary services such as grocery shopping and banking, their need for use of such services, and their ability to use these services in their current living situations. Older drivers are at increased risk for motor vehicle accidents secondary to functional impairments, medications, and medical conditions. The Older Drivers Project, created by the American Medical Association (AMA) and the National Highway Traffic Safety Administration (NHTSA), have produced materials to help physicians approach this issue.

### Spirituality

Spirituality, whether affiliated with a formal religious denomination or nonreligious intangible elements, has increasingly been recognized as an important influence on health. Recent data indicate that frequent attendance of religious services is associated with lower health care utilization and mortality rates. Formal instruments assessing spirituality have been developed but are not yet widely used in clinical practice. Simply asking older persons whether religion or spirituality is important to them may provide insights that may facilitate their care. Especially in hospital settings, involvement of pastoral care may be valuable in supporting the patient and in framing medical decisions in the context of the patient's personal belief system.

### Advance Directives

Discussions of advance directives are important for all patients and should be initiated early on to discuss the patients' goals and preferences for care should they become unable to speak for themselves because of progressive cognitive impairment or acute illness. Physicians can assist patients by focusing on patients' overall goals of care, rather than specific detailed interventions, and incorporating these goals into the patients' current clinical situation. A particularly important time to discuss such preferences is prior to surgery because of the possibility of surgical complications or postoperative delirium, which may preclude discussions following the procedure. The durable power of attorney for health care, which asks the patient to designate a surrogate to make medical decisions if the patient loses decision-making capacity, is often less emotionally laden than specifying treatments that the patient may or may not want. Such discus-

sions should be revisited any time there are significant changes in a patient's medical condition and a better understanding about prognosis becomes available. Patients often revise their thoughts about the benefits of treatment. Cultural differences regarding preferences for advance directives and end-of-life care should be recognized and respected.

### A Strategic Approach to Geriatric Assessment

The practice of medicine in office settings is in a state of transition from a previous era of medicine when physicians practiced more like individual artisans to an approach in which physicians function as members of a health care team. Much of the germane information of the medical history can be obtained from old records, other professional or nonprofessional staff, or by self-report from patients or family members completing forms, rather than from direct physician interview. Although many physicians and patients lament such changes, this efficiency allows the physician to spend more time following up on issues raised by the available information, conducting the physical examination, discussing treatment, and providing health education.

One effort adopted by many clinical practices has been the use of previsit questionnaires that can be completed by the patient or proxy before the clinical encounter. These questionnaires typically gather information on past medical history, medications, preventive measures, and functional status, including information on who helps when the patient is functionally dependent. As a result, they can markedly reduce the time needed to conduct an initial assessment and can ensure a consistent level of comprehensiveness for every patient. By including validated screening instruments, they can also be used to case-find individuals with common geriatric syndromes. With the advance of technology and electronic health records, patients, families, or caregivers can complete such questionnaires electronically and the information obtained can be seamlessly integrated into the electronic health record.

A second method of streamlining the office visit is to delegate the administration of screening instruments for many of the important geriatric problems to trained office staff. Thus, the clinician may spend a short period of time reviewing the results of these screens and then decide which dimensions, if any, need greater evaluation. Several groups (Tables 11-5 and 11-6) have demonstrated the feasibility and yield of using office staff to administer case-finding and screening instruments that assess many of the dimensions described above. This approach can dramatically improve the practitioner's efficiency and increase the number of new and treatable problems detected in their older patients. However, using office-based staff to screen or case-find has cost implications. Office staff must be properly trained to administer these instruments, which can be quite time-consuming. One published method takes approximately 22 minutes to administer and another takes an estimated 10 minutes to administer. This time must be taken from other office tasks and the cost of screening may be considerable (see Table 11-6). Clinicians must also be able to effectively act on this information to improve clinical outcomes. Nevertheless, as physicians become increasingly pressured to increase their productivity, such methods may be the only way to feasibly ensure that older patients' diverse health needs are addressed comprehensively.

A third approach has been to integrate screening for geriatric conditions into the office workflow and then use structured clinical visit

TABLE 11-5

## Multidimensional Screening Instruments

PROBLEM	SCREENING MEASURE	SCREENING PACKAGE CHARACTERISTICS		
		Positive Screen	Positive Predictive Value	Negative Predictive Value
Vision	Two parts: Ask: "Do you have difficulty driving, or watching television, or reading, or doing any of your daily activities because of your eyesight?" If yes, then: Test each eye with Snellen chart while patient wears corrective lenses (if applicable).	Yes to question and inability to read greater than 20/40 on Snellen chart.	0.75	0.89
Hearing	Use audiometer set at 40 dB. Test hearing using 1000 and 2000 Hz	Inability to hear 1000 or 2000 Hz in both ears or either of these frequencies in one ear.	0.75	0.91
Leg mobility	Time the patient after asking: "Rise from the chair. Walk 20 feet briskly, turn, walk back to the chair and sit down."	Unable to complete task in 15 s.	0.91	0.92
Urinary incontinence	Two parts: Ask: "In the last year, have you ever lost your urine and gotten wet?" If yes, then ask: "Have you lost urine on at least 6 separate days?"	Yes to both questions.	0.86	0.96
Nutrition/weight loss	Two parts: Ask: "Have you lost 10 lbs over the past 6 months without trying to do so?" Weigh the patient.	Yes to the question or weight <100 lb.	0.62	0.92
Memory	Three-item recall.	Unable to remember all three items after 1 minute.	0.60	0.92
Depression	Ask: "Do you often feel sad or depressed?"	Yes to the question.	0.71	0.90
Physical disability	Six questions: "... do strenuous activities such as fast walking or bicycling?" "... do heavy work around the house such as washing windows, walls, or floors?" "... go shopping for groceries or clothes?" "... get to places out of walking distance?" "... bathe, either a sponge bath, tub bath, or shower?" "... dress, such as putting on a shirt, buttoning and zipping, or putting on shoes?"	No to any of the questions.	0.88	0.77

notes (example, [Figure 11-2](#)) to guide more detailed assessment and guide the clinician toward appropriate management steps. This approach has been demonstrated to improve the quality of care for falls and urinary incontinence. Portions of the structured visit note can be delegated to office staff, further increasing efficiency. Some practices have begun to incorporate this strategy into commercially available electronic health records. In this manner, the workflow of patient care can be redesigned, quality can be continuously monitored, and steps to improve quality can be implemented.

This approach to increasing efficiency can be applied to many geriatric conditions. [Table 11-7](#) shows a strategy that optimizes the clinician's time by employing the most efficient methods to obtain assessment information. The initial step provides the clinician with basic information that can quickly be processed and followed with more extensive data gathering, when appropriate. Such a strategy begins with the previsit questionnaire and then is supplemented

by information obtained by office staff. These two data sources are reviewed by the clinician and additional information is obtained from the patient and family at the time of the visit.

## COMPREHENSIVE GERIATRIC ASSESSMENT

CGA is based on the premise that a systematic evaluation of frail older persons by a team of health professionals may uncover treatable health problems and lead to better health outcomes. This evaluation typically includes four dimensions: physical health; functional status; psychological health, including cognitive and affective status; and socioenvironmental factors. Early randomized clinical trials provided convincing evidence that such programs conducted in hospital-based and rehabilitation units, which typically required several weeks of treatment, could lead to better survival rates, improved functional

TABLE 11-6

## Multidimensional Case-Finding Instruments Used, with References and Average Performance Time

PROBLEM	INSTRUMENT (REFERENCE)	AVERAGE TIME TO PERFORM (MIN) (n = 37)	COST PER CASE RECEIVING A NEW DIAGNOSIS OR TREATMENT
Cognitive impairment	Mini-Mental State Examination	9.2	\$68
Depression	Geriatric Depression Scale	5.1	\$17
Gait instability	Performance-Oriented Assessment of Mobility	2.5	\$15
Malnutrition	Mid-arm circumference using gender-specific criteria	1.0	\$15
Recent weight loss	Review of weights in chart	0.275	\$8

status, and more desirable placement (e.g., home rather than nursing home) following discharge from the hospital. Conceptually, CGA is a three-step process: (1) screening or targeting of appropriate patients, (2) assessment and development of recommendations, and (3) implementation of recommendations, including physician and patient adherence with recommendations. Each of these steps is essential if the process is to be successful at achieving health and functional benefits.

Within this broad conceptualization, CGA has been implemented using many different models in various health care settings (Table 11-8). Because of changes in length of hospital stays, an increasing number of CGA programs are relying on postdischarge and community-based assessment. Furthermore, most of the early programs focused on restorative or rehabilitative goals (tertiary pre-

vention), whereas many newer programs are aimed at primary and secondary prevention.

The purpose of the first step, targeting, is to distinguish elderly patients who are appropriate and will benefit from CGA, from those who are either too sick or are too well to benefit. To date, no easily administered targeting criteria have been demonstrated and validated to readily identify patients who are likely to benefit from CGA in different settings. Specific strategies used by CGA programs to identify older persons who are most appropriate for CGA have included chronological age, functional disability, physical illness, geriatric conditions, psychosocial conditions, and previous or predicted high health care utilization. All of these criteria have randomized clinical trial support for their effectiveness in identifying older persons likely to benefit from CGA. However, the definitions

## Strategy for Efficient Office-Based Assessment

Aspect Being Assessed	METHOD AND DEPTH OF ASSESSMENT*				
	Previsit Questionnaire	Office Staff Administered	Clinician Routine	Clinician As Needed	Referral <sup>†</sup> As Needed
Past medical history	D		R		
Geriatric syndromes/health conditions					
Visual impairment	B	B	R		Ophthalmologist or optometrist
Hearing impairment	B	B (if needed)	R		Audiologist
Urinary incontinence	B	B	R	D	Geriatrician, urologist, or gynecologist
Malnutrition	D		R		Dietitian or social worker
Sexual dysfunction	B		R		Urologist or geriatrician
Polypharmacy	B		R		Pharmacist or geriatrician
Dental Problems	B		R		Dentist
Gait, balance, falls	B	B	B	D	Physical therapist
Affective problems	D		R	D	Psychiatrist
Cognitive problems		B	R	D	Geriatrician, psychiatrist, or neurologist
Functional disability	D		R	D	Physical or occupational therapist social worker
Environmental problems	D		R		Home health
Preventive services	D		R		

\*B, brief screen (e.g., less than 2 min); D, detailed evaluation (usually 5 min or more); R, review of collected information.

<sup>†</sup>Examples of referrals to specific health professional or comprehensive geriatric assessment might be used.

**TABLE 11-8****Spectrum of Comprehensive Geriatric Assessment like Interventions**

	<b>MOST INTENSIVE</b>	←—————→	<b>LEAST INTENSIVE</b>
Setting	CGA, GEM, and rehabilitation units	CGA consultation inpatient or outpatient	Community-based and in-home outreach programs
Targeting	Most restrictive		Least restrictive
Process	Large team, extensive evaluations		Screening and referral
Cost	Very expensive		Relatively inexpensive

CGA, comprehensive geriatric assessment; GEM, geriatric evaluation and management.

of these criteria and the interventions that have followed have varied from study to study.

Most CGA programs exclude patients who are unlikely to benefit because of terminal illness, severe dementia, complete functional dependence, and inevitable nursing home placement. Exclusionary criteria have also included identifying older persons who are “too healthy” to benefit.

The second step of CGA, the assessment process itself, continues to be highly variable across programs. The types of health care professionals included in the assessment team, the content of information collected, and the types and intensity of services provided have differed in studies of the effectiveness of CGA. In many settings, the CGA process relies on a core team consisting of a physician, nurse, and social worker and, when appropriate, draws upon an extended team of various combinations of physical and occupational therapists, nutritionists, pharmacists, psychiatrists, psychologists, dentists, audiologists, podiatrists, and opticians. Although these professionals are usually on staff in hospital settings and are available in the community, access to and reimbursement for these services have limited the effectiveness of the CGA process. Frequently, the composition of the team is determined by local expertise and availability of resources rather than programmatic needs. Increasingly, CGA programs are moving toward a “virtual team” concept in which members are included as needed, assessments are conducted at different locations on different days, and conferencing is completed via telephone or electronically.

Traditionally, the various components of the evaluation are completed by different members of the team. There is considerable variability in which professional conducts the assessments. For example, the medical assessment of older persons may be conducted by a physician, nurse practitioner, or physician’s assistant. The core team may conduct only brief initial assessments or screens for some dimensions. These may be subsequently augmented with more in-depth evaluations by additional professionals. For example, a dietitian may be needed to assess dietary intake and provide recommendations; an audiologist may need to conduct a more extensive assessment of hearing loss and evaluate an older person for a hearing aid.

### Components of Comprehensive Geriatric Assessment

The key elements of the process of care rendered by CGA teams can be divided into six steps: (1) data gathering; (2) discussion among the

team; (3) development of a treatment plan; (4) implementation of the treatment plan; (5) monitoring response to the treatment plan; and (6) revising the treatment plan.

### Data Gathering

In early studies of CGA, the data-gathering process simply identified the members of the team and mentioned that each conducted an evaluation. Such descriptions are problematic because of the variability of evaluations among health professionals. A formal training process can reduce this variability, but a popular approach is to standardize the assessment. Standardized assessments can either use instruments developed specifically for clinical purposes or assemble standard instruments that have previously been studied for validity and reliability. The advantage of the former is that teams can customize the information being gathered to best suit the clinical needs of the program. The advantage of the latter is that patients in the program can be compared to patients in other programs. Frequently, however, these instruments were developed for purposes other than to guide clinical decision-making and may provide information that is not very helpful in the care of patients.

### Discussion among Team

Following initial data gathering, the team meets to discuss the patient’s geriatric needs. Although any member of the team could theoretically lead the conference, the leadership is usually determined by local culture. Each conference typically begins with short discipline-specific presentations followed by interactive discussions among professionals. Sometimes additional information will need to be obtained before final recommendations can be made. The team then identifies problems that need action and might be responsive to treatment.

### Development of the Treatment Plan

Based upon this discussion, the team develops an initial treatment plan and goals for the patient. Some CGA programs use protocols that are triggered by specific geriatric conditions whereas others rely on the experience and clinical judgment of the team. If the number of recommendations resulting from CGA is large, it is necessary to prioritize recommendations. CGA teams should advise primary care physicians and patients to focus on the major recommendations, those that are most likely to produce the desired outcomes. The urgency of recommendations must also be determined. Although some recommendations may need to be implemented immediately to confer short-term benefit such as stopping a medication that may be the cause of delirium, many more may be better implemented once the patient is stable.

At the time of the assessment, a plan for implementation of each recommendation must be developed. It needs to be determined who will assume responsibility for initiation and completion of the recommendation. Similarly, the team must establish a plan for monitoring the patient’s progress as treatment is being delivered.

### Implementation of the Treatment Plan

Because of the problem of poor adherence to CGA recommendations, the issue of implementation is particularly critical to the success

of CGA consultation programs. Among inpatient CGA models, poor implementation rates may explain some negative trials of hospital consultation models of CGA. Failure to implement recommendations is usually attributable to three problems: (1) poor receptivity among primary care physicians whose patients have been assessed using consultative models; (2) inadequate resources to implement recommendations; and (3) poor continuity or follow-through on recommendations after hospital discharge. In ambulatory settings, patient adherence to recommendations emanating from CGA looms as an even larger obstacle to implementation. Patients may simply choose not to return to see the CGA team (in continuity of care models) or ignore recommendations in a consultative model.

A variety of options for implementation are available ranging from direct implementation of recommendations by the team to merely advising physicians and patients by a note in the chart or verbally. In consultative models of CGA in some ambulatory settings, patients have been provided with direct advice and instructions on how to approach their physicians to discuss CGA recommendations (patient empowerment). This method, coupled with direct communication to primary care physicians, has resulted in high implementation rates of CGA recommendations. Other approaches to improve adherence by primary care physicians have been by direct telephone contact, letters, faxes, and e-mail.

### Monitoring

To ensure that recommendations are implemented and to follow a patient's progress through the treatment plan, patients must be monitored directly by the CGA team or by the primary care physician. If the team is to monitor the patient, key issues are how frequently and for how long this monitoring should occur. The more intensively and the longer patients are followed, the more resource-intensive the consultation becomes. In some models (described below), the CGA team may temporarily assume primary care for several months before returning the patient to the primary care physician for ongoing care.

### Revising the Treatment Plan

By monitoring the patient, CGA teams can continually assess the patient's progress toward meeting the goals established by the team. If progress is not proceeding according to expectations, the team may need to reevaluate the patient and resume the team discussion. Treatment recommendations and implementation plans may need to be revised. Any modification will require additional monitoring. The frequency and extensiveness of reevaluations and additional discussions are important influences on the cost of CGA consultation.

### Effectiveness of Comprehensive Geriatric Assessment

In virtually all studies of CGA, the process itself has resulted in improved detection and documentation of geriatric problems. However, such identification of problems has not always led to improved outcomes. Meta-analysis, a technique to pool the findings of individual trials to provide more precise estimates of effectiveness, has been used to evaluate five models of CGA (geriatric evaluation and management units, inpatient geriatrics consultation services, home assessment services, home assessment services for patients who had recently been discharged, and outpatient assessment services). The

first major CGA meta-analysis was published in 1993 and some components have been updated as new trials have been published.

### Geriatric Evaluation and Management Units

Geriatric Evaluation and Management Units (GEMUs), which are often designed to be environmentally friendly to older persons, confer two advantages over consultation models. First, physicians staffing the unit generally assume primary care of the patient, thus facilitating the implementation of recommendations. Second, the availability and experience of a dedicated team of providers (e.g., nurses and therapists) increases the consistency and geriatric orientation of hospital and postacute care. The meta-analysis indicated that the hospital or rehabilitation unit model of CGA had the strongest and most consistent benefits on living at home and functional status. However, the geriatric evaluation and management unit may no longer confer the same benefits in the current American health care environment. A multisite randomized clinical trial within the U.S. Department of Veterans Affairs published in 2002 demonstrated little benefit of such units when compared to usual care, which may have improved considerably since the early 1980s. In addition, differences in health care delivery systems across various countries may help explain inconsistent results of more recent studies.

### Inpatient Consultation

Both the 1993 meta-analysis and a subsequent large negative randomized clinical trial of inpatient geriatric assessment consultation have suggested little benefit from this model of CGA and it has largely been abandoned except in teaching settings.

### Posthospital Discharge Assessment and Management

Similarly, posthospitalization CGA conducted in the home was ineffective in the meta-analysis in reducing mortality, functional decline, or readmission rates. Although a subsequent randomized clinical trial confirmed these negative findings, a nursing-led program of comprehensive discharge planning and home follow-up has been more effective. Key elements included use of targeting criteria to identify appropriate patients, a program of comprehensive discharge planning (including multidimensional assessment) and home follow-up with advanced practice nurses who visited the patients at least every other day during the hospitalization and at least twice during the 4 weeks following discharge. These visits were supplemented by telephone calls. In a randomized clinical trial, this intervention was associated with reduced hospital readmissions and costs.

### Outpatient Consultation

The 1993 meta-analysis did not demonstrate any benefit from outpatient CGA consultation. A subsequent randomized clinical trial was also negative. More recently, a model that combines CGA with an adherence intervention has been developed and tested. This program provided outpatient CGA for community-dwelling older persons with functional disability, urinary incontinence, falls, or depressive symptoms. The assessment was then linked to an adherence intervention that was designed to empower the patient to take action and educate the physician. In a randomized clinical trial, this strategy was associated with less functional decline, less fatigue, and better

social functioning and was cost-effective when compared with many commonly used treatments.

### In-Home Assessment

Home assessment programs are a variation of CGA that focuses primarily on preventive rather than rehabilitative services and are aimed at patients at low rather than high risk of nursing home admission. A 2002 meta-analysis concluded that these programs were effective in reducing nursing home admissions only if they included at least five follow-up visits and in reducing functional decline only if they included multidimensional assessment. A beneficial effect on mortality was only found for younger patients (72.7–77.5 years).

### Lessons Learned from Geriatric Assessment

Despite unresolved issues regarding the effectiveness of CGA, the principles of CGA have been incorporated into a number of programs that have been demonstrated to be effective. Several new models of outpatient care for older persons modify the basic structure of care delivery. These models adopt various components of CGA including targeting, assessment, and interventions.

Geriatric evaluation and continuity management is a direct outgrowth of CGA. These programs differ from CGA in that they become the source of ongoing primary care usually by interdisciplinary teams in geriatrics clinics. Randomized trials have indicated that this ongoing care has resulted in better perceived health, life satisfaction, affective health status, and quality of health and social care. One study demonstrated a significant benefit of GEM on instrumental activity of daily living functional status at 2 years. However, a large trial of GEM within the Department of Veterans Affairs demonstrated no effect on most outcomes. Another type of continuity GEM assumes primary care of older persons who are at high risk for high health care utilization for an average of 6 months and then returns patients to the care of their primary care physicians. When evaluated in a randomized clinical trial, this approach reduced the risk of functional decline and reduced the likelihood of depression at a modest cost (\$1250 per person). Randomized trials of collaborative practice models using physicians, nurses, and case assistants, and physicians, nurses, and social workers for targeted patients have demonstrated reduced 2-year mortality and fewer hospitalizations, respectively.

Other new models that have yet to be evaluated in clinical trials also include core elements of CGA as part of the assessment and management functions of the care of older persons but may not include a CGA team as part of the process. Several of these bring CGA into primary care physicians' offices rather than creating a separate parallel delivery system or relying on primary care physicians' acceptance of CGA recommendations.

In addition, CGA has been adapted to specialty treatment of older persons including oncology, emergency department postdischarge management, inpatient orthopedic care, and the preoperative evaluation of elderly patients undergoing thoracic surgery. Elements of CGA have also been incorporated into disease management programs, including stroke and heart failure.

In summary, geriatric assessment continues to evolve as an integral component of the care of older persons. As assessment techniques

become better standardized and validated, more efficient yet comprehensive approaches are possible. To date, implementation of such strategies has not occurred on a widespread basis. Cost, logistical, and training issues are still important barriers. However, as national initiatives to improve quality move forward, screening for geriatric conditions and appropriate assessment of patients who screen positive will gain more acceptance. Advances in technology and newer approaches to data collection have unleashed possibilities for incorporating geriatric assessment and management that could not have been imagined a decade ago. The research agenda still must include testing whether these more efficient strategies can lead to better health outcomes.

CGA has also changed considerably as medicine has become increasingly cost conscious. Though effective, the long-stay units can no longer be sustained and the emphasis must shift to extending the effective components and principles into less expensive settings and programs. Although several examples of such successful progeny have already been developed and tested, undoubtedly, additional generations of CGA-like interventions will be forthcoming.

# Mental Status and Neurological Examination in Older Adults

*James E. Galvin*

## THE NEUROLOGY OF AGING

### What Is Normal Neurological Aging?

The diagnosis of neurological disease in the older adult requires recognition not only of abnormal signs and symptoms but also an understanding of what changes are expected as part of the normal aging process. To distinguish neurological dysfunction related to disease from the neurological changes associated with normal aging, the clinician must conduct a comprehensive mental status and neurological examination. When establishing a neurological diagnosis, the clinical history (i.e., history of the present illness, past medical history, social habits, occupational experience, family illness, and disorders) assists the clinician in generating a differential diagnosis that can be further explored and refined by pertinent observations documented on the mental status and neurological examinations. The mental status assessment should evaluate cognition, emotion, and behavior. Because cognitive and affective disorders occur commonly in older adults, historical information should be obtained not only from the patient but a reliable informant such as the spouse, adult child, or caregiver. The neurological examination should be performed on all older adults regardless of the chief complaint as up to 60% of older patients have either a primary or secondary neurological sign or symptom. A complete mental status and neurological examination provides the necessary data to develop reasonable diagnostic hypotheses and drive the necessary laboratory, imaging, or specialized assessments to care for the patient.

### Age-Related Changes in the Neurological Examination

Before discussion of the individual components of the examination, it would be useful to discuss changes that are expected as part of

the aging process (Table 12-1). Normal age-related changes are due to progressive and irreversible changes associated with tissue senescence and the inability of nervous system to repair and regenerate secondary to the ravages of time. The frequency and qualitative characteristics of these changes vary from individual to individual but are present in many older adults.

### Cognitive Changes

There continues to be a debate as the extent of cognitive changes associated with aging due largely to differences between cross-sectional and longitudinal study designs. When comparing older adults to young adults on similar cognitive tasks such as the Wechsler Adult Intelligence Scale, older adults generally score lower on both performance and verbal subtests. However, when differences in performance are considered in light of motor slowing and educational attainment, these changes are less apparent. Longitudinal evaluation of older adults has generally demonstrated little change in verbal intelligence with aging while performance is influenced significantly by motor and processing speed. Forgetfulness therefore is *not* part of normal aging. While it may take longer to process new information and retrieve well-learned information, new learning and memory formation occurs in older adults. This is one reason why delayed recall of word lists is effective in discriminating older adults with cognitive impairment from those without impairment.

### Changes in Cranial Nerve Function

Visual and hearing changes are common in the older adult. Visual acuity declines because of a number of ophthalmologic (cataracts, glaucoma) and neurological (macular degeneration) causes. Pupillary size is typically smaller with age and pupils are less reactive to light and accommodation, forcing many older adults to use glasses for reading. There is also a restriction in eye movement in upward gaze. Also associated with aging is a decline in speech discrimination

**TABLE 12-1****Neurological Changes Associated with Normal Aging**

Psychomotor slowing
Decreased visual acuity
Smaller pupil size
Decreased ability to look upward
Decreased auditory acuity, especially for spoken language
Decreased muscle bulk
Mild motor slowing
Decreased vibratory sensation
Mild swaying on Romberg test
Mild lordosis and restriction of movement in neck and back
Depression of Achilles tendon reflex

due to presbycusis, a progressive elevation in the frequency threshold for hearing. There are also age-related degenerative changes in inner ear including loss of hair cells, atrophy of stria vascularis, and thickening of the basilar membrane.

### Changes in Motor Function

There is a progressive decline in muscle bulk and strength associated with aging. Most of the muscle loss is found in the intrinsic muscles of the hands and feet, and around the shoulder. There is a weakening of the abdominal muscles, which may accentuate spinal lordosis and contribute to low back pain. Muscle loss is associated with denervation on electrophysiological studies and with type II atrophy on muscle biopsy. In addition to loss of strength and muscle bulk, changes in the speed and coordination of movement increases with advancing age. The changes may interfere with activities of daily living (dressing, putting away the dishes, getting out of a chair) and recreation activities (golfing, shuffleboard). On examination, these changes may manifest as mild bradykinesia and dysmetria on finger-nose-finger and heel-shin tests.

### Changes in Sensory Function

By far the most common change will be the loss of vibration perception in the lower extremities and to a lesser extent position-sense may be affected as well. As vibration sensation becomes impaired in lower extremities, there is an ascending pattern, from toe to ankle and knee. Pain and temperature sensation is also diminished in the older adult, but in the absence of a pathological cause, usually does not elicit much symptomatology. The mild impairment in position sense often manifests as a mild swaying during the Romberg test.

### Changes in Gait and Station

Changes in gait and station in old age may be attributed in part to decreased muscle strength, weakening of abdominal muscles, arthritis, and degenerative joint disease, diminished vibration and position sense, impairment in motor speed and coordination. These changes make it more difficult for older adults to tandem, heel, or toe walk for extended periods of time. Despite this, most older adults have ad-

equated postural righting reflexes and are not likely to spontaneously fall (distinct from what is seen in Parkinson's disease).

### Changes in Deep Tendon Reflexes

The most common age-associated change is the depression or loss of the Achilles tendon reflex. Other reflexes usually remain present but are diminished in response. An extensor plantar response (Babinski sign) is *not* a normal age-related change but instead is always associated with some underlying pathology in the upper motor neuron.

## THE NEUROLOGICAL HISTORY

There is no substitution for a carefully elicited history detailing the onset, duration, quality, and location of symptoms. The history helps the clinician develop a differential diagnosis and focus on the neurological examination. The history will also guide the formulation of diagnostic evaluations and develop a treatment plan. In addition, a compassionate clinician will be able to build a trusting relationship with the patient that will enhance patient adherence to medical recommendations. As a general comment, to avoid bias, it is often useful to gather historical facts *de novo* and not read other records or review laboratory studies such as imaging before taking the history and performing the physical examination. In this section, we discuss two aspects of neurologic history taking—from the patient and, when available, from an informant.

### Neurological History from the Patient

An accurate history requires that absolute attention is paid to detail, both verbal (what the patient is saying) and nonverbal (what the patient is doing). This is critical to match the chief complaint with the patient's body language. For example, someone complaining about severe low back pain but appears to be sitting comfortably in the chair may raise suspicion. Likewise, the older adult who offers no complaints but is noted to have a rest-tremor should prompt more detailed questioning. One of the most important attributes of a skilled clinician is the ability to be a good listener and to focus in on critical historical points. The most effective historians gather information by a combination of open-ended and structured questions. After asking the patient why they are in office and offer a chance to express concerns or worries in their own words, specific topics can be addressed by focused questioning.

Another important aspect of the history is to elicit qualitative and quantitative aspects of the chief complaint. It is not enough to elicit a history of a "headache" or "pain." What are the characteristics of the complaint, when did it start, what makes it better, what makes it worse? Has this happened before, and if so, did it present in the same fashion? Use simple scales to quantify the extent of the complaint by asking "On a scale of 1 to 10, with 10 being the worse (symptom). . . ." These qualities can help focus a differential diagnosis and helps to build trust with the patient.

### Neurological History from an Informant

In many instances, gathering information from a third party will be invaluable in determining the onset, duration, and extent of the

neurologic problem. In cases where there are problems with cognition or alertness, this may be the only reliable way to gather information. Again, using both open-ended and structured questions will often provide the clinician with important information about the chief complaint and assist in the development of a differential diagnosis.

## MENTAL STATUS EXAMINATION

The elements of a comprehensive mental status examination include observational, cognitive, functional, and neuropsychiatric assessments. Although each of these elements is presented separately, they are interrelated and collectively characterize the neurobehavioral function of the patient. The initial contact with the patient affords the opportunity to assess whether a cognitive, attention, or language disorder is present. Questioning of an informant may bring to light changes in cognition, function, and behavior that the patient either is not aware of or denies.

### Observational Assessment

Observation of a patient's level of arousal or alertness, appearance, emotion, behavior, movements, and speech provides insight into their mental status.

### Level of Consciousness

An accurate assessment of a patient's mental status and neurologic function must first document the patient's alertness or level of arousal. Altered levels of consciousness can directly impact the patient's cognitive performance on mental status testing and influence the examiner's interpretation of the test results and maybe indicative of a medical or neurologic condition requiring immediate medical intervention (e.g., cardiopulmonary intervention, neurosurgical evaluation).

Abnormal patterns of arousal include hypoaroused or hyperaroused states. Decreasing levels of arousal include lethargy, obtundation, stupor, and coma. The lethargic patient is drowsy or fatigued and falls asleep if not stimulated; however while being interviewed, the patient will usually be able to attend to questioning. Obtundation refers to a state of moderately reduced alertness with diminished ability to consistently engage the environment. Even in the presence of the examiner, if not stimulated, the obtunded patient will drift off. The stuporous patient requires vigorous stimulation to be aroused. Responses are usually limited to simple "yes/no" responses or may consist of groans and grimaces. Coma, which represents the end of the continuum of hypoarousal states, is a state of unresponsiveness to the external environment. In the elderly, hypoarousal states can be associated with systemic infection, cardiac or pulmonary insufficiencies, meningoencephalitis, increased intracranial pressure, toxic-metabolic insults, traumatic brain injury, seizures, or cerebrovascular disease. Coma requires either bilateral hemispheric dysfunction or brainstem dysfunction. Another important consideration is the role of polypharmacy. Drug interactions are more common in the older adult and can significantly impair consciousness.

Hyperarousal states, on the other hand, are characterized by anxiety, autonomic hyperactivity (tachycardia, tachypnea, hyper-

thermia), agitation or aggression, tremor, seizures, or exaggerated startle response. In the elderly, hyperarousal states are most often encountered in toxic-metabolic disorders including withdrawal from alcohol, opiates, or sedative-hypnotic agents. Other causes include tumors (both primary and metastatic), viral encephalitis (particularly herpes simplex), cerebrovascular, and hypoxemia. Some patients may experience fluctuating periods of both hypo- and hyperarousal.

### Appearance

Assessment of a patient's physical appearance should acknowledge body size and type, apparent age, posture, facial expressions, eye contact, hygiene, dress, and general activity level. A disheveled appearance may indicate dementia, delirium, frontal lobe dysfunction, or schizophrenia. Wearing excessive makeup or flamboyant grooming or attire in an old individual should raise the suspicion of a manic episode or frontal lobe dysfunction. Patients with unilateral neglect may fail to dress, groom, or bathe one side of their body. Patients with Parkinson's disease may display a flexed posture, whereas patients with progressive supranuclear palsy have an extended, rigid posture. The overall appearance of an individual should also provide information regarding their general health status. The cachectic patient may harbor a systemic illness (e.g., cancer), or have anorexia or depression.

### Emotional State and Affect

Affect describes the mental representation of external reality and the patient's internal feelings about external reality, while emotional state describes the objective display of emotion through facial grimaces, vocal tone, and body movements, and the subjective component of how the patient reports what he or she feels internally: "I feel sad, happy, apprehensive, cynical."

Depression is the most frequent mood disturbance in the older adult and occurs in a variety of neurologic disorders (Table 12-2). Euphoria or full-blown mania occurs less often than depression in the course of neurological illness. Euphoria is most common with

**TABLE 12-2**

#### Causes of Depression in the Older Adult

Idiopathic
Secondary to life situation (loss of spouse, child, friends)
Cerebrovascular accident
Hypothyroidism
Alzheimer's disease
Parkinson's disease
Frontotemporal dementia
Dementia with Lewy bodies
Head injury
Drug withdrawal
Drug intoxication (alcohol, barbiturates, sedative-hypnotics)
Medications (beta-blockers, reserpine, clonidine)
Multiple sclerosis
Epilepsy

TABLE 12-3

## Common Movement Disorders and Signs

SIGN	DESCRIPTION	ETIOLOGY
Bradykinesia	Slowed initiation and sustained movements	Parkinson's disease, drug-induced, may be normal variant
Dyskinesia	Abnormal involuntary movements either slow or fast	Drug-induced, Huntington's disease, Parkinson's disease, idiopathic
Action or postural tremor	Fast frequency (10–15 Hz) associated with movement (action) or sustained posture (postural), may improve with small amount of alcohol	Benign, essential tremor, drug-induced
Rest tremor	Low-frequency (3–5 Hz) with pill rolling quality, may involve extremities or chin	Parkinson's disease, drug-induced
Intention tremor	High-frequency (10–15 Hz), worsening as approaching target	Cerebellar disease
Myoclonus	Lightning fast movements from brief muscle contractions	Stroke, sleep, Huntington's disease, epilepsy, Creutzfeldt-Jacob
Asterixis	Sudden loss of limb tone during sustained muscle contraction, sometime considered "negative" myoclonus	Hepatic, renal or pulmonary disease, drug-induced, encephalopathy, bacterial infection
Chorea	Brief, rapid, irregular contractions	Huntington's disease, Sydenham chorea, drug-induced
Ballismus	Large-amplitude, jerky movements with flinging of extremities	Subthalamic nucleus lesions
Tics	Sequenced coordinated movements or vocalizations that appear suddenly	Tourette's, drug-induced
Dystonia	Sustained muscle contraction with twisting or repetitive movements, may be painful	Idiopathic, infarcts, drug-induced
Athetosis	Slow, writhing movements predominantly proximal	Huntington's disease, infarcts
Akathisia	Internalized restlessness with urge to move	Drug-induced, encephalopathy, Parkinson's disease, Restless Legs Syndrome

frontal lobe dysfunction (trauma, frontotemporal degenerations, infections) and with secondary mania. Anxiety occurs in a variety of neuropsychiatric conditions including anxiety disorders, metabolic encephalopathies (e.g., hyperthyroidism, anoxia), toxic disorders (e.g., lidocaine toxicity), and degenerative diseases (e.g., Alzheimer's disease, Parkinson's disease). Objective and subjective emotional components may be incongruent in certain psychiatric disorders (e.g., schizophrenia and schizotypal personality disorder), and in neurologic conditions such as pseudobulbar palsy.

The range and intensity of the observable component of emotion should be noted. Constriction or flatness is observed in apathetic states; for example, in the context of negative symptoms of schizophrenia, severe melancholic depression, or in demented patients with apathy. Increased intensity, on the other hand, is seen in mood disorders such as bipolar illness, and in personality disorders such as borderline personality.

Lability is a disorder of emotional regulation. Patients with marked lability are irritable and shift rapidly among anger, depression, and euphoria. The emotional outbursts are usually short-lived. Labile mood is seen in mood disorders such as bipolar illness and in certain personality disorders such as borderline personality. It also may occur in frontotemporal dementia and pseudobulbar palsy.

### Behavior

Behavioral observations can reveal important information regarding the mental status and neurological function of the patient. A variety of personality alterations can be encountered with focal brain lesions. Orbitofrontal dysfunction maybe characterized by impulsiveness or undue familiarity with the examiner, lack of judgment or lack of social anxiety, and antisocial behavior. Individuals with dorsolateral frontal lobe dysfunction may be inattentive and distractible. Apathy

(lack of motivation, energy, emotional reciprocity, social isolation) may be caused by medial frontal dysfunction. Dementias are associated with increased rigidity of thought, egocentricity, diminished emotional responsiveness, and impaired emotional control.

### Movement

Observation of patient's movements may provide evidence of parkinsonism, chorea, myoclonus, or tics (Table 12-3). Psychomotor retardation (i.e., slowed central processing and movement) may be indicative of vascular dementia, subcortical neurological disorders, parkinsonism, medial frontal syndromes, or depression. Psychomotor agitation may be indicative of a metabolic disorder, choreoathetosis, seizure disorder, mania, or anxiety.

### Speech and Communication

Observation of spontaneous speech is the first step in formal language testing and can be assessed during history taking as well as in the course of the mental status examination. The examiner first observes spontaneity of speech as well as the timber, pitch, and modulation of voice. Mutism maybe encountered in several neurological conditions such as akinetic mutism, vegetative state, locked-in syndrome, catatonic unresponsiveness, or large left hemispheric lesions. Akinetic mutism is characterized by absent speech in the setting of alert-appearing immobility. The patient's eyes are open, and the individual may follow environmental events. The patient exhibits regular sleep-wake cycles but may be completely inert or display brief movements or postural adjustments spontaneously or in response to vigorous stimulation. Akinetic mutism may be seen with large frontal lobe injuries, bilateral cingulate gyrus damage, or midbrain pathology. Akinetic mutism should be distinguished from a vegetative

state where the patient exhibits sleep–wake cycles with open eyes. A vegetative state can occur after severe brain injury. Locked-in syndrome occurs with bilateral pontine lesions, rendering the patient mute and paralyzed. Intellectual function, however, is not impaired and the patients can communicate by eye movements or eye blinks.

Spontaneous speech is characterized by its rate, rhythm, volume, response latency, and inflection. Accelerated speech may be encountered in mania, disinhibited orbitofrontal syndromes, or festinating parkinsonian conditions, whereas a reduced rate of speech output can occur as a component of psychomotor retardation. Response latencies may be prolonged or the patient may impulsively interrupt the examiner, anticipating the question. Perturbed speech prosody (loss of melody or inflection) can be encountered in brain disorders affecting the right hemisphere or the basal ganglia. Empty speech with hesitations or circumlocutions can be exhibited in patients with word-finding difficulties. Word-finding impairment may occur in aphasias, metabolic encephalopathies, physical exhaustion, sleep deprivation, anxiety, depression, or dorsolateral frontal lobe damage in the absence of an anomia.

Aphasia is characterized by impairment in oral and/or written communication. Deficits will vary depending on the location and extent of anatomic involvement. Aphasias are generally characterized as nonfluent or fluent (Table 12-4). Nonfluent aphasias are characterized by a paucity of speech, often with a hesitant quality. There is impairment in word searching and writing. The patient may appear frustrated or depressed because of awareness of the language deficit and the inability to communicate with family and health care providers. Fluent aphasias are characterized by empty speech. Word production is normal or maybe increased but there is a lack of comprehension about what words mean, often associated with impairment in reading ability. The patient often displays little insight to the language deficit and instead may become agitated because others are not following the conversation.

## Cognitive Assessment

The assessment of cognitive function should be conducted methodically and should assess comprehensively the major domains of neuropsychological function (attention, memory, language, visuospatial skills, executive ability). The patient's age, handedness, educational level, and sociocultural background may all influence cognitive function and should be determined prior to initiating or interpreting the evaluation.

### Attention

Two tests are useful in assessing attention: digit span forward and continuous performance tests. In the digit span forward test, the patient is asked to repeat increasingly long series of numbers (e.g., 1, 3–7, 4–6–3, 5–1–9–2, etc). The examiner says the numbers at a rate of one per second. A normal forward digit span is seven digits; fewer than five is abnormal. Concentration is evaluated by a continuous performance test. An example would be to say the months of the year in reverse order, starting with the last month of the year (December). Distractible patients tend to lose track and skip one or two months. Serial subtraction can also be used to test concentration but heavily dependent on educational attainment and mathematical abilities. Confusional states such as delirium are characterized by impaired attention.

### Memory

Learning, recall, recognition, and memory for remote information are assessed in the course of mental status examination. Asking the patient to remember three words and then asking him or her to recall the words 3 minutes later can help assess learning, recall, and recognition. However, the shorter the list, the more easy it is to remember, particularly in high-functioning individuals. When told to remember items, patients will often remember the first two items heard (known as “primacy”) and the last two items heard (known as “recency”), therefore longer lists of 10 words may be preferable. After a delay, recall of less than five words is considered abnormal. Patients having difficulty with recall may be given clues (e.g., the category of items to which the word belongs or a list of words containing the target) to distinguish between storage and retrieval deficits. Prompting and clues will not aid patients with storage deficits (e.g., amnesia); patients with intact storage but poor recall (e.g. retrieval-deficit syndrome) may be aided by clues. Amnesic deficits are thought to be caused by lesions in the hippocampal–thalamic circuit while retrieval deficits are likely due to lesions of frontal–basal ganglia circuitry.

Information is gathered on the patient's remote memory function while taking a history of the patient's illness, inquiring about the patient's life events (marriage, births of children, etc.), and asking about important historical events. An informant may also be helpful here to verify these events. The temporal profile of remote memory may be diagnostically important. Amnesic syndromes such as dementias usually feature normal, nonmemory cognitive functions, a period of retrograde amnesia following the onset of the disorder, variable periods of anterograde amnesia, and intact remote memory beyond the period of the retrograde amnesia. Psychogenic memory loss may include variable patterns of amnesia particularly in long-term events (e.g., not recall birth of children, not recall being married).

### Language

Language assessment entails the evaluation of all aspects of communication including spontaneous speech, comprehension, repetition, naming, reading, and writing. Aphasic disturbances are characterized as fluent or nonfluent. Fluent aphasias are characterized by normal or excessive amounts of speech, preserved phrase length, intact speech melody, usually in combination with a paucity of information. Phonemic paraphasias (substitution of one phoneme for another); semantic paraphasias (the replacement of one word with another); or neologistic paraphasias (the construction of new words) may occur. Wernicke, transcortical sensory, conduction, and anomic aphasias are fluent aphasic syndromes.

Nonfluent aphasias feature reduced verbal output, short or one-word replies, agrammatism, poor speech initiation, reduced speech prosody, and dysarthria. There are few paraphasias. Broca, transcortical motor, global, and mixed transcortical aphasias are nonfluent aphasic disorders. Interestingly, nonfluent aphasic patients may have preserved abilities to curse fluently and sing well-learned songs (i.e., Happy Birthday) with few errors.

Primary progressive aphasia is a disorder seen in patients with asymmetric frontotemporal degeneration that involves dominant hemisphere. Progressive nonfluent aphasia involves primarily unilateral left frontal, left frontoparietal, or left frontotemporal degeneration and is characterized by agrammatism, paraphasias, and anomia. Bilateral temporal lobe atrophy and hypoperfusion with more

**TABLE 12-4**

**Characteristics of Aphasias**

FEATURE	BROCA APHASIA	WERNICKE APHASIA	CONDUCTION APHASIA	GLOBAL APHASIA	TRANSCORTICAL MOTOR	TRANSCORTICAL SENSORY	TRANSCORTICAL MIXED	PURE ANOMIA	THALAMIC
Anatomic localization	Inferior frontal (Broca's area)	Superior temporal (Wernicke's area)	Arcuate fasciculus	Middle cerebral artery distribution	Supplemental motor areas	Inferior parietal	Watershed areas	Angular/Supramarginal gyrus	Dorsomedial or ventral anterior nuclei
Fluency	Nonfluent	Fluent	Fluent	Nonfluent	Nonfluent	Fluent	Nonfluent	Fluent	Nonfluent
Repetition	Impaired	Impaired	Impaired	Impaired	Normal	Normal	Normal, may be only preserved language function	Normal	Normal
Rhythm of speech	Effortful with dysarthria	Quickened, long-winded, effusive	Normal	Severely impaired, mute	Slightly effortful	May appear normal	Effortful, slow	Normal	Effortful, slow
Content	Aggrammatical, telegraphic	Mispronunciation and neologism (nonsense words)	Occasional use of wrong words	Abnormal	Agrammatical	Circumlocution, tangential	Variable impairment	Often normal, but uses descriptive language	Variable
Paraphasias	Common	Common	Common	Common	Variable	Variable	Variable	Common	Variable
Comprehension —Spoken	Good	Abnormal	Variable	Poor	Good	Abnormal	Abnormal	Normal	Abnormal
Comprehension —written	Worse than spoken	Better than spoken	May be normal	Poor	Good	Fair	Fair	Abnormal	Good
Writing	Impaired, with grammatical and spelling errors	Preserved, but inaccurate	Variable	Severely impaired	May be impaired	Preserved	Variable	Abnormal with spelling errors	Good
Naming	Poor	Poor	Fair	Poor	Poor	Good	Variable	Poor	Poor
Other findings	Hemiparesis, apraxia	Visual field deficits, hemisensory loss, apraxia	Mild hemiparesis, neglect	Hemiplegia, visual field deficits	Hemiparesis	Neglect, sensory loss	Variable with mild motor and sensory findings	Gerstmann syndrome (acalculia, agraphia, finger agnosia, left-right confusion)	Cognitive impairment, hemiataxia, hemiparesis, hemisensory loss

pronounced involvement of the left anterior temporal lobe may cause semantic dementia that is characterized by progressive loss of knowledge about objects, people, facts, and words, often accompanied by visual agnosia (inability to name or recognize objects presented visually).

Language comprehension is tested by asking the patient to follow increasingly complex linguistic constructions. The easiest commands are one-step orders such as “stand up” and “turn around,” “open your mouth,” and “stick out your tongue.” Asking the patient to point to room objects or body parts is the next level of comprehension difficulty. Finally, more complex questions such as “If a lion is killed by a tiger, which animal is dead?” are asked. Impaired comprehension usually implies dysfunction of parietotemporal regions of the left hemisphere. Comprehension is abnormal in most fluent and global aphasic syndrome but may be preserved in nonfluent syndromes. In the elderly, it is important to establish that hearing is intact before testing comprehension. Failure to comprehend commands may reflect the inability to hear as opposed to impaired comprehension.

Repetition is assessed by asking the patient to repeat increasingly long phrases or sentences, generally beginning with simple phrases such as salutations (“Hello”) and progress to more complex phrases (“Around the ragged rock, the rugged rascal ran”). Omissions and paraphasic substitutions may disrupt accurate repetition. Repetition is impaired in Wernicke, Broca, conductive and global aphasia, but is generally preserved in transcortical aphasias.

Naming tests involve asking the patient to name objects, parts of objects, and colors. Errors include paraphasias, circumlocutory responses, and simply making no response. Aphasic patients may use descriptive terms rather than give the proper name. For example, a “watch” becomes “the thing you tell time with.” Anomia occurs in aphasia, dementia, delirium, and can sometimes be seen as a consequence of head trauma. Adequate vision and object recognition must be ensured before errors are ascribed to naming deficits.

When assessing reading, the patient’s ability to read aloud and to comprehend what is read must both be tested. Adequate vision must be ensured before failures are ascribed to an alexia. Most aphasias have concomitant alexias; however, the converse may not be true. In alexia with agraphia and alexia without agraphia, reading abnormalities may occur in the absence of other signs of aphasia.

Mechanical or aphasic abnormalities may cause agraphia. Micrographia is a characteristic aspect of parkinsonism in which the script becomes progressively smaller as the patient writes a sentence or extended series of numbers or letters, and mechanical agraphias occur in patients with limb paresis, limb apraxia, or movement disorders such as tremor and chorea. Aphasic agraphias accompany aphasic syndromes and errors similar to those noted in verbal output are present in written form. In Gerstmann syndrome (agraphia, acalculia, right–left disorientation, finger agnosia), alexia with agraphia, and disconnection agraphia (occurring with injury of the corpus callosum), agraphia occurs without aphasia. Agraphia also occurs in dementia and delirium.

### Orientation

Orientation to time is tested by asking the patient to identify the correct day of the week, date, month, and year. Although some patients may make excuses (e.g., they are retired, they do not need to know, etc.), count only correct answers. This should be followed by asking the patient to guess the correct time of day without looking

at a watch or clock. The patient should be within 1 hour of the correct time. Orientation to place is assessed by asking about city, county, state, and current location. If the patient is from out of town, major landmarks may be substituted for less well-known information such as county. Lastly, orientation to situation can be assessed by asking the patient why they are in the office today.

### Abstraction

Similarities, differences, idioms, and proverb interpretation can all be used to assess abstracting capacity. These tests are heavily influenced by culture and educational attainment. Abstraction abnormalities are a nonspecific indicator of cerebral dysfunction. Patients with frontal lobe disorders have disproportionately severe abstracting disturbances.

### Judgment and Problem Solving Abilities

Assessing judgment assists in exploring the patient’s interpersonal and social insight. Judgment is impaired in many neurologic conditions. Damage to orbitofrontal subcortical circuit (e.g., in frontotemporal dementia, trauma, or focal syndromes) produces marked alterations in social judgment. Problem solving can be assessed by giving a scenario “If in a strange town, how would a person locate a friend they wished to see?” Correct answers might include use of phone book, the Internet, or city directory.

### Visuospatial Skills

There are a number of visuospatial abilities including spatial attention, perception, construction, visuospatial problem solving, and visuospatial memory. Constructional tasks are most widely used to assess visuospatial ability. In the clock drawing test, the patient is asked to draw a clock and draw in the clock hands to indicate a specific time. The hands should be of different lengths. Watching the patient complete the clock is sometimes as informative as the finished product.

Patients with executive dysfunction may draw a clock face that is too small to contain the required numbers (poor planning), whereas patients with unilateral neglect will ignore half of the clock face.

Tests of copying involve having the patient reproduce figures such as a circle, intersecting circle and triangle, overlapping pentagons, cube, or more complex figures. Abnormalities include failures to reproduce the shapes accurately, perseveration on individual elements, drawing over the stimulus figure, or unilateral neglect. Drawing disturbances are common with many types of neurologic conditions including focal brain damage, degenerative disorders, and toxic and metabolic encephalopathies.

### Calculation

In assessing calculation skills, patients are asked to add or multiply one or two digits mentally or to execute more demanding problems with pencil and paper. Calculation abilities are related to education and occupation. Acalculias may occur in association with a number of aphasic syndromes while visuospatial disorders lead to incorrect alignment of columns of numbers. Primary arithmetias (inability to do math) are produced by damage to the posterior left hemisphere.

**TABLE 12-5****The AD8, A Brief Informant Interview To Detect Dementia**

Remember, "Yes, a change" indicates that there has been a change in the last several years caused by cognitive (thinking and memory) problems.	<b>YES, A CHANGE</b>	<b>NO, NO CHANGE</b>	<b>N/A, DON'T KNOW</b>
1. Problems with judgment (e.g., problems making decisions, bad financial decisions, problems with thinking)			
2. Less interest in hobbies/activities			
3. Repeats the same things over and over (questions, stories, or statements)			
4. Trouble learning how to use a tool, appliance, or gadget (e.g., VCR, computer, microwave, remote control)			
5. Forgets correct month or year			
6. Trouble handling complicated financial affairs (e.g., balancing checkbook, income taxes, paying bills)			
7. Trouble remembering appointments			
8. Daily problems with thinking and/or memory			
<b>TOTAL AD8 SCORE</b>			

### Executive Function

Executive function is assessed by asking the patient to perform tasks mediated by frontal–subcortical systems. Frontal–subcortical systems are complex neural circuits that include the dorsolateral prefrontal cortex, striatum, globus pallidus/substantia nigra, thalamic nuclei, and connecting white matter tracts. Patients with executive dysfunction manifest perseveration; motor programming abnormalities; reduced word list generation (left dorsolateral dysfunction); reduced nonverbal fluency (right dorsolateral dysfunction); poor set shifting; abnormal recall with intact recognition memory; loss of abstraction abilities; poor judgment; and impaired mental control. These abnormalities are common following head trauma, frontal lobe degenerations, frontal lobe neoplasms, multiple sclerosis, Huntington's disease and other basal ganglia disorders, subcortical infarctions, and in some brain infections such as syphilis.

Digit span backwards is a test of mental control and complex attention, as well as executive dysfunction. It entails saying increasingly long series of numbers and asking the patient to say them backwards (give 2–5–8, response should be 8–5–2). A normal digit span in reverse is five digits; fewer than three is abnormal.

### Word List Generation

Word list generation is very useful and involves asking the patient to think of as many members of a specific category (most commonly animals) as possible within 1 minute. Normal individuals can name approximately 18 animals within 1 minute; less than 14 is considered abnormal. Word list generation deficits occur with anomia, frontal–subcortical systems dysfunction, and psychomotor retardation. It is a highly sensitive test but lacks specificity.

### Informant Assessment

In many instances, asking questions of the informant will provide a wealth of information regarding the baseline abilities of the patient. There are several structured interviews that are short, easy to administer, and do not require specific training. Functional abilities and activities of daily living can be assessed with the Functional Activities Questionnaire, the Physical Self-Maintenance Scale, Instrumen-

tal Activities of Daily Living Scale, or the Barthel Index. Baseline cognitive abilities can be assessed with brief informant interviews such as the AD8 (Table 12-5) or the IQCODE. The AD8 was developed in a research sample and validated in a clinic population and asks eight questions regarding change in the patient's memory, orientation, judgment and problem solving abilities, executive function, and interest level. Endorsement of two or more items suggests cognitive dysfunction and should trigger a more formal evaluation.

### Neuropsychiatric Assessment

The neuropsychiatric interview of the patient includes the evaluation of thought form, thought content, and insight. The new onset of disturbances in any of these domains in the elderly is unusual in the absence of a brain disease. Their emergence should trigger the search for a neurologic or psychiatric condition.

#### Thought Form

Formal thought disorders such as tangentiality, circumstantiality, loose associations, illogicality, derailment, and thought blocking are much less common than disturbances of thought content as a manifestation of psychosis in neurologic diseases. Thought disorders have been observed in the psychoses accompanying epilepsy, Huntington's disease, and idiopathic basal ganglia calcification.

Perseveration and incoherence are disorders of the form of thought that are common in neuropsychiatric conditions. Perseveration refers to the inappropriate continuation of an act or thought after conclusion of its proper context. Intrusions are a special case of perseveration with late recurrences of words or thoughts from an earlier context. Perseverations and intrusions are seen in aphasia and dementing illnesses. Incoherence refers to the absence of logical association between words or ideas. It is observed in delirium, advanced dementias, and as part of the output of fluent aphasia.

#### Thought Content

Several types of disorders of thought content occur in neurologic diseases. Delusions are the most common manifestation of psychosis in

neurologic disorders and are characterized by false beliefs based on incorrect inference about external reality. Common types of delusions encountered involve being followed or spied on, theft of personal property, spousal infidelity, or the presence of unwelcome strangers in one's home. Theme-specific delusions such as the Capgras syndrome (the belief that someone has been replaced by an identical-appearing impostor) may also be observed in neurologic illnesses. Delusions are common in a number of dementia etiologies including Alzheimer's disease and dementia with Lewy bodies, and may occur in vascular dementia, frontotemporal dementia, and Huntington's disease.

Hallucinations occur in many neurologic disorders. Hallucinations are sensory perceptions that occur without stimulation of the relevant sensory organ. Hallucinations and delusions occur together in psychosis; hallucinations are nondelusional when the patient recognizes the sensory experience to be unreal. Hallucinations may involve any sensory modality (visual, auditory, tactile, gustatory, olfactory) and maybe formed (e.g., people or things) or unformed (flashing lights or colors). Hallucinations occur with ocular and structural brain disorders as well as Charles Bonnet syndrome, epilepsy, narcolepsy, and migraine. Well-formed visual hallucinations (children, furry animals) are a prominent early sign in dementia with Lewy bodies. Less well-formed visual hallucinations occur in the moderate to severe stages of Alzheimer's disease. Gustatory or olfactory hallucinations are most common in seizure disorders, bipolar disorders, and schizophrenia, and with tumors located in the medial temporal lobe. Tactile hallucinations are most commonly associated with schizophrenia, affective disorders, or drug intoxication or withdrawal.

### Insight

Patients with neuropsychiatric disease may display limited insight and be unaware of their medical conditions or limitations in function, thus assessment of a patient's insight into the severity of their illness can yield useful diagnostic information and assist in developing a therapeutic plan. For example, patients with Alzheimer's disease have impaired insight into their memory and cognitive difficulties, whereas patients with vascular dementia and dementia with Lewy bodies often exhibit more appropriate concern regarding their cognitive dysfunction. Lesions of the right parietal lobe are associated with unawareness, neglect, or denial of the abnormalities of the contralateral side.

### Behavior and Personality

A variety of changes in personality and behavior have been described in neuropsychiatric disease in the older adult. Personality changes may include increased egocentricity and thought rigidity, impaired emotional control and diminished emotional responsiveness, loss of interest and apathy, and lack of concern for the feelings of others. No brief personality rating scales are available but in the proper setting the Neuroticism-Extroversion-Openness Five Factor Inventory (NEO-FFI) can be used to evaluate personality. Behavioral changes including irritability, depression, anxiety, hallucinations, delusions, and vegetative changes can be assessed with the Neuropsychiatric Inventory (NPI). There both long and short forms of the NPI available.

## NEUROLOGICAL EXAMINATION

The neurologic examination includes assessment of cranial nerve function, strength, coordination, sensation, muscle stretch reflexes, pathologic/primitive reflexes, and neurovascular status. Examination of head and neck may provide additional important information.

### Cranial Nerve Examination

#### Cranial Nerve I: Olfactory

In normal aging, loss of olfaction may be a nonspecific or clinically insignificant finding. Olfaction maybe impaired following head trauma, infection, zinc deficiency, Vitamin A deficiency, frontal lobe dysfunction, B-12 deficiency, and frontal lobe tumors (olfactory groove meningioma). Olfaction is tested by asking the patient to identify a variety of odors. When testing, it is important to use simple and familiar odors (coffee beans, vanilla, or cinnamon). Complex scents such as perfumes and noxious agents (i.e. ammonia) should not be used. Ideally, the patient should close their eyes and each nostril should be tested separately.

#### Cranial Nerve II: Optic

Examination of the optic nerve includes visual inspection of the nerve head, testing of visual acuity, and mapping of the visual fields. In aging, visual acuity maybe impaired and can be due to a number of neurological and ophthalmologic causes. First, casual inspection of the corneal, sclera, and mucosal tissue should be carried out to evaluate structural abnormalities. Visual acuity can be evaluated with a Snellen visual chart or Rosenberg card held 14 inches from the eye. Screening should be done in a well-lit environment and to the patient's advantage allowing them to use their corrective lenses. If they do not have their glasses with them, refractive errors can be partly corrected by using a pinhole. Visual fields are tested at the bedside by confrontation. The examiner should face the patient, sitting or standing at a similar height and each eye should be tested independently. The patient is asked to look at the examiner's nose and the examiner's arms are extended laterally. The patient is asked to differentiate between one or two fingers. Each quadrant should be tested separately. After testing each eye individually, both eyes should be tested simultaneously for visual neglect. Monocular visual field deficits can be associated with glaucoma. Abrupt changes in visual fields or acuity should alert the clinician to potential vascular etiologies. Homonymous field deficits reflect disruption of the optic pathways posterior to the optic chiasm.

Pupillary examination should include evaluation of size and shape. Up to a 1 mm difference in size is generally considered normal. Pupillary responses are tested with a bright flashlight (not the ophthalmoscope). A normal pupil reacts to light by constricting; the contralateral pupil should also constrict. The pupils also constrict when shifting focus from a distant object to a near object (accommodation) and during convergence such as when patients are asked to look at their nose. Abnormalities of pupillary responses are associated with a number of neurologic disorders (Table 12-6). A review of medications is also important as a number of drugs can affect pupillary size. Mydriasis (pupillary dilation) can be caused

TABLE 12-6

## Causes of Pupillary Changes in Older Adult

MIOSIS (PUPILLARY CONSTRICTION)			MYDRIASIS (PUPILLARY DILATATION)		
Pontine lesion			Dorsal midbrain syndrome (Parinaud's)		
Organophosphates			Amphetamines and sympathomimetics		
Cholinergic agents			Anticholinergic agents		
Opioids (except meperidine)			Meperidine		
Pilocarpine-like agents			Atropine-like agents		
Barbiturates			Cocaine		
Phenothiazines			Phenothiazines		
MAO inhibitors			Antihistamines		
Phencyclidine (PCP)			Lysergic acid diethylamide (LSD)		
Argyll-Robertson (syphilis)			Seizures/postictal state		
Horner's syndrome (usually unilateral)			Thyrotoxicosis		
Hypothermia			Hypermagnesemia		
			Third nerve compression (usually unilateral)		

SITE OF LESION	PUPIL SIZE	DIRECT RESPONSE	CONSENSUAL RESPONSE		
			Ipsilateral	Contralateral	ACCOMMODATION
Retina	Normal	Impaired	Impaired	Normal	Normal
Optic nerve	Normal	Lost	Lost	Normal	Normal
Optic chiasm	Normal	Normal	Normal	Normal	Normal
Optic tract	Normal	Normal	Normal	Normal	Normal
Optic radiation	Normal	Normal	Normal	Normal	Normal
Oculomotor nerve or nucleus	Dilated	Lost	Normal	Lost	Lost
Argyll-Robertson	Constricted	Lost	Normal	Lost	Normal
Sympathetic	Constricted	Normal	Normal	Normal	Normal

by atropine-like drugs, while miosis (pupillary constriction) can be caused by parasympathomimetic drugs.

A careful examination of the optic nerve should be performed in all patients. It is not always necessary to do a dilated examination, but the room should be darkened to increase pupillary size. The sharpness of optic disk margins, the ratio of optic cup to disk, venous pulsations, the caliber of blood vessels, and the presence of exudates, hemorrhages, emboli, and retinal pallor should be noted. Papilledema is characterized by blurring or elevation of the disk margins with the loss of normal venous pulsations and reflects raised intracranial pressure. As pressure increases, hemorrhages may be found adjacent to the disk. Glaucoma increases the size of the optic cup relative to the disk.

### Cranial Nerves III, IV, and VI: Oculomotor, Trochlear, and Abducens

The oculomotor, trochlear, and abducens nerves mediate ocular motility, pupillary responses, and eyelid position. The trochlear nerve innervates the superior oblique muscle, the abducens nerve innervates the lateral rectus muscle, while the oculomotor nerve innervates the remainder of the extraocular muscles. The oculomotor nerve also innervates the levator muscles of the eyelid and carries parasympathetic nerves to the pupil. Testing each eye individually helps to identify ocular motility dysfunction. In aging, ocular motility may be reduced. Normal elderly can exhibit restricted convergence and limitation of conjugate upward gaze. Other nonspecific

concomitants of normal aging include the evolution of small sluggishly reactive pupils, loss of Bell phenomenon (upward eye deviation on eye closure), and the inability to dissociate ocular movements from head movements. The clinician should be concerned when an elderly patient exhibits new onset diplopia, pupillary asymmetry, nystagmus (Table 12-7), or extraocular movement disorders. Ptosis (drooping of the upper lid) can be caused by a number of disorders (Table 12-8). Isolated abducens palsies may be a sign of elevated intracranial pressure since the 6th nerve has the longest intracranial course.

### Cranial Nerve V: Trigeminal

The trigeminal nerve is divided into three divisions: ophthalmic, maxillary, and mandibular. The first two divisions are pure sensory nerves mediating facial and corneal sensation. The third division carries both sensory fibers and innervates the muscles of mastication. The corneal reflex is mediated by the ophthalmic division and can be tested by lightly stimulating the cornea with a wisp of cotton. When the cornea on one side is stimulated, both eyes should close. Facial sensation is tested with a safety pin or cold handle of a tuning fork. Motor function is tested by asking the patient to bite down or open the jaw against resistance. Tumors of the middle fossa and in the cerebellopontine angle may compress the fifth cranial nerve and produce a cranial nerve syndrome with decreased corneal reflex and sensory loss on the ipsilateral face. Tic douloureux (trigeminal neuralgia) is a paroxysmal pain disorder triggered by touching

**TABLE 12-7****Types of Nystagmus and Ocular Oscillations**

MOVEMENT	DESCRIPTION	LOCALIZATION
Physiologic end stage	Fine, regular horizontal jerking at extremes of lateral gaze	No pathological significance
Jerk	Horizontal and rotary	Vestibular disorder
Vertical	Jerk movements in vertical plane	Posterior fossa disease, sedatives, anticonvulsants
Downbeating	Rhythmic, horizontal gaze still possible	Cervicomedullary junction lesion
Upbeating	Rhythmic, horizontal gaze still possible	Lesion in pons, cerebellar vermis or medulla
Ocular bobbing	Arrhythmic, coarse movement with horizontal gaze palsy	Pontine lesion
Seesaw	Vertical dysconjugate movements with rotary component	Lesion by optic chiasm
Periodic alternating	Horizontal nystagmus with periodically alternating direction	Lower brainstem
Rebound	Horizontal jerk nystagmus transiently after sustained gaze to opposite side	Cerebellar pathways
Convergence-retraction	Eyes converge and move rhythmically back into the orbits on attempted upgaze	Periaqueductal gray (midbrain)
Ocular dysmetria	Overshoot or terminal oscillation of saccadic movements	Cerebellar pathways
Hypometric saccades	Slowed movements	Parkinson's disease, basal ganglia
Opsoclonus	Chaotic multidirectional conjugate saccades	Paraneoplastic syndrome (neuroblastoma, breast, lung)
Square-wave jerks	Small saccades interfering with visual fixation	Progressive supranuclear palsy
Ocular myoclonus	Rhythmic oscillations, usually vertical	Associated with palatal myoclonus, brainstem lesion

sensitive zones usually within the mandibular division. The cause may be idiopathic due to compressive lesions or demyelination at the root entry zone.

**Cranial Nerve VII: Facial**

The facial nerve supplies the facial musculature, lacrimal and salivary glands, and taste fibers of the anterior tongue. The motor function is tested by asking the patient to wrinkle their forehead, close their eyes, and smile. Unilateral weakness may cause a flattening of the nasolabial fold. If very weak, the patient may experience drooling. The eyelid is usually not severely affected with central lesions and the upper forehead is spared. In peripheral lesions such as Bell's palsy (Table 12-9), patients are unable close their eye or wrinkle their forehead. The facial nerve also innervates the stapedius muscle of the middle ear, which helps to modulate tympanic membrane vibration. This motor branch can be damaged during closed head trauma leading to hyperacusis, an increased perception of sound.

**TABLE 12-8****Causes of Ptosis in the Older Adult**

Congenital
Myopathic-causes
Myasthenia gravis
Oculopharyngeal muscular dystrophy
Myotonic dystrophy
Polymyositis
Hypothyroidism
Horner's syndrome
Vasculitis
Diabetes mellitus
Third nerve lesions (ptosis is rarely isolated finding)
Nuclear lesion in mesencephalon
Third nerve compression

The sense of taste is not often tested, but can be done at the bedside using sugar, salt, or lemon juice. The patient is asked to stick their tongue out and a small amount of solution is placed on one side of the tongue. The patient is asked to describe the taste, and then allowed to drink some water before the next solution is applied.

**Cranial Nerve VIII: Cochlear and Vestibular**

Hearing and vestibular function are mediated by the eighth cranial nerve. Evaluation of hearing at the bedside is sometimes difficult. Use of a 512 Hz tuning fork can help discriminate conduction from sensorineural hearing loss. The Rinne test is done by placing a vibrating tuning fork on the mastoid process. As soon as the patient is unable to detect sound, the tuning fork is moved to a position near the external auditory canal. If the patient has normal hearing, air conduction should be better than bone conduction. If the patient has conduction deafness, the sound will not be heard because of pathology in the middle ear. In nerve deafness, air conduction is better than bone conduction but both will be reduced. The Weber test looks for

**TABLE 12-9****Causes of Bell's Palsy**

Idiopathic
Pregnancy
Guillain-Barre syndrome
Lyme disease (may present as bifacial weakness)
Herpes Zoster (Ramsey-Hunt syndrome)
Neoplasms
Sarcoidosis
Head trauma
Acute intermittent porphyria
Lead poisoning
Brainstem infarction (rare)

TABLE 12-10

## Differential Diagnosis of Tinnitus

TONAL TINNITUS	NONTONAL TINNITUS
Otitis media	Contraction of muscles in eustachian tube
Disorder of tympanic membrane	Contraction of stapedius muscle
Inner ear disorder (hair cells, organ of Corti)	Contraction of tensor tympani muscles
Cochlear nerve lesion	Palatal myoclonus
Acoustic Schwannoma	Carotid bruit
Meningioma	Arteriovenous malformations
Neurofibroma	Glomus jugulare tumor
Meniere's disease	
Head trauma	

lateralization. The tuning fork is placed in the middle of the skull and the patient asked to decide where they best hear the sound. In normal hearing, the sound is heard equally in both ears. In conduction deafness, vibrations are best heard in the abnormal ear. In nerve deafness, the sound is best appreciated in the normal ear. Decreased hearing for high-pitched sounds and lack of perception of background noise are common findings in normal aging and by themselves should not be considered a pathologic finding. Sensorineural deafness is characterized by loss of high-pitched sounds while conduction deafness is characterized by loss of low-pitched sounds. Tinnitus or ringing in the ears is a common symptom in adults. Tonal tinnitus is subjective and heard only by the patient. Nontonal tinnitus is more objective because in certain circumstances, the tinnitus can be heard by the examiner. The differential diagnosis of tinnitus is presented in Table 12-10.

Vestibular lesions produce nystagmus and vertigo. Vestibular nystagmus is horizontal or combined horizontal-rotatory and is typically accompanied by vertigo and nausea, whereas lesions disrupting vestibular connections in the central nervous system can produce nystagmus in any direction but are usually not associated with vertiginous or nauseous sensations. When characterizing nystagmus, only the fast component should be described. The complaint of dizziness in the elderly is not uncommon; however, the examiner must determine whether the dizzy patient is experiencing lightheadedness or true vertigo. If true vertigo is present, then the clinician should further discern whether it is peripheral (vestibular) or central (brainstem) in origin as well as associated features (Table 12-11). Causes of vertigo associated with vestibular disease include benign positional vertigo, Ménière's syndrome, and trauma.

## Cranial Nerves IX and X: Glossopharyngeal and Vagus

The ninth and tenth cranial nerves control pharyngeal and laryngeal function, taste, and the gag reflex. Glossopharyngeal lesions cause asymmetric elevation of the palate and deviation of the uvula. Hoarseness, aphonia, and dysphagia occur with vagus nerve lesions. In normal aging, the gag reflex can be reduced and, when accompanied by a decrease in the cough reflex, can result in difficulty handling bronchial secretions. Glossopharyngeal neuralgia is a rare paroxysmal pain syndrome involving the posterior pharynx or tonsils usually triggered by excessively hot or cold foods or liquids.

## Cranial Nerve XI: Accessory Nerve

The spinal accessory nerve innervates the upper half of the trapezius and the sternocleidomastoid muscle. In the normal elderly, frank weakness of the trapezius or sternocleidomastoid muscle is not a typical finding and, if present, should be investigated further. A delayed shrug may be an indication of a mild ipsilateral hemiparesis.

## Cranial Nerve XII: Hypoglossal

The hypoglossal nerve innervates the tongue. Patients are asked to stick their tongue out; deviation to either side implies a lesion on the side of deviation. The tongue should also be examined for atrophy and spontaneous muscle contractions (fasciculation), suggesting upper motor neuron disease. Fasciculation is best detected on the lateral aspects of the tongue. Tongue weakness is also common in pseudobulbar palsy.

## Motor System Examination

Muscle bulk, strength, tone, and coordination are assessed as part of the motor system examination.

## Muscle Bulk

Muscle bulk is examined by visual inspection and palpation. Muscle wasting may occur with disuse; muscle, nerve, or spinal disease; and in generalized weight loss secondary to malnutrition, systemic illness, or advanced brain diseases. Mild muscular wasting without associated weakness can be encountered in normal aging most commonly involving the intrinsic hand and foot muscles, calf and shoulder girdle muscles.

## Muscle Tone

Muscle tone maybe increased or decreased in neurologic disorders. Muscle tone is decreased in muscle and peripheral nerve disease, with cerebellar disorders, early in the course of many choreiform disorders, and acutely following an upper motor neuron lesion. Increased muscle tone is encountered in spasticity with pyramidal tract lesions and rigidity with extrapyramidal disorders. Cogwheel rigidity of Parkinson's disease is best palpated when manipulating the distal limbs, usually in a circular motion. "Gegenhalten" refers to the active resistance to movement encountered in advanced brain diseases.

## Strength

Strength is graded as 0 (no evidence of muscle contraction), 1 (muscle contraction without movement of the limb), 2 (limb movement after gravity eliminated), 3 (limb movement against gravity), 4 (limb movement against partial resistance), or 5 (normal strength). Distal weakness is most indicative of peripheral neuropathies, whereas proximal weakness is more consistent with primary muscle disease. In aging, mild generalized weakness may occur; however, focal weakness is indicative of a neuropathologic process. Focal weakness often is subtle and maybe detected only with careful examination. Hemipareses occur with lesions of the pyramidal system. When testing strength, the examiner should attempt to isolate individual muscles (thumb abduction) rather than test whole groups (hand grip) to detect subtle signs of weakness. A pronator drift is seen with mild forms of weakness.

**TABLE 12-11****Causes of Vertigo and Associated Findings**

<b>ANATOMIC LOCATIONS</b>	<b>CAUSES</b>	<b>OTOSCOPIC EXAMINATION</b>	<b>OTHER NEUROLOGICAL FINDINGS</b>	<b>TESTS OF EQUILIBRIUM</b>	<b>NYSTAGMUS</b>	<b>HEARING LOSS</b>
Labyrinth	Benign positional, trauma, Meniere's, drug toxicity, viral infection	Usually negative	None	Ipsilateral past pointing, lateral pulsion to side of lesion	Horizontal or rotary to side opposite lesion, paroxysmal, positional	May be normal, sensorineural, or conduction deafness
Vestibular	Vestibular neuronopathy, herpes zoster	Zoster vesicles in auditory canal, tympanic membrane, and palate	7th and 8th cranial nerves	Ipsilateral past pointing, lateral pulsion to side of lesion	Positional	Sensorineural
Cerebellopontine angle tumor	Acoustic neuroma, meningioma, glioma, glomus jugulare	Normal	Ipsilateral 5th, 7th, 9th, and 10th cranial nerves, ataxia Increased intracranial pressure	Ataxia	Gaze-paretic, positional, coarser to side of lesion	Sensorineural
Brainstem and cerebellar lesions	Infarct, gliomas, encephalitis	Negative	Multiple cranial nerves, sensory or motor tract signs, ataxia, dysmetria	Ataxia	Horizontal and/or vertical, gaze-paretic	Normal
Cortical lesions	Infarct, glioma, trauma	Negative	Fluent aphasia, visual field cuts, hemimotor/sensory findings, seizures	Usually no change, mild ataxia	Usually absent	Normal

## Abnormal Movements

During the interview and examination, the clinician should be observant for any movement that is not purposeful including tremor, chorea, dyskinesias, and ballismus. Tremor is usually described as action (associated with a movement) or rest (disappears with movement of affected extremities). “Essential” tremor is a usually benign hereditary condition associated with movement or sustained posture and may involve arms, legs, head, chin, or voice. Essential tremors often improve after drinking small amounts of alcohol.

## Sensory Examination

Primary modalities, including light touch and temperature are tested to assess sensory function. Sensory examination is quite subjective and it is important to consider the consistency of responses and how sensory complaints relate to other signs and symptoms. Peripheral causes of sensory loss typically present bilaterally and are largely symmetric. Unilateral sensory loss occurs with lesions of primary sensory cortex or its projections.

### Light Touch

Evaluation of light touch is not particularly helpful in discriminating pathology but is useful in defining the presence or loss of sensation. Lightly stroking the fingers or a wisp of cotton across the skin may help elicit dermatomal patterns of sensory loss for further evaluation.

### Pain and Temperature

Pain and temperature sensation is carried by small unmyelinated fibers. Pain can be assessed with the use of a disposable safety pin while temperature can be assessed with the handle of the reflex hammer or tuning fork. The loss of pain sensation due to a metabolic or toxic peripheral neuropathy typically follows a stocking glove pattern, while lesions due to a radiculopathy follow a defined dermatome.

### Vibration

Vibration is carried by large myelinated fibers and is assessed with a 128 Hz tuning fork. The tuning fork should be struck and placed on a bony prominence. Causes of pathologic decreased vibratory sensation include peripheral neuropathies, diabetes, tabes dorsalis, vitamin B-12 deficiency, and myelopathies.

### Position

Proprioception is assessed by having the patient close their eyes and the examiner gently moves toes or fingers in the vertical plane. Skin proprioception can be assessed by lightly stroking the skin in an up or down fashion. The Romberg sign is performed to assess the integrity of the dorsal columns. The patient is asked to stand with their feet together and eyes closed. The presence of a sway suggests a positive test. If the problem is due to a proprioceptive deficit, the patient is able to correct themselves with their eyes open. Position sense loss can be caused by peripheral neuropathies, diabetes, tabes dorsalis, vitamin B-12 deficiency, and myelopathies.

**TABLE 12-12**

### Elements of Ataxia and Cerebellar Dysfunction

SIGN	DESCRIPTION
Dysmetria	Overshooting or undershooting a target
Dysdiadochokinesia	Impairment in rapid-alternating movements
Tremor	Coarse, rhythmic movement on action
Ataxic speech	Abnormal variability of volume, rate and phonation
Dysarthria	Slow and slurred speech
Gait Ataxia	Wide-based, unsteady

## Cerebellar Examination

Cerebellar function and coordination maybe disrupted by many types of motor and sensory abnormalities. Tests of coordination include rapid alternating movements, fine finger movements, finger-to-nose movements, and heel-knee-shin maneuvers. During aging, there is an overall decrease in speed of coordinated movements that is of no pathologic consequence. However, gross abnormalities in cerebellar function are not anticipated and should be evaluated thoroughly (Table 12-12).

When unilateral cerebellar dysfunction is present, patient will overshoot target but may improve after a few trials. Dysdiadochokinesia occurs when the patient is asked to rapidly change hand or finger movements; difficulties in maintaining smooth movements are characteristic. Cerebellar lesions can also affect muscle tone causing hypotonia. Cerebellar tremors tend to be coarse and irregular, worsening in the terminal one-third of a movement.

### Gait and Station

Gait and posture depend on motor, sensory, and cerebellar function. In normal aging, posture becomes more flexed, slowed, and may have a slightly unsteady quality. When assessing gait in the older adult, it is important to recognize gait abnormalities that may be secondary to joint pain and arthritic conditions. Gait is assessed by having the patient walk straight for at least 10 yards, making a turn and maneuvering in a tight corridor. It is important to note the presence of armswing and the distance of the stride. The patient should also be asked to tandem walk, walk on their toes and heels, and if possible walk up a few steps. Postural stability is assessed by asking the patient to stand with their shoulder-width apart. A forceful pull is given to their shoulders and the righting response is assessed. The clinician should be prepared to catch the patient. One step of retropulsion is considered normal. Table 12-13 lists common causes of gait disturbance in the elderly.

### Muscle Stretch Reflexes

Decreased muscle stretch reflexes are found in muscle, peripheral nerve, and nerve root disorders, while increased reflexes occur with upper motor neuron lesions. Lateralized hyperactive reflexes in conjunction with spasticity and the Babinski sign are indicative of a contralateral lesion of the pyramidal system. In aging, deep tendon reflexes tend to become hypoactive. Ankle reflexes may be absent in normal aging, but knee reflexes persist. Reflexes are initially

TABLE 12-13

## Gait Abnormalities in the Older Adult

GAIT	CAUSE	DESCRIPTION	ASSOCIATED SIGNS
Festinating	Parkinson's disease	Slow, shuffling picks up speed and may require wall or furniture to stop	Postural instability, rest tremor, bradykinesia, decreased arm swing, masked face, rigidity
Antalgic	Joint pain	Slow, gingerly pace	Facial grimaces
Spastic	Stroke	Stiff extremity, may require circumduction or scissor movements	Scuffing toe of affected leg across ground, weakness
Ataxic	Cerebellar disease	Wide-based	Dysmetria, dysdiadochokinesis
Sensory Ataxia	Peripheral neuropathy	Wide-based, high steps with foot slapping	Sensory loss, weakness
Apraxic	Normal pressure hydrocephalus	Feet appear "nailed" to floor, lower extremity bradykinesia	Dementia, urinary incontinence
Stooped	Lumbar stenosis	Forward flexion	Pain, lordosis, kyphoscoliosis
Myopathic	Proximal myopathy, myasthenia gravis	Uses arms to help push themselves up stairs or out of a chair (Gowers sign)	Muscle cramps, weakness, myoglobinuria
Astasia-Abasia	Psychosis, malingering	Wildly lurching, "hurky-jerky" movements, however patient does not fall	Signs of intoxication, delusions, hallucinations. Secondary gain.

hyperactive in cervical and lumbar spondylosis, however in advanced cases absent or diminished reflexes may be found as nerve roots become compromised.

### Pathologic and Primitive Reflexes

The Babinski sign is dorsiflexion of the great toe with plantar stimulation. It is produced by upper motor neuron lesions. The grasp reflex (involuntary gripping of objects in or near the patient's hand) occurs in patients with advanced brain disease and with lesions restricted to the medial frontal lobes. The sucking reflex (sucking movements of the lips, tongue, and jaw elicited by stimulation of the lips) occurs in patients with frontal lobe and diffuse brain dysfunction.

The palmomental reflex (ipsilateral contraction of the mentalis muscle in response to stroking of the thenar eminence of the hand) can be seen in normal aged individuals and maybe regarded as pathologic when it is unilateral or when it does not fatigue with repeated palmar stimulation. The glabellar reflex (Myerson's sign) is elicited by tapping the patient between the eyes. After a few blinks, the patient should suppress further blinking. Patients with Parkinson's disease and other basal ganglia disorders will continue to blink.

### Higher Cortical Function

Cortical sensory modalities, including two-point discrimination, graphesthesia, and stereognosis should be assessed. Two-point discrimination is best performed with calipers. Graphesthesia is performed with the patients eyes closed and numbers are traced onto the palm with the back of the reflex hammer. Stereognosis is also performed with the patients eyes closed. Common objects are placed into the patients' hand and they are allowed to move them about without using the other hand. Deficits imply dysfunction in the contralateral parietal lobe. Cortical sensory function should be assessed independently for each upper extremity. It is important to first assess primary sensory modalities. In the presence of prominent sensory loss, cortical sensory function cannot be assessed.

### Neurovascular Assessment

Examination of vascular system, including auscultation for cranial and carotid bruits, palpation of peripheral pulses, and assessment of blood pressure (lying, sitting, and standing) complements the neurologic examination and should be performed on every patient.

### CONCLUSION

A variety of neurologic disorders (e.g., stroke, Parkinson's disease, Alzheimer's disease) preferentially present in the older adult. A comprehensive mental status and neurologic examination should be performed in every patient to document changes in neurologic function (i.e., memory/cognition, behavior/personality, cranial nerves, motor function, and sensory perception) associated with pathologic conditions that affect the nervous system, and distinguish them from the functional changes associated with normal aging. Limited memory and cognitive function changes occur as one ages. Subtle changes in memory that do not interfere with normal functioning in society and that do not impair activities of daily living occur in normal aging. More significant declines in memory and cognitive function can be encountered in dementia (Table 12-14).

Altered cognitive function in the setting of a clear sensorium is consistent with dementia secondary to a neurodegenerative process or medical illness. Dementias (e.g., Alzheimer's disease, frontotemporal dementias, dementia with Lewy bodies) are characterized by a specific constellation of signs and symptoms. In Alzheimer's disease, the individual typically exhibits limited insight into their cognitive deficits that involve memory, language, and visuospatial skills. Patients with frontotemporal dementias present with a predominance of features consistent with frontal and/or temporal degeneration. These individuals exhibit early changes in behavior and personality, such as social inappropriateness, disinhibition, apathy, perseveration, and oral/dietary changes. Other accompanying features may include language/speech impairment, executive dysfunction, and preserved

<i>Epilepsy</i>

posterior functions (e.g., visuospatial ability, calculations). In dementia with Lewy bodies, patients may exhibit fluctuating cognition, recurrent well-formed and detailed visual hallucinations, and extrapyramidal signs consistent with parkinsonism. Dementia can occur as a consequence of other neurological and medical illnesses such as cerebrovascular disease, vitamin B-12 deficiency, hypothyroidism, Parkinson's disease, and meningoencephalitis.

Delirium, on the other hand, causes alteration in sensorium and level of consciousness and is usually due to medications (Table 12-15), infection, head injury, or metabolic derangements. Associated features include disruption of sleep-wake cycle, intermittent drowsiness and agitation, restlessness, emotional lability, and frank psy-

chosis (hallucination, illusions, delusions). Symptoms of delirium are often worse at night and occurs in up to 20% of hospitalized patients. The risk increases in the older adult the longer the hospital stay. Predisposing factors include advanced age, dementia, impaired physical or mental health, sensory deprivation (poor vision or hearing), and placement in intensive care units.

A functional decline in some aspects of cranial nerve function (e.g., vision, hearing, vestibular function, taste, and smell) can be anticipated in normal aging and should be distinguished from pathological conditions afflicting the nervous system. Similarly, older individuals experience decreased mobility as they age. Subtle changes in gait, posture, coordination, and strength are expected concomitants of aging. However, more profound changes that significantly alter mobility and/or present as focal weakness or impaired coordination should alert the clinician to the possibility of a neuropathologic disorder.

Alterations in sensory perception can be indicative of neuropsychiatric dysfunction. Subtle deficits in vibration and other primary sensory modalities may be encountered in normal aging. However,

**TABLE 12-15****Medications Causing Delirium in the Older Adult**

Alpha-methyl DOPA
Amantidine
Anticholinergics
Antihistamines
Antipsychotics
Atropine
Barbiturates
Benzodiazepines
Bromides
Chlordiazepoxide
Chloral hydrate
Cimetidine and other H2 blockers
Clonidine
Codeine and other opioids
Cocaine
Dextromethorphan

Propranolol
Reserpine
Theophylline
Tricyclic antidepressants

marked deficits in sensory function are suggestive of neurologic disease and require further diagnostic testing.

In conclusion, neurologic findings of normal aging include subtle declines in cognitive function, mildly impaired motor function, and altered sensory perceptions. However, exaggerated impairments in cognitive, behavioral, motor, and sensory function suggest the onset of neurologic diseases that commonly afflict the older adult. A comprehensive mental status and neurologic examination is the foundation for identifying neuropathologic conditions that necessitate further laboratory and imaging investigation.

# Assessment of Decisional Capacity and Competencies

*Margaret A. Drickamer* ■ *James M. Lai*

## INTRODUCTION

The medical profession has been charged with the seemingly conflicting responsibilities of respecting patients' autonomy while protecting from harm those patients who are incapable of protecting themselves. Assessing a patient's capacity to make decisions is a role with which all clinicians should be familiar. Although certain situations may call for specialized assessment, generalists, internists, subspecialists, geriatricians, and advanced practice nurses, among other health professionals, should be sufficiently familiar with the principles and process to handle most situations. The purpose of this chapter is to explain some of the ethical underpinnings to this responsibility, to highlight the strengths and weaknesses of approaches to assessing decisional capacity, and to describe the types of situations in which the clinician may play a role.

Autonomy is defined as self-determination (see also Chapter 34). Respect for individual autonomy is understood to be an elemental principle of our society. Nonetheless, all of us face limitations on how much we can truly determine our fates. Limitations of resources and opportunity, societal and legal prohibitions, and the limits imposed by the rights of others not to have their autonomy infringed upon all limit one's self-determination. There are also limitations on who qualifies as an autonomous "self." The full right to self-determination is generally recognized to apply only to adults who are "of sound mind."

Paternalism is defined as limiting an individual's autonomy in order either to prevent that individual from doing harm to themselves or to prevent the person from missing a substantial benefit. The circumstances under which paternalism is acceptable are not defined by the action the individual may wish to undertake, or by the probable untoward consequences of an action, but rather by the individual's ability to make decisions. In other words, our wish to protect an individual from doing themselves harm does not justify paternalism; we cannot prevent an individual from doing things that may cause them harm (overeating, bungee jumping, etc.). We

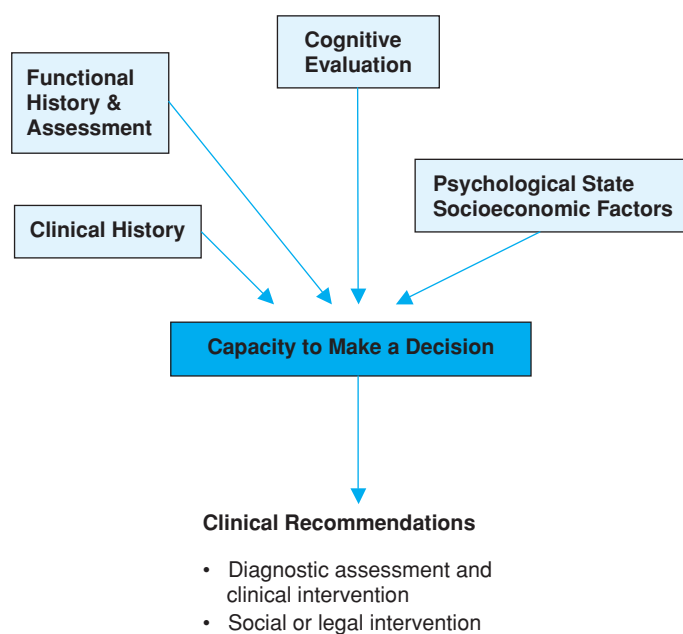

can only justify intervention if we judge that an individual lacks the capacity to make decisions. In such a case, we are responsible for protecting the person from the possible harm of an incapable decision.

The interplay between these concepts becomes apparent when the person is no longer felt to be "of sound mind." This chapter will focus on those individuals who have cognitive impairment or a clouded sensorium (fixed lesions, dementia, or delirium) and will not discuss the competence of individuals whose decisional capacity may be impaired by psychiatric illness. When patients are cognitively impaired, clinicians have an obligation to respect their rights, to protect their persons, and to consider the safety of the public. This often requires careful balancing of conflicting imperatives.

## DEFINITION OF DECISIONAL CAPACITY

In the broadest sense of the word, for an individual to be competent, that individual must be well qualified to do whatever task they are doing. In the context in which we are talking, competence is viewed as a legal term. It refers to a judge's ruling as to whether an individual has been deemed capable of making their own decisions. An individual adjudicated to be incompetent must have a guardian appointed to make the decisions for the area (or areas) in which the person has been found to be incompetent. Although guidelines vary somewhat from state to state, it is generally accepted that a ruling of incompetence cannot be made solely on the basis of a medical diagnosis, age, level of education, or personal eccentricity. An adjudication of competence or incompetence is based on an assessment of the individual's decisional capacity and that individual's demonstrated ability or inability to carry out a plan. Therefore, the assessment of decisional capacity should include not just the patient's cognitive ability, but other factors that may be influencing their ability to decide. This would include emotional state, functional ability,

**FIGURE 13-1.** Components included in assessment of decisional capacity.

psychosocial situation (especially with regard to coercion), and financial and environmental limitations (Figure 13-1).

There are four necessary elements to making a capable decision; understanding, appreciation, reasoning, and expressing a choice (Table 13-1). First, the individual must be able to comprehend the information being considered sufficiently well to understand the important or relevant facts. That information must have been presented in a clear and concise manner with special attention taken to ensure that barriers such as hearing impairment, illiteracy, or language difference do not constitute the sole reasons that the person is unable to understand the information. Other issues, such as aphasia, delirium, or depression, may also interfere with the individual's ability to comprehend and retain information.

**TABLE 13-1**

**Four Elements that Constitute Decision-Making Abilities**

ABILITY	DESCRIPTION
Understanding	<ol style="list-style-type: none"> <li>1. Comprehension of appropriately communicated information</li> <li>2. Retention of information long enough to be able to recall it in discussion</li> <li>3. Perception of the relationship between interventions and outcomes</li> </ol>
Appreciation	<ol style="list-style-type: none"> <li>1. Recognition of how the information relates to his or her own circumstances</li> <li>2. Insight into the advantages and disadvantages of a proposed solution.</li> </ol>
Reasoning	<ol style="list-style-type: none"> <li>1. Manipulation of information to generate comparisons between different alternatives and their consequences</li> <li>2. Justification of a rationale as a context for making these comparisons</li> </ol>
Expressing a choice	Articulation of a clear choice with regard to a specific decision

Second, the individual must have the conceptual ability to appreciate the consequences of the decision that he or she is making. This includes both an appreciation of the risks and benefits of options and the ability to identify the consequences these risks and benefits will have on his or her life.

The individual must be able to reason, within their own frame of reference, why she or he is choosing a course of action. This is different than saying that a decision seems “reasonable” to the other parties involved, but rather it refers to the cognitive processing of values and beliefs in view of the information given. Judging the rationality of a decision can be tricky. Even if we feel—and even if most of society would feel—that an individual's decision is irrational, it does not give us grounds to negate the person's right to self-determination. Our society has a great respect for individuality and one's right to express that individuality in a wide variety of ways. Nonetheless, an individual's ability to give a plausible rationale for his or her decision is sometimes used as secondary evidence of decisional capacity. That is, demonstrating justification for one's choices (e.g. religious belief, personal value, etc.) provides another level of assurance that the patient's decision rests upon intact reasoning, rather than a set of delusional or incoherent beliefs that may often exist in the setting of cognitive impairment or psychiatric illness.

Finally, the person must be able to make a choice and communicate the decision. This is the lowest bar for decision-making capacity but one which may be impaired by specific damage in language or frontal lobe function as well as in severe global cognitive impairment.

One other consideration is sometimes used in judging an individual's decisional capacity: consistency of the person's decision. The inconsistency of an individual's decision with past decisions made by that person provides an important clue to possible underlying cognitive or psychiatric problems that deserve exploration. But, in itself, inconsistency does not negate the person's right to make decisions. Inconsistency of a specific decision over time may indicate that the individual has had difficulty with remembering or understanding the information provided and their cognitive abilities should also be explored.

## LEGAL AND PRACTICAL ASPECTS IN DETERMINING DECISIONAL CAPACITY

In protecting an individual who is incapable of making decisions, one action that may need to be taken is applying to the local probate court asking that the individual be adjudicated to be incompetent and to have someone else appointed to make decisions. Although specifics of probate statutes vary among states, most follow a general pattern articulated in the Uniform Probate Code. Once an individual has been adjudicated incompetent, another person is appointed to represent his or her interests. This person is variably referred to as a guardian, conservator, or legal surrogate. We will use the term conservator. Although there are movements toward “limited conservatorship” that restrict the powers of the conservator to decision making in specific areas where a person has been shown to be incapable, there are two broad categories of conservatorship that are commonly used, those of finance and of person. Conservatorship of finance is a fairly self-evident term. Conservatorship of person grants a more global responsibility for assuring that the individual is kept safe and that decisions are made either as substituted judgment or

on the basis of the individual's best interests (see Chapter 34). These decisions may involve, for example, medical care, where a person will live, what help the person will receive to maintain himself or herself. The person may retain the ability to make a will (testamentary competence), even when he or she has been adjudicated as incompetent of person and finance.

It should be emphasized that not all incapacitated individuals need to be conserved. There are no statistics available to say how many incapacitated individuals have informal care management by relatives and never require probate action. Personal experience would lead us to believe that most adults with cognitive deficits fall into this category. Probate adjudication of a conservator may not be needed if financial management has been allocated to a family member by a power of attorney prior to the individual becoming incapacitated, and if there is a general agreement among concerned and interested parties that decisions should be made either by a specific individual or group consensus. If the individual involved has granted someone a durable power of attorney for health affairs (see Chapter 34), there may not be a need for court action. Turning to a court will prove unnecessary even when interested parties disagree, provided they are willing to respect the individual's appointment of a surrogate decision maker.

Even when the court has been asked to take action, 75% to 85% of the time the court appoints a family member as conservator. The ability of an appointed conservator to act as an appropriate surrogate varies considerably. One advantage of having a court-appointed conservator is that the probate court has some oversight responsibilities for the management of the individual's affairs. Oversight by a judge may prove beneficial to individuals who might otherwise not be scrupulous about managing an incapacitated individual's funds. A judge who does not wish to choose a family member as conservator may appoint an individual from the community, an attorney, a social worker, or an agency to fill that role.

Although courts tend to see the ability to make decisions as an all-or-nothing phenomenon, a person's ability to make decisions falls on a continuum ranging from complete capability to incapacity. Furthermore, not only ability, but also circumstance, influences the need for intervention. For instance, a person's ability to capably manage financial affairs will be influenced by the size and complexity of the finances requiring management. If the need for complex medical decision making does not arise, then the ability of an individual to make those types of decisions is not questioned. If the individual is in a situation where others are managing household affairs and looking out for the person's needs, then the person's ability to care for self may not be examined. It is only when a problem arises that the individual's ability to make these types of decisions becomes an issue. Also, as mentioned above, even if the patient is incapable and others need to make decisions, this can often be handled without court participation.

Preventive legal measures, enacted in the course of patient care prior to episodes of incapacity, may negate the need to involve the court system. For example, a "springing" durable power of attorney may be drafted to designate a chosen person to have legal authority over financial matters at some time or event in the future when the patient is deemed unable to perform those actions. Other legal planning methods, such as designation of a conservator in advance of need or in vivo trusts, may also be useful mechanisms for securing appropriate surrogate decision makers for persons who may anticipate future incapacity.

## PROCESS OF DETERMINING CAPACITY

The individual's inability to make decisions is determined in two different ways. Specific testing can measure cognitive dysfunction, and observing the person's decision-making process can demonstrate his or her inability to complete the decision-making task capably. In order to understand and apply both of these methods, one needs to understand the cognitive processes involved in decisional capacity. These processes can be understood both as discrete neuropsychiatric functions and as contributors to the holistic process of making decisions.

The brain functions that contribute to decision making are centered in the cortex and frontal lobes. Cortical (parietal and temporal lobe) functions involved in decision making include immediate memory and language. Immediate memory is defined as the ability to remember rehearsed or consolidated materials for 30 seconds to 30 minutes (e.g., first repeating three objects then recalling them in 5 min). Immediate memory is clearly important in the individual's ability to participate in a discussion around a specific decision. Cortical language abilities are those that affect comprehension and the ability to produce the intended words when expressing one's thoughts in both spoken and written communication. The ability to understand language is highly correlated with an individual's ability to comprehend the information needed to make a decision. Problems with expressive language ability from cortical lesions can lead to statements by the individual that misrepresent his or her thoughts (i.e., through misuse of words, word substitutions, or paraphrastic errors). The ability to understand and manipulate numbers may also be affected.

Frontal lobe functions involved in the process of making capable decisions include the abilities to concentrate, express oneself, use abstract reasoning, initiate actions, solve problems, monitor one's behavior, and use judgment. The frontal lobe is responsible for filtering out both internal and external stimuli that interfere with the individual's ability to concentrate and to understand instructions or explanations. Frontal lobe dysfunction can lead to inattention that interferes with the ability to complete necessary tasks appropriately. The intrusion of internal stimuli can lead to inappropriate and impulsive behaviors that can interfere with the individual's functioning and decision making.

### Traditional Mental Status Tools

Tools commonly used for the assessment of cognition in patients, such as the Mini-Mental State Examination (MMSE) or the Executive Interview (EXIT), test specific cognitive functions (memory, language, praxis, concentration, etc.) or the integration of these functions into simple processes (three-step command, story telling). Looking at performance on individual items and extrapolating to predict how performance will affect the processes necessary for decision making may help the clinician to evaluate a patient. No single cut-off score on any of these tests will divide those capable of making a decision from those not capable. This is particularly true because different types of decisions require different skills. These tests also do not look at the patient's actual function. On the other hand, a score may signal a level of such diminished cognitive abilities that it is highly unlikely that persons with that score will be capable of making decisions. Looking at individual items on these tests and

having knowledge of how the cognitive function tested may influence the individual's ability to make decisions is important. These tests may also serve as important triggers to further investigation of the individual's decisional capacity.

The MMSE is representative of tests for cortical function that have been shown to have some correlation with an individual's ability to make decisions. The MMSE tests skills, such as immediate memory, word finding, understanding simple verbal and written material, integrating that understanding into a simple action, and expressing basic ideas verbally or in writing, which may affect a person's ability to make decisions. MMSE scores of less than 10 have been shown to be diagnostic of a person so impaired that he or she is unable to make decisions.

Testing of frontal lobe or executive functioning is of great importance in assessing decisional capacity. The EXIT examination and clock drawing are the two measures most commonly used by clinicians. The EXIT 25 has been shown to have the best correlation with subjective measures of competency of any neuropsychological test. An overall score of 15 on the EXIT (higher being less capable) indicates very significant impairment. Again, recognizing errors on individual items and the correlative cognitive dysfunctions will be important in assessing less grossly impaired cases. Functions that may be most reflective of problems with decisional capacity include poor insight, impulsivity, poor self-monitoring, and impaired ability to plan and follow-through on the plan. Although individual items of these tests do not correlate directly with each of these functions, observing the individual as he or she does the test with these functions in mind can clarify areas of deficiency. For example, when the individual makes an obvious error, does he or she realize it and go back and correct the mistake? Is the person able to plan how to draw the face of a clock? If the person draws a clock face that is too small, does he or she notice this and correct it? Does the concrete stimulus of the numbers interfere with the abstraction of how the hands indicate time? Similar observations can be made while watching an individual take the EXIT examination. Does the person plan out how to approach a problem such as telling a story? Can the person correct errors in sequencing? Does the person let internal overlearned stimuli interfere with his or her ability to hear and repeat?

Test results can be deceptive: Individuals may have significant frontal lobe dysfunction, enough to impair their capacity for making decisions, and still score very well on the MMSE. There are more complex neuropsychological tests that can be done to test the same areas of function in more detail. These are not practical in the clinical setting, and the clinician should refer the patient to a neuropsychologist if there is any question of the nature or severity of neuropsychological deficits.

### Tests of Decisional Capacity

There are tests that are specifically designed to assess an individual's capacity for making medical decisions. These tests may utilize hypothetical vignettes to demonstrate whether the individual is capable of the four elements of decision making, namely, understanding the vignette (usually written at a sixth-grade level), appreciation of the issues and the potential options involved in solving this issue, being able to reason with the material, and then being capable of verbalizing an opinion. An example of such a test is the Capacity to Consent to Treatment Instrument in which the individual must read a series of case vignettes and then consider two different treatment options.

The Hopkins Competency Assessment Test consists of a short essay that describes informed consent and durable power of attorney and a series of questions to assess the individual's comprehension of the material. The MacArthur Competence Assessment Tool-Treatment (MacCAT-T) is an example of a structured interview that allows the clinician to test the individual's ability to make a specific medical decision. The first two tests deal with theory or theoretical situations and have the advantage of being able to be used prior to the need for a decision. The MacCAT-T, however, focuses on an individual's ability to make a specific, real-time decision at the time of the testing.

## CAPACITY TO MAKE SPECIFIC DECISIONS

It is not always possible to make a definitive and enduring diagnosis of decisional incapacity. This is because decisional incapacity is task-specific and may be time-limited. Although one may be adjudicated to be either incompetent or competent in the two broad legal categories of person and finance, the ability of an individual to make decisions or at least to participate in decisions needs to be thought of in much more flexible terms. We will discuss incapacity in matters of person (medical decisions and ability for self-care), finance, wills, advance directives, and research.

### Medical Decisions

Because patients have the right to refuse medical interventions and they have the right to be informed before consenting to medical treatments, their ability to make these decisions has been widely discussed. The need to make a medical decision frequently prompts the first assessment of decisional capacity, often at a time when clinicians face pressure to make speedy judgments. For the patient facing these types of decisions, the neuropsychological functions of memory, language, and reasoning are the most crucial.

Although tests can help to measure the patient's ability to make medical decisions, observing the patient's ability to handle the information given is more valuable, and more important, than administering any test. Among tests, the EXIT examination has been shown to have the highest correlation (specificity and sensitivity) for testing medical decisional capacity when compared to expert assessment. Sometimes a formal structure or score is necessary, in which case the MacCAT-T provides a good framework from which to work. Here the interviewer is asked to stop and rate the individual's abilities in six steps of the process: (1) appreciation of the disorder, (2) understanding of the treatment and risks or discomforts, (3) appreciation of the treatment, (4) understanding of alternate treatments, (5) reasoning, and (6) expressing a choice.

Documentation of a formal score for any test is not necessary in most cases when a patient faces medical decisions. A thoughtful interview with the patient and a written description of the areas in which the patient is unable to function is usually sufficient for this purpose, although learning structured observation will enhance the clinician's ability to assess capacity.

### Problems of Self-Care

Formal assessments of decision-making ability may be necessary when a patient demonstrates an inability to care for self or to accept the help needed to remain safe in his or her present environment.

Issues of cognitive impairment versus denial are difficult to sort through without formal testing. A person's tendency to be "eccentric" is not always easily distinguishable from dangerous behaviors stemming from increasing cognitive impairment and an inability to make decisions around self-care. Gross impairment of cortical functioning, especially short-term memory, can pose problems for day-to-day function. What is more evident is the impact of frontal lobe dysfunction. The inability to plan, initiate action, monitor one's behavior, and self-correct are essential to being able to care for oneself. A combination of findings on frontal lobe testing and demonstrated inability to care for oneself is often sufficient evidence for action, especially in combination with an inability to accept a level of care which would keep them safe. Alternatively, persons who demonstrate an inability to administer their own medications or safely prepare their own meals but who have accepted care, which will obviate these problems (e.g. home care, Meals-on-Wheels), may be regarded as having intact decision making with respect to solving these functional deficits.

There are as yet no clinical tools specifically designed to assist clinicians in assessing a person's ability to make a decisions related to self-care in the face of functional problems. A reasonable approach in this scenario, however, would involve a structured assessment where the patient must demonstrate an ability to: understand and appreciate a known functional problem; understand and appreciate the potential options to solving this problem, as well as the risks and benefits of those options; describe the consequences associated with these options; choose an option; and, then explain how this choice is superior to the other options not chosen. Similar to the MacCAT-T, this approach assesses decision-making ability with respect to the clinically relevant problem and measures decisional skills based on the legal standard.

### Problems of Finances

There are times when an individual remains able to make medical decisions and decisions related to self-care but is no longer capable of managing the finances. When bills are going unpaid or gross mistakes are made in handling money, then someone else will need to take over financial management. Specific tests for measuring the ability to calculate, to understand a checkbook, to monitor bank accounts, or a more specific financial management assessment, such as the Financial Capacity Inventory, can be administered by an occupational therapist or a neuropsychologist, but usually a demonstrated problem with this area is sufficient to warrant supervision. If the individual has enough insight to understand the problem and a reliable person is available to help, granting that person a power of attorney for finances should suffice. If the incapacitated person is reluctant to relinquish control, or court monitoring is deemed advisable, then the family, the clinician, or other concerned party should seek a conservator of finance.

## OTHER ISSUES OF DECISIONAL CAPACITY AND CONSENT

### Legal Documents

The ability to make a Last Will and Testament is felt to be retained even after the ability to handle finances and make decisions of person

have been lost. An individual's ability to remember what he or she is doing with the estate and to express some logic behind choices is usually sufficient evidence of capability. Despite the risk of exploitation of an impaired person, the courts are usually very liberal in allowing someone to change a will, even when the person has cognitive problems.

In contrast, the ability to grant someone Durable Power of Attorney for Health Affairs or to make a Living Will requires higher levels of cognitive function than does day-to-day decision making. Both of these areas deal with hypothetical situations that can often be hard even for cognitively intact individuals to fully understand and conceptualize. Scales such as the Hopkins Competency Assessment Test or the Capacity to Consent to Treatment Instrument may help to establish this ability, but these may not be practical for use in most clinical settings. At the very least, clinicians should question an individual's ability to fully understand the process if he or she has demonstrated problems with memory or language or has shown signs of frontal lobe dysfunction. The clinician must also recognize that even very cognitively impaired individuals may still be able to portray wishes and desires (see "Consent vs. Assent")

### Temporary Loss of Decisional Capacity

Individuals may be transiently incapacitated for decision making or their ability to recover their cognition may not be known, such as when a patient is delirious or has suffered a recent stroke. In these situations, the clinician should seek an interim solution. An informal surrogate, the person granted durable power of attorney for health affairs, or a temporary conservator can make decisions while the clinician clarifies the prognosis for decisional capacity. The decisions needed during a time of uncertainty should fall on the side of aggressive protection of the individual's life or continued function until the person can make his or her wishes known or the permanence and extent of the impairment becomes clear.

### Consent Versus Assent

Even when an individual is no longer able to give informed consent to a procedure or a change in living situation, he or she may still participate in the decision making process. Substituted judgment is the process that a surrogate (legal or otherwise) is supposed to apply as the basis on which a decision should be made. Substituted judgment enjoins one to take into account the patient's prior wishes and long-held beliefs as the basis for one's decision, "deciding as they would have decided" (see Chapter 34). Assent refers to the impaired individual's willingness to cooperate with a plan of care. It is, in essence, a way to take into consideration the individual's present desires when making a decision. Although it has been used primarily in the ethics and legal literature when looking at the role of adolescents in the process of medical decision making, the principles apply to impaired adults as well. In cognitively impaired adults, there is a continuum of incapacity, even amongst those who do not retain the full capacity to make decisions. An individual who is incapable of understanding the complexities of a situation or decision may retain high levels of understanding around specific aspects of the process and be able to express their opinions. Even very cognitively impaired patients can give indications of what brings them pleasure and what gives them pain. Clinicians and surrogates should consider this information in the decision-making process.

Clinicians trying to obtain consent for medical treatment or research protocols may wish to use a combination of surrogate consent and patient assent (shared decision making). This may be essential in some cases where the patient's ability to cooperate will be necessary in order to carry out the treatment or procedure. Even the courts are moving toward the recognition of the need for "limited conservatorship," which reflects that decisional capacity is not an all-or-nothing phenomenon. Decisional capacity is situation-dependent and can change with time.

### Informed Consent in Research

An individual's ability to consent to participate in research is also difficult to judge. The understanding of the risks and benefits of being in a research study must be even greater than that for accepting or declining an established medical treatment. The risks and benefits are more theoretically based and therefore harder to make concrete to an individual who may be having difficulty with abstract thinking. This is an important time for dual decision making as outlined in the section above.

# Principles of Screening in Older Adults

*Louise C. Walter*

This chapter focuses on the topic of screening, particularly the issues that need to be considered when making a decision to screen an older person for cancer. This decision highlights many of the special philosophical and practical challenges inherent in recommending preventive services to older persons. One obvious challenge to recommending cancer screening (and many other preventive services) to older adults is that few studies of preventive interventions have enrolled persons older than age 75 years. The absence of age-specific data requires clinicians to extrapolate data about the effectiveness of screening in younger persons and apply it to older persons. Furthermore, even if trials suggest that the effectiveness of screening is similar in younger and older populations, challenges remain about how to apply data from trials to an individual older person. Trials show the average effectiveness of an intervention, but they generally do not address individual patient characteristics, such as comorbid conditions or functional status, which may change the likelihood of receiving benefit or harm from screening. Given these challenges, the need to individualize screening decisions is especially important for older people, because individuals become increasingly unique in their particular combination of health, function, remaining life expectancy, and values with advancing age.

The important issues that need to be considered when making individualized screening decisions in elderly persons are not fully addressed by current guidelines. Although many screening guidelines that used to recommend upper age limits for stopping screening are now recommending screening an older person if the individual has a “reasonable life expectancy,” current guidelines offer little guidance about how to estimate life expectancy or how patient preferences should factor into screening decisions. This chapter outlines a systematic framework for individualizing cancer screening decisions in older adults that includes consideration of an individual’s life expectancy and the individual’s preferences regarding the potential benefits and harms of screening (Figure 14-1).

Like many medical decisions, informed screening decisions are best made by using quantitative estimates of life expectancy and

screening outcomes to anchor decisions, tempered by qualitative consideration of how an older person values the potential benefits and harms of screening. While potential benefits of screening include increased survival, this should be balanced against the potential harms of screening, which encompass adverse effects on survival, comfort, function, and psychological well-being emanating from all procedures that result from screening. For older patients who are bothered by the discomfort and risks of screening tests, the decrease in quality of life in the present may outweigh the small chance of future benefit.

## GENERAL FRAMEWORK FOR MAKING INFORMED CANCER SCREENING DECISIONS

### Estimate Life Expectancy

The first step in individualizing cancer screening recommendations is to estimate an older person’s life expectancy, because life expectancy affects the likelihood of receiving benefit versus harm from screening. For example, finding an asymptomatic cancer in a person who will die of something else before the cancer would become symptomatic does not benefit the person and may cause considerable harm. The risk of such a scenario depends upon the life expectancy of the individual and the age-specific mortality rate of the particular cancer. With advancing age, the mortality rates of most cancers increase, yet overall life expectancy decreases. The need to weigh these two opposing factors when estimating the likelihood that a person will die of a screen-detectable cancer makes cancer screening decisions in older people complex.

In estimating life expectancy, it is useful to have a general idea of the distribution of life expectancies at various ages. For example, when estimating the life expectancy of an 80-year-old woman, it is useful to know that approximately 25% of 80-year-old women

**FIGURE 14-1.** The benefits and harms that need to be weighed when making informed cancer screening decisions. Patient preferences act like a moveable fulcrum of a scale to shift the magnitude of the benefits or harms needed to tip the decision toward recommending the screening test (net benefit likely) or recommending against the screening test (net harm likely). NNS, number needed to screen to prevent one cancer-specific death.

will live more than 13 years, 50% will live at least 9 years, and 25% will live less than 5 years. Figure 14-2 presents the upper, middle, and lower quartiles of life expectancy for the U.S. population according to age and sex, and illustrates the substantial variability in

life expectancy that exists at each age. Although it is impossible for clinicians to predict the exact life expectancy of an individual person, it is possible to make reasonable estimates of whether a person is likely to live substantially longer or shorter than an average person in his

**FIGURE 14-2.** Upper, middle, and lower quartiles of life expectancy for women and men at selected ages. Data from the Life Tables of the United States, 2001. or her age cohort. Such estimates, while not perfect, would allow for better estimations of potential benefits and harms of screening than focusing on age alone.

There are many factors clinicians can use to estimate whether an older person is typical of someone at the middle of their age-sex cohort or is more like someone in the upper or lower quartiles. For example, the number and severity of comorbid conditions and functional impairments are much stronger predictors of mortality in older people than chronological age. Congestive heart failure, end-stage renal disease, oxygen-dependent chronic obstructive lung disease, severe dementia, or functional dependencies in several activities of daily living are examples of factors that would cause an elderly person to have a life expectancy substantially below the average for his or her age. The absence of significant comorbid conditions or presence of excellent functional status identifies older individuals who are likely to live longer than average.

### Estimate Benefits of Cancer Screening

The next step is to consider the potential benefits of screening. The main benefit of cancer screening is the reduction in cancer mortality experienced by a few people whose early-stage disease is detected and treated, which otherwise would have been lethal during their remaining lifetime. While the impact of cancer screening on quality of life or functional decline has not been studied, there is good evidence that mammography, fecal occult blood testing (FOBT), and Papanicolaou (Pap) smears are effective in reducing cancer-specific mortality. However, the strength of the evidence that these tests are effective in older adults is limited by the small number of older patients included in screening trials. In addition, even screening tests likely to be effective in older populations may not provide survival benefit to individuals with short life expectancies, because the benefit from screening is not immediate. For example, in the randomized controlled trials of FOBT and mammography, the cancer-specific mortality curves between the screened and unscreened groups do not separate significantly until at least 5 years after the start of screening. This period is likely even longer for persons older than 70 years of age because some evidence suggests that the length of time that a screen-detectable cancer remains clinically asymptomatic increases with advancing age for both breast and colorectal cancer. This suggests that older persons who have life expectancies of less than 5 years will not derive survival benefit from cancer screening.

For patients with estimated life expectancies greater than 5 years, it is important to have a general idea of the potential benefit of screening tests in absolute terms. The absolute benefit of a screening test can be conveyed by the absolute risk reduction (the absolute difference in proportions of persons with a given outcome from two treatments or actions), or more effectively by calculating the number needed to screen (NNS), which is the reciprocal of the absolute risk reduction. Considering older persons at average risk for developing cancer, the approximate NNS to prevent one cancer-specific death is listed in Table 14-1 for screening tests that have been shown to be effective in reducing cancer-specific mortality. All the numbers in Table 14-1 assume a 5-year delay between the onset of screening and survival benefit. The numbers are presented according to age and life expectancy because life expectancy defines the potential number of years available for screening. For example, 240 very healthy

80-year-old women would have to be screened with mammography during their remaining lifetime to prevent one death from breast cancer. Table 14-1 emphasizes the importance of considering life expectancy when making cancer screening decisions, as illustrated by the example that an 85-year-old woman in the upper quartile of life expectancy is more likely to benefit from screening than a 75-year-old woman in the lowest quartile. The precision of the estimates of life expectancy, and, in turn, number needed to benefit, is greatly enhanced by considering comorbidity rather than chronological age alone.

### Estimate Harms of Cancer Screening

The third step is to consider the potential harms of screening, as all screening tests pose direct and indirect harms. Harms that would be accepted to treat a symptomatic person with known disease are less acceptable when they are caused by screening tests, which benefit only a few individuals but expose all screened individuals to the harms. In addition, harms occur immediately, whereas it takes several years for a survival benefit to occur after cancer screening. Therefore, as the likelihood of benefit declines with decreasing life expectancy, the balance between harms and benefits from screening will shift in the direction of net harm.

Individuals who are found not to have cancer after work-up of an abnormal screening result (false-positive result) clearly have experienced harm from screening, as they were subjected to physical and psychological distress from additional testing and procedures that would not have been necessary had they not been screened. However, what is often forgotten is that in older persons some of the greatest harms from screening occur by finding and treating cancers that would never have become clinically significant. The risk of identifying an inconsequential cancer increases with decreasing life expectancy as well as with the increasing likelihood that screening will detect certain neoplasms that are unlikely to progress to symptoms in older persons, such as ductal carcinoma in situ (DCIS). Fewer than 25% of DCIS lesions progress to invasive cancer within 5 to 10 years, yet because of the inability to distinguish which lesions will progress, many older women with DCIS will undergo surgery. Women who have surgery for DCIS that would never have become symptomatic in their lifetime have suffered serious harm from screening.

In addition to physical harms, the psychological distress caused by cancer screening should be considered. Potential psychological harms range from the emotional pain of a diagnosis of cancer in persons whose lives were not extended by screening, through the alarm of false-positive results to the stress of undergoing the screening test itself. Many older persons may have cognitive, physical, or sensory problems that make screening tests and further work-up particularly difficult, painful, or frightening. Considering factors that increase the likelihood of harm is vital to making appropriate screening decisions.

### Integrate Patient Values and Preferences

The final step is to assess how individuals value the potential harms and benefits of screening and to integrate their preferences into screening decisions. Because many cancer-screening decisions in older persons will not be answered solely by quantitative assessments of benefits and harms, talking to older persons about their values

and preferences is especially important. The value placed on different health outcomes will vary among older people, as will preferences for screening. For example, some women undergoing screening mammography value “peace of mind” after a negative screening result, whereas women with dementia likely receive no such comfort. In considering the benefits versus harm of screening, clinicians must elicit how individual persons value the trade-offs among longer survival, comfort, and functional status.

Clinicians should consider a person’s usual approach to medical decision making to decide how to approach the discussion of screening. In some cases, clinicians will need to learn a person’s values, apply them to the known benefits and harms of screening, and make a formal recommendation. For other people, the clinician will want to discuss the benefits and harms with the person and allow the person to apply his or her values to the outcomes and come to a decision together. For people with dementia, discussion about preferences should be held with an involved caregiver. However, it should be remembered that despite being unable to articulate consent, many persons with dementia can still effectively communicate refusal. Assent from a person with dementia is essential if invasive or potentially harmful testing or treatments are being considered (see Chapters 13 and 34). If a person with dementia is likely to be frightened or agitated by a screening test, the caregiver and clinician should forgo the test. Also, there should be a general discussion prior to screening about the possible procedures and treatments that may be required after an abnormal screening result. Persons who would not want further work-up or treatment of an abnormal result should not be screened.

## APPLICATION OF SCREENING PRINCIPLES TO SPECIFIC CANCERS

### Breast Cancer

#### Risk of Dying of Breast Cancer

For very healthy 75-year-old women who have life expectancies in the top twenty-fifth percentile, the lifetime risk of dying of breast cancer is approximately 2.8%. The risk of dying of breast cancer declines with decreasing life expectancy, such that unhealthy women older than age 75 years who have estimated life expectancies in the lowest twenty-fifth percentile for their age cohort have less than a 1% chance of dying of breast cancer.

#### Benefits of Breast Cancer Screening

Methods for screening for breast cancer are mammography and breast examination. Mammography has the strongest evidence for screening efficacy based on pooled evidence from randomized controlled trials showing an overall relative risk reduction in breast cancer-related mortality of 27% for women between the ages of 50 and 69 years. There is little information regarding the absolute benefits of screening mammography in women older than age 70 years, so data from trials in younger people must be extrapolated to older people (see Table 14-1). There are no data from randomized trials to indicate that clinical breast examination or breast self-examination,

without accompanying mammography, reduce mortality from breast cancer in any age group.

### Harms of Breast Cancer Screening

On average, 1 in 15 elderly women sent for a screening mammogram will have a false-positive result and 1 in 1000 women will have DCIS detected, which would otherwise not have been found without screening. Most DCIS lesions are unlikely to have an effect on the life expectancy of older women, yet many will undergo surgery once DCIS has been found by screening. Frail older women are at increased risk for experiencing harms from screening. One study of frail community-living women found that 17% experienced burden from screening mammography as a result of work-up refusals, false-positive results, or identification of clinically insignificant lesions. Women with multiple comorbid conditions are also likely to experience adverse effects from surgery, radiation, and chemotherapy.

### Recommendations

Most guidelines recommend mammography alone or supplemented by clinical breast examination (Table 14-2). There is no evidence of a specific age cut-off at which potential benefits of screening suddenly cease or potential harms suddenly become substantial for everyone, so most guidelines recommend continuing screening women over age 70 years, despite the lack of this age group in screening trials. Decisions to stop screening should be based on whether a woman has advanced age and comorbid conditions that limit her life expectancy. The author recommends against screening for breast cancer if a woman has an estimated life expectancy of less than 5 years. For women who have a life expectancy between 5 and 10 years, the decision to screen is a close call, and patient preferences should play a major role in the decision to screen. For healthy older women who have a life expectancy greater than 10 years, biennial screening mammography, regardless of age, is a reasonable recommendation based on the data available.

### Colorectal Cancer

#### Risk of Dying of Colorectal Cancer

For very healthy 75-year-olds who have life expectancies in the top twenty-fifth percentile, the lifetime risk of dying of colorectal cancer is approximately 3.5% for men and 3.3% for women. The risk of dying of colorectal cancer declines with decreasing life expectancy, such that men and women older than age 70 years with life expectancies in the lowest twenty-fifth percentile for their age cohort have less than a 1% chance of dying of colorectal cancer.

#### Benefits of Colorectal Cancer Screening

Methods for screening for colorectal cancer include FOBT, flexible sigmoidoscopy, colonoscopy, and barium enema. Nonhydrated FOBT has the strongest evidence for screening efficacy based on two randomized controlled trials, showing a relative risk reduction in colorectal cancer-related mortality of 15% to 18% for persons between the ages of 45 and 75 years. Table 14-1 lists estimates of absolute benefits of screening FOBT according to life expectancy. Case-control studies show that sigmoidoscopy provides protection

TABLE 14-2

## Guideline Recommendations for Cancer Screening in Older Adults

Cancer Site	Test	Frequency	USPSTF Guideline	ACS Guideline	AGS Guideline
Colorectal	Fecal occult blood test or	Annual	Screen all adults $\geq$ 50 yr Discontinuing screening is reasonable in persons whose age and comorbid conditions limit life expectancy	Screen all adults $\geq$ 50 yr. Discontinuing screening is reasonable in persons with severe comorbidity that would preclude treatment	Screen all adults $\geq$ 50 yr Persons too frail to undergo colonoscopy and persons with short life expectancy (3–5 yr) should not be screened
	Sigmoidoscopy or	Every 5 yr			
	Colonoscopy or	Every 10 yr			
	Double-contrast Barium Enema	Every 5 yr			
Breast	Mammography with or without	Every 1–2 yr	Screen all women $\geq$ 40 yr Women with comorbid conditions that limit life expectancy are unlikely to benefit from screening	Screen all women $\geq$ 40 yr, continuing for as long as a woman is in good health and would be a candidate for treatment.	Screening should continue for older women who have a life expectancy $\geq$ 4 yr
	Clinical Breast Exam	Annually			
Cervical	Pap smear	Every 1–3 yr	Discontinue screening in women who have had a total hysterectomy and in women $>$ 65 yr who are not at high risk for cervical cancer and have had adequate recent normal Pap smears	Immunocompetent women $>$ 70 yr who have had $\geq$ 3 normal Pap smears in a row and no abnormal results within 10 yr may elect to stop. Screening may be stopped in women who have had a total hysterectomy and women with severe comorbid illness	It is acceptable to stop screening women $>$ 70 yr who have had $\geq$ 2 normal Pap smears since age 60 and women who have a short life expectancy or would be unable to tolerate treatment

USPSTF, United States Preventive Services Task Force; ACS, American Cancer Society; AGS, American Geriatrics Society.

Adapted from Walter LC, Lewis CL, Barton MB. Screening for colorectal, breast, and cervical cancer in the elderly: a review of the evidence. *Am J Med.* 2005;118:1078..

from distal colorectal cancer that lasts up to 10 years. Case-control studies also suggest that colonoscopy has a long-lasting protective effect because persons who died of colorectal cancer were less likely to have had a colonoscopy in the prior 10 years (odds ratio = 0.43; 95% CI: 0.30–0.63). No randomized trials have examined the effectiveness of barium enema in reducing mortality from colorectal cancer, and studies of its accuracy are of poor methodological quality.

### Harms of Colorectal Cancer Screening

Approximately 1 of 10 older adults who submit a screening non-rehydrated FOBT will have a false-positive result. Colonoscopy is the standard work-up following a positive FOBT and may have serious complications, such as perforation (1/1000), serious bleeding (3/1000), and cardiorespiratory events (5/1000). Complications may be higher if polypectomy is performed or if persons are in poor health. Discomfort from flexible sigmoidoscopy or colonoscopy may occur, and many older persons may experience substantial distress from the bowel preparation.

### Recommendations

Most guidelines recommend annual screening FOBT and/or flexible sigmoidoscopy every 5 years or colonoscopy every 10 years for average-risk persons starting at age 50 years (see Table 14-2). There is no evidence available to determine which screening method is preferable or when screening should stop. Most guidelines do not recommend using upper age cut-offs to decide when to stop screening. Rather, most guidelines recommend that the decision to discontinue screening should be individualized, based on whether an older person has characteristics that considerably decrease the benefit-to-

risk ratio of screening (e.g., limited life expectancy or conditions that increase the risk of colonoscopy, such as cardiopulmonary disease or dementia). The author recommends against screening for colorectal cancer if a person has an estimated life expectancy of less than 5 years. For persons with life expectancies between 5 and 10 years, the decision to screen is a close call, and patient preferences should play a major role in the decision to screen. For healthy older people who have a life expectancy greater than 10 years, screening with FOBT and/or flexible sigmoidoscopy or colonoscopy, regardless of age, is a reasonable recommendation based on available data.

### Cervical Cancer

#### Risk of Dying of Cervical Cancer

For very healthy 75-year-old women who have life expectancies in the top twenty-fifth percentile and who have not been previously screened for cervical cancer, the lifetime risk of dying of cervical cancer is approximately 0.2%. The risk of dying of cervical cancer declines with decreasing life expectancy and is extremely low for older women who have had normal screening examinations in the past.

#### Benefits of Cervical Cancer Screening

The principal method for screening for cervical cancer is through the use of cervical cytology. Since screening with Pap smears was initiated, population studies in the United States show a 20% to 60% decline in mortality rates from cervical cancer. Table 14-1 lists estimates of absolute benefits of screening Pap smears according to life expectancy. Decision models suggest that older women who have

had repeated normal Pap smears during their reproductive years do not benefit from continued Pap testing beyond age 65 or 70 years. However, these models make variable recommendations about the number of normal Pap smears required prior to stopping screening.

### Harms of Cervical Cancer Screening

For women older than age 70 years, the risk of a false-positive Pap smear result has not been studied, but for postmenopausal women with a normal Pap result in the previous 2 years, the positive predictive value of an abnormal cervical smear is less than 1%. Harms of false-positive results include needless patient concern and invasive procedures, such as colposcopy or biopsy. Discomfort and anxiety during Pap smears also occurs as does the identification and treatment of clinically unimportant cervical lesions.

### Recommendations

Most guidelines recommend that Pap smears be performed in women over age 70 years who have not been regularly screened before. For these women, screening may stop after two normal Pap smears 1 year apart, although little data exist about benefits and harms of Pap smear screening in elderly women. For women who have been regularly screened, Pap smears may be performed less frequently (every 3 years) after three or more smears have been normal. Women with repeatedly normal Pap smears may stop screening at age 65 or 70 years, as can women at any age who have a life expectancy of less than 5 years or who no longer have a cervix (see Table 14-2).

### Other Cancers

Although prostate-specific antigen (PSA) testing is frequently performed, no compelling evidence demonstrates that PSA testing reduces prostate cancer mortality at any age and the harms of screening are substantial, especially in older men. For example, the specificity of PSA decreases with advancing age, leading to higher rates of false-positive results requiring needle biopsies or cycles of repeat testing and anxiety. Even if prostate cancer is identified, modeling studies suggest that most cancers detected by screening men over age 70 years would never have produced symptoms during their lifetime. In addition, if prostate cancer identified by screening is treated, elderly men suffer more complications, including incontinence, impotence, and even death. Therefore, while controversy surrounds PSA screening in young, healthy populations, no organization currently recommends PSA screening in older men who have a life expectancy of less than 10 years. In addition, no organization currently recommends screening for lung, pancreatic, or ovarian cancer.

## SCREENING FOR NONCANCEROUS DISEASES

Like cancer-screening decisions, decisions to screen older people for other types of diseases also need to be individualized by considering life expectancy, comparing potential benefits and harms, and understanding individual values and preferences. However, the role of life expectancy and individual preferences in other types of screening decisions may be different than that presented for cancer screening. The decision to recommend cancer screening to an older individual

is highly dependent upon life expectancy because there is a substantial delay (generally more than 5 years) between when the screening test is performed and when benefit may occur. As a result, persons with limited life expectancies are very unlikely to derive survival benefit from cancer screening. However, the lag time between initiation of other screening tests and potential benefit often is much shorter than that for cancer screening. For example, the potential to benefit occurs quickly after initiating screening for depression or visual impairment, such that even persons with limited life expectancies may benefit from these screening tests. Similarly, individual preferences play less of a role when a preventive intervention has public health implications than when benefits and harms apply only to the individual being screened, as is the case for cancer screening. For example, prevention of contagious diseases by screening for tuberculosis is very important in nursing homes and should be universally recommended for patients and staff.

Survival is the benefit described for cancer screening as the effect on quality of life and function has not been studied. Many other screening tests in older people, however, are targeted at improving quality of life or at preventing functional decline, rather than improving survival. Much of the screening performed during a geriatric assessment, such as screening for incontinence or auditory impairment, for example, is aimed at improving quality of life rather than lengthening survival (see Chapter 11). Some types of screening have been associated with both improved survival and overall quality of life, such as screening older persons for hypertension. Several studies have shown that treatment of hypertension reduces the risk of stroke and cardiovascular events in older persons and may have a slight positive effect on cognitive and physical function and overall well-being.

In summary, the approach to making informed screening decisions is similar to that for many other medical decisions in which the potential risks and benefits are considered and patient preferences are understood. The emphasis should be on individualizing screening decisions by offering the best proven, least risky screening tests to those persons most likely to develop burdensome diseases. While the number of potential screening tests is large, prioritizing tests based on available evidence and estimations of life expectancy can help narrow the choices. For example, screening in older persons with limited life expectancies should prioritize quality of life outcomes and tests in which the lag time to benefit is short. By encouraging individualized decisions, screening may be more appropriately targeted to older persons for whom the potential benefits outweigh the potential harms.

# Health Care System

*Chad Boulton*

## INTRODUCTION

This chapter describes and critiques the “system” that provides health care for older Americans. The system comprises many elements, including providers of health care, providers of supportive services, “alternative” healers, patients, families, insurers, regulators, and liaisons among these elements. The health care system is addressed primarily from the perspectives of health care professionals and their older patients, particularly patients with multiple chronic conditions and complex health care needs. Strategies for optimizing care within the system and examples of recent innovations designed to improve the system are described.

Strictly speaking, a system (from the Latin noun *systema*) is a set of procedures or structures that direct or coordinate the orderly flow of other processes. In the case of complex health care for chronically ill older Americans, however, the fragmentation, lack of coordination, and disorderly flow of information and interactions is not a true system of health care. Nevertheless, this chapter uses the term “health care system” to refer to the aggregate of the many elements involved in providing health care to older patients.

The chapter begins with brief introductory descriptions of individual elements of the current system, many of which are described in greater detail in the chapters that follow, e.g., care in hospitals, emergency departments, subacute facilities, rehabilitation units, and nursing homes; complementary and alternative care; and care during transitions between providers. The next section describes the present system’s performance in addressing the multifaceted needs of chronically ill older patients, followed by a section on the roles of primary care clinicians in caring for this population. Later sections examine opportunities for creating a more effective, efficient, and patient-centered system and summarize some recent initiatives designed to improve the system’s quality and outcomes.

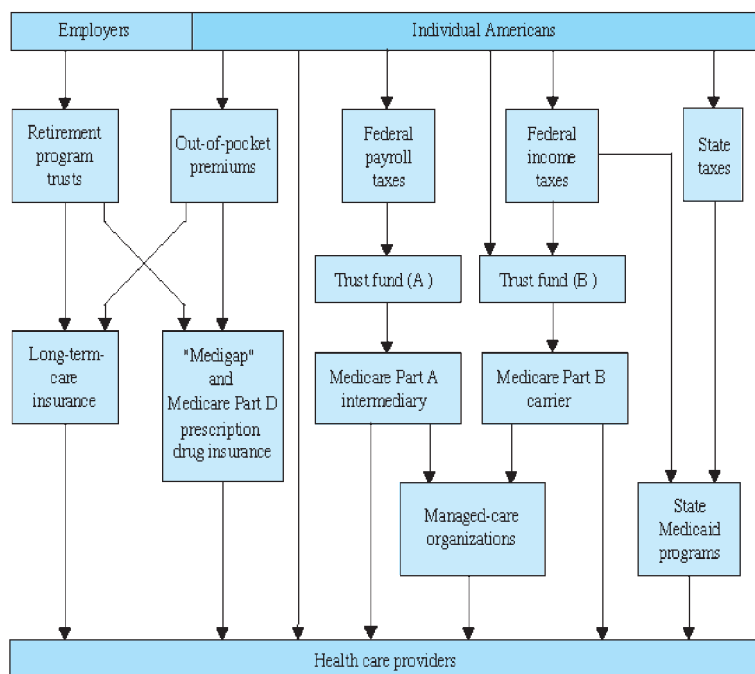

## THE ELEMENTS OF THE SYSTEM

The pluralistic U.S. health care system consists of five interacting elements: providers, patients and caregivers, insurers, liaisons, and regulators.

### Providers

Providers include health care professionals, health care organizations, and supportive community services. Among health care professionals are primary care and specialty physicians, nurses, social workers, rehabilitative therapists, pharmacists, dentists, mental health professionals, health care aides, and complementary and alternative medicine (CAM) practitioners. In the past, primary care physicians (PCPs) managed their patients across settings of care, providing valuable continuity and advocacy as their patients moved through emergency departments, hospitals, and rehabilitation facilities. Today, increased specialization by site of care has constrained primary physicians mostly to providing ambulatory care. Hospitalists, emergency physicians, and skilled nursing facility specialists (SNFists) provide much of the care in institutions. Although such specialization may have improved some aspects of care within hospitals, emergency departments, and SNFs, it has also eroded continuity of care and contributed to the further fragmentation of an already fragmented system (see Chapter 16). Unfortunately, no one clinician may know the patient well.

The system’s health care organizations include acute care hospitals, long-term care hospitals (LTCHs), emergency departments, rehabilitation units, home care agencies, house call practices, skilled nursing facilities (SNFs), hospice programs, long-term care facilities, personal care providers, and disease management companies. Some hospitals operate multidisciplinary Acute Care for Elders (ACE) units to meet the complex needs of older adults who become acutely ill or injured.

**FIGURE 15-1.** Flow of funds to providers of health care for older Americans.

A variety of organizations sponsor Programs of All-inclusive Care for the Elderly (PACE) that provide comprehensive community-based long-term care for older persons with significant disabilities. A few physician house call practices, often affiliated with medical schools, provide primary care at home to homebound patients. Although satisfying to patients and physicians, house call practices are challenged by low reimbursement.

Commercial disease management programs focusing on patients with congestive heart failure, diabetes, emphysema, or depression have proliferated in recent years as a new strategy for containing the high costs of these chronic illnesses. Disease managers, many of whom are nurses, follow standard protocols in communicating with patients by telephone to encourage them to see their physicians, use their medication appropriately, and adopt healthy behaviors. Most disease management programs work under contract with insurers; many use sophisticated health information technology (HIT) to remind patients to obtain appropriate preventive services and to track their use of health resources.

Community-based providers of supportive services include Area Agencies on Aging (AAA), Meals-on-Wheels, senior centers, transportation services, adult day care centers, condition-specific resources (e.g., the Alzheimer's Association), home modification programs, chore services, support groups, exercise programs, and congregate housing.

## Patients and Caregivers

Most of the work of caring for chronic conditions is done (for better or for worse) by the patients who have the conditions and by their informal (i.e., unpaid) caregivers, such as family or friends. The degree to which patients are able to adhere to medication regimens, healthy diets, physical activity programs, professional follow-up, and regular self-monitoring is a powerful determinant of the quality, cost, and clinical outcomes of their care. Out-of-pocket spending for health care by older patients and their families includes insurance premiums, deductibles, copayments, and the costs of products and

services not covered by their health insurance, such as long-term care, eyeglasses, hearing aids, dental care, and medications. Such expenses can be significant. In 2000, older Americans' out-of-pocket spending for health care averaged 21.7% of their incomes. For low-income women in poor health, the figure was 51.6%.

## Insurers

Both public and private organizations provide health insurance for older people. (Figure 15-1) Public health insurance programs include Medicare, Medicaid, the Veterans Health Administration, and Tri-care (for military retirees). Private health insurance coverage for older Americans is provided by managed care organizations (MCOs), private indemnity insurers, and Medicare Part D providers.

## Public Health Insurance

The Medicare program, which is administered by the federal Centers for Medicare and Medicaid Services (CMS), reimburses health care organizations and health care professionals for providing health care for Americans who are 65 years and older, disabled, or suffering from end-stage renal disease. As originally enacted, Medicare comprises two separate fee-for-service (FFS) plans (Part A and Part B), each of which pays predetermined amounts for specified health-related goods and services that are needed by its beneficiaries (Table 15-1). More than 80% of older Americans are covered by both plans.

Medicare Part A contracts with regional insurance companies ("intermediaries") to pay hospitals, nursing homes, home-care agencies, and hospice programs for the acute and subacute Medicare-covered services they provide. Older Americans (and their spouses) who have had Medicare taxes deducted from their paychecks for at least 10 years are entitled to coverage through Part A without paying premiums. Others may be able to purchase Part A coverage (for up to \$423 per month, depending on how long Medicare taxes were deducted from their paychecks).

TABLE 15-1

## Health Insurance Coverage for Older Americans

	FFS MEDICARE		SUPPLEMENTAL COVERAGE		MEDICARE HMO PLAN†

FFS, fee-for-service; HMO, health maintenance organization; OT, occupational therapy; PT, physical therapy; SNF, skilled nursing facility; ST, speech therapy.

\*Under the Balanced Budget Act of 1997, state Medicaid programs were given the option whether or not to pay deductibles and co-insurance costs.

†Some Medicare Advantage plans require members to pay deductibles and co-payments.

‡For days 1–60 each benefit period, after the beneficiary or secondary insurer pays the deductible amount (\$992).

¶For the first 20 days of SNF care following a hospital stay of at least 3 days.

§Patient makes co-payments of \$5.00 per outpatient prescription and 5% of cost of respite care.

\*\*When patient is receiving Medicare-covered home care.

††100% of allowed cost of fecal occult blood test, Pap smear interpretation, prostate-specific antigen test, blood tests for diabetes and cardiovascular disease, and influenza and pneumococcal vaccinations; 80% of allowed cost of mammograms and clinical examination of breast and pelvis (no deductible applies); after the annual Part B deductible has been paid, 80% of allowed cost of a general physical examination at age 65, glaucoma screening, sigmoidoscopy or colonoscopy or barium enema, digital examination of rectum (men), measurement of bone mass, hepatitis B vaccination, and diabetic education and equipment.

‡‡Some Medicare Advantage plans cover additional preventive services.

§§Benefits and costs vary widely among medigap insurance plans and state Medicaid plans.

¶¶Per benefit period (first 60 days following hospital admission).

\*\*\*Annual.

Medicare Part B contracts with other regional insurance companies (“carriers”) to pay physicians, nurse practitioners, social workers, psychologists, rehabilitation therapists, home-care agencies, ambulances, outpatient facilities, laboratory and imaging facilities, and suppliers of durable medical equipment for the Medicare-covered goods and services they provide. At age 65 years, people become eligible for Part B coverage if they are entitled to Part A coverage or if they are citizens or permanent residents of the United States. To obtain this coverage, eligible persons must enroll in Part B and pay monthly premiums (\$96 to \$238 in 2008), usually by agreeing to have them deducted from their monthly Social Security checks.

Physicians must choose whether to participate in the FFS Medicare program. For each Medicare-covered service provided, a participating physician submits a claim to the Part B carrier, accepts Medicare’s fee for the service (80% of a preestablished “allowed” amount), and collects a 20% coinsurance payment from the patient or her secondary insurer. For services not covered by Medicare, the physician may bill the patient, if the patient agrees in advance in writing.

Physicians who choose to be “nonparticipants” in Medicare are permitted to bill patients directly for up to 15% more than 95% of Medicare’s allowed amounts. Such patients pay their physicians

and then submit requests for partial reimbursement (i.e., for 80% of 95% of the allowed amounts) to the carrier. A few physicians choose to opt out of Medicare altogether; instead, they enter into “private contracts” with their older patients. Under these contracts, Medicare (and private “medigap” insurance plans) pay nothing, and patients pay physicians the full amount of the fees specified by the contracts.

Neither Part A nor Part B of the Medicare program covers periodic physical examinations, dental care, hearing aids, eyeglasses, orthopedic shoes, cosmetic surgery, care in foreign countries, or custodial long-term care at home or in nursing homes. Part B covers some preventive services (see Table 15-1). In 2008, beneficiaries paid out-of-pocket:

- Monthly payments for Part B (\$96 to \$238)
- Annual deductible for Part B (\$135)
- The deductible for Part A (\$1024 per benefit period, i.e., the first 60 days following a hospital admission)
- Coinsurance payments (usually 20%) for goods and services for which Medicare or other insurance pays a portion

- The full cost of those goods and services that are not covered by Medicare or other insurance.

CMS receives its mandates directly from Congress, with input from scientists and policymakers in the Congressional Budget Office. As such, CMS is subject to current Congressional law and, therefore, has limited authority to modify Medicare benefits or reimbursements beyond these provisions.

Medicaid is a joint federal-state health insurance program for some Americans—young and old—with low incomes and limited assets. With supervision and matching funds from CMS, each state operates its own unique Medicaid program that provides supplemental health insurance to low-income Medicare beneficiaries and primary health insurance to younger people of limited means. Most states' Medicaid programs pay the Part B premiums for Medicare beneficiaries who are also eligible for Medicaid (“dual eligibles”); some also pay their Medicare deductibles and coinsurance costs. The criteria for Medicaid eligibility and the additional benefits covered by Medicaid plans, such as eyeglasses, hearing aids, and dental services, vary considerably from state to state. Most important, Medicaid covers room and board in nursing homes for Medicaid-eligible, disabled people, many of whom have become eligible by liquidating their assets (i.e., by “spending down”) to pay their medical and long-term care expenses. In many states, a limited number of disabled Medicaid recipients qualify (under “waiver” programs) for some long-term care services at home. Recently, several states have begun contracting with managed-care organizations to integrate Medicaid and Medicare benefits for “dual eligibles.”

The Veteran's Health Administration (VHA) is a large, complex, integrated system that insures and provides comprehensive health care for “honorably discharged” military veterans. The VHA Medical Benefits Package covers preventive services, outpatient diagnostic and treatment services, inpatient medical and surgical care, medications (prescription and over-the-counter), and medical supplies. The VHA stratifies veterans into eight priority groups based on income, area of residence, and history of illness or injury during military service. The highest-priority patients, who are not required to make copayments, have service-connected health problems that are rated at least 50% disabling or that have caused them to be unemployable. Veterans receiving VHA benefits may simultaneously enroll in Medicare or Medicaid, giving them access to non-VA physicians and

drugs that are not on the VA formulary. Unlike CMS, the VHA is authorized to bargain with pharmaceutical companies to limit the costs of prescription drugs through mass purchasing contracts.

The VHA underwent a major overhaul in the 1990s, driven by the aging of the veteran population, the growing burden of chronic health care needs, and Congressional concerns over poor quality and value of VHA services. The leadership of the VHA began to emphasize primary care, centralized goal-setting and resource management, standardized data reporting, information technology, and accountability for the quality of care. The VHA electronic health record system replaced paper charts throughout the network, making highly detailed patient records available at the point of clinical encounter. As a result of these changes, and of improvements in various quality indicators, the VHA is now considered by some to be a model of integrated health care.

### Private Health Insurance

For older Americans who choose private health insurance, coverage is provided by MCOs, private indemnity insurers (e.g., “medigap” and long-term care insurance plans), and Medicare Part D providers. MCOs include Medicare health maintenance organizations (HMOs), which offer “Medicare Advantage” plans, as well as preferred provider organizations (PPOs) and point of service (POS) plans (Table 15-2).

### Medicare Advantage

Medicare Advantage plans hold contracts with CMS specifying that, for each Medicare beneficiary they enroll, they will provide at least the standard Medicare benefits in return for risk-adjusted monthly “capitation” payments. In order to induce Medicare beneficiaries to switch from their traditional FFS Medicare coverage to a Medicare Advantage plan, some MCOs also cover additional benefits and charge low or no premiums, deductibles, and copayments. Medicare Advantage plans achieve cost savings by managing their enrollees' use of services within their networks of providers, with whom they negotiate price discounts in return for patient volume. As long as they provide at least the standard Medicare benefits to their enrollees, Medicare Advantage plans have considerable flexibility to test new models of care delivery without CMS's approval. Thus, some

**TABLE 15-2**

#### Advantages and Disadvantages of Four Types of Health Insurance

TYPE OF INSURANCE	PRIMARY ADVANTAGES	PRIMARY DISADVANTAGES
FFS Medicare (Parts A, B and D)	Traditional Medicare benefits, choice of any provider that participates in the Medicare program, partial coverage for prescription medications	Cost of coinsurance, deductibles, noncovered goods and services (e.g., eyeglasses, hearing aids)
Medicaid	Coverage of coinsurance, deductibles, and some benefits* not covered by Medicare	Choice of providers restricted to a single network in some states
Medigap insurance	Coverage of coinsurance, deductibles, and some benefits† not covered by Medicare	Out-of-pocket monthly premiums range from \$40 to \$400, depending on the coverage provided by the policy purchased
Medicare Advantage plan	Traditional Medicare benefits plus coverage of additional goods and services‡	Choice of providers restricted to a single network; potential for changes in premiums, copayments, deductibles, benefits, and providers at the discretion of the plan

FFS, fee-for-service; HMO, health maintenance organization.

\*Benefits vary from state to state.

†Benefits vary from plan to plan.

Medicare Advantage plans may provide fertile ground for testing innovations in the health care system.

Each January, Medicare Advantage plans have the option of changing their premiums, benefits, and provider networks—or of discontinuing their plans in some or all of their service areas. Each November, beneficiaries covered by Medicare Part A and Part B have the option of joining any Medicare Advantage plan operating in their area; they cannot be denied enrollment because of health problems, except end-stage renal disease. Enrollees must continue to pay their monthly Medicare Part B premiums, and they must obtain their health care from the plan's provider network. They have the option of leaving the plan at any time and going back to the FFS Medicare program. Extensive information about all the options is available to consumers at each state's medical assistance office, at 1-800-MEDICARE (1-800-633-4227) or 1-877-486-2048 for hearing impaired TTY users, and at the Medicare Personal Plan Finder ([www.medicare.gov/MPPF](http://www.medicare.gov/MPPF)). In 2008, 20% of the Medicare population was enrolled in Medicare Advantage plans.

### Supplemental Health Insurance

Private supplemental health insurance often covers health care costs that primary insurance, such as Medicare or VHA coverage, does not. Private insurance companies offer “medigap” plans of 12 types (A through L), classified according to the benefits they cover. A-level policies cover a person's Part A and Part B coinsurance costs, for example, 20% of Medicare's allowed fees for physicians' services and durable medical equipment. B-level plans cover Part A and Part B coinsurance, plus the Part A deductible (\$1024 per benefit period). Each higher level of “medigap” policy provides additional benefits and costs more. J-level plans cover coinsurance, deductibles, care in foreign countries, and preventive services. Consumers can obtain “medigap” coverage with lower premiums by purchasing plans that require the insured to pay high deductibles (K- and L-level plans) or plans that cover the services of only selected physicians and hospitals (“Medicare SELECT” policies). Within 6 months of their initial enrollment in Medicare Part B, beneficiaries are entitled to purchase any “medigap” policy on the market at advertised prices. After this open enrollment period, “medigap” insurers can charge higher premiums or refuse to insure individual beneficiaries because of their past or present health problems.

### Long-Term Health Insurance

The cost of long-term care in a nursing home averages more than \$40,000 a year, and the cost of home care for disabled persons averages more than \$6000 a year. Although more than a quarter of these long-term care costs are now paid directly out-of-pocket, fewer than 5% of Americans own long-term care insurance policies. Among older persons whose health qualifies them as eligible for long-term care insurance, only a small minority can afford to pay the premiums required for comprehensive long-term care policies, and less expensive policies may not provide adequate coverage for care at home or in a nursing home.

### Medicare Part D

Medicare beneficiaries have the option of enrolling in one of many private Medicare Part D plans to obtain partial coverage for their

prescription medications. Those who enroll pay annual premiums (about \$300), deductibles (\$285), and coinsurance (25% of the next \$2295 of their medication costs). If their total medication costs exceed \$2580, they then enter a coverage gap, or “doughnut hole,” in which they pay 100% of the costs until their total out-of-pocket spending for drugs reaches \$4050, after which their Part D plan pays 95% of any additional costs. Low-income beneficiaries may qualify for subsidized plans with lower premiums and cost-sharing requirements.

### Regulators

Regulators are charged with the task of monitoring and improving the performance of specific elements of the system. For example, state medical and nursing boards regulate physicians and nurses; the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) regulates hospitals and home care agencies; regional Quality Improvement Organizations (QIOs) assist providers in improving the quality of the care they deliver to Medicare beneficiaries; state insurance commissions regulate private health insurers; and state health departments regulate nursing homes. The roles of some of these regulatory groups are described in “Improving the Health Care System.”

### Care Management

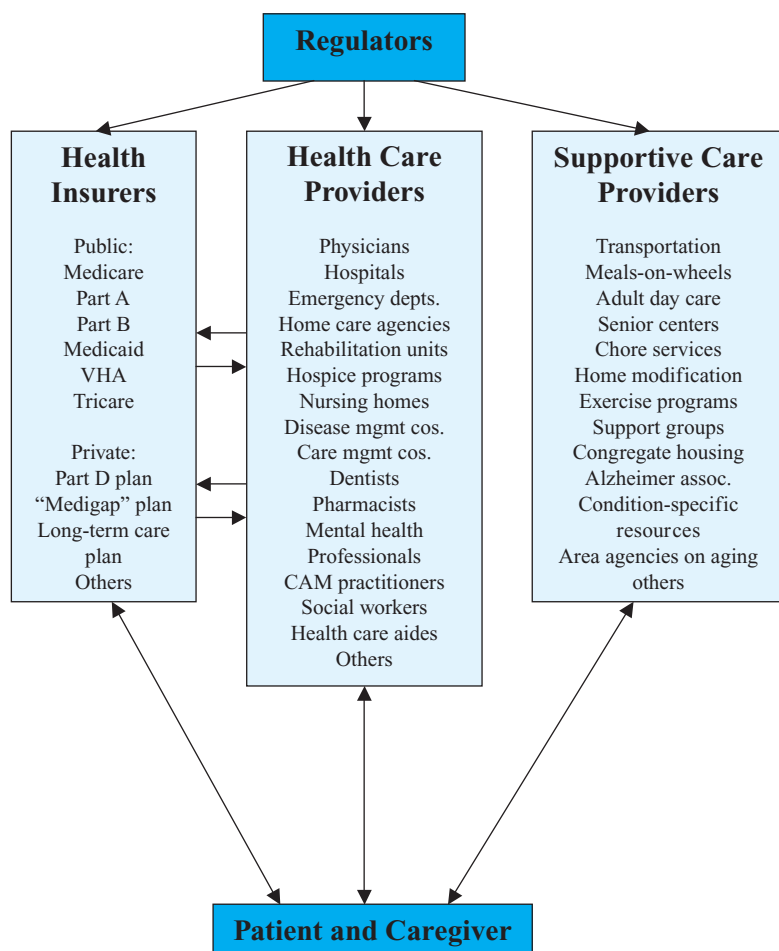

Liaisons include care managers and case managers who coordinate the efforts of providers, patients, caregivers, and insurers to optimize the efficiency and the outcomes of patients' care. Care management services, usually provided by nurses or social workers, may be offered gratis to older persons for discrete episodes of illness by their insurance companies or for a fee indefinitely by private care management companies. Care management programs vary in their intensity of service, target population, focus (single disease or general), and intervention style (protocol-based, vs. individual discretion). Care managers' caseloads vary depending upon the intensity of involvement with each client.

## PERFORMANCE OF THE SYSTEM

The United States leads the world in developing diagnostic and therapeutic technology, and almost all older Americans are covered by the Medicare program. As a result, the U.S. health care system provides most older Americans with unparalleled technical care for acute illnesses and injuries.

In caring for persons with chronic conditions requiring complex care, however, the system is less developed, less effective, and very inefficient. [Figure 15-2](#) illustrates the “provider-centricity” of the present system. Patients and caregivers encounter many challenges when attempting to interact from the periphery with the multiple insurers and providers of the system.

As a result of deficiencies in all five elements of the health care system, care for older Americans with chronic conditions is marked by discontinuity, poor coordination, high costs, low quality, inaccessibility, and dissociation from patients' values and preferences. As the population of older Americans with chronic conditions grows rapidly in the decades ahead, the U.S. health care system, if not

**FIGURE 15-2.** The present U.S. health care system.

transformed, will become increasingly inadequate and financially unsustainable.

At the root of the system’s poor performance in chronic care has been the nation’s unwillingness to make the substantial investments that would be required to transform all five elements of its health care system. Each element, therefore, continues to perform suboptimally.

- **Insurers.** By continuing to pay providers for each covered service they provide, insurance programs reward the provision of more (even duplicative) services, rather than the provision of higher quality or more effective services. By continuing to pay inadequately, if at all, for coordination of providers’ efforts or for empowerment of patients or caregivers, insurers discourage providers from emphasizing these activities.
- **Regulators.** Because no regulatory agency evaluates coordination between providers, providers continue to operate as independent “silos.” Because regulators’ quality indicators focus on the completion of tests and the prescription of drugs, the quality of other processes that are essential to good chronic care, such as coordination, education, and empowerment, are not monitored, rewarded, or improved.
- **Providers.** Lacking potent financial and regulatory incentives to improve chronic care, many provider organizations do not expend significant resources to adopt networked HIT, to coordinate care across providers, or to encourage patients to manage their own chronic conditions. Physician groups, hospitals, and other organizations often function in isolation, providing care without

having complete information about the patient’s condition or medical history, the services they have obtained in other settings, or the medications other clinicians have prescribed. Under the incentives of prospective payment, they often expedite patients’ early transfer to other settings, further disrupting the continuity of care and increasing the probability of medical errors. Furthermore, most physicians are not well trained in the principles of high-quality chronic care, and they are not paid adequately for delivering such care.

- **Patients and caregivers.** Many older persons lack the knowledge, skills, and motivation to manage their chronic conditions proactively and to use providers appropriately. Instead, they have unhealthy life styles and rely on the health care system to take care of them when they get sick.
- **Liaisons.** Care management is a popular field for nurses and social workers, but limited investment has constrained the number of available positions. Little is known about which backgrounds, education, or activities of liaisons produce cost-effective health-related outcomes for their patients.

## ROLE OF PRIMARY CARE CLINICIANS

Primary care clinicians, such as general internists, family physicians, geriatricians, and advanced practice nurses, play pivotal roles in the health care system’s provision of chronic care. As chronically ill

patients' primary point of contact with the system, these clinicians are well positioned to provide some essential chronic care services and to facilitate and coordinate others. In a sophisticated health care system, primary care clinicians, working individually or in teams, would provide chronically ill older patients with the following:

1. Comprehensive assessment of crucial health-related domains, such as medical, psychological, functional, cognitive, social, and nutritional status—and of values and advance directives
2. Preventive services, such as screening tests and evaluations, immunizations, and support for healthy lifestyles
3. Treatment of chronic conditions with prescriptions for medications, diets, behavior modification, and physical activity
4. Referrals to specialist physicians and community agencies
5. Coordination of care with all other providers
6. Education and encouragement for patients to manage their chronic conditions
7. Information and support for informal caregivers
8. Proactive monitoring of health status, medication effects, and adherence to plans
9. Oversight of transitions between sites of care, including reconciling different medication lists

Unfortunately, most primary care clinicians are unable to provide many of these services routinely. The majority of U.S. primary care providers operate in solo or small-group practices with only rudimentary HIT that does not support disease registries, the sharing of clinical information, identification of high-risk patients, evidence-based clinical decision-making, or prompts for preventive interventions like mammograms or influenza vaccinations.

Except for geriatricians, most American physicians have received little training in the principles of chronic disease management. Medicare and most supplemental insurers remunerate many of these services insufficiently (# 1 and 2) or not at all (# 4–9), and their payments for treating diseases (#3) are inadequate and shrinking each

year in relation to inflation (Table 15-3). Many physicians compensate by focusing mostly on treating diseases (# 3), scheduling shorter and more frequent patient visits, and discontinuing the practice of caring for their patients through hospital, rehabilitation, and nursing home settings.

Steadily increasing administrative pressures on the primary care practice environment distracts clinicians from providing high-quality chronic care. Clinicians must master and monitor the ever-changing idiosyncrasies of Medicare's requirements for documenting clinical services and submitting bills, as well as attending to the other complex, unpaid responsibilities of operating an office practice. These pressures have produced several unintended consequences. Some primary care providers are limiting the number of Medicare beneficiaries their practices will accept. The number of young physicians choosing careers in family medicine has decreased by 50% in recent years; and the proportion of internal medicine residents choosing to become generalists has also decreased by half. The nation's workforce of board-certified geriatricians has been declining since 1998.

Care for individuals is increasingly provided by specialists who focus on single diseases. The average older patient is cared for by 3.5 different care providers. There is often little coordination among these providers, resulting in uncoordinated, fragmented care with increased potential for medical errors. The capacity of the U.S. health care system to provide sustainable chronic care, which is already minimal, is threatened further by these trends toward diminishing roles in the system for primary care providers.

## IMPROVING THE HEALTH CARE SYSTEM

### Chronic Care Model

Structural change does not come easily or quickly in the pluralistic U.S. health care system, but major structural changes will be

**TABLE 15-3**

#### Fee-for-Service Reimbursement by Medicare, Year 2008

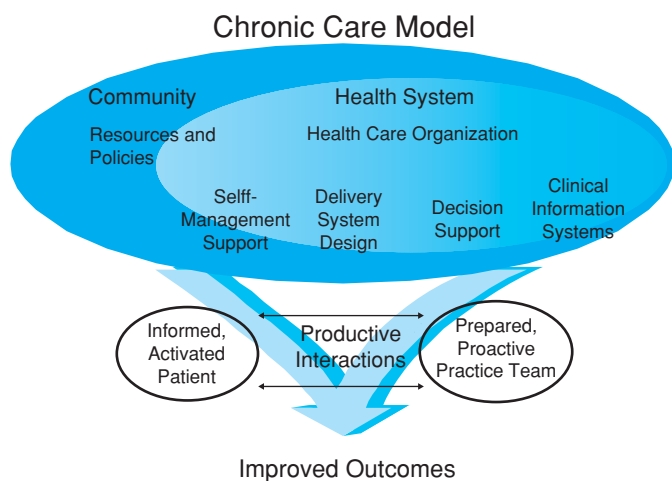

E&M SERVICE	E&M CODE	"ALLOWED" AMOUNT(\$)*	80%	CMS PAYMENT(\$)†
Comprehensive office visit, new patient	99205	180	× 0.80 =	144
Detailed office visit, established patient	99213	62	× 0.80 =	50
Detailed office visit (mental health problem), established patient	99213	62	× 0.50 =	31
Comprehensive office consult	99245	228	× 0.80 =	182
Comprehensive inpatient consultation‡	99255	198	× 0.80 =	158
Complex hospital admission	99223	176	× 0.80 =	141
Complex hospital follow-up visit	99233	93	× 0.80 =	74
Comprehensive nursing facility initial assessment	99305	109	× 0.80 =	87
Detailed nursing facility follow-up visit	99308	60	× 0.80 =	48
Comprehensive initial home visit	99345	197	× 0.80 =	158
Detailed follow-up home visit	99349	114	× 0.80 =	91
Home-health certification	G0181	108	× 0.80 =	86

†For eligible services provided by nurse practitioners, payment is 85% of the amount shown.

‡Hospital or nursing facility consultation.

**FIGURE 15-3.** The chronic care model.

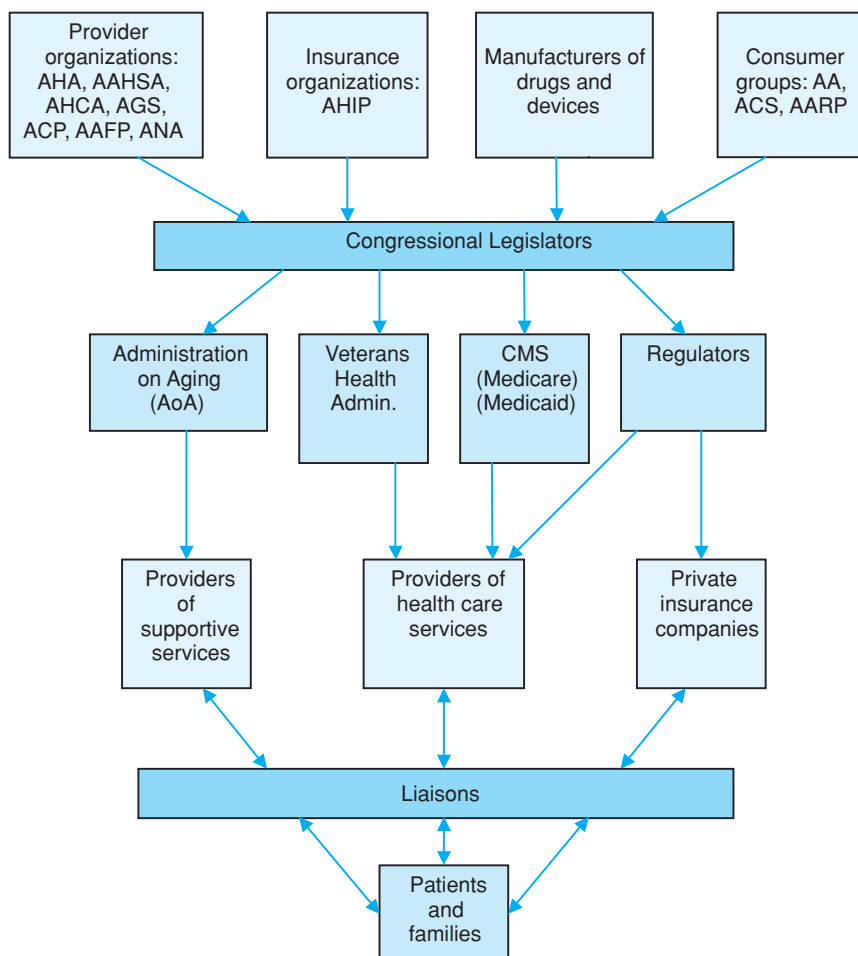

necessary to improve the quality of health care for chronically ill older Americans. The “Chronic Care Model” provides a guide to the changes in health care organizations, providers, patients, and caregivers that would improve chronic care in the U.S. health care system (Figure 15-3). The Chronic Care Model postulates that improved functional and clinical outcomes could be achieved through produc-

tive interactions between prepared, proactive practice teams and informed, activated patients and families. These enhanced interactions could result from changes in six areas of the health care system: (1) tighter links between health professionals and community resources; (2) enlightened, committed leadership of health care delivery organizations; (3) better patient self-management of chronic conditions; (4) evidence-based clinical decision-making by providers; (5) redesign of the delivery system; and (6) improved clinical information systems.

The changes called for by the Chronic Care Model could be invoked both from “top-down” decisions and actions by the U.S. Congress and other national organizations and from “bottom-up reform” by individual clinicians, academicians, patients, and family caregivers.

### Top-Down Organizational Change

As shown in Figure 15-4, the top-down approach involves a panoply of organizations lobbying legislators to use the power of the U.S. Congress to influence the priorities and programs of the elements of the health care system over which it has direct control: CMS, the Veterans Health Administration, the Administration on Aging (AoA), and regulatory agencies. The actions of these elements, in turn, influence the actions of other elements of the system: providers, insurers, liaisons, patients, and caregivers.

**FIGURE 15-4.** The top-down policy approach to improving the system. AHA, American Hospital Association; AAHSA, American Association of Homes and Services for the Aging; AHCA, American Health Care Association; AGS, American Geriatrics Society; ACP, American College of Physicians; AAFP, American Academy of Family Physicians; AHIP, America’s Health Insurance Plans; AA, Alzheimer’s Association; ACS, American Cancer Society.

Ultimately, the most profound improvements in the performance of the health care system will occur when national and state legislators commit to fundamental long-term reforms in large health care programs, such as Medicare, Medicaid, the Veterans Health Administration, and the Administration on Aging. Older patients and their family caregivers could accelerate such reform “from the top–down” by supporting consumer organizations and by voting preferentially for “pro-chronic care” political candidates and “from the bottom–up” by “shopping” for high-quality care, by asserting their care preferences to their providers, and by becoming informed, active “self-managers” of their own health conditions.

### Bottom–Up Change

The bottom–up approach to improving the system also involves actions by clinicians, educators, researchers, provider organizations, and private insurers. Clinicians who are committed to high-quality chronic care could help propel improvements in its quality and cost-effectiveness by:

- Participating actively in medical education about the principles of chronic care, as both learners and teachers
- Advocating for access to HIT that would facilitate evidence-based medical decision-making, electronic sharing of clinical information among providers, identification of high-risk patients, maintenance of disease registries, and prompts for preventive and follow-up care
- Embracing novel chronic care practice designs, e.g., group visits and collaboration with patient liaisons and interdisciplinary teams
- Contributing to the relevant clinical, educational, and governmental programs of professional organizations such as local and state medical societies, the American Geriatrics Society, the American College of Physicians, the American Academy of Family Physicians, and other professional societies
- Providing expert testimony at governmental hearings about the obstacles to and opportunities for improving the quality and efficiency of health care for older Americans

### Role of Academic Health Centers

Academic health professionals have additional opportunities to improve the health care system by conducting research and improving education in chronic care. Conducting and reporting the results of rigorous research on innovative approaches to chronic care is a crucial process for improving the health care system. Innovations that succeed in improving outcomes in research settings must then be translated into widespread clinical practice. For such diffusion to occur rapidly, innovations must be acceptable to insurers, providers, patients, families, and regulators—and they must be promoted to each of these elements for many years. Innovations are most likely to permeate the health care system if they rely on accessible technology and labor pools and provide immediate benefits to most of the elements of the system (i.e., cost savings for insurers, increased revenue or decreased net costs for providers, and improved quality of life for patients and families) without running afoul of existing regulations. Innovations which improve only clinical outcomes or

have unknown effects on costs are unlikely to be adopted widely by all the elements of the system.

Most U.S. physicians and nurses are under-trained to provide state-of-the-art comprehensive care for older patients with chronic conditions. Academicians have opportunities to improve chronic care education by leading curricular reform in their home institutions and by participating in national campaigns to remediate the curricula of

- Medical schools (e.g., through the Association of American Medical Colleges)
- Nursing schools (e.g., through the American Association of Colleges of Nursing)
- Residencies (e.g., through specialty certification boards, the Accreditation Council for Graduate Medical Education, and CMS, which funds most residency education)
- Programs of continuing education (e.g., through specialty recertification requirements and the Accreditation Council for Continuing Medical Education)

Some academicians and clinicians with advanced knowledge and skills in management have additional opportunities to assume leadership roles to help facilitate improvement in the quality of the education and chronic care provided by their organizations. Under the influence of top–down forces (e.g., changes in funding and regulation) and bottom–up initiatives (e.g., new research findings and a sharper focus on high-quality chronic care by clinicians, educators, patients and families), executives of provider and insurance organizations would be motivated to transform chronic care by implementing the Chronic Care Model. As chronic care becomes increasingly important to their business plans, these leaders will perceive greater incentives to invest in sophisticated HIT, innovative delivery models, health care professionals trained in chronic care, and ongoing programs for improving the quality and efficiency of chronic care.

## RECENT QUALITY IMPROVEMENT INITIATIVES

Numerous initiatives intended to improve the quality of health care for older persons with chronic conditions have been launched during the past decade. Some have emanated (top–down) from Congressional policy mandates to CMS, while others have evolved (bottom–up) from clinical innovations by health care providers.

### Policy-Driven Initiatives

To improve the quality of health care for Medicare beneficiaries during the past decade, CMS has implemented several mandatory systems for collecting, reporting, and acting on information about the quality of care provided by Medicare Advantage plans, nursing homes, home care agencies, hospitals, and physicians. Medicare Advantage plans must collect and report performance data, e.g., the Health Plan Employer Data and Information Set (HEDIS) and the Health Outcomes Survey (HOS). Plans must also operate Quality Improvement Systems for Managed Care (QISMC) to enhance beneficiaries’ health status and functional independence. CMS also requires the ongoing collection and reporting of standardized quality

data by nursing homes (i.e., the Minimum Data Set [MDS]), by home health agencies (i.e., the Older Americans Standardized Information System [OASIS]), and by hospitals (e.g., care for beneficiaries with heart attacks, heart failure, and pneumonia). These data are available at [www.Medicare.gov](http://www.Medicare.gov).

The Medicare Modernization Act of 2003 (MMA 03) required CMS to implement

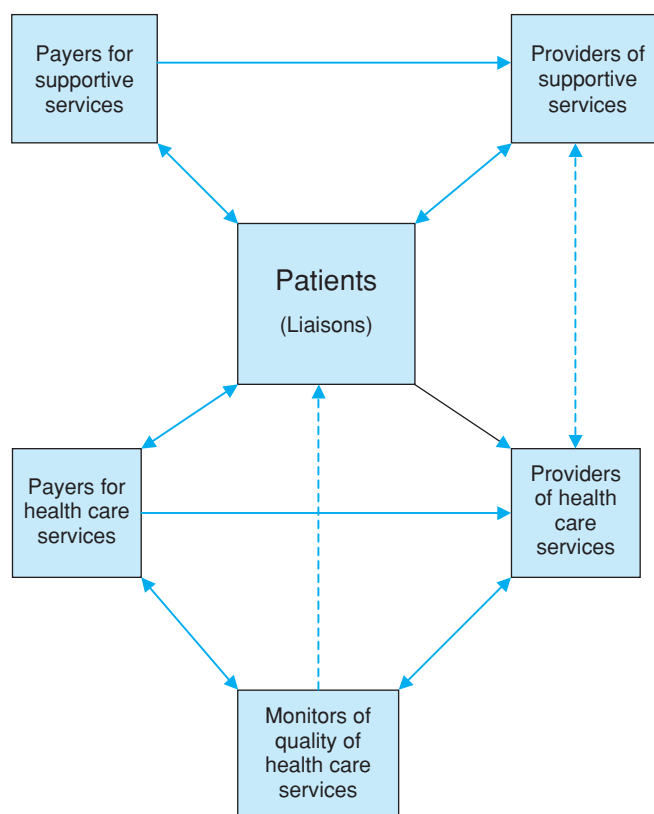

- the optional “Medicare Part D” program, which covers part of the cost of participating beneficiaries’ prescription medications,
- a pilot test of eight large regional disease management programs (now called the “Medicare Health Support” programs) involving hundreds of thousands of beneficiaries with diabetes, heart disease, or emphysema, and
- several Medicare demonstration projects.

In response to this and previous legislation, CMS is now conducting dozens of demonstration projects designed to improve the quality and outcomes of care for beneficiaries with chronic conditions. In most of these demonstrations, CMS is paying supplemental capitated fees to provider or managed care contractors who are providing case management or disease management services to high-cost beneficiaries with chronic conditions, such as heart failure, diabetes mellitus, or other “special needs.”

Many of the recently designed demonstrations are based on the principle of “pay for performance” (P4P) according to which CMS pays the capitation fees only to the extent that the contractor attains preestablished performance standards, e.g., performing specified diagnostic tests in certain percentages of the population, prescribing medications according to evidence-based practice guidelines, reducing Medicare’s overall FFS payments, and receiving high satisfaction ratings by beneficiaries. Despite the intuitive appeal of linking payment to quality, little is known about the most effective ways to make this linkage. For example, which quality indicators should be included, what is the right amount of payment, should payment emphasize improved quality or high quality, and how much quality improvement and cost savings can be expected? The results of evaluations of many of the ongoing P4P demonstration and pilot programs are expected by the end of the decade.

In January of 2006, CMS launched an initiative designed to improve the quality of care that physicians provide to FFS Medicare beneficiaries: the Physician Voluntary Reporting Program (PVRP). Initially, participating physicians reported to CMS their adherence to a set of quality indicators in caring for their Medicare patients, e.g., ordering specific screening tests and prescribing proper medications. The next phase of implementation (called the Physician Quality Reporting Initiative [PQRI]) began in July of 2007. In this voluntary “pay for reporting” phase, participating physicians received a bonus of up to 1.5% of their FFS Medicare payments for reporting their adherence to dozens of predefined quality indicators for specified health conditions. Evaluations of the PVRP and the PQRI as well as plans for a subsequent P4P phase were incomplete when this chapter went to press.

In December 2006, Congress passed the Tax Relief and Health Care Act, which required CMS to conduct a national demonstration of a concept called the “Patient-Centered Medical Home” (Figure 15-5). In this model of care, Medicare beneficiaries select physician practices to function as medical homes. Medicare then pays the practice a supplemental capitation fee in return for the

**FIGURE 15-5.** A patient-centered health care system.

practice team’s provision of care coordination, patient education and empowerment, and communication with family caregivers. Additional details about this demonstration were not available when this chapter went to press.

### Provider-Driven Initiatives

Several recent innovations with potential to improve the system’s performance for chronically ill older patients have originated with health care providers. Some focus primarily on patients, caregivers, and/or liaisons, while several others are designed to improve providers’ performance.

A “Chronic Disease Self-Management” (CDSM) program provides structured training and peer support that empowers older persons to assume an active role in managing their chronic conditions. In this program, groups of 10 to 15 older persons with chronic conditions meet weekly for six sessions with trained laypersons to learn self-management methods and to discuss the challenges they face. Participants learn to create and implement “action plans” for dealing with pain, functional deficits, physician visits, and health behaviors such as diet and physical activity. Randomized trials by Lorig et al. have demonstrated that CDSM participants have improved self-management skills, enhanced quality of life, and reductions in the use of health care services.

Other promising programs are centered on health care liaisons who facilitate older adults’ transitions across health care settings. One model relies on the expertise of advance practice nurses to identify hospitalized older adults who are at risk for early readmission and to coordinate their care as they return home after discharge. These

nurses collaborate with the patient, the caregiver(s), the primary care provider, and the patient's other providers to ensure that the gains made in the hospital are sustained in the postacute setting. As discussed in Chapter 16, this model of transitional care is effective in decreasing readmissions and reducing insurance expenditures.

Several initiatives have created interdisciplinary teams to strengthen the role of primary care in the health care system. In one initiative, a dyad consisting of a nurse practitioner and a primary care provider provides and coordinates care for residents of long-term care facilities. By evaluating and treating residents in their living environments, the nurse practitioner and primary care provider gain accurate insight into residents' functional status, which informs care plans that are tailored to their needs and available resources. The dyad works closely with the nursing home staff and administration to increase the probability that emerging health and behavioral problems are detected early and can be treated on site. Studies have demonstrated that this model leads to high resident satisfaction and significant cost savings, primarily through the early detection and management of acute problems, thus averting the need for transfers to emergency departments and hospitals.

Another innovation is the provision of primary care to groups of patients who have several chronic conditions. The primary goal of the group meeting is to facilitate self-management of chronic illness through targeted education, strategies to promote self-care, peer and professional support, and attention to the psychosocial challenges of living with chronic conditions. Group visits are designed to complement rather than replace the traditional one-on-one office visit. The visits are held monthly and typically last 90 minutes. Participants include the primary care provider and nursing staff, a pharmacist, dietitians, and social workers participate on an ad hoc basis, leading discussions on topics relevant to their professional fields. The meetings begin with a brief socialization period to facilitate cohesion among the participants. A health care practitioner then gives a presentation on a health topic, such as medication management, nutrition, or advance directives. Following the presentation, the health care team provides primary health services to the patients, including immunizations, blood pressure assessment, and medication refills. The group then discusses the session's health topic and shares personal strategies for overcoming barriers to managing their condition and living with particular symptoms. The remaining time is devoted to brief one-on-one visits, if necessary, with the primary care provider or nurse. Group visits have been shown to decrease the use of hospital and emergency services and to improve patients' self-management, quality of life, and satisfaction with health care. Their effects on health status, however, have been less impressive. A recent two-year, randomized, controlled trial of group outpatient visits for chronically ill older adults by Scott et al. found no significant changes in functional or health outcomes.

Depression is common and costly among older persons. Although medications and counseling can control most depressive symptoms, few depressed older patients receive effective treatment. A recent innovation in primary care has shown promise for improving the care and the quality of life for such patients. In this approach, a depression care manager—a nurse or psychologist trained to deliver a structured, multisession model of psychotherapy—collaborates with the patient's primary care provider in providing education, pharmacotherapy, counseling, and care coordination for a year. A multi-

center randomized controlled trial by Unutzer et al. showed that the likelihood of recovery from depression was 3.5 times greater for older patients who received such care, compared to those who received "usual" care. Efforts to disseminate this approach throughout the U.S. health care system are ongoing.

A similar collaborative modification of primary care has been designed and tested for older patients with Alzheimer's disease and their caregivers. In this approach, an advance practice nurse leads an interdisciplinary team that uses standard protocols in collaborating with the patient's caregiver and primary care provider to manage the psychological and behavioral symptoms of dementia. In a randomized controlled trial by Callahan et al., patients who received care under this model had significantly fewer behavioral and psychological symptoms of dementia after 18 months, and their caregivers reported significant improvements in distress and depression.

Low-income persons often have difficulty obtaining needed health-related services as they grow older. A recent innovation in health care is designed to meet these needs in collaboration with the patient's primary care provider. An interdisciplinary geriatrics team uses care protocols and an electronic medical record to help the primary care provider assess, manage care, and coordinate a wide range of community-based services. In a randomized controlled trial by Counsell et al., this approach improved low-income patients' mental health, vitality, and social functioning, while decreasing the use of emergency and hospital services by those at highest risk for hospitalization.

A comprehensive interdisciplinary model of primary care designed to improve the quality of life and efficiency of resource use among chronically ill older patients is known as "Guided Care." In this model, primary health care is infused with the operative principles of several proven innovations. A registered nurse who has completed a supplemental educational curriculum works in a practice with several primary care providers to provide comprehensive chronic care to 50 to 60 of their multimorbid older patients. Using an electronic health record, the Guided Care nurse collaborates with the patient's primary care provider in conducting eight clinical processes: assessing the patient and primary caregiver at home, creating an evidence-based care plan, promoting patient self-management, monitoring the patient's conditions monthly, coaching the patient to practice healthy behaviors, coordinating the patient's transitions between sites and providers of care, educating and supporting caregivers, and facilitating access to community resources. The effects of Guided Care are now being measured in a 5-year, multisite, cluster-randomized, controlled trial in the mid-Atlantic region of the United States. Early results include improved quality of care and reduced use and cost of health services.

## CONCLUSION

The aging of the baby-boom generation, coupled with technology-driven increases in health care spending and a decline in the number of workers per Medicare beneficiary, will soon create serious financial challenges for the Medicare program. Similarly, increases in the number of older Americans with serious disabilities will soon surpass most states' ability to pay for their long-term care. To improve the performance of the health care system rapidly, the nation needs

both prompt, profound reform of its health care policies and bold leadership by innovative health professionals.

# Transitions

*William L. Lyons* ■ *Eric A. Coleman*

## INTRODUCTION

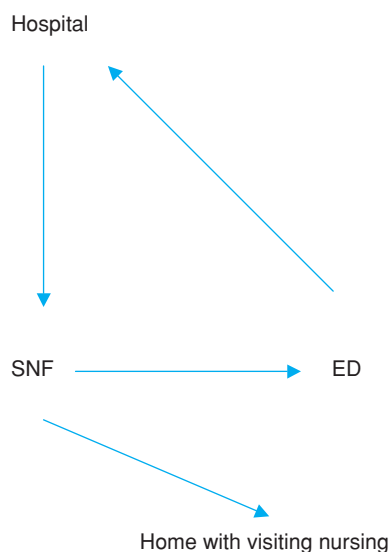

In developed countries the care of complex older patients commonly entails their transfer from one health care setting to another and from one team of providers to another, as their medical and functional needs evolve. In theory, this allows an economical application of specialized resources to be applied at each stage. As an example (Figure 16-1), an elderly woman may be admitted to an acute hospital for diagnosis and initial management of community-acquired pneumonia. After stabilization and initiation of treatment, she is transferred to a skilled nursing facility (SNF) for rehabilitation, continued antibiotic treatment, and close monitoring by nursing. If she decompensates in some manner in the nursing facility (for example, by becoming acutely delirious), she may be transferred to an emergency department (ED) for urgent physician evaluation; rehospitalization may follow. After further diagnostic work and treatment, she returns to the nursing facility to complete her rehabilitative program before finally returning to her home in the community, where a visiting nursing agency assists family in her care. In this sequence her changing care needs prompted physical transfers and encounters with a succession of professionals—hospitalists and acute care nursing in the hospital; then a new provider, nursing, and rehabilitation staff at the SNF; then new providers and nursing in the ED; probably new hospitalists and nurses on her rehospitalization; and finally a new set of nurses, rehabilitation team, and outpatient provider when she returns home. To keep this patient from falling through the cracks, her various providers (and their organizations) must exercise considerable diligence and attention to detail. Active involvement from the patient and her family is necessary as well.

This chapter discusses transitional care, the actions taken to ensure coordination and continuity of health care as patients are transferred among various care settings. Good transitional care entails not just the physical transfer of a patient, but the orderly transfer of responsibility of care of the patient as well. The chapter is meant to

be of particular use for those clinicians (physicians, physician assistants, and nurse practitioners) charged with direct responsibility for managing care transitions.

For a number of reasons, the challenges of transitional care appear to be growing in the United States. Compared to the situation faced by physicians a century ago, our patients are much older, with longer problem (and medication) lists, and greater functional disability. Families may live in other cities and offer little ability or willingness to provide care at home. Health care venues have proliferated and become specialized. Typical care settings found in many large American cities are listed in Table 16-1. Providers themselves have also become more specialized, and in some instances (as with hospitalists, intensivists, SNFists, or emergency medicine physicians), their specialty is defined by the setting in which they practice. Changes in medical education are introducing new challenges as well, with resident work hour limits forcing more handoffs than existed before. Finally, coordination and continuity of care is made more difficult by the fact that the United States lacks a health care “system” per se.

Transitional care is at the confluence of two ascendant movements in modern health care—improved patient safety and patient-centered care. Poorly executed transitions place patients at risk of injury and other adverse events. Well-executed transitions intrinsically incorporate patients’ individual goals, needs, and values. The quality of transitions also influences resource use, such as ED utilization and need for rehospitalization. For all these reasons (Table 16-2), a number of influential advisory, professional, and funding organizations have shown interest in the topic. The Institute of Medicine has called for greater integration of care delivery across health care settings. The Society of Hospital Medicine, the American Geriatrics Society, and the American Board of Internal Medicine all have urged greater professional commitment to transitional care. The Joint Commission on the Accreditation of Healthcare Organizations (JCAHCO) has adopted a patient tracer methodology, which allows surveyors to determine how a patient fares during a sequence of transitions. JCAHCO also has begun confirming that surveyed organizations

**FIGURE 16-1.** Common traffic pattern for older patients undergoing health care transitions. SNF, skilled nursing facility; ED, emergency department.

employ medication reconciliation (discussed below) and standardized approaches for patient handoffs.

Hospitals are required, as part of Medicare Conditions of Participation, to employ a discharge planning process for all patients, with policies and procedures in writing. Further, hospitals must identify

**TABLE 16-2**

**Effects of Poorly Executed Transitions**

- Adverse events in peridischarge period (e.g. medication discrepancies or errors)
- Recidivism to the emergency department or hospital
- Reduced patient, family, provider satisfaction
- Increased cost of care

all patients who are likely to suffer adverse health consequences after discharge in the absence of adequate discharge planning. Hospitals also are required to provide for the initial implementation of the discharge plan. Despite Medicare's evident interest in promoting high-quality transitional care, the program currently lacks vigorous monitoring and reimbursement incentives.

Beyond an appropriate alignment of “sticks and carrots,” improvements in transitional care quality will require research advances, inculcation, and cultural change within health care organizations and professions, and discipline-specific training. In that spirit, this chapter is intended to provide didactic material for training health care providers who are responsible for managing the care transitions of elders with complex care needs. Much of the data presented and recommendations made apply to transfers from acute hospitals, but the key principles apply to transitions involving other health care settings as well.

**TRANSITIONS TRAFFIC AND TRANSITIONS QUALITY**

With increasing pressures to shorten hospital lengths of stay, it is becoming less common for an older patient to be cared for in the hospital until she feels well, at which time she is discharged home in the care of her family. National statistics from 2004 for Medicare patients discharged from acute hospitals show that about a quarter of them were transferred to another institution (such as a nursing home or rehabilitation facility), and an additional 14% were discharged to their home with the involvement of home health professionals. Recent work also confirms many providers' impressions that the period immediately following hospital discharge can be characterized by continued movement from place to place. A recent study of Medicare beneficiaries examined the 30-day period following hospital discharge, and found that 60% of patients made a single transfer, 18% made two transfers, 9% made three transfers, and 4% made four or more. These frequent transfers represent discontinuities in patients' care where vital information may be lost and care plans become fragmented.

The risk for hospital readmission is greatest in the period immediately after discharge. A study of patients with hip fracture discharged from New York City hospitals, for example, found that 32% were readmitted within a 6-month period, and over a third of these readmissions occurred within the first month after discharge. It is increasingly recognized that the “peridischarge” period is a dangerous time for patients. In one prospective cohort study of patients discharged home from the medical service of an academic medical center, 6% of patients had suffered preventable adverse events by about 3 weeks after discharge. An additional 6% experienced adverse events whose severity might have been reduced by improved quality of care. In another single-institution study of patients discharged from an academic medical service, researchers examined

**TABLE 16-1**

**Venues of Care Available in Typical Urban Centers**

DOMAIN	CHARACTERISTICS
Hospital	Medically and technologically intense. Minimal emphasis on longitudinal management of acute or chronic illness.
Postacute skilled nursing/subacute	Continuation of care begun in hospital. Less physician contact and diagnostic emphasis. Greater emphasis on skilled nursing and rehabilitation.
Long-term care	Nursing and supportive care for physically frail and cognitively impaired.
Assisted living	Wide spectrum of care, with scant regulation. Nursing and supportive care for physically frail and cognitively impaired, but residents less frail than in long-term care, and professional nursing staff may be minimal.
Acute rehabilitation	Intense inpatient provision (several hours daily by multiple disciplines) of rehabilitation therapy, typically for patients who have suffered acute orthopedic or neurologic injury.
Home care	Generally for “homebound” elders with “skilled needs”. Care provided primarily by RN, PT, OT, ST, SW, aides.
Hospice	Inpatient (limited capacity) or home. Palliation of symptoms and maintenance of dignity for persons whose life expectancy is anticipated to be less than 6 months.

RN, registered nurse; PT, physical therapy; OT, occupational therapy; ST, speech therapy; SW, social work.

inpatient and outpatient records for evidence of three types of errors arising from discontinuity of care: (a) medication continuity errors, (b) test follow-up errors (in which test results were pending at the time of hospital discharge, but were not acknowledged in the outpatient chart), and (c) work-up errors (in which an outpatient test was recommended or scheduled by the inpatient team, but did not take place). About half of the patients' charts were found to contain at least one of these discontinuity errors, and those patients with work-up errors were over six times more likely to be rehospitalized than patients without these errors.

A major cause of the peridischarge hazard may be communication failures between hospital physicians and physicians who see patients soon after discharge. Historically, the same physician attended to the patient in hospital and in clinic, but the increased use of hospitalists and covering physicians creates opportunities for information discontinuities. In one study, only 3% of primary care doctors reported discussions with hospital physicians about discharge plans. In other studies, about half of discharge summaries are received by primary care physicians by 4 weeks of discharge; a quarter of summaries never reach the primary physician. And those summaries that are received commonly lack important information. Diagnostic test results are missing in 38%, consultant recommendations in 52%, discharge medications in 21%, and test results pending at discharge in 65%. There is a pressing need to improve the fidelity of information transfer from hospitals to primary care providers and other physicians and care providers.

Poor communication between hospital providers and patients (or families) probably contributes as well to peridischarge risk. Patients often report that they do not understand potential adverse effects of their discharge medications, when they may resume normal activities, which questions to ask and whom to address them to, and which warning signs to watch for. More globally, many patients express a lack confidence in their ability to make sure the care plan reflects their particular preferences, goals, and needs.

Metrics are needed to implement a quality improvement effort in transitional care. Coleman et al. developed the Care Transitions Measure (CTM), a patient-focused instrument that can be used to track performance changes over time. Two versions of the instrument, one with three items and another with 15, can be found at [www.caretransitions.org](http://www.caretransitions.org). The CTM encompasses four domains of quality in transitional care (Table 16-3). The first domain is the fidelity of information transfer. Is accurate information transferred from sending clinicians to receiving clinicians in a reliable and timely manner? The second domain is patient and family preparation. Do they understand the purpose of the new care setting? If the patient is going home, do they understand the things they are responsible for managing in the care plan? The third domain is support for

**TABLE 16-3****Four Domains of Quality in Transitional Care**

1. Fidelity of information transfer
2. Preparation of patient, family, caregiver
3. Support for patient self-management
4. Patient empowerment to assert goals and preferences

*With permission from Coleman EA, Smith JD, Frank JC, et al. Development and testing of a measure designed to assess the quality of care transitions. Int J Integr Care [online]. 2002;2 Jun 1. Available at: [www.ijic.org](http://www.ijic.org)*

patient self-management. Does the patient know the warning signs and symptoms to watch for after discharge, and the purpose and adverse effects of the medications? Finally, the fourth domain is patient empowerment to assert individual goals and preferences. Does the patient feel the hospital staff took into account her particular goals when determining what her health care needs are, and where they could best be met after discharge? Lower CTM scores have been shown to predict reduced likelihood of ED use and rehospitalization in the postdischarge period. While developed for quality improvement efforts, all clinicians would benefit from considering the CTM items or Table 16-3 when contemplating individual patient transfers. The National Quality Forum has endorsed the CTM for use in public reporting.

**PREDICTORS OF PROBLEMATIC TRANSITIONS**

Experienced clinicians develop a sense for which patients are likely to experience difficulties after a transition to a new setting. In hospital jargon these patients are potential “bounce-backs” or candidates for early readmission. One statistical model that helps to identify such at-risk patients is provided in a study by Coleman et al. (Posthospital care transitions: patterns, complications, and risk identification. *Health Serv Res*, 2004;39(5):1449). A consensus of factors that help to identify patients at risk of hospital readmission is listed in Table 16-4. Several of the items are not surprising—older patients, those with more serious illnesses, those with need for activity-of-daily-living assistance but with marginal support, and those with a history of previous hospitalizations are all more likely to require rehospitalization soon after discharge. In addition to physical ailments, however, depression predicts readmission, as does a worse self-rating of patient health. Patients who have difficulty with treatment adherence (to medication regimens or follow-up appointments) are at risk as well. Finally, patients (or families) who have not received education around the time of discharge are more likely to suffer complicated transitions.

**TABLE 16-4****Risk Factors for Complicated Care Transitions\***

DEMOGRAPHICS	MEDICAL DIAGNOSES	PSYCHOSOCIAL	OTHER
Increased age	Heart disease Stroke history Diabetes mellitus Cancer	Medicare and Medicaid eligible Caregiver needed for ADL assistance Inadequate social support Depression	Prior hospital use Worse self-rating of health Inadequate patient/family preparation Instructions given without regard to health literacy or cognitive ability
	High Charlson comorbidity score		

\*A complicated transition is one that transfers a patient to a higher-acuity care setting.

Knowledge of risk factors for problematic transitions is important for clinical leaders who are contemplating new programs and innovations in transitional care. Such programs may be time- and labor-intensive; administrative leaders or funding agencies will look for evidence of cost-effectiveness. A key strategy in creating a cost-effective program is to employ targeting criteria that help in identifying patients most in need of special help. Patients who lack such criteria (such as those shown in Table 16-4) are less likely to require costly interventions in order to avoid transitions-related mishaps.

## INNOVATIONS IN TRANSITIONAL CARE

A number of interventions to improve care transitions have been studied; the majority involve discharge from the acute hospital. One systematic review of 54 randomized, controlled trials involving interventions designed to improve outcomes of discharge of elders from hospitals found that the location of the intervention appeared to be an important factor. The most successful interventions, in terms of reducing readmission risk, were those that took place in the patients' homes, or in both hospital and at home, but not exclusively in the acute setting. One such landmark trial, reported by Rich and coworkers, focused on the discharge of high-risk elders with congestive heart failure (CHF). This diagnosis is the leading cause of hospital admission for Medicare patients and is associated with frequent readmission. Rich's multifactorial intervention included intensive education about CHF provided by nurses; social work involvement for help with discharge planning and arrangement of care after discharge; review of the drug regimen by a geriatric cardiologist; dietary assessment and education by a dietician; high-intensity follow-up by the hospital's home care services; and additional home visits and telephone consultation as needed by the research team. Those patients in the intervention arm of this prospective, randomized, controlled trial demonstrated a lower risk of readmission, reduced cost of care, and greater quality-of-life scores.

A later study by Naylor and colleagues considered a broader range of diagnoses for hospitalized elders being discharged to the community. The study population in this prospective, randomized trial included elders with one of several medical or surgical diagnoses, and known to be at risk (using predetermined criteria) for poor discharge outcomes. The intervention made use of advanced practice nurses who assumed responsibility for transitional care from the time of admission to the hospital. These advance practice nurses followed their patients into the home following discharge, and substituted for visiting nurses during the first 4 weeks after patients left the hospital. As with the Rich study, the Naylor study found that the intervention reduced risk of readmission, as well as total cost of care.

Coleman and colleagues reported on the results of the Care Transitions Intervention, which introduced two conceptual innovations. First, this intervention was designed to encourage older patients (and their caregivers) to assert their own preferences, and to acquire self-management skills relating to transitions across care settings. Second, the intervention introduced the role of a "transition coach," who, although a nurse practitioner by training, did not function as a health care provider. Rather, she encouraged self-management and direct communication with primary care providers. The transition coach visited patients in the hospital and at home, and also made frequent follow-up telephone calls. Patients worked with the transition coach for about 28 days after their discharge to home.

Major areas of emphasis included medication self-management; use of a patient-centered record (maintained by the patient, and listing medical problems, medications, and other vital information); empowerment of the patient to schedule and complete follow-up visits with physicians; and patient's understanding of events that suggest that a health condition is worsening. Patients who received this program were significantly less likely to be readmitted to the hospital and the benefits were sustained for 5 months after the end of the 1-month intervention. More than simply managing posthospital care in a reactive manner, the Care Transitions Intervention imparted self-management skills that proved beneficial after the end of the program. Anticipated cost savings for 350 chronically ill adults extending from an initial hospitalization over 12 months is almost \$296 000. Patients who received this program were also more likely to achieve self-identified personal goals around symptom management and functional recovery.

A number of hospitalist programs have set up postdischarge follow-up clinics in which patients are seen soon after discharge by the physician who provided care in the acute setting. The benefits of these programs have not yet been demonstrated in large, prospective trials. Nevertheless, a large cohort study using an administrative data base for hospitalized patients in Ontario, Canada, found that patients who followed up after discharge with their inpatient provider had a reduced combined rate of readmission and 30-day mortality.

Several pharmacist-led transitions interventions have been recently reported. One intervention involved simply a follow-up phone call placed by pharmacists to patients 2 days after discharge, during which patients were asked whether they had obtained their medicines and understood how to take them. Patients receiving the phone call returned to the ED less often than those who did not (10% vs. 24% at 30 days). Another randomized study examined the effect of pharmacists counseling patients at hospital discharge, and calling 3 to 5 days later. Patients receiving the intervention showed a lower rate of preventable adverse drug events 1 month after hospital discharge. The process of medication reconciliation (discussed below), conducted by pharmacists, was tested in a preintervention/postintervention study involving patients who resided at a nursing home, were hospitalized, and subsequently discharged back to the nursing facility. After the intervention began a pharmacist reconciled the nursing home and hospital medication lists, and reported discrepancies to patients' physicians. Compared to the preintervention group, the postintervention group showed significantly reduced odds of suffering discrepancy-related adverse drug events (odds ratio 0.11,  $p = 0.05$ ).

Use of electronic methods to transfer patient information between various sites of care (e.g., hospitals, nursing facilities, EDs) is being piloted in a number of locations. Preliminary reports suggest these methods may improve outcomes, such as reducing the number of hospital readmissions. Although these approaches present challenges (nursing homes would need to master electronic interfaces and equipment and to use federally endorsed standards), they appear promising.

## ROLES AND RESPONSIBILITIES

A crucial first step in making systematic improvements in transitional care is for the various parties in this activity—the team of

**TABLE 16-5****Roles and Responsibilities in Transitional Care***Sending Team*

- Ensures that patient is clinically stable for transfer
- Confirms the receiving venue can meet patient's medical, nursing, and rehabilitation needs
- Ensures that patient/caregiver understand purpose of transfer
- Communicates necessary information (e.g. via transfer summary) to receiving team in a timely manner
- Ensures recommendations from consulting physicians and other professionals (e.g., social work, occupational therapy, physical therapy, clinical pharmacy, psychology) are transmitted to receiving team
- Arranges and communicates timely follow-up appointments with appropriate health care professionals
- Is available for questions after transfer (and provides contact information)

*Receiving Team*

- Reviews transfer information and orders prior to or upon patient's arrival
- Identifies and clarifies discrepancies or questions (regarding patient's status, goals, care plan, etc.) directly with sending care team

*Both Sending and Receiving Teams*

- Begin planning for next transition at time of admission to own setting
- Elicit goals and preferences from patient/caregivers, and incorporates these into care plan
- Identify patient's system of social support
- Determine current and baseline level of function
- Use preferred mode of communication (phone, fax, e-mail, etc.) for professionals in other care settings.

*Patient/Family/Caregiver*

- Participates in decisions about transfer destination and purpose
- Knows whom to contact (and how) if questions arise during transfer
- Understands which medications to take, how to take them, why they have been prescribed, and potential side effects. Has a "system" for organizing and taking medications
- Is knowledgeable about their major health conditions, knows which symptoms to watch out for, and whom to call should they arise
- Asks questions of doctor or nurse before transfer from current location
- Understands follow-up arrangements with next provider or with primary provider

From Coleman EA. *Aspen Transitional Care Conference proceedings*.

clinicians sending a patient to a new setting, the receiving team, and the patient (and family)—to clearly understand their respective roles and responsibilities. As shown in [Table 16-5](#), certain responsibilities belong to one party alone, but some are common or shared.

When the sending team plans to transfer a patient from a higher-acuity to a lower-acuity setting, it is incumbent on them to make a determination that the patient is clinically stable for the move. Predictors of instability for patients leaving a hospital include new incontinence, chest pain, dyspnea, or confusion; pronounced vital sign abnormalities, including fever and oxygen desaturation; poor oral intake; and wound infection. The sending team is also obliged to confirm that the new setting can meet the patient's needs for medical, nursing, and rehabilitative care. The sending team has several communication responsibilities. First, they must explain the purpose of the transfer and confirm that the patient (or caregiver) understands. Second, they must communicate essential information (described further below) to the receiving team and in a timely manner. This information includes recommendations made by consulting physicians and other health professionals of various disciplines. The sending team arranges follow-up appointments (e.g., with primary care providers, surgeons, consulting physicians), and notifies the patient, family, and receiving team. The sending team must provide contact information and be available for questions (from receiving team, patient, family) after transfer.

The receiving team has two general responsibilities in the transfer process. First, before or at the time of the patient's arrival, they must review the information and orders transmitted by the sending team. Second, after this review, and after their independent evaluation of

the patient, they should identify any questions or discrepancies, and contact the sending team for assistance. An expected but missing beta-blocker on the medication list, for example, may represent an oversight or a deliberate decision.

A number of responsibilities are common to both the sending and receiving teams of clinicians. Both teams should begin planning for transfer of the patient at the time of admission to their own setting. Both elicit care goals and preferences (e.g., recovery of function, "comfort care") from patients and families, and incorporate these into the care plan at their own setting. Both must identify their patients' social support (family, friends, church group, etc.), and surrogate decision makers. Both must determine their patients' baseline and current functional abilities, including activities of daily living and mobility. And both should attempt to employ the mode of communication (phone, fax, e-mail) preferred by clinicians in other care settings.

The division of these responsibilities among various disciplines (medicine, nursing, pharmacy, for example) on a team at a given setting will depend on local custom and capabilities. An organization choosing to launch a quality improvement program in care transitions might begin by convening a meeting of leaders of various disciplines, clarifying responsibilities, and obtaining commitments to fill the roles listed in [Table 16-5](#).

Patients and families have important responsibilities as well. They need to participate in discussions with clinicians about the destination and purpose of contemplated transfers. They should keep a record of whom to contact if questions come up during or after their transfer. They need a basic understanding of their medication

regimen—which drugs are on the list and why, how to take them, what side effects to watch for—as well as a system (such as a pillbox) for organizing them. Similarly, they must have a good understanding of their major health conditions, including what symptoms constitute “red flags” that should be reported, and to whom. Patients and families should remember or write down questions they should pose to their doctor or nurse before transfer. Finally, they should note and understand the follow-up arrangements that have been made for the next provider, their primary provider, and consultants.

## STRATEGIES FOR EXCELLING AT TRANSITIONAL CARE

Clinical teams or organizations endeavoring to provide outstanding transitional care first need consensus about the information that must be transmitted to the next care setting along with each patient. [Table 16-6](#) offers a list of essential data elements in nine domains. Although it is not necessary or customary for clinicians to transmit each indicated piece of information, sending organizations should assign some member of the clinical team the responsibility for communicating each item.

*Overall care goals* refers to what the patient and family hope to accomplish at the new care setting. Examples of general goals include recovery from an acute illness, followed by return to the previous residence; custodial care for the remainder of the patient’s life; or hospice care.

*Medical* information comprises the bulk of a typical hospital discharge summary, with an enumeration of the patient’s various diagnoses, how they were treated, and how the patient fared.

*Functional* information includes the patient’s self-care abilities (basic and instrumental activities of daily living), mobility, need for assistance, and assistive devices.

*Treatments* include a listing of the scheduled and as-needed medications, history of drug-related ill effects, and recommended non-pharmacologic therapies to be provided at the new setting (rehabilitative, psychological, etc.).

*Social background and support* provides vital background information about the patient’s family and/or caregivers, their willingness to provide assistance to the patient, the presence of additional help from the community (e.g., from church groups), and the patient’s previous (and ultimate) residence.

*Communication and culture* refers to important aspects of how patients comprehend health-related information and make decisions about their care. If a patient’s primary language is other than English, this formation needs to be passed along. Low levels of literacy, if known, also should be communicated so that the receiving team does not provide written materials without the necessary assistance. Health beliefs (for example, a fatalistic view about stroke risk in a patient with atrial fibrillation) and decision-making style (for example, all major decisions are discussed with adult children) should be documented as well.

*Advance directives* must accompany patients to new care venues. These may be as simple as the designation of a surrogate, such as a durable power of attorney for health care, or may be more involved, such as instructions regarding the use of life-supporting technologies or resuscitation attempts.

Patients frequently need specialized *durable medical equipment* at their new site of care. Examples might include wound vacuum devices for use in the nursing home or provision of a hospital bed at home. Although not typically spelled out in detail by physicians, this information (devices, vendors’ names) should be provided by the responsible disciplines at the sending institution.

Physicians also are unlikely to provide the receiving team or institution with information about details of *insurance benefits and coverage*, home health agencies, or provider networks. This responsibility should be assumed by a defined member of the sending team.

A succinct yet informative transfer summary is an important component of good transitional care. We offer as an example [Table 16-7](#), a hospital discharge summary for a representative 85-year-old woman admitted for pneumonia. Several features of this model summary are worth noting. First, the discharge diagnoses list not only the usual medical problems (pneumonia, diabetes, and so forth), but also cognitive diagnoses (dementia from Alzheimer’s disease), behavioral problems (“sundowning”), affective disorders (depression), and functional problems (gait disorder with history of falls). The Hospital Course portion of the summary includes multiple, brief, problem-labeled paragraphs; this format has been shown to be preferred to a chronological recollection of the hospital stay. The discharge instructions include red flags to watch for (worsening dyspnea, fatigue, etc.), as well as where to call if these problems arise.

The discharge medications section of [Table 16-7](#) contains information that will be essential for the receiving care team, and which too often is neglected in hospital discharge summaries. In addition to the dose, route, and frequency for each drug, an indication is provided. Tapering schedules or stop dates (for drugs like systemic

**TABLE 16-6**

### Essential Information to be Passed to New Care Setting

DOMAIN	INFORMATION
Overall care goals	E.g., recovery of previous function with return to community versus maintenance of comfort
Medical	Admitting medical problems and others complicating management Status of these problems and prognosis
Functional	Baseline and current basic and instrumental activities of daily living; mobility
Treatments	Comprehensive medication list Drug allergies, intolerances, adverse effects history Physical therapy, occupational therapy, speech therapy, psychology, etc.
Social background and support	Primary caregiver (name, relationship, contact information) Ability and willingness to provide ongoing care Community-level support Patient’s previous residence
Communication and Culture	Language, literacy, health beliefs
Advance directives	Preferences (e.g., for CPR, ventilator support, artificial nutrition/hydration, dialysis) Power of attorney
Durable medical equipment	Current needs, vendor’s name and contact information
Coverage/benefits/insurance/suppliers	Provider network for SNFs, home health agencies, hospice, respite, durable medical equipment

CPR, cardiopulmonary resuscitation; SNF, skilled nursing facility.

**TABLE 16-7****Sample Hospital Discharge Summary**

Patient name: Jane Q. Doe.

Medical record number: 12345678

Admission date: 1-2-07

Discharge date: 1-9-07

Attending physician: Ralph Green, M.D.

Referring physician: Susan Brown, M.D.

Resident physician: Sally White, M.D.

Discharge diagnoses:

Community-acquired pneumonia.

Dementia secondary to Alzheimer's disease.

Delirium, with episodic "sundowning"

Diabetes mellitus, type II

Depressive disorder

Hypertension

Multifactorial gait disorder with falls, due to Parkinson's disease and knee osteoarthritis

Procedures performed during hospitalization:

Right-sided thoracentesis performed by Dr. Steven Gray in Interventional Radiology

Hospital Course:

Mrs. Doe is an 85 yr-old woman who was admitted to the Medical Service on January 2<sup>nd</sup> for 3 days of worsening dyspnea, cough, confusion, and poor oral intake. Please see the dictated admission note from that date for additional information about her admitting physical examination and laboratory data.

1. Pneumonia. Her admitting chest film showed a right lower lobe infiltrate and right-sided pleural effusion. Blood cultures were sterile, but her admission white cell count was 15 000, and her oxygen saturation was 88% on room air. She was treated with IV ceftriaxone and azithromycin for 6 days before being switched to oral levofloxacin on the day before discharge. A modified barium swallow showed no evidence of aspiration. Thoracentesis showed her right-sided effusion to be exudative. Culture of the pleural fluid is no-growth. Oxygenation on the morning of discharge was 94% on room air.
2. Delirium. Mrs. Doe was oriented to her own name at admission, and showed episodes of verbal aggressiveness early during her stay. By hospital day five she had returned to baseline (oriented to self and place). Haloperidol was used as needed the first three days of her admission.
3. Diabetes. To reduce the risk of lactic acidosis, her outpatient drug, metformin, was held. She required minimal doses of sliding scale regular insulin to maintain glucose under 140. We will leave it to her outpatient physician whether to start an alternate oral diabetic agent.
4. Gait disorder (see below). Physical therapy evaluated Mrs. Doe for gait and balance training, and has recommended that she employ a wheeled walker. Physical therapy instructed her on its use. Prosthetics provided her with a walker at discharge.
5. Parkinson's disease. Her carbidopa/levodopa was continued without change in dose from the outpatient setting.
6. Knee osteoarthritis. We urged her to discontinue use of ibuprofen, and she agreed to try scheduled acetaminophen.
7. Hypertension. Hydrochlorothiazide was continued without change.

Discharge instructions: Mrs. Doe should resume her previous diet (prudent diabetic) and employ her new walker when ambulating. If she experiences worsening dyspnea, fatigue, confusion, or reduced oral intake, her daughter Kate agrees to call the Medical Clinic at 555-1234.

Discharge medications:

Drug	Dosing	Indications	Remarks
Levofloxacin	250 mg PO qd	Pneumonia	Last dose 1/15/07
Citalopram	40 mg PO qd	Depression	Unchanged from outpatient
HCTZ	12.5 mg PO qd	Hypertension	Unchanged from outpatient
Carbidopa/levodopa (25/100)	One tab PO qid	Parkinson's disease	Unchanged from outpatient
Acetaminophen	650 mg PO qid	Knee arthritis	New

Note that metformin and ibuprofen (previously in outpatient regimen) have been *stopped*.

Rehabilitation orders: The hospital team has deemed Mrs. Doe to be homebound. She will be seen in her home by visiting nursing, and we have asked for an in-home physical therapy assessment by the agency as well.

Follow-up appointments: With primary care physician Dr. Brown on 1/16/07 at 2 pm, and with neurologist Dr. Black on 2/1/07 at 10 am.

Pending laboratory studies: Await final cytology reading on pleural fluid specimen.

Family/caregiver/surrogate decision maker: Patient's daughter, Kate, lives with her and is her durable power of attorney for health care. Kate's cell phone is 555-0000.

Goals/Preferred Intensity of Care/Code Status: We reviewed Mrs. Doe's overall prognosis, in light of her moderate Alzheimer's disease, comorbidities, and functional status. Kate took part in the conversation as well. They still desire that Mrs. Doe be "full code" in the event of cardiopulmonary arrest, but they are very clear that she would not wish to receive artificial nutrition and hydration in the event of end-stage dementia.

Functional status at transfer: (see also Nursing documentation) Requires assistance with bathing and dressing; now employing wheeled walker to ambulate.

Dictated by: Sally White, M.D.

CC: Susan Brown, M.D.

**TABLE 16-8****Information for the Preadmission Medication History**

- Which medications taken at which times
- Identities of prescribing providers
- Identities of pharmacies dispensing medications
- Non-oral medications used (eye drops, suppositories, patches, inhalers, creams, etc.)
- Assessment of patient's (or caregiver's) understanding of drug indications
- OTCs and herbals/vitamins/supplements
- Allergies and adverse drug reactions history
- Assessment of adherence (e.g., number of doses missed per week)
- How patient (or caregiver) manages the regimen at home (e.g., use of pill box)

OTCs, over-the-counter medications.

corticosteroids, antibiotics, or anticoagulants) are given as needed. Finally, the transfer medication list is *reconciled* with the regimen at entry to the facility. In the case of a hospital discharge, the discharge medication list would be compared to the patient's earlier outpatient list. Properly performed, medication reconciliation answers three questions: (a) Which of the patient's transfer medications are new, that is, were not taken until after the patient was admitted to the current venue? (b) Which of the patient's previous medications are to be stopped? (c) For those medications that have been continued from the earlier setting, which doses have changed?

A well-reconciled discharge medication regimen requires complete understanding of the preadmission regimen. **Table 16-8** lists components of a thorough preadmission medication history. This includes not only information that is essential for the subsequent reconciliation (drugs, doses, use of over-the-counter remedies and herbals, etc.), but other beneficial items like identities of prescribing providers and pharmacies, assessment of the patient's understanding of the regimen, impression of adherence to the prescribed regimen, method of administration at home (pill boxes, etc.), history of adverse drug reactions, indication, and consideration of continued need.

Some additional important sections follow the discharge medications list in **Table 16-7**. Follow-up appointments, arranged before transfer, spell out which provider is to be seen and when. Pending laboratory studies highlight tests whose results are still outstanding. This situation occurs more frequently with short lengths of stay. The specification of caregiver/surrogate decision maker and of goals/preferred intensity of care in **Table 16-7** illustrates how this information (called for in **Table 16-6**) might be spelled out in practice to good effect. Finally, information on functional status at transfer is typically provided in greater detail by documents prepared by nursing and rehabilitation disciplines, but deserves mention in a synthesized way by the physician as well.

Hospital discharge summaries ideally are available for review by the next care team or primary care clinician before their encounter with the discharged patient. Unfortunately, these summaries all too often fail to reach primary providers in a timely manner. To assure that these providers have access to vital information about their patients at the time of hospital discharge, we recommend that certain information (**Table 16-9**) be faxed or e-mailed by hospital providers. At the time of hospital discharge, a patient's primary provider should be apprised of the discharge diagnoses (with emphasis on the reason for the hospitalization), the complete list of discharge medications,

**TABLE 16-9****Items to Fax or E-mail to Primary Care Provider Upon Hospital Discharge**

- Discharge diagnoses
- Discharge medications
- Results of major tests and procedures
- Tests still pending
- Follow-up arrangements, and ideal follow-up interval
- Contingency plans
  - What may go wrong, and what to do
  - Immediate follow-up needs at first posthospital visit

From Kripalani S, Jackson AT, Schnipper JL, et al. Promoting effective transitions of care at hospital discharge: a review of the literature. *J Hosp Med* 2007;2(5):314–323.

results of major tests, a listing of tests that have been done but whose results are still outstanding (biopsy results, for example), and follow-up arrangements (especially those involving the primary provider and visiting nursing). A couple of other items also deserve inclusion in this abbreviated summary and may require a bit of thought on the part of the transferring clinicians. First, given what is known about the patient in question, what problems might arise soon after discharge, related perhaps to potential disease exacerbations or family dynamics? What action might be taken if these problems occur? Second, which issues will require follow-up attention at the first postacute visit?

Up to this point, we have emphasized communications between sending and receiving clinicians involved in a transfer. Excellent transitional care requires that effective communication take place with the patient (or caregiver) as well. **Table 16-10** lists informational items that must be communicated to the patient, as well as tips on performing this function. It is not necessary that all these items be communicated by a physician—some might better be discussed by nursing or pharmacy personnel—but leaders in the transferring organization should assure that lines of responsibility are clear. Because of variations in the health literacy of patients and their families, transfer instructions should be provided at about a 6th grade level.

Important new diagnoses (particularly those that precipitated an acute illness episode) should be shared with the patient around the time of discharge, if this has not occurred already. The discharge

**TABLE 16-10****Communications with Patient/Caregiver at Time of Transfer**

- Review important discharge diagnoses.
- Review the reconciled medication list.
- Review possible adverse effects of medications.
- Discuss necessary activity limitations (e.g., joint range-of-motion, showering).
- Share functional prognosis, if known.
- Review worrisome signs/symptoms or red flags, along with whom to contact.
- Discuss what to expect at any new site of care.
- Review new self-care tasks (e.g., wound care, fingerstick glucose testing).
- Review dates of follow-up.
- Minimize jargon.
- Provide written materials.
- Check for understanding (have patient repeat back what she has heard; have her demonstrate important self-care tasks).
- Finish with "What questions about your transfer can I answer?", and make time to answer these.

medication list should also be reviewed, including the indications for the drugs, the changes made from the regimen the patient had followed before, and potential adverse drug reactions. Important limitations in the patient's activity, such as physical exertion or bathing concerns, should be discussed. Patients and families should be apprised of functional prognoses: "I think you have a good chance of getting back to your previous ability to walk around your home after about four to six weeks of rehabilitation at the nursing facility." Signs or symptoms that may signal early trouble should be related, along with information on what the patient should do should they arise. Important follow-up appointments (with primary providers, surgeons, or specialists) should be made and communicated to patient and family.

If the patient is headed to a new care venue, such as a SNF, it is helpful to say a few words about what to expect there: "You will not be seeing your doctor or nurse practitioner at the rehabilitation center as often as you have in the hospital, particularly if things are progressing well. The emphasis there will be much more on rehabilitation. You and the therapy staff will be working hard to recover your ability to walk like before and take care of yourself." Important self-care tasks, such as wound care techniques or glucose self-monitoring, must be taught or reviewed prior to discharge. To confirm that patients and families are learning what they need to know, clinical personnel should check for understanding by having them repeat back what they have heard and by demonstrating the requisite self-care skills: "Just to be sure I have done a good job of teaching you how to change this dressing, let's have you try it now."

A great deal of information is transmitted by clinicians to patients and families around the time of transfer. Some communication routines may help to maximize the chances that this information is understood and remembered. First, information and instructions should be given in lay language: avoid jargon and Latin abbreviations. Second, written materials should be provided for later review and reference. Finally, at the completion of the discharge instructions, the patient and family should be asked, "What questions about your transfer can I answer?"

The Care Transitions Intervention, discussed earlier, was specifically designed to be low-intensity, low-cost, and brief in duration. One particular strategy was the encouragement of patient "ownership" over core elements of their medical history through the use of a portable personal health record. This record included medical diagnoses, current medications, allergies, and primary care providers. A second strategy was the employment of Transition Coaches. Several leading health care organizations, operating under different financial structures, have adopted the Care Transitions Intervention.

Clinician leaders (e.g., chiefs of medical staff) and managers of health care organizations may wish to employ well-established methods of quality improvement to foster better transitional care. One such method involves the collection of vital process data—such as the fraction of discharge summaries that include a reconciled medication list, the fraction of discharged patients who were given follow-up appointments, or patient satisfaction survey data—and the use of these data in Deming cycles (Plan-Do-Study-Act) designed to improve the studied measure. Another method is the use of regular "customer-supplier" exchanges. Regularly scheduled meetings between representatives of hospitals and postacute nursing homes, or between hospitalists and primary providers, allow for the identification of interface concerns, prioritization of improvement efforts, and the nurturing of improved communication and rapport.

## SPECIAL CASES OF CARE TRANSITIONS

More than a quarter of nursing home residents are transferred each year at least once to an ED for urgent evaluation. These transfers are often perilous given their urgency, the difficulties of many nursing home residents in recalling and relating their history, and the problems of reaching families or surrogate decision makers. Conversely, when nursing home residents return, facility staff often report confusion about diagnostic findings or therapeutic recommendations from the ED. A recent study reported on the results of focus groups involving nursing home staff, ED personnel, and emergency medical services providers. [Table 16-11](#) summarizes the authors' findings on recommended information exchange between health professionals working in the two care settings. ED personnel need to know the reason for transfer, as well as whom to contact at the nursing facility for additional information. The patient's physician (with contact information) should be identified. Important clinical information the ED will need includes the patient's past medical history, medications and drug allergies, baseline cognitive and physical function, latest vital signs, and recent laboratory and x-ray results. Advance directives and surrogate decision maker or family contact are vital as well. Finally, in the event that the ED is contemplating a return of the patient to the nursing facility with new orders, it will be important for ED providers to be made aware of the capabilities of the facility to provide technical or nursing-intensive care, such as intravenous medication administration. Nursing home leaders (medical directors or directors of nursing) may wish to create a blank form listing the items from [Table 16-11](#), and assure that nurses who transfer patients for emergency evaluation complete the form and send along photocopies of related documents.

**TABLE 16-11**

### Information Exchange Between Nursing Homes and Emergency Departments

#### *Information from Nursing Home to Emergency Department*

- Name and contact information for nursing home
- Physician's name and contact information
- Patient's demographics (name, age, birthdate)
- Reason for transfer to emergency department
- Past medical history
- Medications and allergies
- Baseline cognitive and physical function
- Advance directives ("code status", living will)
- Power of attorney or family contact
- Most recent vital signs
- Recent laboratory and radiologic results
- Nursing home capabilities (e.g., wound care, IV antibiotics)

#### *Information from Emergency Department to Nursing Home Providers*

- Working diagnosis from emergency department
- Treatment provided by the emergency department
- Emergency department vital signs
- Tests performed, with results
- Pending results, with plans for transmission to nursing home staff
- Recommendations for further treatment
- Legible copy of emergency department chart, including consultants' notes
- Contact information for any outpatient follow-up

*From Terrell KM, Miller DK. Challenges in transitional care between nursing homes and emergency departments. J Am Med Dir Assoc. 2006;7:499.*

Information needed by nursing home personnel when residents return from the ED includes the working diagnosis rendered by emergency personnel, vital signs from the ED, results of testing performed there, treatment provided in the ED, and recommendations for further treatment or follow-up. A legible copy of the chart from the ED is generally essential. Just as nursing facility leaders may implement a standardized transfer form for patients sent to the ED, leaders from emergency medicine and nursing may institute their own transfer-back-to-nursing-home form or checklist, and employ quality improvement methods to confirm that the needed information is reliably transmitted.

Another common transition involving older patients is the admission to the program of a home health nursing agency. As with transfers between nursing homes and EDs, it is helpful to employ a checklist (Table 16-12) of informational items that the home nursing agency will need. Much of this is “the usual”—provider name and contact information, patient name and demographics, medical history and problem list, medication list and drug allergies, functional status, advance directives, and names of surrogate decision makers. A few items are more peculiar to the home care setting. First, if the home health program services are to be covered by Medicare, it will be important to specify the skilled care needs and to state that the patient meets “homebound” criteria. Second, what are the goals of care that the nursing personnel should keep in mind? Articulating these will not only help to prioritize their work, but will indicate when discharge from their program is appropriate. Third, what are the clinical and psychosocial issues (e.g., laboratory values, functional improvements) that are to be reported?

A third common care transition involving elders is the handoff of the hospitalized patient from one physician to another, such as for night or weekend coverage. Solet and coworkers reviewed the literature on such handoffs (few high-quality studies exist), and evaluated the handoff process at the four hospitals staffed by one Midwestern internal medicine residency program. Based on their work, they make four overall recommendations. First, handoffs of hospitalized patients should generally be made face to face, to allow the doctor assuming care of the patients to ask questions, to practice read-back skills, and to register nonverbal information such as facial expression, tone of voice, and body language. Second, the format for information transfer should be highly standardized. Third, the skill of handing off the care of complex and potentially unstable patients to another provider needs to be explicitly taught. And fourth, handoff skills need to be practiced repetitively, as is done by professionals in other

high-risk occupations, such as air traffic handling. We believe these are reasonable recommendations, based on the information available to date, and we also endorse the authors’ list of essential elements that should be passed on at the time of handoff. These elements include: patient identification, location, date of admission, a brief synopsis of the patient’s admitting presentation, a list of currently active and pertinent past medical problems, medications and drug allergies, venous access (and how important it is that this be maintained), code status, key laboratory data, foreseeable problems with recommended contingency plans, and psychosocial concerns. Some or all of this information should be transmitted in written or electronic form (via computer or personal data assistant) as well as orally.

## EDUCATING PROFESSIONALS IN CARE TRANSITIONS

Educational scholarship in the field of transitional care is at an embryonic stage. Reports of needs assessments have been few in number and have involved small sample sizes. One such assessment employed focus groups and surveys to determine the educational needs in geriatrics for medical students and internal medicine residents. Trainees perceived training gaps in four major areas; one of these was in transitional care (primarily involving discharge from the hospital). Another needs assessment performed at a single internal medicine residency of an academic medical center found that house staff received little instruction in, or role modeling of, good transitional care; that residents learned to create better discharge summaries primarily from experience; and that resident-generated discharge summaries demonstrated a need for improved format and information content.

Few reports are available describing transitional care educational interventions and their effects. Some medical schools are beginning to incorporate the topic into their curriculum using teaching methodologies such as lectures, video, group discussions, and interdisciplinary exercises. A number of residencies have also incorporated instruction on the subject, primarily on how to compose a proper hospital discharge summary. Educational techniques have included didactic instruction, individualized feedback to residents, and technologies that permit the incremental preparation of discharge summaries during a patient’s hospital course.

Although we cannot (yet) cite studies to support our views, we believe that trainees will receive improved transitions education if a few approaches are adopted. First, attending physicians should be role models for excellence in this area. They should demonstrate mastery of the assessment and communication skills required to manage care transitions. Increased faculty development efforts at many centers will probably be required to assure that teaching faculty members master the needed skills. Second, attending physicians must evaluate their learners for transitional care performance, provide generous and specific feedback, and incorporate their assessments into learners’ end-of-rotation formal evaluations. Third, transitional care topics should be incorporated into teaching conferences. One natural place to do so is the “M&M” (morbidity and mortality) conference. While usually a forum to discuss cases in which a patient suffered from a hard-to-diagnose malady, or in which some procedural misfortune ensued, the M&M conference presents an opportunity to dissect a systems breakdown, such as a fumbled patient handoff.

**TABLE 16-12**

### Information Needed by Home Health Nursing for Patients Admitted to Their Care

- Name of physician overseeing care, with contact information and preferred mode of communication
- Patient name and demographics
- Medicare: Skilled care needs? Homebound?
- Past medical history, medications, allergies
- Cognitive and physical function
- Advance directives, surrogate decision makers
- Overall goals of care and preliminary care plan
- Issues to monitor and report

An indication that a training program has succeeded in incorporating transitional care into its curriculum is that its trainees give as much effort and thought to patient transfers as they do to admissions.

## SUMMARY

A confluence of trends in American health care is pushing transitional care quality onto the agendas of professional leaders, certifying and regulatory bodies, third-party payers, and patient advocacy groups. Well-executed transitional care is patient-centered and improves patient safety. Given the aging of the population, the accretion of chronic medical and functional problems, the specialization of care venues, the pressure to reduce lengths of stay, and increasing disincentives for many clinicians to provide care across a continuum of settings, transitional care will only grow in prominence.

Research has shown that older patients and members of other vulnerable populations are most likely to suffer mishaps during handoffs of care. Nevertheless, we are learning which approaches and techniques seem to improve the odds of good outcomes. There is a growing consensus about what informational elements should be transmitted to patients, families, and the next team of providers. Empowering patients and their caregivers is vital. Employing professionals, such as transition coaches, whose role definition includes navigating patients through the health care system, has proven beneficial. And providing explicit, dedicated training in care transitions to physicians, physician assistants, nurse practitioners, nurses, and pharmacists is imperative.

Yet substantial improvement in the quality of American health care transitions will require a combination of approaches and strategies. First, the scientific foundation for the field is still being constructed, and important research questions abound. What are the best measures of transitional care quality? Which factors predict transitions mishaps? Which transitional care interventions are beneficial and cost-effective?

Second, a commitment to improve care transitions creates a demand for educating the professionals who plan and execute these transitions. Health professions educators will need to incorporate the topic into an already crowded curriculum. Particularly challenging is that the best method for teaching the subject may require a genuinely interdisciplinary approach.

Finally, a refined scientific database at the disposal of committed and energetic teachers may only yield improvement around the edges. Health care professionals, being human, still respond to the mix of incentives and disincentives they face. The fee-for-service model that dominates provider payment in the United States hinders efforts at providing coordinated care for patients. Whether substantial and widespread improvements in transitional care can occur in the United States without extensive modifications of the payment system is open to doubt.

# Acute Hospital Care

Scott A. Flanders ■ Paula M. Podrazik  
■ Chad Whelan ■ Caroline Blaum

The nearly 25% of adults 65 years and older who are hospitalized each year represents a higher proportion than for any other age group. Many of these older adults experience protracted or permanent functional decline and worsening health after their acute hospital stay. Although people 65 years and older comprise only about 12% of the U.S. population, they account for one-third of acute hospital admissions and about 46% of the national costs for acute hospital care.

National data show that older hospitalized patients have a more complex hospital course than younger hospitalized patients (Table 17-1). In 2003, the length of stay for patients 65 years and older was 1.7 days longer than for those under 65 years old, although the length of stay for the major discharge diagnoses has dropped since 1997. The mean total hospital costs were 46% higher for the 65 years and older group compared with the younger group. Hospital costs for older patients have increased over 25% since 1997. Although hospital deaths are decreasing, people 65 years and older have nearly five times the in-hospital mortality as younger hospitalized patients.

While many principles of acute hospital care are the same for all age groups, the elderly patient population is at increased risk of collecting comorbidities and accompanying medications, functional decline, cognitive impairment, and dwindling social supports. Therefore, there are several issues related to the hospital admission, hospital stay, and discharge that deserve specific attention when considering the care of the geriatric population. The care of hospitalized elders requires a systematic approach to the evaluation and management of commonly seen geriatric conditions and perhaps implementation of structural changes specifically designed to address the needs of this often medically complex and potentially vulnerable population.

## HOSPITAL ADMISSION

### Reasons for Admission for Geriatric Patients

The major diagnoses for which older adults are hospitalized are related to chronic diseases and respiratory conditions. The 15 most common conditions, accounting for 48% of the hospital admission diagnoses, are listed in Table 17-2. Also common and important to recognize, but less likely to be reported as the reason for admission, are conditions more likely to occur in older adults such as failure to thrive, falls, adverse drug effects, or change in mental status. In addition, older adults maybe admitted with an atypical presentation of another condition, such as when change in mental status is due to underlying fluid and electrolyte disorder or urinary tract infection (UTI). Often the reported diagnosis for a hospitalized older patient may not fully capture the underlying reasons that necessitated the admission and does not explain the hospital course and subsequent health status of the patient. While many of the 15 most frequent conditions reported as causes for hospitalizations among older adults represent acute exacerbations of chronic diseases, the reasons why a stable older adult with heart failure suddenly decompensates or a 90-year-old assisted living resident is admitted with a broken hip, often relate as much to the physical and/or social vulnerability of many older adults as to their complex health status.

In addition to the primary problems that led to the admission, the effect of comorbid chronic diseases must be considered. Over 60% of Medicare patients have two or more major chronic diseases and 24% have four or more. In 2004, people 65 years and older admitted to the hospital had an average of 2.3 comorbid conditions. Comorbid chronic diseases have several consequences for the hospitalized

TABLE 17-1

**Characteristics of Hospitalizations Among Nonelderly and Elderly Populations, 2003**

	YOUNGER THAN 65 YR	65 YR AND OLDER
Percentage of U.S. population	88%	12%
Percent of hospital stays	65.3%	34.7%
Mean length of stay (days)	4.0	5.7
Admitted through emergency department (%)	36.2%	57.4%
Died in hospital (%)	0.9%	4.7%

elder and for the clinician. Multiple diseases often mean multiple outpatient physicians, complicating communication between inpatient and outpatient providers. Multiple diseases lead to the use of multiple medications. Multiple medications, even if indicated, can result in confusion about medications, difficulty with medication reconciliation and drug adherence, and adverse drug events (ADEs) including amplified side effects, drug–drug or drug–disease interactions, and errors in drug administration. A high burden of chronic disease can lead to self-care difficulties, patient and caregiver frustration and burnout, and physiological instability for the patient.

In older patients, especially those 75 years and older, common conditions such as vision or hearing impairment, mobility impairment and fall risk, poor nutrition, incontinence, depression, cognitive impairment, and functional impairment often occur in conjunction with the major chronic diseases that lead to hospital admissions. For example, 2004 data from the Health and Retirement Survey (HRS), a nationally representative health interview survey sponsored by the National Institute on Aging demonstrate that the geriatric conditions of falls and incontinence are common in older adults with heart failure, coronary heart diseases, and diabetes (Table 17-3).

Conditions commonly seen in older patients often labeled as “geriatric” conditions can contribute to the need for the acute ad-

TABLE 17-2

mission, and substantially influence the hospital course and discharge plans. Cognitive impairment, one such geriatric condition, is a major risk for delirium. At admission, it may be impossible to distinguish between delirium and dementia or to determine a patient’s baseline cognitive performance. Delirium is associated with longer

**Proportion of Respondents aged 65 yrs and Older with Index Disease or Condition Who Have Other Diseases/Conditions\***

INDEX DISEASE OR CONDITIONS (% OF TOTAL SAMPLE)	WEIGHTED PERCENTAGES <sup>2</sup>						
	Coronary Disease	Heart Failure	Diabetes	Incontinence	Falls	≥ 1 Other Condition	≥ 2 Other Conditions
Coronary Disease (8.7%)		24.1% (20.9–27.6)	30.4% (27.2–33.8)	33.4% (29.3–37.9)	38.6% (35.1–42.3)	72.6% (68.9–76.0)	37.0% (32.9–41.3)
Heart Failure (4.8%)	43.8% (38.6–49.1)		36.5% (31.3–42.0)	36.7% (32.2–41.5)	43.0% (38.3–47.7)	82.2% (77.9–85.9)	49.7% (44.8–54.6)
Diabetes (19.4%)	13.6% (12.1–15.4)	9.0% (7.6–10.6)		28.2% (26.1–30.4)	28.8% (26.7–30.9)	52.4% (49.7–55.1)	20.5% (18.5–22.6)
Incontinence (25.0%)	11.6% (10.2–13.3)	7.0% (6.0–8.3)	21.9% (20.1–23.8)		36.6% (34.6–38.7)	55.0% (52.8–57.1)	16.7% (15.1–18.4)
Falls (23.2%)	14.5% (12.8–16.3)	8.9% (7.6–10.3)	24.0% (22.2–25.9)	39.4% (37.2–41.6)		60.4% (58.2–62.5)	19.9% (18.0–21.9)

\*From the Health and Retirement Study, 2004 wave;  $n = 11113$ .

<sup>†</sup>Weighted percentages are derived using the Health and Retirement Study (HRS) respondent population weights to adjust for the complex sampling design of the HRS survey. Row percentages are shown. For example, among older adults with reported coronary heart disease, 24.1% report heart failure and 38.6% report falls.

hospital length of stay, greater functional disability, and increased mortality following hospitalization. Several prospective studies have documented that hospital mortality is related to nutritional status, cognitive dysfunction, and functional disability. These factors independently predict mortality even when the comorbid diseases and diseases leading to hospitalization are considered.

Often physicians caring for an acutely ill, unstable or unsafe older adult who requires acute hospitalization are advised to identify or “screen” for frailty. There is as yet no universally accepted definition or measure of frailty. The term “frail” tends to be used to refer to an older adult who is physiologically or socially vulnerable. Recently, researchers have tried to develop empiric definitions of frailty, which, while promising, may not yet be clinically applicable. The idea of a vulnerable or at-risk elderly person may be clinically more helpful. The presence of comorbid conditions, functional decline, cognitive impairment, or inadequate or abusive social situations suggests vulnerability. Since functional decline and cognitive impairments increase with age, the advanced age of a patient (e.g., >75 years) may strongly factor into a clinician’s decision to “screen” for risk of frailty and perform screens of memory, functional status, hearing, and sight, and take an in-depth social history during the hospitalization. These issues require attention from the admission process through discharge planning and postacute care transitions.

Geriatric conditions can be the reason for admission. Examples include falls or “failure to thrive,” defined as poor nutrition and weight loss associated with diseases, dementia, functional disability, and sometimes inadequate caregiving. Assessment of comorbidities and geriatric conditions (e.g., falls, failure to thrive, dementia, urinary incontinence) upon admission and during the hospitalization with simple screening questions and physical evaluation will help the clinician operationalize the ideas of “vulnerable” and frail, and provide targets for therapy such as increased nutrition, physical therapy, glasses, and hearing aids. Social issues, such as inability to buy medications, inadequate caregiving and/or insufficient help at home, elder neglect and abuse, and elder self-neglect are unfortunately relatively common. They can be missed if they are not specifically considered and investigated.

### Admission Screening

At the time of admission, much of the focus is on evaluation and management of a disease-specific, perhaps life-threatening illness. However, the admission also provides an opportune time to screen for issues of importance in the care of elderly patients, particularly issues likely to affect the course, treatment, and prognosis of the illness that precipitated the hospitalization. Important components of the admission screen are described.

### Communication with Family and Primary Care Providers

While many patients can provide accurate descriptions of their home situations and presenting symptoms, every effort should be made to discuss these issues with family members who can often provide additional information about social issues that may have contributed to admission or who may describe symptoms or events that help clarify the admitting diagnosis. Older patients often present with complex symptoms and atypical presentations of disease requiring increased attention to the factors that led up to the admission. Similarly, the patient’s primary outpatient provider of care should be

contacted. It is increasingly common for patients to be cared for by inpatient physicians, such as hospitalists, who do not care for patients in the outpatient setting. This means many elderly patients are being “handed-off” at admission. Studies have shown that most primary care providers want to be contacted at admission. Primary providers can help clarify the acute problem and can provide a more complete medical history including other comorbid conditions, previous diagnostic testing, and response to previous treatments. Depending on the reason for admission and the hospital course, communication with the patient’s specialist physicians may also be necessary.

### Medication Reconciliation

Hospital admission is an important time for medication review. Clarification of the patient’s medications, often prescribed by multiple physicians, and identification of potential adverse drug reactions (ADRs) are two important aspects of medication review. ADRs may lead to hospital admission and are more common as numbers of medications and comorbid illness increase. While age alone is not an independent predictor of ADRs, older patients are more likely to have multiple comorbid conditions and be on multiple medications. In addition, there are certain medications or classes of medications that have been identified by expert consensus panels as being at high risk for ADRs in elderly patients with relatively low clinical benefit and often a safer alternative medication exists. These high-risk medications should likewise be identified and discussed with the primary care physician. Careful attention should be paid to medications most likely to lead to ADRs including analgesics, sedatives, cardiovascular medications, and psychoactive drugs. Regulatory bodies, such as the Joint Commission for Accreditation of Healthcare Organizations (JCAHO), are requiring that all institutions have a process in place to reconcile, or review, medication lists for high-risk or unnecessary medications. This process needs to happen throughout the hospitalization, but is especially important at admission. Medication reconciliation is a time-consuming, but important process involving a rigorous review of each medication for appropriateness in conjunction with comorbidities and the other medications the patient is taking and requires discussion with the primary care physician and, often, specialty physicians at the point of discharge for continuity of care, best drug choices, and safety. Aspects of medication reconciliation can be aided by computerized physician order entry systems and clinical pharmacists.

### Identify Frailty

While precise definitions of frailty are elusive, studies have shown that patients of advanced age (e.g., >80 years) or with functional impairments are the most vulnerable and should be considered “frail.” At least one survey of a general medicine service in an urban medical center estimated 25% of elderly patients were frail or vulnerable, according to the Vulnerable Elderly Survey-13 tool that scores age, self-perceived health, and aspects of functional status to predict increased risk of morbidity and mortality. Frailty puts patients at risk for further functional and cognitive decline, delirium, prolonged hospitalization, increased costs, and mortality. Identification of frailty at admission should alert the hospital physician to the need to further evaluate for dementia and other geriatric conditions and can help frame discussions about prognosis. It also signals the need to start advanced discharge planning.

## Functional Screen

Functional measures are stronger predictors of mortality and contribute more to prognosis in the hospitalized older patient than comorbid illness, disease severity, and diagnoses. Assessing activities of daily living (ADLs) and instrumental activities of daily living (IADLs) are well-known measures of functional impairment. The hospital physician should also be comfortable in performing routine assessments of mobility, such as the “Get Up and Go” test (see Chapter 115). Any documented mobility or ADL impairment should trigger physical therapy and/or occupational therapy assessments and should signal the need to institute early mobilization and early institution of discharge planning.

## Dementia Screen

Screening for dementia is particularly important in the elderly patient who is losing weight, noncompliant with medications, admitted from a nursing home or readmitted to the hospital. Impaired judgment and insight can impact a patient’s ability to make health decisions, discuss end-of-life issues, and live independently after discharge. It also identifies patients at risk for the development of delirium in the hospital and readmission after discharge. While diagnosis of dementia is based on DSM-IV criteria, two common screening tools, the Mini-Mental Status Examination (MMSE) and the Mini-Cog (see Chapters 11 and 12), can be used to quickly identify patients at high risk for dementia. Both tests have similar sensitivities, but the MMSE is the only one to have been validated in the hospital setting, while the Mini-Cog is faster to perform. Impairments on either test should result in active planning for cognitive stimulation during the hospitalization, comprehensive discharge planning instituted at the beginning of the hospital stay, and family/caregiver involvement.

## HOSPITAL STAY

Hospitalization presents many hazards for older patients. While the outcome of hospitalization is dependent on the severity and type of acute illness and the patient’s baseline vulnerability, elderly patients are at five times increased risk for iatrogenic complications during hospitalization. Older patients have an average 35% risk of functional decline during acute hospitalization. In addition, they are at increased risk for the development of delirium. After discharge, they are at increased risk for needing institutionalization and hospital readmission. While the hospital may be considered “unsafe” for vulnerable elderly patients, hospitalization is often necessary to treat acute illness. Thus, considerable attention must be given to creating a systematic approach to preventing and treating common hospital complications in the geriatric population. This topic has appropriately generated considerable attention recently among researchers, payors, regulatory bodies such as JCAHO and the federal government, as well as patients and their families.

## Common Problems in Hospitalized Elderly Patients

### Delirium

The incidence of delirium in hospitalized older patients is as high as 50% and is associated with increased mortality, hospital length of

stay, and need for placement in long-term care. Because delirium in elderly patients can present atypically (such as the hypoactive form), it often goes unrecognized by physicians and nurses. Understanding risk factors, making the diagnosis, and instituting strategies for prevention of delirium are critical for the hospital physician.

In a study group of patients >70 years old, risk factors for delirium included severe illness, cognitive impairment (MMSE < 24), and BUN / Cr ratio  $\geq 18$ . Precipitating factors for delirium were use of restraints or a bladder catheter,  $\geq 3$  medications added, an iatrogenic event, and malnutrition (see Chapter 53). Patients at risk for delirium should have targeted strategies to prevent its development. Many institutions have put formal delirium prevention programs into place. These programs are designed to prevent cognitive impairment, sleep deprivation, immobility, dehydration, as well as vision and hearing impairment. The Hospital Elder Life Program (HELP) uses an orientation board and a program of cognitive stimulation to reduce the rate of confusion from 26% to 8%. Even in the absence of a formal program, the hospital physician should have the patient’s family stay overnight if possible, remove unnecessary foley catheters, avoid restraints, eliminate unnecessary medications, order early mobilization and visual / hearing aids, and address dehydration. While attention to these issues by individual physicians is important, the case can also be made for a more systematic, interdisciplinary approach.

Over a 6-month period, a community hospital was able to demonstrate a 14% reduction in the rate of delirium and cost savings of over \$600,000 for a 40-bed unit by implementing portions of the HELP program. The program showed sustained results including higher nursing and patient satisfaction. This program succeeded despite limited resources that required them to eliminate portions of the original HELP program.

### Immobility and Falls

During an acute hospital stay, the older patient is at high-risk for falls. These inpatient falls are not only common, but carry significant risk of short- and long-term adverse effects for the frail elderly patient. Estimates for inpatient falls among all hospitalized patients range from two to seven falls per 1000 patient-days. However, not all hospitalized patients face the same risk. In a single urban academic center, rates for medical patients were significantly higher (6.2 falls/1000 patient days) as compared to surgical patients (2.18 falls/1000 patient days).

Inpatient falls are frequently associated with injury, with estimates of one-third to almost one-half of falls resulting in injuries. Most concerning is that an estimated 8% of falls result in moderate to severe injuries. These falls and injuries are associated with significant in-hospital adverse outcomes. Patients who suffer falls with injury have longer lengths of stay and higher costs than similar patients who do not suffer a fall. In addition to the in-hospital effects, a fall with injury may lead to serious long-term health outcomes as well. Falls among elderly patients with and without injuries are risk factors for increased use of health care resources in the future, functional decline, loss of independence, higher rates of discharge to extended care facilities, and even death.

While all elderly patients are at risk for falling, as the risk of falls increases with age, in hospitalized patients, there are multiple well-described risk factors that can better identify patients at the highest risk (Table 17-4). These risk factors include patient-specific baseline characteristics, patient-specific effects of the acute

**TABLE 17-4****Risk Factors for Falling among Hospitalized Patients**

Increasing age
History of falls
Dementia/delirium
Visual deficits
Dehydration
Frequent toileting/incontinence
Dizziness
Difficulty in balance, transfers, or walking
Polypharmacy
Use of sedatives/hypnotics
Lower extremity muscle weakness
High patient to nurse ratio

illness superimposed on baseline risk, and environmental factors. As may be expected, multiple risk factors increase the risk of falling for patients. In one study, elderly patients with four risk factors had a 10-fold increased risk of falling as compared to those with no risk factors. Although this study was conducted in community dwelling elderly persons, it is likely that this increase in fall risk with each additional risk factor is similar for hospitalized elderly patients as well.

Given the well-described risk factors for falls among hospitalized elderly patients, a tool for identifying those patients at highest risk would prove very useful. Several tools designed to screen for risk of falls have been developed and are easy to use. However, these currently available tools have been found to have significant limitations when evaluated outside of the initial population used for development of the instruments. The major limitation is that the tools often have very high sensitivities and low specificities so that they tend to identify a large percentage of patients as high-risk. Understanding this limitation of risk assessment tools is important as a high sensitivity/low specificity tool is a reasonable method of screening for at-risk patients. The Morse Fall Scale, consisting of questions addressing history of falls, presence of multiple diagnoses, use of ambulatory aids, presence of intravenous therapy or heparin lock, gait and transfer ability, and mental status and the St. Thomas's Risk Assessment Tool in Falling Elderly Inpatients (STRATIFY) instrument, consisting of five items that address risk factors for falling: history of falling, patient agitation, visual impairment affecting everyday function, need for frequent toileting, and transfer ability and mobility are two of the most commonly used falls screens in the acute hospital setting.

While all clinicians caring for elderly hospitalized patients should be aware of the risks and implications of falls, systematic interventions have proven most successful to date in lowering the risk of falls. These systematic interventions rely on identifying at-risk patients using baseline risk, preventing or minimizing the effects of the acute illness/injury on risk of falls, and affecting environmental changes that limit the falls as well as reducing the risk of injury from any falls that do occur. Reductions in total in-hospital falls have been reduced by as much as 19% with an even more dramatic 77% reduction in falls with injuries with reductions sustained for as long as 2 years. These interventions have utilized a multipronged approach and it is unclear as to what aspects of the programs are most effective. It is important to note that not all published reports have been able

to demonstrate this level of effectiveness. While additional work is required to better understand the components of an effective falls and injury prevention program, it is appropriate for hospitals and clinicians caring for elderly patients in the acute care setting to develop local programs modeled on successful programs and then to evaluate their programs locally.

### Nutrition

Poor nutritional status is common among hospitalized elderly patients. Studies have estimated that up to 50% of all hospitalized older patients are nutritionally at risk and up to 25% meet criteria for malnourished. The causes of these nutritional deficiencies are usually multiple and are related to issues including chronic host issues, effects of the acute illness, and environmental factors prior to hospitalization. Among hospitalized older patients, poor nutritional status is associated with worse clinical outcomes than matched nutritionally intact patients. During the hospitalization, nutritionally at-risk patients are more likely to suffer from a hospital-acquired complication, particularly infection. Compared with patients with good nutritional status, poor nutritional status is associated with longer length of stay, higher readmission rates, increased likelihood of being discharged to an extended care facility, and higher mortality rates.

Given the prevalence and importance of poor nutritional status in the older hospitalized patient, strategies aimed at early identification and intervention should be instituted. Several screening tools have been developed included the Chandra scale, the Nutrition Screening Initiative, and the Mini Nutritional Assessment. The Mini Nutritional Assessment has been shown to be predictive for in-hospital mortality, longer length of stay, and greater likelihood to be discharged to a long-term care facility. None of these instruments should be used as diagnostic tools; they are reasonable to use as part of a system of nutritional screening that can be followed up by a more thorough assessment.

Interventions on at-risk patients can be effective at improving nutritional markers. These interventions include dietary counseling, oral supplementation, or enteral feeding in select populations. When possible, oral feeding is the optimal method for nutritional repletion and maintenance. While these interventions can improve nutritional markers, there is less clear evidence that they affect important clinical outcomes. Despite this lack of evidence in the hospitalized older patient, it is reasonable to provide these nutritional interventions given the positive effects seen on intermediate outcomes.

A difficult situation that often arises in the hospital setting is the question of whether to place a gastrostomy tube (or equivalent) for long-term nutritional support. These feeding tubes do have a role in patients who have reversible deficits in oral feeding ability (e.g., postesophageal surgery) and in patients who are cognitively intact but may have a long-term need for enteral feedings due to mechanical issues. However, often the decision in the acute hospital setting involves older patients who have underlying cognitive deficits, most often dementia, who are no longer able to maintain adequate oral nutrition even with oral supplements. It is important to recognize that this is a marker of end-stage dementia and that there is harm associated with placing feeding tubes in these patients with no benefit to cognitive or functional status and can negatively impact quality of life. This can be a difficult decision for family members to make and can be a trigger to begin or continue discussions about goals of care in these patients.

## Preventing Nosocomial Infections

Infections are one of the most common adverse events in health care, affecting over 2 million people, contributing to over 90 000 deaths, and costing over \$4.5 billion yearly in the United States. Up to 10% of patients admitted to acute care hospitals develop hospital-acquired infections; this rate is rising. The majority of hospital-acquired infections are due to UTIs, pneumonia, surgical site infections, and bloodstream infections. A full discussion of the management of all these infections is beyond the scope of this chapter, but older patients are disproportionately affected by UTIs, pneumonia, and increasingly, *Clostridium difficile* infections. Putting strategies in place to address these infections (and in particular, preventing them) and practicing good infection control is critical for inpatient physicians focused on the care of elderly patients.

### Hospital-Acquired Urinary Tract Infections

UTI is the most common hospital acquired infection, accounting for up to 40% of all nosocomial infections. Hospitals acquired UTIs lead to bacteremia in up to 4% of patients, and carry a mortality rate between 15% and 30%. Females, older patients, and patients with severe underlying illness are at greatest risk. Urinary catheterization is a contributing factor in the majority of infections in hospitalized patients. The National Nosocomial Infection Surveillance (NNIS) System reports a median rate of catheter associated UTI per 1000 catheter days of 3.9. While classic UTIs present with dysuria, frequent urination, and urgency, these symptoms are less common in older patients, and are difficult to evaluate in the patient with a catheter in place or with cognitive impairment. In addition, asymptomatic bacteriuria in hospitalized patients is a common finding. Its significance in patients with a catheter remains unknown, and most experts recommend against treatment in the absence of symptoms. When symptomatic, most cases of UTI in the hospital are caused by *Escherichia coli*, *Enterococcus*, *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, and *Candida* species.

Most of the focus on preventing nosocomial UTIs is on mitigating the risk imposed by urinary catheters. Indwelling urinary catheter (IUC) use varies by hospital unit and patient type, but they are used in up to 25% of elderly hospitalized patients. In addition to contributing to infection risk, catheters are known to increase the risk of delirium and falls and have been referred to as a “one-point restraint.” While systematic reviews have shown that some types of antimicrobial catheters (nitrofurazone or silver alloy coated) reduce rates of bacteriuria in hospitalized patients, most effort has been spent on trying to avoid catheters in the first place. Appropriate use of catheters includes patients unable to void, postanesthesia use, monitoring of urine output in patients unable to comply with collection, protection of an open wound in an incontinent patient, and use in palliative care. Unnecessary use is common; some reports have suggested that up to 30% of hospital physicians are unaware that their patients even have a catheter. One of the most important risk prevention strategies is avoiding unnecessary catheter use. In institutions with computerized order entry, clinical decision support, electronic reminders, and automatic stop orders have been effective at reducing the overall use and duration of use of urinary catheters. Paper reminders are also effective in institutions lacking computerized order entry. In male patients who require a urinary catheter (other than for urinary retention), recent work has shown that condom catheters in addition to being rated as more comfortable, reduce the composite

risk of bacteriuria, symptomatic UTIs, and death. Of note, most of the benefit was in the reduction of asymptomatic bacteriuria. This protective effect of condom catheters may be diminished in patients with dementia who frequently pull off their catheters. Each time the condom catheter is replaced, swabbing of the meatus is required which may increase the risk of bacteriuria and subsequent infection when it occurs repeatedly.

### Hospital-Acquired Pneumonia

Hospital-acquired pneumonia, also referred to as nosocomial pneumonia, includes both ventilator-associated pneumonia and nonventilator-associated pneumonia that develops 48 or more hours after hospitalization. Almost all the data on hospital-acquired pneumonia comes from intensive care units (ICUs) and the study of ventilator-associated pneumonia. Extrapolation to the non-ICU population may not be appropriate. A third class of nosocomial pneumonia that is increasingly common and important for the geriatric population is health care-associated pneumonia. Patients at risk for health care-associated pneumonia include patients receiving home IV antibiotics, home nursing or home wound care, residence in a nursing home or long-term care facility, patients who have been hospitalized for  $\geq 2$  days in the past 90 days, and patients who have received dialysis or IV therapy at a hospital-based clinic in the past 30 days. Health care associated pneumonia develops in the community, but has a spectrum of causative organisms, and an approach to management that is similar to hospital-acquired pneumonia.

Pneumonia is the second most common nosocomial infection with an incidence of 5 to 10 cases per 1000 hospitalizations. The rates in patients with endotracheal tubes are up to 20 times higher. The mortality attributable to nosocomial pneumonia is debated, but maybe as high as 30%. An episode of nosocomial pneumonia clearly increases hospital length of stay and costs.

Nosocomial pneumonia results from microbial invasion of sterile lung parenchyma as a result of microaspiration of contaminated oropharyngeal or gastric secretions. A defect in host defenses, aspiration of a large inoculum of organisms, or aspiration of a particularly virulent organism may contribute to parenchymal infection. Risk factors for the development of nosocomial pneumonia that are commonly found in older patients are listed in [Table 17-5](#). Understanding the risk factors is critical to implementing effective prevention strategies. Many prevention strategies for ventilator-associated pneumonia have been well-described elsewhere and are best directed at the ICU physicians and other ICU personnel. However, there are several important strategies to prevent nosocomial pneumonia that are important for physicians caring for hospitalized elders in the non-ICU setting.

One of the best ways to prevent pneumonia is to avoid intubation in patients with respiratory failure. Increasingly, the use of noninvasive ventilation has been effective in reducing the need for intubation. In selected patients with acute COPD or heart failure exacerbations, noninvasive ventilation reduced the need for intubation and was associated with less pneumonia, shorter hospital length of stay, and in some studies, lower mortality. Patients with facial trauma and altered mental status are generally not recommended for noninvasive ventilation due to increased risk of complications such as aspiration.

Keeping patients upright, or semirecumbent, has been shown to reduce rates of pneumonia. In one study, elevating the head of the

TABLE 17-5

## Risk Factors for Nosocomial Pneumonia in Elderly Patients

Impaired host defenses/increased aspiration
Endotracheal tubes
Nasogastric tubes
Enteral feeding tubes
Supine positioning
Impaired mental status
Sedation
Large inoculum of organisms
Bacterial colonization
Gastric alkalization (enteral feeds/H <sub>2</sub> -receptor blockers, proton pump inhibitors)
Iatrogenic (forced hand ventilation)
Sinusitis
Malnutrition
Contaminated respiratory equipment
Overgrowth of virulent organisms
Prolonged antibiotic use
Iatrogenic (inadequate hand washing)
Central venous lines
Comorbid illness
Frequent hospitalizations
Prolonged hospital stays

bed >45° reduced rates of ventilator-acquired pneumonia significantly. While little data exist for this practice outside the ICU, head of bed elevation is likely to reduce episodes of hospital-acquired pneumonia outside the ICU, especially in patients at risk for aspiration. Stress ulcer prophylaxis increases gastric pH and allows for colonization of the gastrointestinal tract by potentially pathogenic organisms. Studies have suggested that use of medications that raise gastric pH (primarily H<sub>2</sub>-antagonists) is associated with an increased risk of pneumonia. While these medications are necessary in some patients, they are likely overused and may contribute to episodes of hospital-acquired pneumonia. In general, the only patients shown to benefit from stress ulcer prophylaxis are those with shock, respiratory failure, and coagulopathy. Data on risks for the use of proton pump inhibitors (PPI) in hospitalized patients is limited. However, studies in the community setting link these agents to increased rates of community-acquired pneumonia suggesting similar mechanisms. In the hospitalized elder, every effort should be made to assure an appropriate indication exists for continued use of H<sub>2</sub>-antagonists or PPIs. Given the role of colonizing oropharyngeal bacteria, it would seem that improving oral hygiene could prevent nosocomial pneumonia. While no study has been performed in hospitalized patients, improved oral hygiene in nursing home residents—by the use of antiseptic mouthwash, brushing teeth after meals, and weekly plaque removal—has been linked to reduced rates of aspiration pneumonia. Improved oral hygiene in hospitalized elderly patients (mouthwash and brushing), is low cost, can involve the family in resource-constrained environments, and may prevent pneumonia.

### *Clostridium difficile*

*Clostridium difficile* is the most common cause of health care-acquired diarrhea, occurring at a rate of 61 cases per 100 000 discharges in 2003. In the past few years, several outbreaks in hospitals and nursing homes have been described. These outbreaks have been

associated with high morbidity and mortality. Concurrent with recent outbreaks are reports of poor response to therapy, and high rates of relapse. Many of the epidemic outbreaks that have been associated with highly morbid disease have been linked to a previously uncommon strain, B1/NAP1.

The biggest risk factors for infection include antibiotic use and hospitalization. Additional risk factors relevant to the care of a geriatric population include advanced age, severity of illness, use of proton pump inhibitors, and use of tube feeding. While clindamycin is classically associated with *C. difficile*, any antibiotic (including metronidazole and vancomycin used to treat the disease) can cause infection. Cephalosporins are widely used and commonly cause *C. difficile* infection. More recently, fluoroquinolone use has been associated with outbreaks of the B1/ NAP1 strain.

Prevention of *C. difficile* requires both infection control measures and antibiotic stewardship. Outbreaks have been successfully controlled by patient isolation in a single room, implementation of contact precautions (gown and gloves for anyone entering the room) and, because clostridia spores are not easily killed by alcohol-based hand rubs, liberal handwashing with soap and water for all persons entering and leaving the patient's room. The implementation of formal antibiotic rotation programs and restriction of particular antibiotics during outbreaks may also be required to combat *C. difficile*.

### Infection Control

Prevention of hospital-acquired infections also includes careful attention to hand hygiene and preventing the spread of antimicrobial resistance. With careful hand washing before and after patient contact, the incidence of nosocomial infection is reduced. Existing data suggest that plain soap and water, antibacterial soaps (chlorhexidine based), and alcohol-based hand rinses have equivalent effect. The use of alcohol-based rinses in bedside dispensers may improve compliance with hand hygiene recommendations.

The numbers of organisms in U.S. hospitals displaying resistance and the mechanisms by which they develop resistance have both increased dramatically in recent years. Particular problem organisms include among the gram positives, methicillin-resistant *Staphylococcus aureus* (MRSA), and vancomycin-resistant enterococcus (VRE), and among the gram negatives, drug-resistant *Pseudomonas aeruginosa*, *Acinetobacter baumannii*, and extended spectrum beta-lactamase-producing Enterobacteriaceae. Infections with these organisms are associated with increased morbidity, mortality, and costs. Physicians should be familiar with their institution's resistance profile and understand when infection with these organisms is possible in order to give timely, appropriate antibiotic therapy. Delay in the initiation of adequate antibiotic therapy (i.e., antibiotics that are active against the organism that is ultimately isolated) has been associated with increased mortality in many types of infection.

Preventing the development and spread of these organisms is critical. The use and misuse of antibiotics has been associated with the development of resistance. Considerable attention has been given to antibiotic stewardship programs that focus on development of appropriate antibiotic formularies and treatment recommendations, restricted use of certain agents, and feedback to providers on prescribing practices. Many of these programs have been effective in controlling the emergence of resistance and in stopping outbreaks of highly resistant organisms. Prevention of the transmission of these

organisms once they emerge is also critical. Preventing person-to-person spread has been most successful with gram-positive organisms. Contact precautions (i.e., gowns, gloves) and isolation of infected patients in private rooms are the usual strategies. Caution is warranted when caring for elderly patients who are placed in isolation. Studies have shown that patients in isolation are less likely to be examined by health care providers. This potentially places these patients at increased risk of a missed diagnosis. It can also mean less physical therapy, less contact with nursing and family, and the potential for development of delirium. Extra effort may be required to continue the best practices of geriatric care for elderly patients who are in contact isolation.

### Venous Thromboembolism Prophylaxis

Prevention of venous thromboembolism (VTE), which includes deep venous thrombosis (DVT) and pulmonary embolism (PE), is an important consideration in hospitalized patients, leading to serious morbidity and mortality. Venous thromboembolism, while not uncommon in hospitalized medical patients, is often unrecognized. While there is no consensus on quantifying patient-specific risk factors, patients admitted with heart failure, severe respiratory disease, or malignancy, patients confined to bed, and older patients are considered to be at increased risk for VTE. Multiple studies, including several meta-analyses, have demonstrated the efficacy of pharmacologic prophylaxis against VTE in high-risk hospitalized patients. These studies have shown that both low molecular weight heparin (LMWH) and unfractionated heparin reduce the risk of both DVT and PE without a significant increased risk of major bleeding (minor bleeding episodes, including development of hematomas, maybe more common in patients receiving pharmacologic prophylaxis). Prophylaxis has not been associated with a mortality benefit and its cost-effectiveness has not been well studied. For patients at high risk of bleeding, the use of intermittent pneumatic leg compression is a reasonable substitute for heparin products.

The use of standard order sets and reminders built into computerized order entry systems facilitate routine use of VTE prophylaxis in high-risk patients. The effect of avoiding bedrest and encouraging frequent mobilization on reducing the occurrence of DVTs and PEs has not yet been studied.

### Patient Safety

Hospitalized older adults are more likely than hospitalized younger adults to suffer iatrogenic complications of hospitalization because older adults have longer, more complex hospitalizations, and greater physiological vulnerability. Since the Institute of Medicine Report focusing on patient safety, some of these “iatrogenic” complications are now understood as patient safety problems. For example, infectious complications of catheters and devices are common among older patients, who often have urinary catheters, other lines, and devices. Thromboembolic events, nosocomial infections, falls, ADEs, and drug errors due to incorrect reconciliation of a complex medical regimen, all are more common in older hospitalized patients and are targets of patient safety improvement. National Patient Safety Goals, approved by the Joint Commission on the Accreditation of Health Care Organizations in 2008, address many risks faced by older adult hospital patients. The goals include reducing risk of health care-associated infections, reconciling medications accurately across the

care continuum, reducing falls and fall risk, preventing pressure ulcers, and assessing risk of pressure ulcer development. Geriatricians and other physicians and providers caring for older hospitalized patients should be actively involved with planning and implementing patient safety interventions in the acute hospital setting.

### Palliative Care

In contrast to the ideal vision of death in which most people see themselves dying at home with family, many Americans die in hospitals. As recently as 2001, it was estimated that nearly 50% of people who died did so in hospitals. In some cases death is unexpected, but in most cases it is not. Despite the fact that many people die in hospitals, we do not yet do a good job of delivering end-of-life care. Surveys of patients and families have shown that patients dying in hospitals believe they do not have enough contact with physicians, emotional support, information about what to expect of the dying process, and unfortunately, a substantial percentage report moderate or severe pain in the last 3 days of life. Delivering high-quality end-of-life care requires experience, as well as a substantial investment in time. Providers working in today’s hospitals recognize these problems, yet struggle with increasingly complex patients, as well as demands for both increased quality and efficiency of care. As a result, many hospitals have developed formal palliative care programs to adequately address the needs of dying patients. Most palliative care programs focus on maximizing comfort and quality of life rather than delivering curative therapy. Formal palliative care programs focus on pain and symptom control, communication challenges, addressing spiritual needs, and facilitating care transitions. As of 2002, it was estimated that 26% of academic medical centers and 17% of all hospitals had hospital-based palliative care programs. While many hospitals use a variety of practitioners to staff their programs, geriatricians, hospitalists, and oncologists are well-represented in most programs. There now are formal palliative care fellowships and plans for board certification in this discipline. Any comprehensive approach to care of the hospitalized elder must address issues of end-of-life care. A full discussion of end-of-life care can be found in Chapter 31.

## HOSPITAL DISCHARGE AND CARE TRANSITIONS (see also Chapter 16)

The transition of elderly patients from the inpatient to outpatient setting is fraught with risk. At discharge patients are routinely transitioned from the care of an inpatient physician to that of their primary care provider, one or more specialist physicians, or a health care provider at a nursing home or rehabilitation facility. This “handoff” creates the opportunity for information to be lost or miscommunicated, resulting in the potential for adverse clinical consequences. The Institute of Medicine (IOM) report, “To Err is Human,” estimated that after discharge 49% of patients experience at least one medical error; 19% to 23% of patients suffer adverse events. These adverse events are associated with deficiencies in health literacy, patient education, communication among providers within and between systems, medical follow-up, and medication issues. The medication issues at discharge are well documented. Recent research has shown that 14% of patients experience one or more medication discrepancies after discharge, and that at 30 days, readmissions were twice as common in patients who had experienced a discrepancy.

Other studies have shown an ADE rate of 11% at 3 weeks after discharge. Patients who recalled having medication side-effects explained to them prior to discharge had fewer ADEs. While these transition problems are not unique to the geriatric population, older patients are disproportionately affected.

There is widespread agreement among health care professionals that improving safety during transitions of geriatric patients from the inpatient to outpatient setting is a health system priority. Unfortunately, there are no national standards outlining criteria for assessing the adequacy of discharge planning for older adults and there is no consensus on the best strategy to optimize the discharge process. A systematic review of the literature indicated little evidence for the effectiveness of discharge planning as a means of reducing length of stay, mortality, or costs.

The problems that occur at discharge highlight the need for systems-level solutions to track information and facilitate communication during this transition. Four key areas need to be addressed at discharge:

1. *Hospital physician–primary care (and specialist if indicated) provider communication:* While communication with a patient's primary physician is valuable at key points of the patient's hospitalization, it is critical at discharge. A phone call at discharge to the primary care provider is preferred, but timely communi-

cation of a summary of the patient's course, medication changes, and required follow-up can be automated and sent by e-mail or fax. The Society of Hospital Medicine has developed a discharge checklist that can be used to identify elements to include in a discharge summary and information that needs to be communicated to the physician following the patient as an outpatient (Table 17-6).

2. *Medication reconciliation:* Reconciliation ensures that an accurate up-to-date list of medications is maintained and is consistent with the patient's plan of care. Regulatory agencies require that this occurs at discharge. A standardized approach needs to be developed by the inpatient team; the approach can include physician- or nurse-based reconciliation and education. The process can be automated or can involve the use of clinical pharmacists. Several studies have shown that involving clinical pharmacists in the medication reconciliation process at discharge leads to fewer ADEs after discharge and in some cases has reduced readmissions. Many of the more robust pharmacist-based programs also call patients after discharge to troubleshoot medication problems.
3. *Pending tests and labs:* Many patients are discharged with labs and test results pending. Studies have shown that physicians are often unaware of tests requiring review and follow-up after hospital discharge. While automated mechanisms to track pending

results are the ideal, they remain uncommon. Checklists, creating extra layers of safety for important results (i.e., more than one care provider scheduled follow up appointment), and careful communication of what action should be taken based on the pending test result will help ensure important results do not fall through the cracks.

4. *Patient/family empowerment/discharge coaches*: Involving the patient or their family in the discharge process has been associated with improved outcomes and provides an extra layer of safety for follow-up of test results pending at discharge and communication of important events that occurred during the hospitalization. Studies have shown that encouraging patients to take a more active role in their care, and providing tools and guidance in the form of “transition coaches” can lower hospital costs and readmission rates for elderly patients. This patient-centered care is a useful strategy to improve care transitions.

## MODELS OF HOSPITAL CARE AND THE ELDERLY PATIENT

The care of hospitalized elders is occurring within a dynamic hospital environment that is changing, in part to address financial and other challenges for providers but also to better meet the needs of the geriatric population, and the increasing demands to provide safer, higher quality, and more cost-effective care. In this section of the chapter, we address some of the changes in models of hospital care relevant for the healthcare provider focused on the high-quality care of hospitalized elders.

### Hospitalist

Concurrent with the increased attention to the needs of hospitalized elders has been the emerging presence of hospitalists. The hospitalist physician, usually a general internist, focuses clinical activity almost exclusively on caring for hospitalized patients. Varied forces have driven the hospitalist movement, including improved efficiency of hospital care, physician ownership of inpatient quality and safety initiatives, and the dual clinical and financial challenges of managing patients in both the office and hospital. Teaching hospitals

also employ hospitalists to mitigate pressures resulting from resident work hour reductions. The rapid growth of the hospitalist field has been supported, in part, by direct financial support from physician group practices, hospitals, and academic medical centers.

There are currently 15 000 practicing hospitalists in the United States, with numbers expected to double by 2010 (Figure 17-1). The American Hospital Association (AHA) found that nearly 30% of U.S. hospitals had hospital medicine groups; the percentage exceeded 60% for hospitals with more than 200 beds. Similar penetration exists at academic medical centers (AMCs). Over half of teaching hospitals and 66% of major teaching hospitals (defined as a member of the Council of Teaching Hospitals and Health Systems) have developed hospital medicine groups. The hospitalist programs at these academic centers tend to be quite large, with an average of 17 hospitalists per program.

As hospital medicine programs have grown, so have the roles of hospitalists. The hospitalist’s primary task has not changed since the formation of the field, namely, the day-to-day clinical care of complex medical patients, in both academic and nonacademic settings. However, in many institutions, they have expanded their scope of practice by establishing palliative care programs as well as quality improvement and patient safety programs all of particular applicability and potential benefit to the hospitalized elderly patient. In addition, hospitals have supported the creation of surgical comanagement programs that focus on both outpatient preoperative assessment and inpatient postoperative management. With the hospital setting as their “office,” hospitalists are often in leading administrative roles within hospitals and academic medical centers.

Teaching hospitals need to support residency programs; this need has catalyzed hospitalist growth in those settings. Driven by the need for increased educational oversight and Medicare billing requirements, academic medical centers have increasingly turned to hospitalists to staff resident teaching services. More recently, in an effort to prevent adverse outcomes related to overly tired trainees, in July 2003, the Residency Review Committee (RRC) began enforcing rules that prevent residents from working more than 80 hours in 1 week or for more than 30 hours in a single shift. Faced with increasing bed occupancy, increasingly complex patient populations, and the perception that the floats, hand-offs, and patchwork coverage solutions were adversely affecting patient care, academic medical centers looked for other options. Many chose to decompress the

**Growth of Hospital Medicine**

Hospitalists in North America

**FIGURE 17-1.** Growth of hospital medicine. Source: Society of Hospital Medicine.

numbers of patients seen on resident services to nonresident services, which are now commonly staffed by hospitalists.

As the hospitalist model of care has spread, the field has changed the way clinical problems are approached and managed. New research questions have been raised regarding the clinical approach to hospitalized patients, implementation of best practices, care transitions, and how to improve patient safety, again with potentially significant benefit to the medically complex and/or potentially vulnerable elderly patient. Representative research topics currently being explored by hospitalist investigators include identifying biomarkers predictive of perioperative outcomes, evaluating methods to prevent health care-associated infection, examining the utility of a variety of care processes for common inpatient diagnoses like pneumonia, studying the intersection between resident education and inpatient safety, and exploring techniques to improve quality during transitions of patient care.

Hospitalists are both ideally suited and situated to play a central role in improving quality and safety of the care of hospitalized elders. As a site-defined specialty, hospitalists spend more time in the hospital than do many other physicians, allowing them to gain insight into the problems commonly encountered in geriatric care and some potential solutions. By working closely with hospital personnel and administration, hospitalists can take the lead in the development and refinements of interdisciplinary teams designed to enhance the quality and safety of inpatient geriatric care.

### Acute Care of the Elderly Units

Acute Care of the Elderly (ACE) units were described and studied in community and academic settings in the mid-1990s. The ACE unit intervention consisted of environmental interventions (rugs, lighting, handrails), patient-centered care model that emphasized independence and rehabilitation from the beginning of the hospital stay, and a multidisciplinary care team consisting of nurses, physicians, therapists, social workers, and nutritionists and pharmacists providing coordinated care within a dedicated inpatient unit. Findings from the randomized controlled trial in 1995 found significantly improved functional status and decreased admission to nursing homes in patients randomized to the ACE unit interventions. Lengths of stay and hospital charges were similar in both groups. Recent retrospective studies have confirmed ACE unit benefits on function and quality of life, without increased hospital charges. Despite favorable results, ACE units are not widely disseminated in U.S. hospitals, largely due to the capital expenditures incurred in creation of such a unit, difficulty in recruiting the qualified specialist leaders, and future concerns with not having enough room for the rapidly expanding elderly patient population in such a space-defined unit. A review in 2003 surveyed hospitals associated with medical schools that had a geriatrics program and found that only 16 had ACE units. The number of community hospitals with ACE units is unknown. Some hospitals or academic medical centers have preferred to develop a virtual ACE team, rather than a dedicated ACE unit. The virtual ACE team is a multidisciplinary geriatrics consult team involving physician, nurse, social work, pharmacy and physical therapy that is designed to improve patients' hospital course and expedite discharge planning and transitional care. The virtual ACE team model provides the expertise and systems approach to the care of the elderly hospitalized population, particularly the vulnerable and medically complex outside the confines of a defined unit.

### Stroke Units

Stroke units use a care delivery model analogous to ACE unit models. A stroke unit is a multidisciplinary team specifically dedicated to the care of the stroke patient. Physicians, nurses, and therapists are involved in a coordinated effort to support the care and rehabilitation of stroke patients. The stroke unit maybe a dedicated hospital unit, a mobile team that manages patient along with the primary inpatient team, or may function within a rehabilitation unit. Stroke units were reviewed in a Cochrane report in 2001, which analyzed results from 23 randomized and quasirandomized trials and concluded that there was evidence that stroke units improved function at discharge, rates of discharge to home, and stroke survival. There was some evidence that dedicated stroke units had better outcomes. Whether there are aspects of poststroke care that can be generalized and systematized to improve elderly patient health care outcomes outside such a unit needs further investigation.

# Emergency Department Care

Scott T. Wilber ■ Lowell W. Gerson

The emergency department (ED) plays a unique and essential role in the care of the older adult. The ED is open 24 hours a day, seven days a week, 365 days a year. It provides access to the millions of people who have no other entry point for health care. It gives care to people who have no established community provider and acts as the gatekeeper between the community and the hospital.

The prevailing model of care in EDs has been established for over 40 years but does not conform well to the needs of the older adult. Based on principles proposed in 1962 by the Committee on Trauma of the American College of Surgeons (ACS), EDs are designed for rapid evaluation and treatment of the emergent and urgent needs of acutely ill and injured patients. ED care differs from care delivered in other settings. Typically, there is no preexisting relationship between the patient and the physician. The process rewards speed, the timeframe is immediate, and the focus is on the patient's complaint. It is not friendly to the older patient with complex needs who require thorough assessment and evaluation and whose care process is slow-moving.

In the 1990s, the Society for Academic Emergency Medicine (SAEM) Geriatric Task Force proposed a model of emergency care for older patients (Table 18-1). The model appreciates differences in disorders and diagnoses by age, atypical presentation of disease, altered physiology of aging, the complexity of diagnosis, and management of older patients, and the need to consider other issues beyond the presenting complaint. The Geriatric Task Force recognized that symptoms may be nonspecific, comorbidities are common, and response to therapy is often difficult to predict. The Task Force proposed a biopsychosocial model of emergency care for older patients. The model has evolved over time and reflects the current thinking about basic principles for emergency care of the older patient.

The ED plays a crucial role in care for seniors. Older people use the ED at higher rates than other populations, present more often with urgent and emergent conditions, and are more frequently transported by ambulance. In addition, the ED is a major care provider

for nursing home residents; one of four nursing home residents is transported to an ED yearly.

Emergency medicine has only recently identified the older population as a group with special needs, but interest in the area is growing exponentially. The first journal article to address the emergency care of elders was published in 1967 and concerned emergency surgery. There were 39 other articles cited for the years 1966 to 1970. From 2001 to 2005, there were 1267 entries, which represents over a 30-fold increase. A major contributor to the growth of geriatric emergency room (ER) medicine was a seminal series of articles in the *Annals of Emergency Medicine*. The articles emerged from a project to evaluate the care of elders in United States EDs, funded by the John A. Hartford Foundation and carried out by the SAEM Geriatric Emergency Medicine Task Force. The task force reviewed the literature and conducted surveys of emergency physicians and residency program directors, reviewed ER records, and held focus groups. The task force found that the evidence base for ED care of the older adult was small and that the discipline had failed to plan ED care to meet the needs of elders. Given the expected growth of the aging population in coming decades and the high volume of ED use among them, there was concern that emergency medicine training programs have no organized content on care for older ED patients and that there have been no organized advocates within either emergency medicine or geriatrics to spearhead change in emergency health care for seniors.

It cannot be known whether the SAEM reports stimulated action to address these concerns, or whether change was inevitable. Without question, the reports brought ED care for the older adult to the attention of leaders within emergency medicine and geriatrics. Today, the SAEM and the American College of Emergency Physicians (ACEP) are represented on a Council of Medical Specialties hosted by the American Geriatrics Society. Moreover, both SAEM and ACEP have developed working groups who focus on older emergency patients. Today, emergency medicine training programs include geriatric content and the qualifying examinations include questions directed at care of older patients.

**TABLE 18-1****Geriatric Emergency Care Model Developed by the SAEM Geriatrics Task Force**

- The patient's presentation is frequently complex.
- Common diseases may present atypically.
- Comorbid conditions must be considered.
- Polypharmacy is common and may be a factor in presentation, diagnosis, and management.
- Cognitive impairment is possible and mental status should be evaluated.
- Standard values for diagnostic tests may not be applicable.
- With age comes decreased functional reserve and this must be anticipated.
- Social support systems are important in care of older patients and should be considered in planning for care.
- Knowledge of baseline functional status is essential in evaluating new complaints.
- Medical problems must be evaluated for psychosocial adjustment.
- The encounter is an opportunity to assess important conditions in the patient's personal life.

**EPIDEMIOLOGY**

The aging of the U.S. population poses a challenge to health care delivery, as older patients consume a disproportionate share of health care resources. Emergency care is one area of heavy resource use by older patients. In 2004, approximately 14% of the 110 million ED visits were by patients aged 65 years and older. Compared to younger patients, older patients have higher levels of disease acuity and the probability of hospital admission from the ED is higher. In one study, 40% of older adults in the ED were admitted, compared to 10% of younger adults. Older adults were also more likely to be admitted to critical care units (4% vs. <1%), more likely to undergo laboratory and radiographic testing, and had longer ED lengths of stay.

Given the high rate of ED use by older adults and the projected growth of the older populations, ED use by older adults will increase further in the future (Figure 18-1). Assuming stable visit rates, the proportion of ED visits that are by older patients will increase to

**FIGURE 18-1.** Projected change in ED visits by older patients.

approximately 25% by the year 2030. In recent years, however, ED visit rates by older people have grown 26%, which is higher than any other segment of the population. Thus the combined effects of an aging population and increasing ED use rates could push the proportion of older adults in the ED even higher.

The presenting complaints of older patients differ from those of younger patients. The most common ED-presenting complaint for both older and younger patients is injury, though this complaint is even more common in younger patients (37%) than older patients (26%). Other common reasons for ED visits are shown in Figure 18-2 and include dyspnea, chest pain, and abdominal pain. The 10 chief complaints in Figure 18-2 comprise about two-thirds of all ED chief complaints for older patients.

**PATHOPHYSIOLOGY AND PRESENTATIONS**

In past years, the role of the emergency physician was primarily triage—determining which patients were ill and required further inpatient work-up and which were safe to be discharged. With the substantial increase in the quality and quantity of available diagnostic tests, this role has shifted. The primary role of the emergency

**FIGURE 18-2.** Common reasons for ED visits in older patients.

physician is now diagnosis. Most often, the correct diagnosis will be made in the ED. However, there are times when making the correct diagnosis is not possible and the focus is on ruling out serious disease. In many instances, emergency physicians also treat the disease they have diagnosed, though it is not uncommon for the patients to require treatment that exceeds the capability of the emergency physician. Given the high proportion of older patients who require hospital admission, the treatment of many older patients exceeds the care that can be provided in the ED.

ED use sometimes has negative connotations. Many physicians seem apologetic when referring a patient to the ED and an ED visit is sometimes even considered a type of adverse outcome in research. These negative connotations may be based on a faulty perception of the role of the ED in the care of older patients. Since the older patient has a higher probability of serious disease, the ED may provide the best place to accomplish diagnosis and treatment of potentially dangerous undifferentiated complaints with relative speed compared to traditional inpatient and outpatient settings.

Typical ED approaches to diagnosis may not work well with the older patient. Older patients may present with undifferentiated complaints that have a broad differential diagnosis encompassing numerous serious diseases. Common diseases may present atypically. Cognitive impairment may limit the ability to obtain an accurate history. Older patients may tend to minimize symptoms; attributing a symptom to a benign rather than a more serious condition. For example, an older ED patient may suggest that their chest pain is due to indigestion rather than heart attack or their abdominal pain is constipation rather than ischemic bowel. Typical presenting signs and symptoms may be absent, and diagnostic tests may be normal despite serious diseases. For these reasons, an extensive evaluation may be appropriate to sort out the complexities of the situation. While commonly considered a sign of poor judgment and derogatively described as “shotgunning,” with the complex older patient, extensive evaluation may be the most thoughtful approach.

Acute cardiac ischemia may be especially difficult to diagnose in the older patient. In the younger-old (e.g., 65–85 years), the majority of patients have chest pain, although atypical presentations can occur. After age 85 years, atypical presentations of cardiac ischemia outnumber typical ones by a 2:1 margin. Common atypical presentations include altered mental status, abdominal pain, dyspnea, and arrhythmia. In fact, acute delirium or change in level of consciousness (stupor or coma) can sometimes be the single presenting symptom of what turns out to be acute cardiac ischemia. Conversely, altered mental status is only rarely due to acute cardiac ischemia; it is the cause of record in only 1% of patients who present to the ED with acute mental status changes.

Abdominal pain in the older adult also presents challenges in the ED. For example, among older patients with acute cholecystitis, most do not have epigastric or right upper quadrant pain, and 5% do not have any pain at all. Over half will be afebrile, and nearly half will have a normal white blood cell count. Only one in five older patients with appendicitis present classically, less than half have an elevated temperature, and a quarter have atypical tenderness on examination that is either diffuse or localized to an area other than the right lower quadrant. In contrast to younger patients with abdominal pain, lack of abnormal laboratory studies or a normal body temperature in an older patient would not help rule out the need for surgical intervention. The nonspecific presentation of serious abdominal disease in the older adults has led to increased reliance on the use of computed

tomography, which has a much higher sensitivity and specificity than the clinical examination in the evaluation of the older patient with abdominal pain.

## EVALUATION

The Geriatric Emergency Care Model (Table 18-1) outlines an approach to older ED patients that differs from the approach to younger patients. In addition to assessing the chief complaint, the care model encourages routine assessment of cognitive and functional status.

Older patients who present to the ED may have cognitive impairment. This impairment may limit the reliability of the medical history and reduce their understanding of and compliance with discharge instructions. Cognitive impairment may be previously diagnosed or unrecognized. Delirium is an important cause of cognitive impairment in older ED patients. About 10% of older ED patients have delirium, but is recognized as delirium in only one-third of cases. The failure to diagnose delirium in ED patients can increase mortality two- to threefold. Screening instruments for cognitive impairment that are useful in other settings may be of limited use in the ED. The Mini-Mental Status Examination, for instance, takes up to 15 minutes to complete in ED patients and some tasks, such as writing, can be limited in patients with extremity injuries or IVs. These limitations make its use impractical for emergency physicians who must therefore use brief, sensitive tests to assess for cognitive dysfunction, leaving more in-depth assessment to primary care physicians and consultants. Examples of brief tests include the Orientation Memory Concentration Test, the Six-Item Screener, and the Clock Drawing Test.

Functional status and the potential for functional decline after discharge are critical but rarely addressed issues in the ED. Factors that contribute to post-ED functional decline are listed in Table 18-2. People with subacute or chronic illnesses often visit the ED at a point where the illness has developed a significant impact on function, especially the ability to transfer and walk. Injuries can produce functional impairment either from the injury itself or from the treatments such as splints and slings. Patients whose basic activities of daily living are affected by their illness or injury require further evaluation or admission to the hospital, even if the treatment of the illness or injury would not require hospitalization. In the ED of the authors, mobility is assessed in older patients with a “Get Up and Go” test (assessing the ability to transfer and ambulate) with or without a walker as appropriate. Those who are unable to adequately

**TABLE 18-2**

### Factors Associated with Post-ED Functional Decline and Adverse Outcomes

- Cognitive impairment
- ADL/IADL impairment (walking, transferring, transportation)
- Requires assistance from caregivers or home nurses
- Recent (30-day) ED use
- Recent (3–6 month) hospitalization
- Multiple medications (>3–5 meds)
- Lives alone, no caregiver
- Visual problems
- ED nursing recommendation

complete the test should not be discharged home from the ED without intensive home support. If such support cannot be assured, it is essential to explore alternatives to discharge, such as hospitalization or admission to a skilled nursing facility.

## MANAGEMENT

### Medication

There are multiple aspects of geriatric pharmacotherapy that are important in the ED. Elders use more prescription and over-the-counter drugs than any other age group. They consume a third of all prescription medications and half of the over-the-counter preparations. Adverse drug events including drug–drug interactions and adverse drug reactions are thought to account for more than 10% of ED visits and a quarter of hospital admissions for older patients.

Many patients receive new prescriptions when they are discharged from the ED. New medications can precipitate problems, such as unanticipated interactions with ongoing medications. The emergency physician may be unaware of the potential interactions or may not have complete information about ongoing medications. Only about 40% of community-dwelling older ED patients can either correctly identify their prescription medications or provide a written list. A third of the lists that are brought to the ED are not accurate.

Inappropriate prescribing can occur in the ED. Using the Beers criteria to identify potentially inappropriate prescriptions, about 4% of ED prescriptions are considered inappropriate. The Beers criteria have not been validated for use in the ED setting and it is possible that short-term use of selected medications deemed inappropriate in the Beers criteria would be acceptable, so 4% may be an overestimate. Inappropriate prescribing is a correctable problem and system changes, like placing a pharmacist in the ED or using warnings as a part of computerized prescription order entry might help minimize these problems.

### Processes and Environment

Older adults are generally satisfied with ED care but are able to identify many areas for improvement. The majority of older patients express satisfaction with the quality of medical care they receive in the ED. They say that their medical problems were handled well and that they had no problems as a result of their care. On the other hand, older adults can identify concerns about the ED process. ED process concerns include long waits, lack of communication with staff and feeling abandoned, difficulty in arranging transportation home when discharged, and the billing processes. Feelings of anxiety are common because patients come to the ED with a suspected serious or life-threatening condition and are frightened by the prospects of care. Anxiety can be reduced by ED personnel who can help by providing updates about the condition, the proposed ED care, and plans for care after ED discharge. The ED environment is another area of concern to both patients and providers. ED patients note that the ED is too cold, there are not enough blankets, the gurneys are uncomfortable, especially for prolonged periods, pillows are not available, and the ED is noisy with disconcerting sights and sounds. ED professionals add that floors can be slippery and in-

crease risk of falls. The physical design of the ED limits interaction with staff; signage is confusing and lighting is harsh. There is often no source of external light. The ED environment is obviously not elder-friendly.

There is a movement to modify EDs along the lines developed by Acute Care of the Elderly (ACE units) (see Chapter 17 on ACE units). Some leaders in geriatric emergency medicine are considering ways of “ACE-ifying” the ED, and some even have suggested the development of geriatric-specific EDs, similar to pediatric EDs. One hospital demonstration project has created an emergency care unit staffed by geriatricians. The concept of the “ACE-ified” ED is consistent with the Geriatric Emergency Care Model proposed by the SAEM Task Force.

Teamwork is crucial for optimum emergency care of older patients. EDs can provide access to team members who can help with elder care, such as geriatric nurse practitioners, social workers, pharmacists, and physical therapists. These team members are especially valuable for communication, coordination of care, and discharge planning. Nonprofessional or volunteer staff can help improve the patient’s comfort by responding to requests for blankets, temperature control, and information.

Changes to the ED environment may also improve care to older patients. The hard gurneys used in EDs are helpful for patient transportation but can be painful for patients. Reclining chairs like those used for dialysis can reduce pain and increase satisfaction for older patients. Other potential changes include sound-proof curtains between beds, nonskid surfaces on floors, rails on walls, large print signage, and large-faced clocks. Since older patients can arrive at the ED without eyeglasses and hearing aids, the ED could have a standing supply of necessary items for sensory problems. A supply of magnifiers, reading glasses, and electronic sound amplifiers can promote communication and make the older patient feel more comfortable. The revolution in computerized medical records afforded by modern information technology (IT) holds great promise for improving the ED care of older patients. Reliable medical records could reduce the time needed to obtain the medical history. Medical errors might be reduced since important information would be automatically downloaded at ED registration. Important information to be accessed should include past medical history, current diseases, recent imaging and laboratory studies, last known medications, allergies, dates of recent admissions, social history, and baseline cognitive and functional status.

## PREVENTION

### Accessing Vulnerable Populations

As noted above, the ED provides a safety net for underserved, vulnerable patients who lack access to routine care in the community. For this reason, there has been an interest in using the ED to provide preventive care. In 2000, SAEM’s Public Health Task Force published a systematic review of the preventive activities recommended by the U.S. Preventive Services Task Force (USPTF) to assess their potential for ED use. Seventeen topics were reviewed, of which two (falls prevention and pneumococcal vaccination) were specific to older patients. Pneumococcal vaccination programs were recommended

and the task force reported that falls prevention programs showed promise and should be further evaluated.

ED-based pneumococcal vaccination programs have been evaluated. They do not affect patient's length of stay, and require only about 4 minutes of staff time. The SAEM Task Force did not consider influenza immunization for older ED patients as part of their review. However, studies have shown that offering influenza vaccine to older ED patients may be an effective approach to reducing influenza morbidity and mortality and also reduce ED crowding during the flu season.

Nearly 2 million people older than 65 years are treated in the ED for a fall each year. Falls prevention activities recommended by the USPTF include exercise (particularly training to improve balance), safety-related skills and behaviors, and environmental hazard reduction, monitoring and adjusting medications, visual acuity testing, hormone replacement therapy, screening for dementia and osteoporosis, and postfall assessment and intervention. Given time constraints and the difficulty in evaluating acutely ill patients, most of these activities are unlikely to be conducted in the ED. However, the ED can educate older patients about falls and provide information and referral to reduce their risk of falling again. The ED visit might be a unique "teachable moment" for patients who have come to the ED because of falls. Patients who have fallen or are increased risk for falls may also be referred for geriatric assessment or falls prevention evaluation. While these activities have been recommended, it should be emphasized that there are few tests of effectiveness of these promising activities.

### Prevention of Post-ED Decline

Elder ED visitors are susceptible to suffering health declines following an ED visit. Between 20% and 50% of older persons experience a significant deterioration in function after an ED visit. The vulnerability to decline in functional status after an ED visit is most likely due to a combination of chronic health conditions, acute illness or injury, coexisting medical and psychiatric problems, lack of social support, and iatrogenic issues such as medication errors. Factors associated with post-ED functional decline are listed in [Table 18-2](#).

Regardless of the reasons for the decline, the ED would be ideal for community surveillance for elders at risk for functional decline who could benefit from multidisciplinary, community-based care management programs. But results of studies in different countries and using different approaches have shown mixed results. One problem is that available ED-based screening instruments have a low specificity and thus find too many cases, resulting in a referral rate that overwhelms community services. Successful programs share three features: identifying patients most likely to benefit, clinical control of care, and long-term follow-up.

There are barriers to providing preventive care in the ED. Those who work in an ED have conflicting priorities and a different approach to patients compared to providers in geriatric inpatient or outpatient settings. While emergency physicians realize that older patients frequently have unique needs and complex clinical presentations, they are pressed by time and the need to prioritize to focus on the presenting complaint and the need to rule out emergent conditions. Linkages between ED and geriatric outpatient units may help reduce barriers to preventive care for older ED patients. These

patients could be screened in the ED for suitability for a community program. Those who are suspected of being at high risk could be referred. This approach has been used with fall prevention programs and in the care management programs noted above.

While not always anticipated, the patients themselves may present barriers to referral to community agencies. Older ED patients are frequently unwilling to participate in community services. The authors attempted to link patients in their ED with a multidisciplinary Medicaid Waiver Program of the local Area Agency on Aging. The ED used the Agency's screening instrument to identify at risk patients who were being discharged home. While many patients screened positive, few were willing to have the home-based assessment. It is possible that EDs with onsite geriatric nurses, care managers, or social workers could perform more focused screening. They might also help educate ED patients to encourage participation in the community agency programs and be directly involved in scheduling appointments.

## SPECIAL ISSUES

### Emergency Medical Services

Emergency Medical Services (EMS) use for older patients ranges between 100 and 167 per 1000 older adults per year. This rate exceeds that for other age groups and has important implications for EMS operations. As with emergency medicine and other areas in general, the EMS community has been slow to modify equipment, training, and procedures to reflect the needs of older adult patients. EMS administrators, government officials, and public health leaders must plan for an increased volume of EMS patients.

In the United States, EMS is generally provided by local communities and overseen by the state. However, the National Highway Traffic Safety Administration (NHTSA) created standard curricula, which have been adopted by many states. There are several levels of training for EMS providers. In the National Standard Curriculum for lower level providers (First Responders and EMT-basic), there is a specific focus on children (who represent 4% of EMS patients), but no similar focus on older persons (who represent one-third of EMS patients). The curricula for higher level providers (EMT-intermediate or EMT-paramedic) do have a specific focus on geriatrics. The curriculum for EMT-paramedic training includes comprehensive sections on physiology across the life span and geriatrics. Overall, this dedicated geriatrics training represents about 1% of the 1000- to 1200-hour curriculum.

The American Geriatrics Society (AGS) and the National Council of State EMS Training Coordinators recognized the deficiency in geriatric training for EMTs and created a coalition of 13 national organizations, which developed a continuing education course, Geriatrics Education for EMS (GEMS). Future cooperation between the EMS community and geriatric professionals is essential to ensure that their training is appropriate and adequate.

EMS equipment and protocols must be adapted to the older patient. For instance, the standard approach to patients with potential neck injuries is to place them in a rigid cervical collar and a backboard with head immobilizing blocks. This approach may be difficult or impossible in older patients with kyphoscoliosis. Immobilization for

prolonged periods can also lead to skin breakdown. An alternative is the use of long vacuum splints that can immobilize patients with kyphoscoliosis in a more comfortable position.

Providers of prehospital care have a rare opportunity among healthcare providers—the ability to assess patients in their homes during their acute illness. Programs have been developed to use EMTs to screen older adults for social issues including abuse and neglect and to assess the home environment. EMTs are trained to identify potential problems, refer at-risk patients to the appropriate agencies for assessment and link the patient to community services. Evaluations of such programs have found a benefit to individual patients.

## Geriatricians and the ED

There are not enough geriatricians for the present population and prospects for reducing this shortfall seem unlikely. Other specialists must develop sufficient geriatric expertise to attend to the special needs of the older patient. There is increasing growth in the number of emergency physicians who identify with geriatric emergency medicine. Part of this growth is a result of the AGSs' initiative to increase geriatric expertise among surgical and related medical specialists. Emergency Medicine has been an active participant in this project from its outset. The project's initial efforts were directed at increasing the geriatric content of residency education and the improving the quantity and quality of research. This project, a collaboration between specialty societies developed a cadre of young leaders and improved the outlook for geriatric expertise in the surgical specialties, especially in emergency medicine.

Geriatricians can actively participate in increasing expertise among emergency physicians. They can contribute to the educational program for emergency physicians in training and in continuing education for board certified physicians. Geriatricians can participate in rounds and can give didactic material to those in training. The future of continuing education is likely to be in computer-based interactive educational modules. Geriatricians can participate in the development of these modules.

Geriatricians and advance practice nurses have been active and important consultants to emergency physicians. Emergency physicians appreciate the difficulty in diagnosis and management of older patients. A cooperative geriatric consulting service is of benefit to both the geriatrician and the emergency physician. Emergency physicians are responsive to service programs that will improve outcomes for their patients. Increasing interest in geriatric emergency care makes emergency physicians particularly amenable to programs that improve outcomes for older patients. Having a relationship of mutual respect further fosters willingness to cooperate. Geriatricians with an idea for a program that links the ED with a service, e.g., a fall prevention or geriatric assessment, will find an ally if they wish to develop that program. Similarly, geriatricians should accept overtures from emergency physicians with ideas.

## The Emergency Department's Relationship with Long-Term Care

Nearly a quarter of nursing home residents are transported at least once each year to the ED. Compared to community dwelling older adults, nursing home residents tend to present to the ED with less information and are more likely to have a nonspecific chief com-

plaint. Thus they are most likely to require special adaptation in ED care. Two-thirds of nursing home residents who present to the ED are cognitively impaired and cannot provide a clear medical history. Often, families are not immediately available or are unaware of recent changes in the patient's condition. For this reason, communication between the nursing home and ED is crucial. However, 10% of nursing home residents are transported to the ED without *any* written documentation and important patient information often is missing in the 90% who arrive with paperwork. If baseline cognitive and functional status is not reported, it is impossible to determine if changes have occurred. The ED is also often a poor communicator when older patients are discharged back to the nursing home. Nursing home personnel report that residents often return from the ED without notification, written documentation, or recommendations for care.

Nursing home to ED and ED to nursing home transfers are a frequent and important type of transition in care. Poor communication during these transitions increases the cost of care, leads to greater use of health care services, and jeopardizes the patient's safety. The interaction between nursing homes and EDs is one area where geriatricians, nursing home personnel, and emergency physicians can interact to improve the care of the older patient.

## Alternatives to Hospitalization

The ED is a gatekeeper between the community and the hospital. The decision to admit a patient to the hospital or to discharge a patient is made in the ED. As noted above, this difficult decision must take into account medical, functional, and social issues. There are several potential alternatives to hospitalization following an ED evaluation. One is the "Hospital at Home" concept. "Hospital at Home" programs have been evaluated for a variety of medical conditions including pneumonia, congestive heart failure (CHF), cellulitis, and chronic obstructive pulmonary disease (COPD). These programs have demonstrated improved satisfaction, lower rates of depression, and lower rates of nursing home admissions, without a difference in functional status or mortality. Another alternative is direct ED admission to skilled nursing facilities. Currently, Medicare requires a three-day inpatient hospital stay to qualify for Medicare skilled nursing facility coverage. Thus a Medicare patient can only be covered for a direct admission from the ED to a nursing home if they have had a qualifying hospital stay in the prior 30 days. For patients with private insurance or who belong to a Medicare health maintenance organization (HMO), the requirement for prior hospitalization may not be applicable. The requirement for prior hospitalization was created decades ago, prior to the many changes in inpatient, ED, and skilled nursing facility care. A change in this rule might lead to improved transitions and more efficient use of health care.

Cooperation between emergency physicians, primary care physicians, and geriatricians is essential to create successful alternatives to hospitalization. Guidelines could help match care settings with appropriate subsets of acutely ill older adults and treatment protocols to ensure patient and caregiver satisfaction, cost-effectiveness, low mortality, and good functional outcomes.

## Disaster Planning

Older people are at increased risk and have unique needs in natural and human-made disasters. However, they often are not recognized

as a vulnerable group during disaster planning and response. Recent disasters demonstrate their vulnerability. In the 2004 Indian Ocean tsunami, there were more deaths in people older than 60 years than in any other age group. Nearly half of those who died in hurricane Katrina, were 75 years or older and 70% were older than 60 years. Even power outages can be a significant problem for elderly who need oxygen, nebulizers, or who depend on motorized wheelchairs or other electric devices.

Elders, especially those with disabilities or chronic medical conditions, do not have the functional reserve to respond to a disaster. Social isolation, impaired mobility, economic constraints, functional dependence, and the need for specialized medical treatments such as dialysis affect the ability of older persons to cope with disasters. Geriatric specialists can help those involved in disaster planning and response understand the unique needs of the older population.

Standard disaster shelters often are unable to accommodate elders who are not functionally independent. Special needs shelters can be created to help care for chronically ill or functionally impaired patients, though these shelters may require patients to be accompanied by a caregiver. Special needs patients often present to hospital EDs during a disaster, even without acute medical emergencies, because their needs cannot be met elsewhere. Unfortunately, they may spend considerable time in the ED or require hospitalization if no other location for care is identified. Since both EDs and hospitals may be functioning at or beyond capacity during a disaster, these limited resources are strained by the nonmedical demands of these special needs patients, and more appropriate settings are preferable for both the patient and the system.

## CONCLUSIONS

The art and science of care for older ED patients is in its infancy. We only now are beginning to understand the complexities in caring for the growing number of older persons. The anticipated growth of older population makes it imperative that we increase the number of

health care professionals with expertise in caring for older patients in the ED and that we develop systems of care that are elder friendly. This requires the cooperation of researchers, educators and clinicians to improve outcomes for our older patients.

# Critical Care

*Eric B. Milbrandt ■ Derek C. Angus*

One in five Americans dies in the intensive care unit (ICU) or shortly after an ICU stay. Regardless of the precise age threshold used to define “elderly,” it is clear that a sizeable proportion of ICU patients are older adults. In the United States, those aged 65 years or older constitute nearly 50% of ICU admissions, a percentage which will grow considerably with the aging of the population. While the proportion of elderly ICU patients maybe higher in the United States than in other countries, most developed countries have seen substantial ICU use by patients older than age of 65 years. Importantly, most studies support that age alone is not an independent predictor of outcome in the ICU and that age should not be used as a criterion for determining which patients can “benefit” from intensive care. Rather, the key issue is the reversibility of the acute illness in the context of the overall health of the patient.

As a group, the elderly present with a unique set of challenges and opportunities for critical care providers. Many of these are well-defined and known, while others are poorly defined and relatively understudied. In this chapter, we briefly review some of the physiologic changes associated with aging and their implications for intensive care. We discuss some of the common admitting diagnoses and associated conditions seen in elderly patients and present data about outcomes of intensive care in the aged. We then explore interventions that may improve outcomes of intensive care, not only for patients, but for their loved ones as well.

## AGE-RELATED CHANGES IN PHYSIOLOGY

Much has been written about the physiology of aging and the reader may refer to the Chapters in Part IV on organ systems for more detail for a thorough review of the topic. Rather than duplicate what has already been written, we focus on some of the key physiologic changes associated with aging and their implications for intensive care. These changes can be summarized as a gradual decline in organ

function and physiologic reserve with an increased prevalence of chronic disease and vulnerability to disease.

The aging cardiovascular system can affect critical illness in two ways. The first is through increased prevalence of cardiovascular disease, which may be the primary reason for presenting to the ICU or a complicating factor when a patient with a noncardiovascular admitting diagnosis subsequently develops acute cardiovascular illness, such as cardiac ischemia. The second way cardiovascular disease can affect critical illness is through decreased cardiac reserve. Though this decrease may not be sufficient to alter daily activities in otherwise healthy subjects, the acute “stress test” of critical illness is often sufficient to make it manifest.

Maximal heart rate, ejection fraction, and cardiac output decrease with age, as does the responsiveness to sympathetic stimulation. The aging heart is therefore somewhat limited in its ability to increase cardiac output in response to stress, relying primarily on increased filling and stroke volume, rather than increased heart rate. This leads to greater preload dependency and amplifies the cardiac output compromising effects of hypovolemia. However, because of age-related stiffening of the ventricles, diastolic dysfunction also becomes common, increasing the risk of pulmonary edema with overly aggressive fluid resuscitation. Ventricular stiffening results in an increased reliance on “atrial kick” for diastolic filling and poor tolerance of atrial fibrillation. Taken together, these changes mandate careful attention to volume status and control of atrial arrhythmias.

Pulmonary function gradually declines with age due to changes in the lung and chest wall. Vital capacity, or the maximum amount of air that can be exhaled after a maximum inhalation, decreases, as does the speed with which it can be exhaled. Because of ventilation–perfusion mismatching and increased airway closure, the oxygen content of arterial blood decreases with a resultant widening the alveolar-to-arterial oxygen gradient. In other words, less of the oxygen that is delivered to the lung is taken up by the body. The sum of these changes leaves elderly subjects less able to respond to the increase respiratory requirements of critical illness even in the

absence of overt respiratory pathology, such as chronic obstructive pulmonary disease.

There is a significant decline in renal function with aging, including decreased renal blood flow, glomerular filtration rate (GFR), and creatinine clearance (CrCl). Urine concentrating and diluting ability also decrease, leaving the elderly patient less prepared to deal with electrolyte and volume status changes. Elimination of renally excreted drugs decreases in parallel with GFR. Approximations of GFR, such as CrCl, should therefore be used to adjust the dosage of these medications. A variety of equations can be used to estimate CrCl, with the Cockcroft and Gault equation most commonly utilized:

$$\begin{aligned} \text{CrCl} &= \text{creatinine clearance} \\ &= \frac{[(140 - \text{age}) \times \text{IBW} (\times 0.85 \text{ for females})]}{(\text{Scr} \times 72)} \end{aligned}$$

In this equation, Scr is serum creatinine and IBW the ideal body weight. For males,  $\text{IBW} = 50 \text{ kg} + 2.3 \text{ kg}$  for each inch over 5 feet; for females,  $\text{IBW} = 45.5 \text{ kg} + 2.3 \text{ kg}$  for each inch over 5 feet.

Age-related changes in hepatic metabolism are much more difficult to predict. Unlike renal function, there is no measure to assess hepatic metabolism. Put simply, hepatic elimination of drugs is either reduced or unaltered. Host factors, such as blood flow, concurrent drug use, nutritional status, gender, disease states, and genetic differences in enzymatic activity, result in considerable metabolic variability from patient to patient. In the setting of known hepatic insufficiency, such as cirrhosis, clinicians should either avoid or reduce the dosage of hepatically eliminated drugs. In such patients, clinicians should also be on the watch for coagulation abnormalities and hypoalbuminemia, the latter of which may require reduced dosing for drugs that are highly albumin bound.

Aging is associated with significant changes in immune function that may have important implications for elderly ICU patients. The term “immunosenescence” has been used to describe these changes, which include unresponsiveness, hyporesponsiveness, or aberrant responsiveness to tissue damage and/or infection. With advancing age, T and B lymphocyte compartments of the immune system deteriorate progressively while the respiratory burst of macrophages and neutrophils becomes impaired rendering them less able to destroy bacteria. This leaves the elderly less responsive to vaccinations and more prone to developing invasive bacterial infections, whether community- or hospital-acquired. Furthermore, aging brings an imbalance of pro- and anti-inflammatory cytokines, leading to either inadequate or overabundant response when the system is challenged. As such, older subjects may not be able to adequately activate the immune system or stop it once it is started. Whether these cytokine imbalances make the elderly ICU patient more likely to develop cytokine-mediated organ dysfunction in the setting of tissue damage or infection is not known, though it seems likely.

In addition to organ system changes, aging brings about a gradual decrease in lean body mass and total body water with an increase in body fat. These body composition changes lead to changes in volume of distribution for many drugs. Fat soluble drugs, such as the sedative propofol, may have an increased volume of distribution, with fatty tissues serving as a slowly clearing drug reservoir once the medication is stopped. Water-soluble drugs, on the other hand, may have a decreased volume of distribution, with a potential need for loading dose reductions. For an excellent review of pharmacokinetics

in the elderly, the reader is referred to Mayersohn. Changes in body composition and physical activity also lead to a decrease in resting energy expenditure. Even so, risk of protein-calorie malnutrition increases, especially during acute illness, highlighting the importance of early nutritional support.

## COMMON ADMITTING DIAGNOSES

Table 19-1 lists some of the more common ICU admitting diagnoses seen in the elderly, many of which represent exacerbations of chronic conditions or diseases to which the elderly are particularly vulnerable. Rather than focusing on management principles of each disease, which are well covered in just about any critical care text, we review two quintessential diseases of the elderly, community-acquired pneumonia (CAP) and severe sepsis.

Pneumonia is often called the old man’s friend because, as pointed out by Sir William Osler more than 100 years ago, pneumonia is a frequent, nonpainful, lethal event in elderly patients. Since Osler’s time, there have been considerable advances in the management of pneumonia, not the least of which is the discovery of antibiotics. Nevertheless, CAP remains common and is still one of the leading causes of hospital admission and death throughout the world. In an analysis of 150 000 elderly Medicare recipients hospitalized with CAP in the first quarter of 1997, Kaplan and colleagues found that almost half of all elderly patients admitted for CAP die in the subsequent year, with most deaths occurring after hospital discharge. One of three elderly patients who survived hospitalization for CAP died in the year following hospital discharge. Their data confirm Osler’s notion and show that even today, with many preventive and therapeutic measures, there is a high risk of death in elderly patients discharged from the hospital after an episode of CAP. These data have important implications for patient prognostication, family counseling, and medical decision making, such as whether to continue life support and aggressive medical care. They also highlight the fact that hospital mortality is not an appropriate outcome measure for studies in elderly patients with CAP, since beneficial or detrimental aspects of interventions may not manifest within this time frame. Given the overall poor prognosis that CAP portends for the elderly, preventive measures, such as pneumococcal and influenza vaccination and smoking and alcohol cessation, will remain key.

**TABLE 19-1**

### Common ICU Admitting Diagnoses in the Elderly

<i>Acute respiratory failure due to</i>	<i>Kidney or urinary tract infection</i>
• Pneumonia	<i>Gastrointestinal hemorrhage</i>
• Congestive heart failure	<i>Nutritional and metabolic disorders</i>
• Chronic obstructive pulmonary disease	• Uncontrolled diabetes mellitus
<i>Cardiovascular conditions</i>	<i>Severe sepsis</i>
• Myocardial infarction/unstable angina	<i>Postoperative states</i>
• Arrhythmias and conduction disorders	• Coronary artery bypass
<i>Falls and fractures</i>	• Cardiac catheterization/percutaneous intervention
<i>Stroke or transient ischemic attacks</i>	• Hip replacement or fracture repair
	• Major bowel procedures

Severe sepsis is a common, expensive, and frequently fatal condition, with as many deaths annually as those from acute myocardial infarction. It is especially common in the elderly and is likely to increase substantially as the U.S. population ages. Angus and colleagues examined the incidence, cost, and outcome of severe sepsis in the 1995 hospital discharge records from seven large states. The authors found that the incidence of severe sepsis increased >100-fold with age (0.2/1000 in children to 26.2/1000 in those >85 years old). The most commonly identified sites of infection were respiratory, genitourinary, abdominal, and wound/soft tissue. Mortality was 28.6%, or 215 000 deaths nationally, and also increased with age, from 10% in children to 38.4% in those >85 years old. Women had lower age-specific incidence and mortality, but the difference in mortality was explained by differences in underlying disease and site of infection. Average costs per case were \$22 100, with annual total costs of \$16.7 billion nationally. Incidence was projected to increase by 1.5% per annum.

The observation that sepsis is a disease of the elderly mandates consideration of the appropriateness of care, including determination of patient preferences. Data suggest that there are already differences in the aggressiveness of treatment in the very old, with lower length of stay, ICU use, and hospital costs in those aged >85 years. Yet, aggressive care is not necessarily futile in the elderly, and the majority of elderly septic patients survive to hospital discharge. Unfortunately, there are limited data on postdischarge survival or quality of life after sepsis in the elderly. Such information will be crucial in determining optimal healthcare policy as the U.S. population ages and the number of cases of sepsis increases.

## ASSOCIATED CONDITIONS THAT MAY COMPLICATE ICU CARE

In addition to age-related changes in physiology, there are a number of associated conditions that may complicate the care and management of critically ill elderly patients (Table 19-2). Atypical presentations of common medical conditions, such as myocardial infarction and CAP, are common in the elderly, which may lead to delayed or incorrect diagnoses and which mandate broad initial differential diagnosis lists. Anemia may be preexisting or a consequence of critical illness. Current guidelines recommend restricting red blood cell transfusion to those patients with hemoglobin values of  $\leq 7$  g/dL, as long as active bleeding or ischemia is not present. Drug-resistant organisms are increasingly encountered, especially in nursing home residents or those who are frequently hospitalized. While it is

important to avoid antibiotic overuse, careful attention to risk factors and local resistance patterns should guide antibiotic selection.

The proportion of elderly patients who are undernourished is high and undernutrition has serious health implications in the ICU, including immune dysfunction, poor wound healing, and increased mortality risk. Dysphagia, poor dentition, swallowing disorders, and constipation not only put patients at risk of aspiration, but may also significantly impair nutritional support measures. Polypharmacy is widespread, increasing the likelihood of drug interactions and life-threatening side-effects. Medication lists should therefore be “trimmed” regularly and reconciled with each care setting transition.

Pressure sores may be a reason for admission, such as when they are a source of infection, or a complication of care, especially if skin care is not meticulously addressed. Skin integrity can be further compromised by urinary or bowel incontinence, though collecting devices, such as urinary catheters, may exacerbate other conditions, such as delirium. Vision and hearing difficulties are frequent and efforts should be made to avoid sensory deprivation due to misplaced glasses or hearing aids. Alcoholism is present in around 10% of ICU patients and even more common in certain patient populations, such as those admitted for trauma. Early recognition of alcohol abuse and dependence is essential and should prompt consideration of several alcohol-specific diagnoses that have important prognostic and therapeutic implications, including alcohol withdrawal, cardiomyopathy, arrhythmias, and electrolyte disorders.

## DEMENTIA AND DELIRIUM

Two associated conditions, dementia and delirium, require special consideration. There are currently 2.2 million Americans living with dementia. Projections suggest that this number will grow to greater than 10 million by 2040 due to the aging of the population and increasing life expectancy among those affected. Although there are no data to support it, there is a prevailing notion in the medical community that patients with dementia have worse outcomes from intensive care than those without dementia. This has led some to suggest that the use of critical care services be restricted for demented patients.

Challenging this notion is a study by Pisani and colleagues that examined short-term outcomes in medical ICU patients with ( $n = 66$ ) or without dementia ( $n = 329$ ). Despite the fact that patients with dementia were older, slightly sicker, and more likely to have a do-not-resuscitate/do-not-intubate order on admission, there were no differences in outcomes between demented and nondemented patients. In fact, ICU and hospital mortality rates were actually lower in patients with dementia, although these differences were not statistically significant. Not surprisingly, patients with dementia were more likely to have their code status changed to less aggressive care. Yet, overall aggressiveness of ICU care, as measured by the use of ICU interventions, was not different between groups. The authors concluded that presumptions of less favorable outcomes of critical care in patients with dementia should not drive treatment decisions in the ICU, with the possible exception of code status determinations.

The findings of Pisani and colleagues raise some interesting ethical challenges. Most critically, how does one elicit preferences for aggressive care from patients with dementia, given that they may or may not have clearly articulated their preferences before cognitive

**TABLE 19-2**

### Associated Conditions that may Complicate Care of Elderly ICU Patients

Atypical presentations of common medical conditions	Polypharmacy
Anemia	Pressure sores
Drug resistant organisms	Urinary or bowel incontinence
Malnutrition/undernutrition	Vision and hearing difficulties
Dysphagia/swallowing disorders	Alcoholism
Constipation	Dementia
Poor dentition	Delirium

impairment became too severe? Furthermore, with less than half of dementia cases being recognized by bedside physicians in the Pisani study, one can envision scenarios where decision-making ability is presumed, yet not present. How can we try to help this process along, and what is the role of the intensivist? A good place to start might be to engage in ICU exit interviews to help families think about what they would do the next time their loved one becomes ill. Better yet would be to get patients better oriented to their potential future and more involved in advanced decision making well before dementia has become too advanced and the window of opportunity has closed.

Delirium is a form of acute cognitive dysfunction that manifests as a fluctuating change in mental status, with inattention and altered level of consciousness. Delirium is very common in the ICU, occurring in as many as 80% of mechanically ventilated ICU patients. Many clinicians consider ICU delirium to be expected, iatrogenic, and without consequence. However, recent data associate delirium with increased duration of mechanical ventilation and ICU stay, worse 6-month mortality, and higher costs. Although there are clearly defined risk factors for delirium, there is little understanding of the underlying pathophysiology. The precise mechanisms are unknown and there are likely to be multiple mechanisms at work in any given patient (Table 19-3). For an in-depth review of potential mechanisms, the reader is referred to Milbrandt and Angus.

Attending to modifiable risk factors is a central tenet of delirium prevention. Areas to consider include: avoiding polypharmacy; minimizing the use of anticholinergics and sedatives while appropriately treating pain; promoting good sleep hygiene by establishing a sleep-wake cycle and avoiding noise and light pollution; preventing sensory deprivation by ensuring use of glasses and hearing aides; and frequent orientation. In the hospital wards, Inouye and colleagues found an intervention that consisted of standardized protocols for the management of six risk factors for delirium (cognitive impairment, sleep deprivation, immobility, visual impairment, hearing impairment, and dehydration) significantly reduced the number and

duration of delirium episodes in hospitalized older patients. To date, no such trial has been conducted in the ICU.

When nonpharmacologic measures fail to prevent or remedy ICU delirium, national guidelines recommend treatment with antipsychotics. Haloperidol has been used for many years to manage agitation in mechanically ventilated ICU patients, and it is the recommended drug for treatment of ICU delirium. Kalisvaart and colleagues compared the effect of haloperidol prophylaxis (1.5 mg/day preoperatively and up to 3 days postoperatively) with that of placebo in 430 elderly hip surgery patients at risk for delirium. Although there was no difference in the incidence of postoperative delirium between treatment and control groups, those in the haloperidol group had significantly reduced severity and duration of delirium (5.4 days vs. 11.8 days;  $P < 0.001$ ). Haloperidol also appeared to reduce the length of hospital stay among those who developed delirium (17.1 days vs. 22.6 days;  $P < 0.001$ ). In a retrospective cohort study that examined haloperidol use in 989 patients who were mechanically ventilated for longer than 48 hours, Milbrandt and colleagues found that patients treated with haloperidol had significantly lower hospital mortality than did those who never received the drug (20.5% vs. 36.1%;  $P = 0.004$ ), an association that persisted after adjusting for potential confounders. Because of the observational nature of the study and the potential risks associated with haloperidol use, these findings require confirmation in a randomized, controlled trial before being applied to routine patient care. Anecdotally, the use of atypical antipsychotics, such as risperidone, olanzapine, or ziprasidone, is in vogue. However, they are no more effective than haloperidol for treating ICU delirium and, like haloperidol, these agents all have the potential to cause QT-interval prolongation and cardiac arrhythmias. Furthermore, the newer medications are 10- to 20-fold more expensive than generic haloperidol.

## OUTCOMES OF INTENSIVE CARE

It is perhaps self-evident that ICU patients have high short-term mortality, the rate of which depends primarily on the admitting diagnosis, the severity of physiological derangement, and the underlying chronic health state of the patient, rather than age itself. For those that survive to hospital discharge, a traditional measure of therapeutic success, subsequent survival trajectories differ markedly from the general population. In other words, survivors of critical illness are at increased risk of mortality long after the acute illness has resolved. In diseases like severe sepsis, this effect may be seen as far out as a year after the illness.

The specialty of critical care has made significant advances in the care of severely ill patients. Mortality rates for many commonly encountered critical illnesses such as severe sepsis and acute respiratory distress syndrome (ARDS) have declined sharply over the past two decades. However, as greater numbers of patients survive intensive care, it is becoming increasingly evident that quality of life after critical illness is not always optimal.

Late nonmortal sequelae of critical illness include deficits in physical function, cognition, and mental health. The majority of studies that have examined post-ICU physical function have focused on survivors of ARDS, a population that tends to be younger than general ICU patient populations. For example, Herridge and colleagues found that 1 year after the illness, the majority of ARDS survivors reported persistent functional disability primarily due to

**TABLE 19-3**

nonpulmonary conditions such as muscle weakness and fatigue. Though the distance walked in 6 minute improved over the 12 months after ICU discharge, at 1 year, it was still only two-thirds predicted. Less than half had returned to work. The absence of systemic corticosteroid treatment or ICU-acquired illnesses as well as the rapid resolution organ dysfunction was associated with better functional status during the 1-year follow-up. At 2 years, exercise limitation persisted while health-related quality of life remained below that of the normal population.

Studies that have specifically examined functional outcomes in elderly ICU survivors have been relatively small and methodologically limited, as reviewed by Hennessy and colleagues. An important underlying theme that emerges from such studies is that elderly ICU survivors, while clearly at risk of post-ICU physical disability, are more frequently satisfied with their post-ICU lives than younger survivors and report preservation of health-related quality of life. This apparent paradox is not unique to ICU-based studies and is well-described in health utility theory. Clinicians and family members, therefore, should not presume that elderly patients who are either pre-morbidly functionally limited or likely to suffer from post-ICU limitations would not want aggressive care during their acute illness. Ideally, such decisions should be made based on the patient's own expressed wishes. When this is not possible, decision makers should be careful not to discount too heavily the value, or utility, that a functionally impaired life might represent for the patient.

Evidence from a variety of cohort studies suggests that 25% to 78% of ICU survivors experience neurocognitive impairments. For instance, nearly half of ARDS survivors manifest neurocognitive sequelae 2 years after their illness, falling to below the sixth percentile of the normal distribution of cognitive function. Considering Terri Fried's observation that 89% of Americans would not wish to be kept alive if they had severe, irreversible neurologic damage, these findings are quite concerning. In general, difficulty with memory is the most frequently observed deficit, followed by executive function and attention deficits, as shown by Hopkins and colleagues. Impairments tend to improve during the first 6 to 12 months after hospital discharge, with little additional improvement after 1 year. Elderly subjects seem to be at greatest risk, especially in the setting of pre-existing mild neurocognitive impairment or dementia. Furthermore, ICU-acquired cognitive insults may accelerate the trajectory of cognitive decline, leading to what some have called "ICU-accelerated dementia." Data regarding the potential mechanisms underlying ICU-acquired neurocognitive deficits are quite limited, though evidence suggests roles for hypoxemia, hypotension, hyperglycemia, delirium, sedatives, and analgesics.

Psychiatric symptoms and disorders, such as depression, anxiety, and posttraumatic stress disorder (PTSD), affect 15% to 35% of ICU survivors months or even years after their acute medical illness, as reviewed by Weinert. In one study of 154 survivors of >48 hours of mechanical ventilation, 32% suffered from depression (Center for Epidemiologic Studies Depression Scale (CES-D) score  $\geq 16$ ) 1 year after their illness. The results were nearly identical to those obtained at the initial 2-month follow-up, suggesting that the burden of depression for ICU survivors may not improve over time. Other studies in survivors of ARDS or other forms of respiratory failure have shown similarly high rates of depression symptoms.

It is not difficult to understand why the experience of critical illness might lead to symptoms of anxiety and PTSD. Similar to combat or natural disaster, there are a number of extreme psycho-

logical stresses in the ICU, including fearing of losing one's life, being routinely subjected to painful procedures, sleep deprivation, drug-induced hallucinations, and a perceived loss of control. Of survivors of ARDS, 28% scored above the threshold value on the Post-traumatic Stress Syndrome Inventory (PTSS-10), which is highly suggestive of the diagnosis of PTSD. Studies of other ICU patient groups, such as survivors of septic shock and those undergoing cardiac surgery, show a similarly high risk of PTSD symptoms. In the ARDS study, those with recall of ICU events seemed to fair worse, suggesting that memories of ICU events were associated with psychologic distress. However, others have shown that the content of recalled ICU memories may be key, in that those with delusional memories and no factual recall appear to be at greater risk of post-ICU depression, anxiety, and PTSD.

Small randomized trials show that depression and posttraumatic stress symptoms can be reduced by interventions during or after critical illness. Kress and colleagues found that mechanically ventilated patients who had their sedation interrupted each day had a trend toward a lower incidence of PTSD (0% vs. 32%,  $P = 0.06$ ) in addition to shorter duration of mechanical ventilation. Jones and colleagues demonstrated that a self-help rehabilitation manual was effective in aiding physical recovery and reducing depression in survivors of mechanical ventilation. In patients suffering from stroke, two studies have shown that prophylactic administration of antidepressants prevents the emergence of depressive symptoms, even when started several weeks after the stroke. Whether such a preventative approach would work in other ICU patient groups at high risk of depression remains to be seen. It is clear, however, that antidepressants can be helpful in established postillness depression, such as after acute coronary ischemia or stroke.

## CAREGIVER OUTCOMES

More than 40 million Americans serve as informal caregivers to their ill loved ones, and often suffer physical, psychologic, and financial burden as a result. Most evidence for caregiver burden relates to the care of the chronically ill, but studies are beginning to show that informal caregivers of ICU survivors and family members of current ICU patients also have significant burden, including increased risk for depression and PTSD. For instance, in the longest longitudinal follow-up to date of the informal caregivers ( $n = 169$ ) of critical illness survivors, Van Pelt and colleagues found an elevated and persistent risk of depression, disruption in lifestyle, and reduction in employment over a 12-month period after the onset of critical illness. One-third of caregivers were at risk of depression (CES-D  $\geq 16$ ) at 2 months. Although the proportion of caregivers at risk of depression decreased over time, this difference was not statistically significant. At 2 months, only 28.7% of caregivers were employed and 13.0% indicated that they had stopped working in order to provide care. Similar to depression risk, there was no statistically significant change in either employment status or lifestyle disruption over time.

Comparing caregivers of ICU survivors with other caregiver populations provides important insight into the negative impact of critical illness. The findings of Van Pelt and colleagues demonstrate lifestyle disruption and risk for depression that are much greater than that of the general population and similar to caregivers of Alzheimer's patients. Considering the tremendous caregiver burden

that frequently results from caring for those with dementia, these findings underscore the severity of the downstream impairment that can occur after critical illness. This study strengthens growing evidence that the negative societal impact of critical illness goes beyond short-term mortality to include significant lifestyle disruption not only for ICU survivors but also their informal caregivers.

## TOWARD IMPROVING OUTCOMES OF INTENSIVE CARE IN THE ELDERLY

There are a variety of interventions that improve outcomes in ICU patients regardless of patient age (Table 19-4). Adherence to these and other measures can be increased by the use of checklists, such as the ICU Quality Improvement Checklist developed by the Kansas Critical Care Collaborative (see <http://www.ksccritcare.org>). In addition, there are a variety of interventions that are particularly well-suited to address specific conditions experienced more commonly in elderly ICU patients. Delirium prevention strategies, which were discussed above, have the potential to reduce medical complications, length of stay, and cost, yet remain largely untested in the ICU. The importance of avoiding polypharmacy to prevent dangerous drug interactions and side-effects cannot be overstated. Yet, a casual review of medication records in most ICUs reveals medication lists that are often much larger than is perhaps necessary.

Prolonged bed rest has well-known adverse physiologic effects, including cardiovascular deconditioning and skeletal muscle atrophy. In healthy volunteers, a mere 14 days of bed rest can produce a 1.7% decrease in lean body mass, with a 4.1% decrease in lean thigh mass. After 6 weeks of bed rest, 25% to 30% of quadriceps strength is lost. Although other factors, such as illness severity and exposure to corticosteroids, no doubt play a role in post-ICU physical disability, the contribution of bed rest should not be discounted. Because of the nature of critical illness and the modalities used to manage it, prolonged bed rest seems to be the rule in the ICU. Physical rehabilitation, which has the potential to restore lost function, is traditionally not started until after ICU discharge. One small study by Bailey and colleagues evaluated the feasibility and safety of early physical activity in 103 patients (mean age 62.5 years) with respiratory failure who required >4 days of mechanical ventilation.

“Early” was defined as the interval starting with initial physiologic stabilization and ending with ICU discharge. Activity events were sitting on the edge of the bed, sitting in a chair, and ambulating with or without assistance. Remarkably, nearly 70% of survivors were able to ambulate >100 ft before ICU discharge. Since the ability to ambulate is often an important determinant of a patient’s ability to return to home, this finding is quite impressive. Participation in activity events was not limited by advanced age, comorbidities, or the presence of an endotracheal tube. Adverse events were infrequent, easily remedied, and did not result in complications that required additional therapy, extra cost, or longer length of stay.

Though many ICU admissions are unanticipated and emergent, a sizeable proportion is anticipated due to elective operative procedures. For these anticipated ICU admissions, preoperative assessment can identify previously undiagnosed or inadequately treated comorbidities. Subsequent medical optimization may reduce postoperative morbidity and mortality, as has been shown for cardiorespiratory optimization prior to major thoracic or abdominal surgeries. Patients undergoing nonthoracoabdominal procedures may also benefit from this approach. In a before and after study, Harari and colleagues found that preoperative comprehensive geriatric assessment incorporating prediction of adverse outcomes combined with targeted interventions reduced postoperative medical complications, such as pneumonia and delirium, and length of stay in elective orthopedic patients aged 65 years and over. There were also improvements in pressure sores, pain control, early mobilization, and inappropriate catheter use. Limiting the broad application of the results of this study are the significant amount of time and resources that comprised the intervention, including both pre- and posthospitalization clinic visits and in-home physical therapy as well as active in-hospital assessment by a geriatrician and nurse.

ICU follow-up clinics have been proposed as a means of identifying and addressing the myriad of potential late sequelae that elderly ICU survivors may face. While still uncommon in the United States, as many as 30% of ICUs providing care to high-level ICU patients in the United Kingdom offered outpatient follow-up their patients in 2006 as shown by Griffiths and colleagues. ICU follow-up clinics can be nurse- or doctor-led and are commonly run on multidisciplinary lines, with patients potentially benefiting from inputs that include physical therapy, dietetics, urology, ear, nose, and throat (ENT), psychology, and psychiatry. Where extended ICU follow-up exists, patients report great satisfaction with the service. A multicenter randomized control trial of the effectiveness of ICU follow-up clinics in improving longer-term outcomes of critical illness, the PRaCTICaL trial (ISRCTN24294750), is currently underway.

Family satisfaction is an important measure of the quality of ICU care. Yet, attention to objective measurement and improvement of family satisfaction is a relatively recent phenomena in the ICU. Clinician–family communication is possibly the most important factor driving family satisfaction. Other factors that may improve family satisfaction include allowing family members more time to speak during conferences, avoiding contradictions in provided clinical information, helping resolve conflicts among family members, and implementing flexible visitation policies.

Having a loved one die in the ICU is an extraordinarily stressful event. Studies of families of dying patients identify effective communication between caregivers and families and having support from caregivers throughout the decision-making process to be important

**TABLE 19-4**

### Interventions to Improve Outcomes in ICU Patients Regardless of Age

INTERVENTION	OUTCOME
Subcutaneous heparin	↓ Deep venous thrombosis
H2-blockers	↓ Gastric “stress” ulcers
Low tidal volume ventilation	↓ Ventilator-induced lung injury ↓ Mortality
Goal-directed sedation with daily sedation interruption	↓ Duration of mechanical ventilation
Spontaneous breathing trials	↓ Duration of mechanical ventilation
Attention to skin care	↓ Skin breakdown
Tight blood glucose control	↓ Mortality
Lower transfusion thresholds	↓ Mortality
Hand hygiene	↓ Hospital-acquired infections

to family members. Yet, communication and support are sometimes inadequate due to the many competing priorities in a busy ICU. Lautrette and colleagues evaluated the effect of a proactive communication strategy in family members of 126 patients dying in 22 ICUs in France. The intervention consisted of an end-of-life family conference conducted according to specific guidelines and that concluded with the provision of a brochure on bereavement. In the control group, interactions between the family and the ICU staff, including the end-of-life conference, occurred according to the usual practice at each center. The authors found that those in the intervention group had longer conferences and more time for family members to talk. Furthermore, intervention family members had decreased symptoms of anxiety, depression, and PTSD 90 days after the patient's death, suggesting that the intervention may lessen the burden of bereavement.

Palliative care is medical care focused on the relief of suffering and support for the best possible quality of life for patients and families facing life-threatening illness. Many clinicians consider intensive care and palliative care to be diametrically opposed. Yet, as pointed out by Ira Byock, each discipline's primary goal (extending life for critical care and comfort and quality of life for palliative care) represents an important secondary goal for the other. ICU care providers are beginning to realize the benefits of early and programmatic palliative care involvement for their sickest patients. Recent successful interventions have included processes for symptom (especially pain) assessment and management; mandatory family meetings; daily patient-specific goal setting; advance care planning; and addressing patient and family emotional and spiritual health. A recent special supplement of Critical Care Medicine introduced by Ira Byock discusses these interventions and other issues surrounding palliative care in the ICU in greater detail.

# Subacute Care

*Edward R. Marcantonio* ■ *Mark Yurkofsky*

A recently aired radio advertisement states, “Nursing Homes: not just for the end of life anymore.” While the number of elderly persons residing permanently in nursing homes has remained stable over the past several years, increasing numbers are admitted to nursing homes for short-term stays, usually for rehabilitation or continuing medical management after an acute hospitalization. Indeed, the past 15 years has seen the establishment of a whole new area of medicine, termed “subacute care,” “postacute care,” or “transitional care,” along with units that specialize in this care. While subacute care can be delivered in both free-standing skilled nursing facilities (SNFs) and in hospital-based transitional care units, the former have come to dominate the industry over the past 5 years. Subacute care is an important component of the continuum of care for elderly persons, and care in this setting is frequently provided by geriatricians and geriatric nurse practitioners. In fact, subacute care is an important clinical niche of geriatric medicine.

This chapter discusses the fundamentals of subacute care from the perspective of clinicians delivering care in this setting. After defining subacute care and its providers, the chapter follows the timeline of subacute care, beginning at the hospital, to subacute admission, assessment, care planning, medical management, and discharge planning. The chapter also briefly touches upon the financial and medicolegal aspects of providing care in this setting and highlights aspects of medical management and decision making that may be unique in the subacute setting.

## DEFINITION OF SUBACUTE CARE

There is some debate about the exact definition of subacute care. In fact, there is a great deal of variation in the settings, patients, and providers encompassed within subacute care. In this chapter, subacute care is defined as the management of discrete episodes of illness requiring medical management and/or functional rehabilitation within the SNF. The intensity of the medical management is

generally less than that provided on a general medical/surgical unit in an acute care hospital, but greater than what can be provided in the traditional nursing home setting, or at home. The level of functional rehabilitation provided is less intense than in a specialized rehabilitation hospital, but greater than that provided at home. Usually, but not always, subacute care provides a continuation of a treatment plan initiated in the hospital. The frequency of medical encounters and the costs of care are also intermediate between the hospital and long-term care settings.

A major distinction between acute care and subacute care is a focus on function. This makes it an ideal setting for geriatricians. Acute care in hospitals is focused on diagnosis and targeted aggressive treatment of acute medical problems. Unfortunately, as a result of hospitalization, many elderly persons suffer nosocomial complications and functional decline that persist well after the acute problem is corrected. Innovative models have been developed to reduce the risk of delirium and functional decline in acute care hospitals; nonetheless, these problems remain rampant, particularly in frail individuals with underlying dementia or chronic medical illnesses. Add to this the continuing pressure to shorten length of stay, and many acutely hospitalized elderly persons are unable to return to their residences at discharge. Subacute care has filled the need for a place where these patients can receive ongoing medical and nursing care, in addition to skilled rehabilitation and discharge planning for eventual return to the community. Length of stay in subacute care varies widely, from less than 1 week up to 100 days (the Medicare limit), but the average is generally 1 to 3 weeks.

Subacute care plays a particularly important role in the managed care system for several reasons. First, the cost pressures engendered under managed care require treating patients in the least costly environment that meets their needs. Second, many managed care plans have per diem rates with acute care hospitals, leading to even more intense pressure for discharge than the traditional Medicare diagnosis-related group (DRG) system. Third, managed care plans are exempt from the “3-day” hospital rule (in traditional Medicare,

patients must be hospitalized for at least 3 nights to qualify for a skilled nursing benefit), so that these patients can access their SNF benefit with a shorter hospital stay, or even be directly admitted from the community (often via the doctor's office or emergency department). For all of these reasons, managed care plans tend to admit sicker patients to SNFs for shorter lengths of stay, and managed care providers have been the leaders in developing expertise in subacute care. Foremost has been the establishment of teams of physicians and nurse practitioners who spend most or all of their professional lives delivering subacute care. These teams have developed protocols for facilitating hospital transfers, assessing patients, delivering sophisticated medical care, addressing acute medical problems, minimizing rehospitalizations, providing case management, and proactive discharge planning. Each of these is discussed in greater detail later in this chapter.

## SUBACUTE CARE PATIENTS

Compared to the usual nursing home population, subacute patients tend to be younger (average age in seventies rather than late eighties), more acutely ill, but less likely to have dementia or major chronic functional limitations. Most patients admitted for subacute care come directly from hospitals and are expected to return to their homes after a specific, planned treatment course. However, a small but significant fraction of subacute patients (10% to 33%) never achieve discharge goals and “convert” to long-stay nursing home patients. Another significant fraction of patients become medically unstable in the subacute setting and need to be rehospitalized (up to 25%). A third group of patients present with advanced illness and receive end-of-life care and die in the subacute setting. These figures depend on the acuity of illness and underlying frailty of the population, as well as on the quality of care provided at the facilities. Except for the dying patients, maximizing return to the community, and minimizing rehospitalizations and long-term care placements are worthy goals of subacute care. Typical subacute diagnoses include hip fracture, other fractures (upper extremity or vertebral), stroke, cardiac and pulmonary conditions (including pneumonia), pressure and vascular ulcers, postoperative care, and deconditioning. Subacute patients may need intensive medical management, functional rehabilitation, or a combination of both. As noted above, some also receive formal hospice or hospice-like services in the subacute setting.

## SUBACUTE CARE PHYSICIANS

Delivering effective care to the subacute population requires a much greater physician presence than traditional long-term care. Just as the term *hospitalist* denotes physicians working primarily in the hospital, *SNFist* and *subacutist* are terms occasionally used to describe clinicians practicing primarily in the subacute environment. Practicing as a long-term care and subacute care clinician requires a special set of skills. Physicians working in SNFs and subacute units are usually geriatricians or other clinicians with strong geriatric skills such as internists, osteopathic physicians, and family practitioners.

A number of clinical, administrative, and interpersonal skills are important for a physician to achieve success in the area of subacute care. To properly manage this challenging patient population, the

**TABLE 20-1**

### Areas of Clinical Expertise in Subacute Care

Geriatric syndromes including delirium, dementia, and urinary incontinence
Postoperative orthopedic and surgical patients
Pressure ulcer prevention and management
Pain and symptom control in the dying patient
Non-ICU hospital conditions such as congestive heart failure and infections
Medication administration and dosing in an elderly population
Wound care
Geriatric rehabilitation

nursing facility clinician must have *clinical expertise* in managing conditions that are a blend of office, hospital, and geriatric practice (Table 20-1).

*Leadership skills* are highly desirable in the physicians practicing in this setting. The physician is the leader of the facility interdisciplinary team whose members include rehabilitation specialists, nurses, social service, and case management. The subacute setting is an environment that benefits greatly from a physician leading the geriatric care team.

*Administrative skills* are also important for the subacute care practitioner. Nursing facilities have a relatively simple administrative structure. The administrator and director of nursing are the primary salaried personnel that run the facility. There is a facility medical director as well. Attending physicians have the opportunity to work closely with these three individuals in a facility. Attending physicians, even if they are not the medical director, can make significant contributions to the quality of care of subacute patients (Table 20-2).

*Interpersonal skills* are the third key area for subacute care practitioners. The ability to form trusting collaborative relationships with patients and families quickly is critical to effective care in nursing facilities. Patients currently entering nursing facilities are often critically ill, are more dependent than previously, fear loss of independence, have caregivers under great stress, and often have financial and housing pressures. They may also be suspicious of nursing facilities and may not understand all of the medical issues. Table 20-3 summarizes the interpersonal skills needed in a subacute care provider in order to handle these issues.

## ROLE OF ADVANCED PRACTICE CLINICIANS

Daily rounding by a clinician with round-the-clock phone availability is essential to providing effective subacute care. To provide

**TABLE 20-2**

### Areas of Administrative Expertise in Subacute Care

**TABLE 20-3****Interpersonal Skills Needed to Provide Effective Subacute Care**

Understand and appreciate the nursing home culture
Be a skilled leader of the interdisciplinary team
Work well with families regarding discharge planning and end-of-life care
Teach staff within the facility
Interface effectively with hospital and outpatient clinicians
Be a good listener and a good communicator

this enhanced clinical coverage, physicians may collaborate with advanced practice clinicians (APCs) such as nurse practitioners and physician's assistants. APCs play a major role in providing care in many subacute units. States and facilities vary regarding the scope of practice for APCs. In some locales, nurse practitioners practice as independent clinicians, while in others, direct physician supervision is required. Many facilities require written guidelines that describe the scope of practice of the APC as well as the manner by which physician supervision will be provided.

The physician working in a subacute care setting may find tremendous benefit from working with an APC. Many APCs have specialized areas of expertise that complement the skills and knowledge of the physician. [Table 20-4](#) lists the roles and duties an APC can assume in a subacute unit.

A physician practicing with an APC has the opportunity to form a team that can improve the quality of care provided and can improve job satisfaction for both providers. As in other teams, excellent communication, trust, availability, and support are essential.

The model of physician-APC collaboration in the subacute setting has many similarities to an inpatient hospital model. The APC may operate much like a first-year resident, managing day-to-day issues, identifying new issues, and requesting support from the physician when needed. By rounding together on a regular basis the MD-APC care team have the opportunity to assess patients together. Patients can be reassured seeing their care team together. There is no substitute for a bedside evaluation in assessing issues such as pain control, cognitive status, anxiety, and medical stability. APCs are able to participate in night and weekend on-call duties. It is essential that if an APC is taking "first call" that there always be a physician available for consultative support.

It is preferable to have a model of on-call coverage that uses clinicians who not only know the patient but also the capabilities of the facility. When it is not possible to have a clinician who is a direct caregiver providing on-call coverage, effective signouts are important. Key clinical information can be transmitted by direct

**TABLE 20-4****Roles of Advanced Practice Clinicians in Subacute Care**

verbal communication or, with HIPAA appropriate safeguards to ensure patients confidentiality, by written summaries that can be faxed or e-mailed to the covering clinician.

**SUBACUTE CARE REGULATIONS**

Subacute care units are licensed and regulated under the same regulations as nursing homes. In 1987, a set of regulations regarding patient care in nursing facilities was enacted in the Omnibus Budget Reconciliation Act (OBRA). These regulations laid out a number of principles that were used to standardize care in nursing facilities. In 1995, the nursing home certification and enforcement regulations took effect. Unless nursing facilities were found to comply with the standards laid out in OBRA, they would not be allowed to participate in the Medicare and Medicaid programs. [Table 20-5](#) summarizes key aspects of the OBRA regulations. These principles provide a framework for providing appropriate clinical care. Physicians must work collaboratively with nursing facility staff to maintain compliance with OBRA regulations. It is particularly challenging managing a high turnover, higher acuity population under these regulations. Excellent assessment skills, complete and accurate documentation, and a well-functioning interdisciplinary team are necessary to meet regulatory requirements, and are also the cornerstone of good subacute care.

**DEFINING QUALITY IN SUBACUTE CARE**

Quality in subacute care goes beyond traditional medical process and outcome measures emphasized in hospitals. Perhaps most important is the quality and availability of the nursing staff. Because of the stress of managing high-acuity patients in the nursing home setting, many subacute facilities are chronically understaffed, or experience high staff turnover, especially of licensed nurses and nursing aides. Significant use of "agency" personnel, with little knowledge of the facility or its patients, can have a major negative impact on quality. Additional issues that are of great importance in the subacute setting include the quality of the rehabilitation services for patients with medical conditions that are likely to improve, and palliative care services for patients whose clinical status is likely to deteriorate. Subacute facilities are also judged on their hotel services in addition to their medical services. Good food, pleasant ambience, television, and clean rooms are all part of the reasonable expectations of patients and their families. Subjective measures, such as patient and family satisfaction, and the facility's reputation in the community, can be good overall measures of quality.

**TABLE 20-5****Key Aspects of the OBRA\* Regulations**

The medical regimen must be comprehensive and part of an interdisciplinary care plan
A decline in the resident's physical, mental, and psychosocial well-being must be demonstrably unavoidable
Restraint use requires rigorous individual clinical assessment
The resident's drug regimen must be justifiable

\*OBRA, Omnibus Budget Reconciliation Act of 1987.

## ADMITTING A SUBACUTE PATIENT: THE HOSPITAL PERSPECTIVE

The vast majority of subacute patients are transferred from acute care hospitals. The providers at the hospitals have a critical role in ensuring the success of the subacute stay. Often, hospital providers operate with little knowledge of the facilities to which they are sending their patients. A brief communication between the hospital and subacute clinicians can help to answer questions about appropriateness, timing of transfer, specific treatments, and overall goals of care. Unfortunately, this type of communication is more the exception than the rule. In general, if the acute care hospital providers have any questions or concerns about transfer of a patient, it is best to ask before acting.

The first question to be asked is who should be sent to subacute care, and who should not? Subacute facilities vary widely in terms of their capabilities, so there is no general answer. Hospital physicians often make the naïve assumption that the nurses “screening” patients for facilities have intimate knowledge of them and can make appropriate referrals. Often, these screeners work for large corporations that may have several facilities in a large urban area. The screeners focus more on “filling beds,” and leave it up to the clinicians to determine appropriateness. It is also important to note that once a patient is accepted by a facility, the actual transfer may not take place for 1 to 2 days. During that time period, the patient may change clinically so it is important to reassess for clinical appropriateness at the time of transfer.

A few rules of the thumb hold: in general, a patient requiring the intensive care unit (ICU) is *not* appropriate for subacute care. The rare exception is a stable ventilated patient who is being transferred from an ICU to a specialized pulmonary subacute facility. In addition to ICU care, few subacute facilities have sophisticated cardiac monitoring, and so patients with active cardiac issues such as unstable angina, poorly controlled congestive heart failure, or arrhythmias requiring continuous monitoring are rarely good candidates for subacute care.

Nursing care in subacute facilities is much less intensive than in acute care hospitals. While hospitals rarely have more than 7 patients per nurse, subacute units may have from 12 to 20 or more patients per nurse—in an 8-h shift, this averages to as little as 20 minutes per patient. Therefore, patients with hemodynamic instability, on multiple intravenous medications, or other situations requiring close nursing monitoring, maybe poor candidates for subacute care. It is therefore critical that an assessment is made to be sure that the needs of the patient can be met with the staffing available. In general, patients with a relatively straightforward treatment plan for acute illness that has shown evidence of improvement, combined with established treatment of chronic illnesses and functional rehabilitation needs, are the most ideal for this setting.

On the opposite end of the spectrum is a patient who will likely be able to go home within a few days. For these patients, an additional facility transfer is probably not worthwhile or necessary, and runs the risk of introducing further discontinuity. In general, subacute stays substantially shorter than 1 week should be avoided in favor of direct discharge to home.

Another issue is selecting the best facility for the patient. This is a complex issue that involves both clinical and psychosocial factors. Screeners and hospital case managers often need to be focused on getting a bed quickly rather than finding the best facility for the

patient. In addition, bed availability can at times be an issue. Facilities vary widely in their capabilities, and some have specialized programs in specific areas, such as orthopedics and stroke care. In general, knowledge of a proven track record of success handling a particular kind of patient is the best proof of the wisdom of transfer. In addition to these clinical issues, patients and family members may prefer a facility close to home, which can facilitate family visits and the like. These preferences should be honored if all else is equal. However, it should be explained to patients and family members that because only a short-term stay is anticipated, established medical care linkages and proven clinical excellence should outweigh geographic convenience to ensure the best possible outcome.

The optimal time for transfer can be defined as the point when the patient’s needs can be met as well or better at the subacute facility as in the hospital. In practice, this is often hard to define, and discharge is often dictated by bed availability or “critical pathways” that predetermine length of stay. Ultimately, it is the physician’s responsibility to determine whether the patient is clinically ready for transfer, and for ensuring adequate transfer of information with the patient for continued implementation of the plan of care. It is better to keep the patient for an extra day in the hospital than to risk a rapid readmission for medical instability or poorly coordinated transfer.

When the time for transfer comes, it is crucial that the appropriate information accompany the patient. [Table 20-6](#) describes the key information required by the SNF. In addition, the physicians at the hospital should review the discharge summary and other key transfer documents to ensure that there are no discrepancies—if so, these should be remedied.

Developing better systems whereby receiving facilities and sending hospitals coordinate the transitions of care is crucial to improving patient care and optimizing outcomes. One approach can be

**TABLE 20-6**

### Key Data Needed for Transfer to a Subacute Unit

A list of clinical problems
Complete medication list matched with the clinical diagnosis
Summary of hospital course
Code status/advance directives
Name of health care proxy/guardian
Wound-care instructions
Weight-bearing instructions
Recent significant laboratory test results
Key health care providers involved in care and how to contact them
Diet including consistency of food/liquids if swallowing is impaired
If on tube feeding, type of tube, rate/time of feeding, amount/time of water flushes
Recent focused physical exam findings
Goals for the subacute stay
Pending tests and how to follow up
Follow-up appointments
Clear anticoagulation orders with recent PT/INR results, INR goals
Indications for urinary catheter if present and when it can be removed
Last bowel movement
Family contacts with accurate names, phone numbers, and addresses
Type of intravenous access

INR, international normalized ratio; PT, prothrombin time.

achieved through sharing information via computer systems. Clearly, this is easiest for onsite transitional care units (which are becoming less common). However, even free-standing subacute facilities can have dial-up or hard-wired computer links with sending hospitals. Only certain members of the subacute staff (particularly the physicians, who may also be on staff at the sending hospital) receive access to key elements of the patient's record, as well as the ability to e-mail hospital providers.

Understanding the limitations of subacute care facilities can help hospital providers better manage the transfer of care. First, consider the timing of transfer. Unfortunately, most patients arrive for admission to SNFs between 4 and 7 P.M. However, staffing at most SNFs is best on the day (7 A.M. to 3 P.M.) shift. Therefore, hospitals should attempt to transfer the patient as early as possible during the day, preferably before noon. Before sending the patient, hospital providers should ensure that all patient needs, including nutritional, are met for the next several hours. Second, consider that most SNFs do not have onsite pharmacies and that it may take several hours for ordered medications to be delivered to the patient. Therefore, all medications, particularly pain medications that the patient will need over the next 4 to 6 hours, should be administered prior to transfer. Finally, SNFs may have difficulty inserting and maintaining intravenous access. Therefore, stable access should be ensured prior to transfer. If the patient will need more than 1 to 2 days of treatment, a more permanent "long-line" catheter is advisable.

One special case deserves mention: direct admissions from the community to subacute care. Because of Medicare's "3-day rule," direct admissions come only in managed care patients (who are exempt from this rule), or patients who have had a 3-day hospital admission in the previous 30 days. Direct admissions should be medically stable and should not require immediate diagnostic or therapeutic intervention. In these cases, it is crucial that appropriate information, including reason for admission, medical history, physical examination, medications, treatments, allergies, and the like, be transmitted from the emergency department or doctor's office. A direct dialog between the sending and receiving physician is often required. Only systems that can care for high-acuity subacute patients should consider direct admission.

## ADMITTING A SUBACUTE PATIENT: THE FACILITY PERSPECTIVE

Those who work in a subacute environment need to understand the crucial role played by the first 24 hours postadmission. From a clinical outcome, patient satisfaction, and a risk management perspective, the first day and night in the facility is key. Case 1 illustrates some of the perils of the hospital–subacute transfer.

### Case 1: Transition of Care Issues in the First 24 Hours

An 85-year-old male retired professor is admitted with a hip fracture, hypertension, and diabetes. Here are some common issues that arise that can impact outcomes in a subacute setting:

1. *Family communication:* The patient's daughter does not know if and when her father is going to the subacute facility and does not know how to get to the subacute facility.
2. *Timing of admission:* The patient is scheduled for a 2 P.M. arrival, but arrives at 6 P.M. because the hospital nurse had another sick

patient and did not get the paperwork done. The patient left the hospital before dinner was served and arrived at the subacute facility after dinner was over.

3. *Avoidable complications:* His blood glucose was 40 mg/dL and he was lethargic by the time his dinner arrived.

4. *Missing information:*

The weight-bearing status is not given on the hospital referral.

The page 1 referral had a "titrate Coumadin to INR of 2.0" order but no dose and no INRs.

The discharge summary did not arrive with the patient.

The hospital was not aware that the patient took glaucoma drops and therefore these medications were not noted on the referral form.

5. *Facility issues:*

Physical therapy had left by the time the patient arrived and nursing was not comfortable transferring the patient out of bed to the toilet.

Diapers were placed on the patient irrespective of continence status.

The room smelled because the patient was incontinent.

Pain medicine was ordered but was not delivered until the next morning.

The daughter arrives, sees her father in diapers, in pain, more confused, and the nurses unsure about his medications, and wants to send the patient back to the hospital and says she is going to write a complaint letter to the Department of Public Health.

The issues that arise in Case 1 are not unusual. Patients arrive unexpectedly, sometimes with medical issues requiring prompt attention, and the information transmitted is inadequate and sometimes contradictory. Interagency referral forms maybe done at different times than discharge summaries and can contain conflicting information.

Nursing home clinicians often manage new SNF admissions telephonically for the first 24 hours. Accurate, complete nursing assessments are important to the SNF clinician who is attempting to manage a patient he or she has never met over the phone. Nurses who work on subacute units need to work effectively with their off-site physician colleagues. An important aspect of this collaboration is judgment as to when to page the physician/APC and what information to have available. Nurses need to perform an appropriate assessment of the patient based on the clinical situation. In addition, it is important to have information on medications being given, as well as recent laboratory results.

A comprehensive history and physical examination is required within 48 to 72 hours of subacute admission. It is best practice if this can be performed within the first 24 hours. In addition to understanding the medical problems identified at the hospital, key issues for the subacute clinician to consider when admitting a new patient include understanding the goals for the SNF stay, making sure medications are appropriately dosed, and assessing pain, bowel status, and cognition. If the patient has an indwelling bladder catheter, the reason it was placed and the ongoing need for it should be assessed.

In addition to the history and physical by the physician–APC team, the newly admitted subacute patient must have a number of assessments performed by many disciplines. The physician or APC, as leader of the interdisciplinary team, needs to be aware of key findings from these team members and integrate them into the initial

**TABLE 20-7****Initial Assessment of the New Patients by Subacute Staff**

Rehabilitation team	Screens by physical, occupational, therapy, and speech
Nursing	Skin, cognition, fall risk, pain, bowel/bladder, medication review and reconciliation
Dietary	Nutritional needs/diet
Kitchen	Food preferences
Social service	Psychosocial evaluation, end-of-life preferences
Case management	Discharge planning including equipment and home care
Administration	Valuables assessment

treatment plan. [Table 20-7](#) provides examples of the assessments that need to be done and the disciplines that do them.

Patients not only have medical issues identified by the hospital, but may arrive with unidentified issues, such as fever, delirium, skin breakdown, constipation, pain, and urinary retention, which may require immediate attention. The subacute clinician has to organize this information and prioritize issues that need immediate attention.

Nursing facilities do not have onsite pharmacies. Delivery of medications can take several hours. To help with this issue, facilities have drug “emergency boxes” that contain dozens of frequently used medications including intravenous antibiotics and a small selection of opioids. Familiarity with the contents of these boxes is important for the subacute care provider to practice effectively. At times, short-term substitutions must be made until the exact medication can be delivered. In addition, like hospitals, facilities have formularies. Medications may need to be changed to meet formulary requirements.

## PATIENT/FAMILY/STAFF INTERACTIONS

In addition to being astute and thorough when assessing a new patient, the subacute clinician must be skilled at establishing trusting relationships with the patient and key family members as soon as possible after admission. Any time a patient changes setting and new caregivers assume care, there are opportunities and dangers. The initial hours after admission are therefore an important window period in which the receiving clinicians can form a strong collaborative relationship with the patient and the family.

Family members provide important clinical and functional information that may otherwise be unavailable. Speaking with family members may help to identify areas of concern related to past care and can point to special issues on which to focus immediately on admission. The physician can establish themselves as a patient advocate and a problem solver. By establishing an early, strong family connection, the subacute clinician is better able to identify and ultimately meet the goals of care, and overcome barriers to discharge.

## PHYSICIAN’S ROLE IN REHABILITATION

In the subacute setting, an interdisciplinary team meeting plays a crucial role in formulating and assessing the plan of care. At the team meeting, key issues of function, medical condition, cognition,

mood, and interactions between family, patient, and staff can be shared. The interdisciplinary team needs to gather and communicate information regarding medical condition, treatment and prognosis, rehabilitation potential and level of function, psychosocial needs, financial options, and family/patient teaching needs. Most internists, primary care physicians, family practitioners, and general practitioners do not receive formal training in rehabilitation. Many physicians working in nursing facilities do not take an active role in assessing the patient’s rehabilitation needs, goals, and progress. There is a vital role that a subacute physician can play in this regard that benefits the facility and the patients, as well as the patients’ families.

The physician understands the pathophysiology of disease processes better than any other member of the interdisciplinary care team. Therefore, the physician has a critical role to play in leading the team in identifying realistic functional goals for patients, understanding, and explaining the impact of intercurrent medical illnesses on patient function, and communicating with patients, staff, and families regarding realistic goals and expected level of function. The physician does not need to know how best to identify weakness in a particular muscle group and what exercises to do to strengthen it, nor what the best assistive device will be for a patient. However, the physician does need to understand whether the goals of treatment outlined by the therapy team are realistic based on the patient’s physical ability, cognitive capacity, as well as their home environment and supports.

How to get the patient walking again is often the major challenge to face nursing facility staff. Generally, physical and occupational therapists are able to provide 1 to 3 hours of therapy per day, 5 to 6 days per week, in the subacute setting. It is essential that other members of the care team provide an environment that encourages patients to get out of bed and ambulate when the therapists are not working with the patient. Nurses and aides need to be taught by the therapists how best to transfer the patient, to observe any weight-bearing precautions, and to learn which assistive devices need to be used. Often schedules need to be set up to get the patient washed, fed, dressed, and out of bed. Identifying what is not working well and brainstorming with other members of the care team to identify solutions is an important role for the physician. There are a number of roles that the physician maybe required to fill in the interdisciplinary team ([Table 20-8](#)).

Clear communication between all members of the interdisciplinary team is essential (see Chapter 26). The physician, nurse practitioner, and physician assistant play an important role in helping set realistic goals and making sure that each member of the care team is providing care that is geared towards achieving those goals. They also play a key role in communicating with family members.

Case 2 outlines the key role of physicians in communicating between providers and altering the plan of care to optimize patient outcomes.

### Case 2: Importance of Communication in Subacute Care

A 78-year-old female with a left hip fracture repair and a history of mild dementia presents to the nursing facility for rehabilitation. The patient arrives with a non weight-bearing status on her left leg. The physician sees the patient and finds she has poor memory and impaired judgment. She lives with her frail but independent husband in a home with eight stairs separating the bedroom and kitchen. The physician orders occupational and physical therapy evaluations.

**TABLE 20-8****Physician's Roles in the Interdisciplinary Team**

Provide medical expertise on prognosis
Determine realistic, achievable functional goals
Determine whether medical improvement is likely, resulting in improved function, or whether medical status has plateaued or will deteriorate with stable or reduced function
Adjust treatment based on input from team members (pain/bowel/anxiety, etc.)
Gather input from specialists and share with team members
Participate in brainstorming to identify solutions
Guide discussions around ethical issues
Determine when skilled care is not beneficial or needed
Facilitate family communication
Determine when discharge to another setting is appropriate
Provide constructive feedback
Assess/improve teamwork between rehabilitation/nurses/nurses aides

On day 2 of the admission, the physician realizes that the patient's functional and cognitive deficits will likely prevent her from keeping weight off the operated leg. Furthermore, it is clear that very few 78-year-olds can ambulate safely on one leg using a walker or crutches. In such situations, the end result is often that until the weight-bearing restriction is removed, which generally takes 1 to 2 months, the patient will not be able to ambulate and will require a prolonged nursing home stay. This places the patient at high risk for needing permanent long-term care. The physician calls the operating surgeon and explains the dilemma. Upon further reflection, the surgeon states that the fracture was minimally displaced, the alignment was good, the repair was reasonably strong, and the patient is only 105 pounds and advances her to a weight-bearing as tolerated status. The treatment plan for this patient has now changed dramatically. Achieving independence with transfers now becomes a realistic possibility. She may be able to negotiate stairs. The plan is now for a 1- to 2-week stay with discharge to a home setting with community supports and the family paying for extra assistance.

Patients with advanced dementia may have great difficulty learning new strategies or compensatory techniques. The physician plays a vital role in identifying patients who can benefit from therapy. In addition to dementia, patients with delirium, depression, pain, or other medical illnesses may have difficulty participating in and benefiting from a rehabilitation program. The physician must identify and treat the depression, pain, or congestive heart failure that is limiting participation in and benefit from the rehabilitation program.

It is often appropriate and necessary to teach nursing facility staff such as nurses' aides how best to feed, transfer, and ambulate patients. The goal is to provide for the patient's safety while maximizing their autonomy. There is a tension at times between getting things done quickly by helping the patient and having the same task be done more slowly but with the patient doing all the work. The patient may take 20 minutes to get dressed, needing periodic verbal cues from the nurses' aide during the process. If the nurses' aide did more of the work the job might be done in 10 minutes. The patient may even prefer to have the aide do more of the work. However, a cornerstone of care for the elderly patient is to encourage as much

independence as possible, and this is even more important in the subacute setting when the goal is to return home.

**PHYSICIAN'S ROLE IN FAMILY MEETINGS**

Family meetings are an invaluable means of sharing information, reviewing goals, making decisions, and identifying action steps. Family meetings should generally take place after there has been an interdisciplinary team meeting without the family present. Complex information needs to be presented in an organized manner that allows time for questions, discussion, and identifying action steps. Ideally, all this needs to be done in less than 45 minutes, so that staff can resume other duties and patients and family members are not overwhelmed. Family meetings can include the patient, key family members, the physician/nurse practitioner/physician's assistant; case manager; social service; the rehabilitation team, including physical, occupational, and speech therapy; nursing; and even aides. Formulating an agenda and goals for the meeting ahead of time helps identify who needs to be present. [Table 20-9](#) summarizes common goals for family meetings.

A staff member such as the physician, case manager, or social worker should run the meeting. It is often very helpful for the senior clinician to provide a brief update regarding the medical issues and prognosis. Knowing what different team members are going to recommend is essential for family meetings to go well. Major differences in the treatment plan between team members should be addressed before the family meeting. For example, the therapist may find the confused patient with a resolving pneumonia is not participating in rehabilitation. However, the physician maybe able to explain that the confusion is likely related to a delirium and may improve quickly as the pneumonia responds to antibiotics. Without the physician present to provide this input, the facility caregivers and family members may not have an accurate picture regarding disease progression, clinical improvement, and overall prognosis. Providing a clear, realistic picture of function and medical prognosis is also a critical part of the discharge planning process.

Several conditions are especially common among subacute patients. Key aspects of these conditions relevant to subacute care are

**TABLE 20-9****Goals of Family Meetings**

Information gathering regarding:
Previous function
Caregiver supports
Financial resources
Home environment
Goals of care
Decision making regarding:
End-of-life care
Rehabilitation goals that need to be attained
Discharge site, e.g., home, long-term care, assisted living
Setting a discharge date
Resolving areas of conflict:
Between family members
Between family and patient
Regarding facility services

discussed below. Other chapters in this text discuss these conditions in more detail.

## MEDICAL MANAGEMENT IN THE SUBACUTE SETTING

### Pain Management

It is well recognized that pain, especially in the elderly person, is often unrecognized and undertreated. Effective pain relief is an essential aspect of subacute care. [Table 20-10](#) outlines some of the negative consequences of untreated pain.

Recognizing and relieving pain are critical skills for the subacute clinician. It is beyond the scope of this chapter to review the broad area of pain relief. However, opioid use in the subacute setting merits special mention.

Opioids play an important role in pain control. Whether for post-operative pain or end-stage cancer, a sound knowledge of principles of pain control and an understanding of nursing facility regulations regarding opioid use is essential. Opioids can be delivered in several different forms. Familiarity with the different routes of administration for opioids is an important aspect of providing pain management. [Table 20-11](#) summarizes routes of administration. Patients arriving from hospitals may have orders written for intravenous “push” opioids. Nurses in nursing facilities do not generally give opioids, or other medications, in this manner. The clinician in the nursing facility needs to reorder these medications in a form that is appropriate for the facility.

The regulatory issues in nursing facilities can, at times, complicate and impair the provision of good pain control. Unlike the hospital setting, nursing facilities regulations require a prescription for each opioid order. The physician must either fax a prescription to the pharmacy or call the pharmacy to obtain an emergency 72-hour supply of the medication. In nursing facilities, exact doses and parameters for “as needed” indications are required, for instance: “Percocet (5/325 mg) 1 tablet orally q4h prn for moderate hip pain (4 to 7 on pain scale) and 2 tablets orally q4h prn for severe hip pain (8 to 10 on pain scale).” Sliding scale dosing orders, such as “Morphine sulfate 1–4 mg subcutaneously Q 1–4 hours PRN,” are not allowed.

**TABLE 20-11**

#### Routes of Opioid Administration

Oral tablets in both short- and long-acting form
Oral liquids
Sublingual liquids in concentrate form
Rectal suppositories
Transdermal patches
Subcutaneous injections
Subcutaneous infusions

Many patients may experience a roller coaster effect when given prn doses of short acting pain medications. The result is many hours of discomfort with just a few hours of pain relief. Familiarity with and use of sustained-release oral opioids is an essential aspect to being able to provide successful pain control in the nursing facility. It should also be noted that most extended release medications should not be crushed. If the patient is not able to swallow the tablet, then an alternate dosing route needs to be considered, such as a transdermal patch.

Finally, a standing bowel program needs to be ordered along with the opioids. Orders for “milk of magnesia prn” or routine stool softeners are inadequate for most patients on opioids. [Table 20-12](#) summarizes key points regarding opioid use in subacute care.

### Urinary Incontinence and Catheters

Many patients arriving at subacute facilities have indwelling catheters or were incontinent at the hospital. Urinary catheters are most commonly used to monitor urine output when patients are first admitted to the hospital. Most patients arriving with catheters from the hospital can have them removed immediately. From both an infection control and a nursing home regulatory perspective, urinary catheters should be used in very limited situations. The two main ones are in the setting of urinary retention when intermittent catheterization is not practical and in the case of severe skin wounds when healing would be impaired by urine from an incontinent patient. Before committing a patient to permanent catheterization for urinary retention, it is important to determine whether there is a reversible cause for the retention, such as stool impaction or a medication side effect. Anticholinergic medications are particularly likely to inhibit proper bladder emptying.

**TABLE 20-10**

#### Impact of Pain in Subacute Patients

Decreased mobility
Incontinence
Constipation/impaction
Pressure ulcers

**TABLE 20-12**

#### Key Issues Regarding Opioid Use in Subacute Care

Be specific regarding dosing/frequency when ordering opioids
Know the contents of the facility’s “emergency box”
Prompt faxing/phoning reduces delays in getting opioids
Order a bowel program with opioids
Evaluate whether a sustained release product is needed with prn “rescue” doses
For new admissions, consider developing a system where it is known what the medications (including opioids) will be before the patients arrives and <i>preorder</i> them so there will not be delays

**TABLE 20-13****Assessing and Managing Incontinence**

Treat a diaper as a red flag: ask why it is on and if not needed make sure it stays off
Do a rectal exam: stool impaction is commonly overlooked and is very treatable
Consider a bedside commode if the patient is slow transferring and ambulating
Make sure there is not a problem with delays answering call lights; if there are delays, involve the director of nursing in formulating a solution
Avoid anticholinergics, especially in men, as they may cause urinary retention or confusion
Get a good history from the patient/family regarding prehospitalization continence
Consider obtaining a postvoid residual volume to rule out urinary retention
Review medications and lab work for causes of incontinence

The hospitalized patient with new incontinence often has an etiology that can be diagnosed and treated in the nursing facility without sophisticated studies. It is important to determine the prehospitalization continence status and the etiology for the incontinence. Infections, medications (diuretics), delirium, immobility, fecal impaction, urinary retention, and deconditioning are common causes of incontinence that are readily treated. Nurses' aides, nurses, and therapists are very important to the clinician as a source of information regarding continence. An interdisciplinary meeting is an excellent way in which to obtain information on continence and to develop a plan to manage it. [Table 20-13](#) summarizes some ways of rapidly assessing and managing incontinence in the nursing facility (see also Chapter 59 on incontinence).

## Swallowing Issues

An appropriate diet and feeding plan can be crucial in the subacute setting. Hospitals may not always supply detailed information on food and beverage consistencies for patients at the time of admission to the nursing facility. Patients with strokes, impaired cognition, and other neuromuscular disorders require special types of diets because of dysphagia. The subacute clinician should be familiar with these diets. Solid foods can be ground or pureed to facilitate swallowing. Liquids can be thickened to nectar or honey-thick consistencies to reduce aspiration risk. Contacting the sending hospital prior to feeding the patient may be necessary to determine the proper diet in a patient with dysphagia.

Speech therapists are important members of the rehabilitation team in nursing facilities. Speech therapists have a dual role. They work on communication techniques and strategies and also screen for and evaluate swallowing difficulties. Speech therapists can assess whether food consistencies are appropriate and whether other interventions are needed such as elevation of the head of the bed, tucking the chin, or turning the head with swallowing.

Swallowing difficulties can develop in the setting of an acute or a chronic illness. Delirium and dementia contribute to swallowing problems, especially if an acute medical illness develops. Stroke, neuromuscular illnesses, anatomical abnormalities, and infections also may cause dysphagia. Coupled with swallowing problems is the

**TABLE 20-14****Speech Therapist's Role in Aspiration Management**

Screening new admissions for swallowing difficulties
Assessing swallowing capabilities
Recommending food and liquid consistency
Teaching the patient compensatory swallowing strategies, e.g., chin tuck
Deciding whether further diagnostic studies are needed, e.g., modified barium swallow
Training facility staff and family members proper techniques

fact that elderly patients entering nursing facilities often have poor dentition, ill-fitting, or missing dentures.

The role of the speech therapist in reducing aspiration risk includes items listed in [Table 20-14](#). [Table 20-15](#) summarizes the physician's role in helping to manage the patient with swallowing difficulties.

## Falls

A significant challenge in managing patients in nursing facilities is the tension between safety and autonomy. Many patients in nursing facilities have cognitive impairment as well as a functional deficit that hinders transfers or ambulation. The physician plays a vital role in working with facility staff in identifying risk factors for falls and reducing those risks. [Table 20-16](#) identifies some of the common causes of falls in a subacute setting.

If a patient does fall, a review of the above issues needs to be undertaken to determine why the fall occurred and to take corrective measures. The use of restraints, whether physical or chemical, to prevent activities or behaviors that increase the risk of falls needs to be carefully scrutinized. Physical restraints may result in injury or even death if improperly used or monitored. Chemical restraints (e.g., sedating psychotropic drugs) have significant morbidity associated with them as well. Finding ways to manage problematic behaviors to decrease the risk of falls or to keep patients safer is challenging ([Table 20-17](#)).

The attending physician or facility medical director maybe asked to review cases prior to admission where restraints could be required. Proper documentation in the medical record regarding fall evaluation and restraint use or nonuse is very important. Occasionally, physicians will need to speak with state surveyors investigating an injury related to a fall. Having a clear, well-documented plan on how to manage the patient who is at risk for falls can be very helpful in this situation in preventing citations or even monetary penalties for the facility.

**TABLE 20-15****Physician's Role in Aspiration Management**

Order appropriate food and fluid consistencies
Order aspiration precautions when appropriate
Coordinate the interdisciplinary team to ensure that the proper diet is provided at all times
Assess whether a feeding tube might be indicated
Identify reversible medical causes of dysphagia

**TABLE 20-16****Causes of Falls in Subacute Settings**

Medication-related postural hypotension
Medication-related confusion
Pain
Poorly fitting footwear
Inadequate lighting
Delays in answering call lights
Incontinence causing a slip and fall
Lack of familiarity with environment
Environmental hazards such as oxygen tubing, bedside trays that roll when leaned on
New stroke or fracture causing weakness in a limb(s)

## Pressure Ulcers

Clinicians practicing in nursing facilities must have a good understanding of preventing and managing pressure ulcers. Pressure ulcers can result in pain, immobility, catheter use, infections, malnutrition, prolonged SNF stays, and hospital admissions. While some pressure ulcers are avoidable, many others are unavoidable. Similar to falls, clinicians and facilities must realize that these ulcers are potential areas for litigation. Excellent documentation and a thorough knowledge of techniques for preventing and treating pressure ulcers are areas with which the subacute clinician must be familiar.

Nursing facilities do skin assessments as part of the admitting process, and again periodically during the stay. It is worthwhile to familiarize yourself with the screening tool used in your facility and to review it once it is completed on new admissions. High-risk patients can be identified in this manner. However, changes can occur in which a low-risk patient can quickly become high risk. For instance, a patient may develop diarrhea and weakness. The physician-APC team must recognize a new increased risk for skin breakdown. [Table 20-18](#) identifies the patients at highest risk for skin breakdown.

By recognizing the at-risk patient population, steps can be implemented that can reduce the likelihood of skin breakdown (see Chapter 58). Even if pressure ulcers develop, demonstrating that

**TABLE 20-18****Conditions Placing Patients at High Risk for Skin Breakdown**

End-stage diseases
Poor nutritional status
Cognitive impairment

Incontinence of urine and stool
Dehydration
Infections
Sensory Impairment
Pain

preventive measures were in place and being monitored can protect the facility and the clinician from censure by local health departments and from litigation ([Table 20-19](#)).

## Medication Issues

A growing awareness of the impact of medication-related morbidity has taken place in recent years ([Table 20-20](#)). The subacute practitioner needs to have a good understanding of the medication delivery and administration systems. As described above, very few nursing facilities have an in-house pharmacy. Medications are delivered after being called or faxed in to an outside pharmacy. It generally takes several hours to deliver medications.

Physicians in nursing facilities must be aware of medications that should be avoided or dose adjusted in older patients. Patients may arrive from hospitals on medications that have a high risk of side effects in this population. It is incumbent on the subacute clinician to carefully review each medicine for necessity, proper dosing, and potential interactions with other medication being administered. Adjusting doses for reduced creatinine clearance is another important aspect of medication management in the subacute setting.

Case 3 illustrates a useful example on medication ordering.

### Case 3: Issues in How Medications Are Ordered

An 80-year-old woman with a history of hypertension, angina, and atrial fibrillation is on metoprolol 50 mg bid. The admitting

**TABLE 20-17****Fall/Injury Reducing Interventions in Subacute Settings**

Identifying the high risk patient
Using a bell instead of a call button—better for some demented patients
Physical/occupational therapy evaluation
Bed or chair alarm—although these often go off after the patient is on the ground
Implement a toileting schedule—this needs to work on all 21 shifts per week
Low beds or putting mattress on the floor
Placing a pad next to the bed
Hip protectors
Encourage time spent in group activities
Use half instead of full bed rails
Identify correlating events, e.g., postprandial hypotension

**TABLE 20-19****General Measures That May Avoid or Minimize Pressure Ulcers**

Pressure-reducing mattresses
Turning schedules
Optimizing nutrition
Vitamin supplements such as zinc and vitamin C
Maintaining hydration
Controlling moisture and soiling from incontinence
Avoiding prolonged sitting
Pressure-relieving devices on chairs
Managing other medical conditions
Using protective devices such as multipodous boots for heel protection

**TABLE 20-20****Common Medication Issues in Nursing Facilities**

Late doses
Missed doses
Giving medications to the wrong patient
Wrong dose administered
Patient refused medication and physician not informed
Mislabeled medication from pharmacy
Wrong dose of medication sent from pharmacy
Medications ordered that should be avoided in the elderly population (e.g., anticholinergics, long-acting benzodiazepenes)

physician is asked by the nurse to provide parameters for the order so “metoprolol 50 mg bid, hold if blood pressure is under 100 systolic or pulse under 55” is written. Two days later, the patient is sent to the emergency department complaining of chest pain and is found to be in atrial fibrillation with a ventricular response of 140 bpm.

On review of the medial record, it is found that the patient had a blood pressure in the 90s and metoprolol was held for three doses. The initial parameters for the metoprolol were written to avoid hypotension or bradycardia. However, the medication was needed for rate control and angina treatment. As in most other aspects of nursing home care, excellent communication is the key to success. Modifying the original order to read “metoprolol 50 mg bid, hold *and call MD* if blood pressure under 100 systolic or pulse under 55” could have alerted the physician to the fact that multiple doses were being missed. The dose could be reduced or another medication used that could ultimately have avoided a hospitalization.

## DEALING WITH COMPLICATIONS OF THE ACUTE HOSPITAL

Subacute providers must often treat complications of hospitalization. In fact, the necessity for postacute care maybe determined more by these complications than by the primary diagnosis itself. Both the principles of geriatrics and empiric research suggest that the most effective approach for dealing with these complications is to prevent them. Unfortunately, subacute providers are not in a preventive position and must effectively manage problems that develop in the hospital.

Foremost among hospital-acquired complications is delirium, or acute confusion, which affects up to one-third of hospitalized patients aged 70 years or older. While some delirious patients clear quickly in the hospital, others remain confused for weeks to months. Because patients with persistent confusion are usually unable to return home, a large percentage of these patients are discharged to subacute facilities. In subacute care, residual delirium may profoundly impact the medical or rehabilitation plan, so that these patients are at high risk of “bouncing back” to the acute hospital, or failing to meet their rehabilitation goals.

Patients with delirium must be identified promptly and evaluated to ensure that all medical problems or medications that perpetuate delirium are eliminated. Probably the most common error among subacute practitioners is to attribute symptoms of delirium to an underlying dementia, and therefore neglecting potential op-

**TABLE 20-21****Strategy to Manage Persistent Delirium in Post-acute Care**

Structured mental status assessment on admission with application of the Confusion Assessment Method to detect delirium.
If delirium detected, contact the physician/APC
Workup to identify and treat reversible causes and contributors to delirium.
Institute measure to prevent or manage common complications of delirium
Avoid physical and chemical restraints, and sedatives at night if possible
Create an environmental milieu conducive to recovery from delirium, including provision of appropriate sensory aids, orientating devices such as clocks, calendars, and an orientation board, consistency of staff (if possible), cognitive and physical rehabilitation.
Educate family members about delirium, and engage them to help reorient the patient

portunities to restore a patient’s cognitive and functional status. To combat this, a brief but structured mental status assessment should be performed on all new admissions to subacute care, with particular focus on identifying key symptoms of delirium as described in the Confusion Assessment Method. Once delirium is recognized, in addition to identifying and treating its causes, a comprehensive cognitive and functional rehabilitation program that recognizes and abates the effect of delirium should be put into place. While “failure to abate delirium” has been introduced as a Medicare quality measure for subacute care, knowledge about detection and management of delirium among subacute care providers remains scant, and delirium abatement programs are far from being implemented at most facilities. Key steps in the management of delirium in subacute care are described in [Table 20-21](#).

Another major problem inherited from hospitals is deconditioning. Elderly patients at bed rest lose muscle strength (and bone mineral density) rapidly, so that after a prolonged hospitalization, many frail elderly patients are unable to walk, even though their primary disease process had nothing to do with ambulation (e.g., pneumonia). Cardiovascular deconditioning may lead to severe orthostatic hypotension that may take months to resolve. Prolonged muscle and cardiovascular reconditioning may be required to restore these patients to their preillness status.

Depression is also very common in elderly patients after acute hospitalization. The presence of significant depressive symptoms, even in the absence of clinical depression, exerts a powerful negative influence on functional recovery in the weeks to months following acute illness. Subacute patients should be evaluated for depression or depressive symptoms using both informal staff observations and a structured assessment tool such as the Geriatric Depression Scale. Those with evidence of depression should be referred for appropriate mental health consultation and/or initiated on antidepressant medication. Because antidepressant medication may take weeks to become effective, psychostimulants such as methylphenidate can be quite useful as a short-term “bridge” in severely depressed postacute patients.

Finally, a mundane but serious consequence of hospitalization is the loss of glasses, dentures, hearing aids, or other assistive devices that elderly persons need for communication, eating, and the like. Often, these are not brought in to the hospital; in this case, the family should be asked to bring these into the subacute facility as part of the patient’s rehabilitative plan. If the devices are indeed lost, prompt replacement maybe required, often at financial hardship to

the patient. An old pair of glasses or pocket amplifier hearing devices may serve as a temporary substitute while a permanent replacement is obtained.

## ACUTE MEDICAL PROBLEMS IN SUBACUTE CARE

The subacute population comprises individuals unable to return home after a hospitalization. These are sick, frail, and medically complex patients, which places them at higher risk for the development of an acute medical problem. Estimates suggest that between 10% and 33% of the subacute population must be urgently transferred back to the hospital. However, the rate of “bounce backs” varies widely among facilities and practitioners. Keeping patients in the facility is a worthy goal and facilities need to be more proactive with medical management and advance directives to achieve this goal. However, some acutely ill patients clearly need to go back to the hospital. We briefly discuss some of the most common acute problems in subacute care, and some of the key issues in determining whether to transfer the patient back to the hospital.

Fever is perhaps the most common acute problem in this setting. The first step is to determine whether the patient is clinically and hemodynamically stable. If so, the ability to perform a prompt diagnostic work-up is a key issue in determining the need for transfer. In addition to the ubiquitously ordered urinalysis and culture, a targeted physical examination, chest x-ray, and blood tests should be part of a basic fever work-up. Results should be available in hours, not days. Once results return, intravenous therapy, either for antibiotics and/or fluids to treat concomitant dehydration, is often required, at least for a few days. When the facility can provide prompt and appropriate evaluation and treatment is often a major determinant as to whether the workup can be done on-site or requires transfer to the emergency department.

Shortness of breath is another common presenting acute problem in subacute care, with many possible etiologies. Prompt work-up will include examination of the lungs and heart, testing for oxygen saturation, and possible electrocardiogram or chest x-ray. Treatment may include oxygen, bronchodilator treatments, diuretics, and respiratory therapy. In addition to clinical severity, facility capabilities may determine whether the patient needs to be transferred.

Perhaps the most vexing issue in subacute care is acute mental status change, or incident delirium. This should be distinguished from prevalent or residual delirium that was present at the time of hospital transfer. Proactive measures, such as careful documentation of a baseline mental status examination, are a key to the proper management of this problem. If new acute mental status change is detected, prompt and thorough evaluation for adverse drug effects and acute medical problems by a physician or APC is required. Often, medical management is relatively straightforward and should be attempted in the nursing facility when possible. At times, the patient's behavior and inability to cooperate with the staff rather than the medical condition itself necessitates transfer. Use of chemical or physical restraints should be avoided, if possible.

## ADVANCE DIRECTIVES AND END-OF-LIFE ISSUES

Every subacute patient should have advance directives discussed, including identifying a substitute decision maker and describing

advance care wishes. The default is often to continue the advance directives from the hospital; however, these should be readdressed at the time of subacute admission. If not already in place, a health care proxy should be completed. Resuscitation status, transfer back to the hospital, and any limits to care, including use of artificial hydration or feeding, should be discussed with the patient and/or family and carefully documented in the medical record.

While most of this chapter has focused on patients whose goal is to return home and to pre-morbid functioning, subacute care is also being increasingly used as a place for the dying. In the past, hospitals would care for patients during the dying process, which may extend from a few days to weeks. Now, however, hospitals face intense pressure to discharge these patients as soon as the decision is made to no longer pursue aggressive medical care. Subacute care facilities have filled a niche for such patients who are unable to go home and can provide a comfortable, supportive environment for the dying patient and the patient's family.

Effectively managing the dying process in subacute care requires expertise and effort that may exceed the capability of facility staff. The staff may need help with pain control and symptom relief or have inadequate time to adequately provide emotional support for the patient and/or family. In this case, involvement of a hospice program in the subacute facility is advised. Depending on the acuity of the dying process, hospice may provide occasional consultation or constant onsite direct-care management. It is often most effective if hospice can have adequate time to develop relationships with the staff, patient, and family before the acute dying process. Learning to recognize the optimal time to involve hospice is an art that can be developed through experience managing these patients. Effectively integrating a formal hospice program into a subacute setting requires strong leadership and commitment, as well as intensive collaboration and education support between hospice and subacute facility staff.

## DISCHARGE PLANNING IN SUBACUTE CARE

Discharge planning from the subacute setting needs to be individualized; however, a number of basic principles and concepts can be applied to all individuals. Discharge planning should begin on or before admission. Patients should be sent to a subacute facility with clear goals for the stay. Often these goals involve rehabilitation to improve mobility, working toward independence with activities of daily living (ADLs) and stabilizing ongoing medical problems. Identifying these goals is helpful in establishing a treatment plan that will reduce barriers to discharge.

A common problem faced by the subacute interdisciplinary team is whether the patient will be safe at home. Common issues are how well someone needs to walk or transfer to be allowed to go home. Autonomy must be balanced with safety. Enlisting extra home supports from family members, friends, and home care agencies, or getting a personal safety alarm, can increase the comfort level of the care team to attempt a discharge to a home setting.

Many people have input into when a patient should be discharged. While the physician has ultimate responsibility for the discharge order, therapists, social workers, insurers, and family members may play a major role in the discharge decision. The physician needs to be skilled at assessing the input received from team members in making this decision. Except in the case of the hospice-type patient, medical stability is a major criterion for discharge.

Independence in the ability to transfer, ambulate, perform ADLs, and take medications properly is not essential if proper supports are in place.

A home visit by the therapy team maybe helpful in assessing what additional goals need to be reached, what equipment needs to be obtained and whether discharge is feasible. Equipment such as walkers and wheelchairs require living spaces without excess clutter and adequate doorways. Stairs, railings, and bathrooms can be assessed as well. Home modifications such as ramps, grab bars, raised toilet seats, and railings may need to be installed prior to discharge.

There is an opportunity when discharging a patient to do a complete review of all medications and treatments. Ideally, this review should be performed by a physician or nurse practitioner because a facility registered nurse cannot make medication or treatment changes. Removing unnecessary prn medications, simplifying dosing schedules, writing out prescriptions, and educating on medication taking are just some of the issues that need to be addressed. The facility case manager needs to work with the physician–APC in deciding on the appropriate home care services and ordering them. Discharge is also a time to update the primary care physician on the patient’s medical status and to make sure that appropriate follow-up appointments are in place.

Sometimes, despite the best efforts of subacute clinicians and facilities, a patient fails to recover sufficiently to return home and needs to be placed in long-term care. This may require discharge to a new nursing home, moving to a different unit within the same facility, or merely “decertification” of a bed. Regardless of the physical arrangement, this move has major financial ramifications because the cost of care must now be borne by the patient, Medicaid, or if this has been purchased, a long-term care insurance provider. At times, it is determined that the patient no longer has skilled medical or rehabilitative needs prior to the use of all possible “Medicare days.” In this case, decertification is sometimes contentious and may require input from the medical director in addition to the attending physician. It is best to give the patient and family as much advance notice as possible of impending decertification, especially if transfer of facility is required.

## RISK MANAGEMENT IN SUBACUTE CARE

Nursing facilities are, in many parts of the country, a growing venue for litigation. There are a number of areas of risk management in nursing facilities that are quite different from those of the ambulatory setting. Practitioners need to educate themselves about these areas of increased risk. As in any clinical situation, documentation is critical to demonstrate that appropriate care has been provided. When there is a lawsuit related to the care of a nursing home patient, the facility is often named as a defendant. The physician might also be named. [Table 20-22](#) describes common causes of lawsuits against nursing facilities.

## SUBACUTE FACILITY REIMBURSEMENT

Beginning in 1999, a dramatic change occurred regarding Medicare nursing home reimbursement, which has driven many individually owned and large national for-profit nursing home chains into bankruptcy. This change in reimbursement is called Prospective

**TABLE 20-22**

### Common Causes of Litigation in Nursing Facilities

Falls
Pressure ulcers
Elopement
Restraints
Weight loss
Physical, emotional, or sexual abuse
Medication errors
Aspiration

Payment System (PPS). Under PPS, nursing facilities must categorize and group each patient into one of several dozen categories. These categories, or Resource Utilization Groups (RUGs), have different daily rates of reimbursement for the facility from Medicare. The medical, rehabilitation, and nursing needs of each patient must be properly and accurately identified in order to obtain the proper RUG classification. The RUG classification is determined by the Minimum Data Set (MDS). The MDS is an assessment tool used for all nursing home patients, including those receiving subacute care. The MDS assists the facility in developing a plan of care for the patient, and also identifies the appropriate RUG category.

The reimbursement that the facility receives from Medicare covers essentially all aspects of care, including rehabilitation, laboratory, x-ray, supplies, and pharmacy. Only by effectively managing these ancillary costs can facilities cover their costs. Achieving success under PPS requires excellent identification and documentation of patient needs and function, cost-effective use of x-ray, laboratory, and pharmacy services, including those services provided outside of the facility, such as ambulance, emergency room, and diagnostic services. Managed care contracts, for the most part, are similar to PPS in that the per diem rate covers rehabilitation, x-ray, laboratory, and pharmacy services. Medicaid and private payments are used primarily for long-term institutional care rather than for subacute care.

Subacute physicians and APCs are instrumental in helping nursing facilities succeed under PPS and managed care. The clinical expertise provided by these practitioners enables facilities to better evaluate the scope and severity of clinical conditions for each patient. Having enhanced clinical presence in the nursing facility can help to identify and treat new illnesses sooner, thereby implementing less-costly interventions and avoiding complications. For example, identifying and treating pneumonia before the patient becomes delirious, dehydrated, and septic is certainly better for the patient and can lead to a reduced need for intravenous therapies, emergency department visits, ambulance services, and hospitalization. The result is a better financial outcome for the facility, as well as a better clinical outcome for the patient.

## REIMBURSEMENT FOR PHYSICIANS

A nursing home practice has some distinct advantages over an office practice. For instance, a nursing home practice can have lower overhead costs. A physician who only practices in SNFs does not have to pay rent on a large office with multiple examination rooms, needs less nursing and administrative staff, and does not have to pay for as much equipment and other office supplies.

Physician billing in nursing facilities is currently based on 10 codes organized into three categories. The first two categories are codes related to discharges and follow-up visits. The third category relates to the performance of a full history and physical examination on admission, or at a yearly physical. Nurse practitioners and physician's assistants can bill Medicare for the care they provide in nursing facilities. At present, the Medicare fee schedule is 85% of the physician payment for the same level of service code. Individual states and insurance carriers may not view coding similarly. It is suggested that physicians learn about coding guidelines in their specific geographic regions. The American Medical Directors Association is an excellent resource for obtaining up to date billing information ([www.amda.com](http://www.amda.com)).

### SUBACUTE CARE AS A SAFETY NET

Subacute care is an important setting to provide medical and rehabilitative services, as well as end-of-life and palliative care. The interdisciplinary approach upon which subacute care is based should benefit patients and society from both quality of care and cost perspectives. Hospitals are discharging increasingly complex patients just getting over a critical illness, often on new medications, and with functional decline. Many of these patients have conditions that are continuing to evolve in the days immediately post hospital discharge. By providing enhanced clinical support services, the subacute site serves as a safety net in the continuum of care for older persons. A large cadre of physicians and APCs with expertise in managing complex illnesses, as well as strong skills in geriatrics and palliative

care, are needed to care for the growing numbers of patients who can benefit from subacute care.

# Nursing Facility Care

Mary Pat Rapp ■ Keith L. Rapp

The current cohort of older Americans is a more robust group than in the past, and the prevalence of disability related to chronic disease is in decline. Despite improvements in the health of older people as a whole, the overall need for services provided by nursing facilities will rise. In the future, the medical needs of nursing facility residents will likely be more complex and require additional services from primary care practitioners, including physicians, nurse practitioners, clinical nurse specialists, and physician assistants. Nursing facilities already show a trend in the increasing percentage of residents who are not able to perform activities such as dressing and bathing independently. As shown in [Figure 21-1](#), over a 20-year span, residents able to feed themselves declined from 67% to 53% and those able to dress themselves, from 30% to 13%.

The term *nursing facility* is inclusive of other commonly used terms, e.g., nursing home, long-term care facility, subacute care unit, or nursing home care unit. Nursing facilities are primarily free-standing in the community or are separate units in hospitals. Patients are usually referred to as residents. On the average, nursing facility residents have a median age of 85, three or more functional impairments, and six chronic illnesses. One-half are cognitively impaired with additional functional impairments and/or chronic illnesses. Most lack sufficient personal and financial support to remain in their homes. Payment for services rendered comes from Medicare Part A, Medicare Part B, Medicaid, Veterans Affairs, private insurance plans including long-term care insurance, and out-of-pocket. Skilled nursing facilities (SNF) are subsets of nursing facilities that receive payment for skilled nursing services under Medicare Part A. SNF services include rehabilitation therapies and/or skilled nursing care, such as intravenous therapy, wound care treatment for deep pressure ulcers, or close-monitoring posthospitalization in medically complex residents.

As shown in [Figure 21-2](#), two populations are distinguished by length of stay and goals. Long-term residents stay more than 6 months and are either cognitively impaired, physically disabled, or both. Short-stay residents of less than 3 months duration are

covering from an acute illness, suffering from a terminal illness, or are medically unstable with a limited life expectancy. From 1985 to 2001, when payment structures for hospitalized older adults changed to encourage earlier discharges, trends in admissions demonstrate hospitals released the same percentage of residents to nursing facilities. However, in 1985, 18% of nursing facility residents admitted from hospitals were discharged to the community versus 30% in 2001. Today, more residents are being admitted for rehabilitation following surgery or acute illness and need a higher level of care for a shorter period of time.

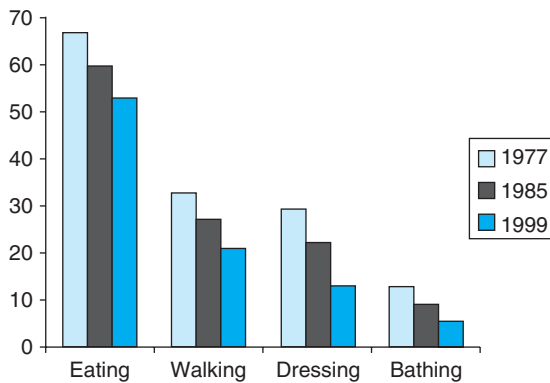

Predictors of admission to a nursing facility include functional determinants, such as decline in strength and balance, and impairment in activities of daily living (ADL), especially in toileting, dressing, and eating. Medical conditions that contribute to functional decline include stroke, diabetes mellitus, and Parkinson's disease. For those older than 75 years of age, a decline in cognition is a consistent risk factor. Adequate caregiver support, both informal and formal, explains why many functionally dependent older adults are able to remain in community settings.

The purpose of this chapter is to help physicians, nurse practitioners, clinical nurse specialists, and physician assistants (hereafter practitioners) understand the nursing facility environment and principles of geriatric care adaptable to this special population. Regulatory issues that influence care processes, the role of nursing facility employees and consultants, and practical aspects of managing a nursing facility clinical practice are discussed.

## REGULATORY ISSUES

Following extensive reforms developed with the 1987 Omnibus Budget Reconciliation Act, The Centers for Medicare and Medicaid Services (CMS) began enforcing the revised nursing facility regulations. In response to consumer complaints and known problems in the quality of care, new rules, including considerable federal

**FIGURE 21-1.** Decline in functional status in residents admitted to nursing facilities from 1977 to 1999. (NCHS. National Nursing Home Survey, 1999. <http://www.cdc.gov/nchs/nnhs.htm>.)

and state oversight, emphasized process and outcomes with less emphasis on structural components. The federal rules for facility participation in Medicare and Medicaid services (commonly referred to as “F-Tags”), together with survey guidelines, clarify regulations, and mandate-specific outcomes and processes of care. By regulation, on-site surveys are federally mandated. They are unannounced, and noncompliance is associated with potential costly fines. State departments of health conduct surveys of quality of care under federal CMS contracts every 9 to 15 months. Additional on-site surveys occur sporadically based on consumer complaints.

### Resident Assessment Instrument

F-Tag 272 stipulates that within 2 weeks of admission, the nursing facility must perform a standardized comprehensive assessment on each resident. Facilities use a federally developed and state-approved Resident Assessment Instrument (RAI) to accomplish this, and the resulting data guides care planning, state inspections, and reimbursement under Medicare Part A and, where applicable, Medicaid. The facility transmits the information electronically to the state regulatory and survey agency.

The RAI consists of the Minimum Data Set (MDS) the Resident Assessment Protocols (RAP), and the RAP Trigger List. The MDS screens residents for the 18 functional problems listed in Table 21-1. Noting a functional problem triggers a more in-depth assessment by the facility interdisciplinary team guided by the appropriate RAP.

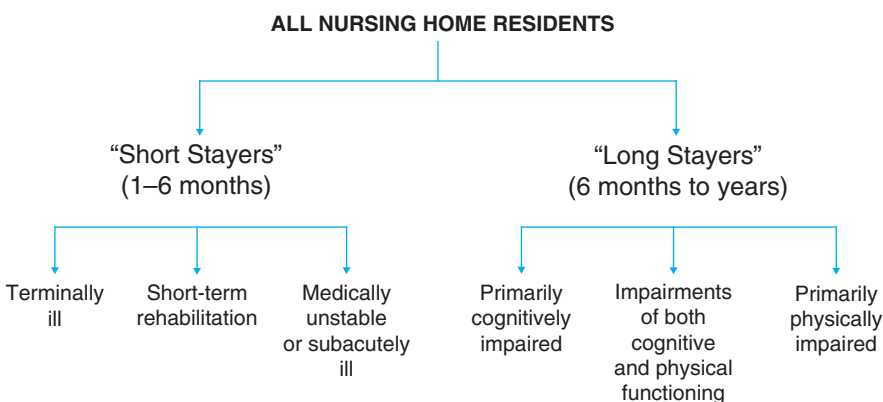

**TABLE 21-1**  
**Resident Assessment Instrument Trigger List**

Delirium
Cognitive loss
Visual function
Communication
ADL functional/rehabilitation potential
Urinary incontinence and indwelling catheter
Psychosocial well-being
Mood state
Behavior problem
Activities
Falls
Nutritional status
Feeding tubes
Dehydration/fluid maintenance
Dental care
Pressure ulcers
Psychotropic drug use
Physical restraints

Minimum Data Set available at <http://www.cms.hhs.gov/NursingHomeQualityInits/Downloads/MDS20MDSAAllForms.pdf>

An interdisciplinary plan of care based on this assessment must be completed by day 21 following admission. Each resident’s MDS and care plan are updated quarterly and completed in entirety annually and when a significant change in condition occurs. For the purpose of the MDS, a significant change in condition is defined as a persistent improvement or decline in mood, behavior, or functional status. More frequent assessments are performed when residents are admitted for SNF care under Medicare Part A. These assessments are a specific responsibility of the facility, and require minimal physician input.

The Center for Health Systems Research and Analysis (CHSRA), the Nursing Home Quality Initiative (NHQI), and measurement experts have identified and validated quality indicators (CHSRA) and quality measures (NHQI) from the MDS. Using a national reporting mechanism, facilities and state surveyors review combined quality indicator/quality measure reports (Table 21-2) to identify potential problems in a facility. The quality indicators/quality measures

**FIGURE 21-2.** Types of nursing facility residents. (Revised with permission from Ouslander J, Osterweil D, Morley J. *Medical Care in the Nursing Home*. 2nd ed. New York, New York: McGraw-Hill; 1996.)

**TABLE 21-2****Quality Indicators and Quality Measures Derived from the Minimum Dataset***Long-Stay Residents*

## Vaccinations

- Percent who were given the influenza vaccine during the flu season
- Percent who were assessed and given the pneumococcal vaccine

## Accidents

- Incidence of new fractures
- Prevalence of falls

## Behavior/emotional patterns

- Residents who have become more depressed or anxious
- Prevalence of behavioral symptoms affecting others

## All

## High risk

## Low risk

- Prevalence of symptoms of depression without antidepressant therapy

## Clinical management

- Use of nine or more different medications

## Cognitive patterns

- Incidence of cognitive impairment

## Elimination/incontinence

- Low-risk residents who lost control of the bowels or bladder
- Residents who have/had a catheter inserted and left in their bladder
- Prevalence of occasional or frequent bladder or bowel incontinence without a toileting plan
- Prevalence of fecal impaction

## Infection control

- Residents with a urinary tract infection

## Nutrition/eating

- Residents who lose too much weight
- Prevalence of tube feeding
- Prevalence of dehydration

## Pain management

- Residents who have moderate to severe pain

## Physical functioning

- Residents whose need for help with daily activities has increased
- Residents who spend most of their time in a bed or in a chair
- Residents whose ability to move in and around their room got worse
- Incidence of decline in range of motion

## Psychotropic drug use

- Prevalence of antipsychotic use in the absence of psychotic or related conditions
- All
- High risk
- Low risk

- Prevalence of antianxiety/hypnotic use

- Prevalence of hypnotic use more than two times in last week

## Quality of life

- Residents who were physically restrained
- Prevalence of little or no activity

## Skin care

- High-risk residents with pressure ulcers
- Low-risk residents with pressure ulcers

*Short-Stay Residents*

## Postacute care measures

- Percent who were given the influenza vaccine during the flu season
- Percent who were assessed and given the pneumococcal vaccine
- Short-stay residents with delirium
- Short-stay residents who had moderate to severe pain
- Short-stay residents with pressure ulcers

report identifies the facility's percentile rank on the items, where this rank can be compared with a group norm. Three items are considered sentinel events warranting closer evaluation: fecal impaction, dehydration, and pressure ulcer development in residents at low risk for pressure ulcers. When surveyors find evidence of noncompliance with regulations, deficiencies are cited and scored based on how many residents were affected and whether there was harm or immediate threat to resident safety. Depending on the scope and seriousness of the deficiencies, facility sanctions range from in-service education to termination of the Medicare and Medicaid contract with significant monetary fines.

In 2001, the Secretary of the Health and Human Services Department convened a group of nursing facility industry stakeholders to develop a plan to further improve the quality of care in nursing facilities. This activity became the Nursing Home Quality Initiative (NHQI), which currently monitors regulation and enforcement, communication with consumers regarding quality, community-based quality improvement programs, and collaboration to enhance knowledge and resources.

The NQHI collaborates with CMS to communicate information to consumers on the Nursing Home Compare Web site ([www.medicare.gov/NHCompare](http://www.medicare.gov/NHCompare)). This site allows consumers to compare the quality of nursing facility care based on the quality indicators and quality measures. The Nursing Home Compare listing distinguishes between short-stay postacute care residents and long-stay chronic care residents. In addition to quality data, the Web site includes basic demographic information for each facility, nursing staff hours, and survey results. This public display of quality data is intended to stimulate nursing facilities to improve health care in order to be competitive (Wunderlich and Kohler, 2001).

A prospective payment system (PPS) based on 53 Resource Utilization Groups (RUG) is now used to determine reimbursement for skilled nursing care under Medicare Part A. Specific items from the MDS contribute to the RUG and the daily rate Medicare pays. Residents hospitalized for at least 3 days during the past 30 days are eligible for a potential 100-day benefit for skilled nursing care. Managed care organizations may waive the 3-day prior hospitalization requirement. The advent of this reimbursement system has resulted in a significant increase in the number of nursing facilities providing skilled nursing services. Regulatory requirements for visits by physicians are similar to requirements for long-stay residents in nursing facilities. In reality, residents who receive skilled nursing services usually need more attention from practitioners because of medical complexity or discharge planning issues.

**NURSING FACILITY ATTENDING PHYSICIAN**

Physicians working in a nursing facility environment manage and coordinate care for residents with multiple chronic medical and functional conditions. Goals are to cure when appropriate, restore and maintain function, and offer comfort. Most nursing facility physicians maintain an active office practice, care for hospitalized patients, and visit their residents in the nursing facility. This is especially true in rural health care environments. An increasing number of physicians are choosing to practice exclusively in nursing facilities. Positive rewards for the full-time nursing facility physician include flexibility in the hours worked and the ability to positively influence medical

care delivery. Many physicians find that as they increase their time commitment to the facility, they are integrated into the facility culture and the work becomes more satisfying. This is particularly true of physicians with dual roles to provide direct patient care and facility medical direction.

Physicians with a part-time nursing facility practice typically devote 2 hours or less per week to nursing facility care. Physicians' perception of low reimbursement, excessive regulations, frequency of telephone calls from families, and extensive paperwork cause some physicians to hesitate to provide more time.

Nursing facilities often lack an organized medical staff typical of most hospitals. Although formal credentialing is usually not required, facilities often ask physicians to complete a medical staff application process to verify medical license and medical liability coverage. To encourage accountability, nursing facility administrators are required to ensure that physicians comply with the minimum standards for frequency of visits and quality of care set forth by federal and state regulations.

Which model of medical staff organization best benefits the resident and the facility is not clear. A closed medical staff comprising a few physicians practicing in a single nursing facility maybe associated with higher quality and intensity of care. One drawback is this limits choices for residents. Nursing facilities may be reluctant to limit the number of physicians on staff if the administrators perceive a potential decline in census because of a lack of physician referral resources. Data do not support the theory that facilities with a larger staff have either a higher census or better profitability. In fact, it appears that profitability is more closely linked to the quality of care, not the number of physician providers.

Providing medical care for nursing facility residents is intellectually stimulating and demands unique knowledge and practice skills. Although limited randomized controlled trials have produced adequate guidance in medical decision making, modifying the medical plan of care based on whether the resident has moderate to severe dementia, is physically frail, or has a limited life expectancy is a reasonable approach. Other considerations include the perceived quality life for the resident, the potential of any intervention to provide a positive benefit, risks, and costs. Physicians must also modify disease-specific management strategies. For example, dietary restrictions recommended for cardiovascular diseases and diabetes mellitus are not appropriate for undernourished residents suffering weight loss.

Medical care in a nursing facility requires an interdisciplinary team of social workers, nurses, physical therapist, pharmacists, and dietitians. Whether acting as the attending physician or medical director, physicians are an integral part of the interdisciplinary team and need to seek out and be receptive of input from the other disciplines.

Expectations of the attending physician are summarized in [Table 21-3](#). According to F Tag 385, residents must be in the care of a physician who is expected to visit the resident in the facility unless specialized equipment is needed or a resident specifically requests an office visit. The physician visits and approves orders at least every 30 days for the first 90 days and then every 60 days thereafter. Qualified nurse practitioners, clinical nurse specialists, or physician assistants may substitute after the first required visit. For residents admitted under a Medicare Part A SNF benefit, the initial comprehensive assessment must be personally performed by the physician. This stipulation does not preclude these other practitioners from making a medically necessary visit prior to the physician's initial

**TABLE 21-3****Role of the Attending Physician in the Nursing Facility**

Assess new admissions within 30 days
Authorize admission orders in a timely manner
Contact the receiving institution or provider following transfer or discharge
Make periodic, on-site visits <ul style="list-style-type: none"> <li>• Visit every 30 days for the first 90 days and at least every 60 days thereafter</li> <li>• Maintain informative, legible progress notes</li> <li>• Periodically review and approve the overall plan of care</li> <li>• During each visit evaluate the resident, talk with pertinent staff, and communicate with responsible parties as necessary</li> <li>• Review the resident's current condition, status of episodic acute events since the last visit, diagnostic test results, and progress of interventions.</li> </ul>
Ensure adequate coverage by alternate providers who will respond appropriately
Provide appropriate evidence-based care to residents
Provide appropriate, timely medical orders and documentation
Follow principles of appropriate conduct

*Data from American Medical Directors Association Resolution and Position Statement: Role of the Attending Physician in the Nursing Home, Position Statement E03, March 2003.*

comprehensive assessment. For residents without the SNF benefit, some states allow nurse practitioners, clinical nurse specialists, and physician assistants to substitute for all required physician visits. Regardless, medically necessary visits are allowed and are covered by Medicare ([Table 21-4](#)).

Visiting on a regular basis is encouraged whether it is daily, weekly, or on monthly schedules. Practice efficiency experts suggest physicians plan to see at least seven residents to make the site of service economically viable. The frequency of visits to the facility is determined by the number of residents under the care of the physician and the acuity. A physician planning well can care for 14 to 16 or more residents a day. Weekly visits permit conducting follow-up visits, attending to new problems, and seeing new admissions. When working with other practitioners who can visit weekly or more frequently, a physician may be able to deliver high-quality care with physician visits less than once a week. Facilities such as hospital-based SNF units or free-standing SNFs may warrant daily visits by practitioners. A balance between the physician and nurse practitioner or clinical nurse specialist visits assures that residents receive the benefits of both medicine and advanced practice nursing. Nurse practitioners, and particularly geriatric nurse practitioners, are well suited to manage syndromes such as falls, pressure ulcers, and weight loss as well as attend to the details of a monthly review of the plan of care. [Table 21-5](#) clarifies approved delegation of physician tasks.

Because of the physician's intermittent presence, day-to-day contact is available via telephone. If allowed by state law and facility policy, standing orders or protocols maybe implemented for commonly occurring low-risk events such as skin tears ([Figure 21-3](#)). If weekly or more frequent visits are made, nurses may use nonurgent communication strategies, such as a communication manual to document follow-up concerns ([Figure 21-4](#)) and may store laboratory reports, dietary recommendations, and pharmacy reviews until the physician or other practitioner is in the building to address the issues. Structured progress notes and comprehensive assessments ([Figures 21-5 and 21-6](#)) are encouraged to ensure comprehensive data collection

date suggest that these practitioners working in concert with the primary care physician provide a higher level of care to nursing facility residents, enhance satisfaction with care, and decrease hospitalization rates while maintaining cost neutrality.

**Nursing Facility Personnel**

The nursing staff provides nearly all of the care provided to residents in nursing facilities. Nursing assistants receive at least 75 hours of training and must be certified within 4 months of employment. They provide the most basic resident care, including bathing, dressing, and eating assistance. Supervising the nursing assistants are the Licensed Vocational/Practical Nurses (LVN/LPN) that often serve as charge nurses and carry out physician orders as well as report changes in the resident’s condition. The 1-year education and training for LPN/LVNs generally focuses on tasks and procedures oriented to acute care with less attention to the supervisory role in the nursing

facility setting. Facilities require a Registered Nurse (RN) to be on duty 8 hours daily, including weekends. The Director of Nurses (DON) manages nursing services and must be a RN. Registered nurses have an associate degree (2 years), a diploma (3 years), or a bachelor's degree (4 years). Descriptions of the key personnel in nursing facilities are noted in [Table 21-6](#).

### Practice Organization

Few nursing facilities utilize electronic medical records. Checklists and flowcharts are most often used to document routine nursing tasks. Facility nurses document vital signs and residents' general condition at least daily in the narrative nurse's notes for residents admitted under Medicare Part A SNF care. For long-stay residents, narrative documentation is limited to unusual occurrences or acute events. Physicians find the nurses' narrative notes a useful source of information. Many nursing facilities also document the resident's condition on a monthly summary form, and these forms help to track trends and response to medications. The plan of care maybe in the medical record or in a separate notebook at the nursing station. Diagnostic test results, consultant's reports, rehabilitation notes, social services records, and dietary consults usually remain in the chart for 1 year or more.

As physicians and practitioners monitor responses to medications and treatments, current daily documentation is found in other locations, usually on flowcharts in notebooks on medication and treatment carts. This documentation typically contains results of finger stick blood glucose testing, the frequency of as needed medications for pain or behavioral symptoms, behavioral monitoring for antipsychotic medications, monthly vital signs, monthly weights, treatments, and wound measurements. Daily or weekly blood pressures and pulses taken to monitor the response to antihypertensive medications or digitalis are found on the medication administration record. Automated blood pressure, temperature, and pulse oximetry equipment is usually located near the nurse's station. Other supplies and equipment to make the day more efficient are listed in [Table 21-7](#).

The American Medical Directors Association (AMDA) suggests visiting long-stay residents monthly and short-stay SNF residents weekly. Physicians and practitioners could routinely plan to see one-fourth of the residents each week, allowing additional time to examine residents who have an acute change in condition, need additional follow-up from prior visits, or receive skilled nursing services. Fol-

lowing the same pattern for visits each month minimizes missing visits with residents. A list of residents by room number, with birth dates, the date of the last history and physical, date of the last physician visit, and a space to make comments assists in organizing the day.

New admissions and residents seen for a routine scheduled visit and those who have returned from the hospital since the last visit can be marked on the census sheet. When working with other practitioners, divide the work load in advance. One option is that in any one month, the physician makes 50% of the regulatory visits and the other practitioner the remaining. Some physicians prefer to conduct regulatory visits and utilize other practitioners for acute medically necessary visits. If functioning as a medical director, allocate time for that responsibility. Advance planning options that make the day go smoothly are shown in [Table 21-8](#). Facility nurses are appreciative of physicians who are considerate of their time as nurses who make rounds also have other tasks, such as administering medications, performing treatments, or calling other physicians. Also, in respect of resident privacy, physician visits should occur in private rooms and not in the common areas.

### Quality of Medical Care

As previously stated, practitioners are charged with periodically evaluating residents and reviewing the appropriateness of current medical plans of care (CMS, 2005). Specific evidence-based care processes guide the practitioners in evaluating and managing complex medical and functional problems. Using evidence-based quality indicators permits the practitioner to specifically identify care processes associated with improved outcomes, to evaluate the care against an accepted standard, and to guide future efforts to improve care and outcomes. The frequency of visits and mandated assessments of residents in the nursing facility affords the practitioner the opportunity to monitor the quality of ongoing assessments, care decisions, and outcomes of chronic care management.

For the nursing facility environment, a consensus panel of physicians, registered nurses, and a health systems methodologist adapted quality indicators from the Assessing Care of Vulnerable Elders (ACOVE) study. The consensus panel identified 11 medical conditions, 7 geriatric syndromes, and 6 quality of life parameters where the management approach differs significantly from that in a community setting. Examples are seen in [Table 21-9](#), where each quality indicator was written as a two-part If-Then statement.

The quality indicators were chosen based on the evidence-based link between the care process and improved outcomes, the overall importance for improving care, the feasibility of measurement by medical record review or resident interview, and the ease of implementation in the average nursing facility. Practitioner assessment prevails over processes when medical conditions suggest the resident has advanced dementia or a poor prognosis with limited life expectancy. Electronic records set to trigger decision making, or simply carrying a notebook with the criteria, would facilitate guideline implementation.

is, screening for hearing and vision loss, depression, and insomnia may be more efficacious than screening for chronic disease or cancer. Components of prevention include vaccinations to prevent some infections, screening for chronic disease such as diabetes mellitus and

thyroid disorders, medications to reduce complications of chronic illness, and counseling to make informed choices. For the physically frail or those with moderate dementia, bedside breast or prostate examinations and fecal occult blood testing maybe indicated after

**TABLE 21-6****Key Nursing Facility Personnel**

TITLE	ROLE	TRAINING
Certified Nursing Assistant	Provides most of the direct care for activities of daily living	At least 75 hours of training specific to caring for residents in a nursing facility
Charge Nurse	Supervises nursing assistants, carries out physician orders, contacts physician in a change in condition	Charge nurses are often LVN/LPNs and may be RNs
Director of Nursing	Coordinates and manages the nursing care	RN
MDS Nurse	Facilitates and/or completes the comprehensive assessment, the Minimum Data Set [MDS]	By regulation, an RN must coordinate completion of the MDS Other licensed personnel may assist in completing the document
Medicare Coordinator	Screens new admissions and assists with discharges of residents admitted to the skilled nursing facility	RN or LVN/LPN
Inservice Coordinator	Orients new employees, helps existing employees maintain skills	RN or LVN/LPN May have a dual role in the facility
Treatment Nurse	Administers topical medications, changes dressings, and may act as the pressure ulcer prevention coordinator	LVN/LPN, RN or RN with additional training in wound care such as a certified wound, ostomy, continence nurse
Restorative Nurses Aide	After physical and occupational therapy will continue restorative care to maintain function, e.g. ambulation	Certified nursing assistant, often one with at least one year experience Reports to either nursing or physical therapy
Medication Aide	Administers oral and topical medications under the supervision of an RN	In some states, certified nursing aides with additional training in medication administration, may administer medications
Administrator	Financial manager	Bachelors Degree with post graduate certificate in Long-Term Care Administration
Admissions Coordinator	Coordinates admission documentation with families and residents Frequently is the person families and residents ask to recommend an admitting physician	High school education or higher
Medical Records Coordinator	Organizes the medical record, thins charts, maintains lists of due dates for key functions e.g., care plan updates, MDS assessments, physician visits	High school education or degree in medical records coordination
Social Services	Provides medically related social services to attain or maintain the highest practicable physical, mental, and psychosocial well-being of each resident.	A facility over 120 beds must employ a full-time social worker with a bachelor's degree in social work or human services
Dietician	Identifies dietary needs, plans, and implements dietary programs	At a minimum a qualified dietician must be available as a consultant
Consultant Pharmacist	Reviews the drug regimen of each resident, must report any irregularities to the attending physician, and the director of nursing, and these reports must be acted upon	Bachelors degree or higher in pharmacy
Medical Director	Responsible for implementation of resident care policies and coordination of medical care in the facility	Licensed physician, may be certified as a medical director
Ombudsman	Citizen advocate for the residents and family	Part of the Older Americans Act, lay persons (often volunteers) are trained to solve problems in the facility

considering the consequences of a positive screening test. More invasive testing, including mammography, colonoscopy, and pelvic examinations, should be evaluated on an individual basis. Given the heterogeneous population in nursing facilities, guidelines for cancer screening and health maintenance need to take into account the residents physical and functional frailty, cognitive impairment, life expectancy, and known wishes.

Certain health maintenance activities have general acceptance and regulatory oversight. Screening for tuberculosis, annual dental and vision examinations, and medical care reviews are federally mandated whereas annual history and physical examinations, while widely accepted, are not. In accordance with F-Tag 334, nurs-

ing facilities offer residents various vaccines, and these include the trivalent-23 pneumococcal vaccine, an annual influenza vaccine, the varicella vaccine for the prevention of herpes zoster, and the tetanus booster every 10 years or the primary tetanus series.

General health maintenance activities occur on a regular basis. Residents are to be screened for cognitive deficits, depression, and gait and balance disturbances at least initially and as needed. In addition, reviewing residents' medications and assessing blood pressure, functional status, and evidence of pain, abuse and neglect are to be performed at each required visit, regardless of the resident's life expectancy and comorbidities. Recording the resident's weight should occur on required visits except for those residents with limited

**TABLE 21-7****Pocket Tool Kit for Nursing Facility Visits**

Pen

life expectancy. As a preventive measure for residents with a life expectancy of more than 2 years, screening for osteoporosis is recommended at least once. Usually, discussions on advance directives occur on admission and are updated as needed. Facility-based restorative nursing programs are effective to maintain resident participation in daily routine activities and to reduce the prevalence of decline in ADLs. In addition, physically frail residents find physical activity incorporating progressive resistance exercises to prevent muscle weakness helpful.

Little evidence exists to guide periodic laboratory monitoring. On admission, obtaining a complete blood count and albumin on admission is reasonable. Recommended disease-specific periodic laboratory testing is shown in [Table 21-10](#). Estimating the creatinine clearance is helpful in choosing the correct dose for medications. Macrocytic anemia (vitamin B-12 and folate deficiency) and subclinical hypothyroidism are common conditions that are easily treated in nursing facility residents and warrant screening on admission and at least every 2 years.

## Behavioral Symptoms

Dementia is the leading cause of institutionalization among older adults, and the prevalence among nursing facility residents is estimated at 50% or more. Although depression is the primary behavioral symptom in the early stages of dementia, it is usually not the primary cause for a nursing facility admission. Families and caregivers seek assistance more frequently in the moderate to later stages

**TABLE 21-8****Organizing Your Clinical Work in the Nursing Facility**

Obtain an update on the residents from the charge nurse
Ask the charge nurse to review the 24-hour reports since your last visit
Check any written communications for non-urgent events ( <a href="#">Figure 21-4</a> )
Review diagnostic tests, pharmacy recommendations and dietary requests
Locate blood glucose testing, weights, vital signs, etc.
Using your census sheet make note of pertinent information
Ask facility staff to take residents to their rooms where they will be seen
Talk to the resident and perform the appropriate exam
Document the history and physical exam at the bedside ( <a href="#">Figure 21-5</a> and <a href="#">Figure 21-6</a> )
When visits are complete retreat to a quiet place to review records, complete the progress note, confer with other members of the care team, write orders, and call families.
Sign consolidated orders
Complete discharge summaries
Respond to pharmacy alerts and recommendations
Respond to dietary requests
Sign telephone orders
Review orders with the charge nurse before leaving the unit

when behavioral symptoms, including agitation, dysphoria, anxiety, apathy, and irritability, are most prevalent. Most aggressive or agitation behaviors are associated with providing assistance with ADLs and include grabbing, biting, kicking, scratching, or pulling hair. Other problematic behaviors are yelling, screaming, wandering, and insomnia. Less reported but still prevalent behaviors include verbal insults, racial slurs, sexual innuendoes, or inappropriate touching.

In terms of personal safety, nursing assistants are at greater risk of assault from aggressive residents than are LVN/LPNs and RNs as the nursing assistants perform most of the nursing duties. While the rate of assaults is declining, the nursing facility rate of 40 assaults per 10 000 workers exceeds that of any other industry. As aggressive behavior occurs frequently when nursing assistants administer intimate care, it maybe that the resident misinterprets personal care as an assault or invasion of privacy. Other factors associated with behavioral symptoms include a premorbid personality with aggressive behavior, delusional thinking, and neurological disorders.

Primary approaches to managing behavioral symptoms include nonpharmacological interventions or administering psychoactive

**TABLE 21-9****Examples of Quality Indicators for the Management of Nursing Facility Residents**

TOPIC	INDICATOR	COMMENTS
Care planning (quality of life)	IF an older adult is admitted to a nursing facility THEN the documentation should demonstrate, or the resident/surrogate should report a discussion to establish goals of care. IF neither the resident nor family participates in planning goals of care THEN the reason should be clearly documented.	Feasible in the average community nursing facility
Calcium or vitamin D for osteoporosis (medical condition)	IF a resident has osteoporosis, THEN calcium or vitamin D supplements should be prescribed within one month of admission or new diagnosis of osteoporosis	Exclude if advanced dementia or poor prognosis
Malnutrition (Geriatric syndrome)	IF the nutritional status Resident Assessment Protocol has been triggered, THEN the presence or absence of malnutrition should be documented by the primary care provider.	

Data from Saliba D, Schnelle, JF. Indicators of the quality of nursing home residential care. *J Am Geriatr Soc.* 2002;50(8):1421–1430.

TABLE 21-10

## Diagnostic Testing and Monitoring

PRACTICE	RECOMMENDED FREQUENCY	COMMENTS
Hemoglobin and hematocrit	Weekly if taking erythropoietin agent Monthly with iron replacement until Hb stabilizes, then every 3–6 months	Modified Diet in Renal Disease (MDRD) equation is recommended to screen for chronic kidney disease. Establish and document target hemoglobin
Ferritin	Baseline prior to starting erythropoietin agent or to differentiate iron deficiency anemia	Erythropoietin more effective with appropriate iron stores, ferritin > 100. Ferritin < 20 associated with iron deficiency
PT/INR	Weekly until stable on warfarin, then monthly	Document duration of expected therapy
Electrolytes, renal function	Potassium prior to and after initiating ACE inhibitors, vancomycin or aminoglycosides Every 2–3 months if on diuretics.	Low salt diets may worsen hyponatremia. SSRIs are associated with SIADH in older adults
Estimated creatinine clearance	On admission or prior to medications dosing with known alterations based on function.	Many antibiotics Histamine-2 blockers Use Cockcroft-Gault for medication dosing
ALT, AST	Baseline and every 6–12 months if taking > 4 g daily of acetaminophen or on statins or fibrates	Recommended frequency in F Tag 329
Albumin or pre-albumin	On admission to screen for under nutrition and periodically for change in condition or weight loss	Order pre-albumin to evaluate current protein stores and to monitor effect of supplemental nutrition
Thyroid function; TSH, T3, T4	After admission and medically stable, when symptomatic, and every 6–12 months if on therapy	TSH may be falsely elevated in acute illness
Vitamin B-12, folate	On admission if indicated and every 2 yrs	Defer if terminally ill.
Blood glucose	QID if making dosage changes in anti-diabetic therapy.	Hb A1c < 8 may be associated with decreased morbidity and mortality with infections
Finger stick	Thrice weekly morning and afternoon if stable	
Hemoglobin A1c	Hemoglobin A1c every 3–4 months	

ACE, angiotensin converting enzyme; SSRI, selective serotonin reuptake inhibitor; SIADH, syndrome of inappropriate antidiuretic hormone secretion; PT, prothrombin time; INR, international normalized ratio.

medications and cholinesterase inhibitors. Examples of nonpharmacological interventions are using an unmet need approach, manipulating the resident's environment, and providing caregiver training. The unmet need approach assumes that all behavior has meaning, the aggressive behavior serves a purpose, and the behavior serves as some reward or consequence for the resident. Unmet need interventions investigate the antecedent, behavior, and consequence to assess the motivation behind the behavior and to design an approach specifically tailored for the resident.

For many residents, meaningful social engagement in the environment has a positive effect on loneliness, helplessness, and boredom. The challenge for the facility is manipulating the environment to find a balance between excessive stimulation and social isolation. One approach is to have residents with similar behaviors, symptoms, or degree of dementia residing on the same hall or unit. Residents in early stages of dementia who remain verbal and interact with their peers with a minimum of disturbing behaviors enjoy living where they can participate in social interaction.

Separating physically and verbally aggressive ambulatory residents from the physically frail provides a safer environment for residents who maybe passive targets of assaults. Security procedures for ambulatory residents prevent unsafe elopement while allowing maximal activity inside and outside the facility. Wandering behaviors that are problematic on a fully open unit are normalized and encouraged in a secure unit.

Residents with end-stage dementia have more labor-intensive needs for eating assistance, skin care, and mobility. To offset this, facilities often use staff from another unit during times of higher needs. For instance, staff from a unit where residents are more independent maybe available to assist with feeding residents who cannot

feed themselves. Another environmental manipulation that is gaining in popularity is permanent assignments for all nursing facility staff. Behavioral symptoms maybe more easily managed and even diminish when the nursing assistants are assigned to the same residents everyday.

Caregivers may precipitate undesirable behaviors. For example, residents are more likely to react aggressively during bathing if caregivers speak negatively, are hurried, are disrespectful of privacy, or fail to give prompts or ask permission before spraying water. Bathing often becomes a battle to get residents clean regardless of their reluctance. Since the 1990s, the National Institutes of Health (NIH) has continuously funded two research teams to develop interventions to improve bathing. Using person-centered methods, ratings of over 500 videotaped baths found a 56% reduction in aggressive behaviors against caregivers, a 62% reduction in care recipient agitation, a 67% reduction in care recipient distress, and a 38% decrease in the proportion of bath time spent crying or screaming. Although not as extensively studied, it makes intuitive sense that similar person-centered approaches would be effective for other caregiving activities such as dressing and toileting.

Using pharmacological interventions to control behavioral symptoms is a common practice. Nearly 64% of nursing facility residents are given psychoactive medications including anxiolytics (17.1%), antidepressants (45.6%), antipsychotics (26.7%), or hypnotics (5.8%). Results are mixed on the efficacy of pharmacological interventions for controlling behavioral symptoms of dementia that include hallucinations, delusions, agitation, aggression, combativeness, and wandering. F-Tag 322 states that residents have the right to be free from chemical restraints imposed for purposes of discipline or convenience when such medication is not required to treat

the resident's medical symptoms. Pharmacotherapy for behavioral symptoms should be limited to specific medical conditions including hallucinations, delusions, and other psychotic behaviors. Further in relation to pharmacotherapy, F-Tag 329 states that residents will not be given unnecessary drugs. Antipsychotic medications should be restricted for the treatment of specific medical conditions clearly documented in the resident's medical record. Planned behavioral interventions are expected when psychoactive medications are prescribed. Evaluation of the effectiveness of the interventions including medications and gradual dosage reductions is performed periodically. At least quarterly, reviewing the target symptoms, effect of the medication on the symptoms, changes in functional status, and medication-related adverse reactions will assist the facility in regulatory compliance. Gradual dose reductions should be attempted in two separate quarters of the first year unless clinically contraindicated. After the first year, a gradual dose reduction should be attempted annually unless clinically contraindicated.

Compared to giving a placebo, residents appear to gain little benefit from typical antipsychotic agents given to control chronic agitation or aggressive symptoms or for anticonvulsants used as mood stabilizers. Olanzapine and risperidone, as atypical antipsychotic agents, have been included in more trials and show modest benefit at the cost of a slight increased risk for stroke and all cause mortality. Because antidepressant agents are effective in reducing symptoms of depression, their use in nursing facilities is increasing.

Cholinesterase inhibitors, approved since 1996, are recommended for mild to severe Alzheimer dementia. The three most commonly prescribed agents are donepezil, rivastigmine, and galantamine. Memantine, a noncompetitive *N*-methyl-D-aspartate receptor antagonist, is the newest agent and was approved in 2003. As a class, these agents appear to improve or stabilize cognition, global functioning, activities in daily living, and moderate behavioral symptoms associated with Alzheimer dementia. In residents with moderate to severe dementia, donepezil and memantine as monotherapy are associated with improved cognition and stabilized function. Donepezil also improves and stabilizes behavioral symptoms. Adding memantine to donepezil as residents reach moderate to severe stages may improve cognition, ADL, and behavioral symptoms. The effects of these agents in clinical trials are modest in relation to placebo. None restore full cognition or functioning and regardless of the length of treatment or dose, the underlying neurological disorder will progress.

Although clinical guidelines on initiating pharmacotherapy for dementia exist, little information suggests when to terminate treatment. Treatment objectives in early stages of dementia include improving independence in ADLs and delaying admission to the nursing facility. However, these objectives need to change as dementia advances (Table 21-11). Some question the ethics of prescribing an expensive medication for a progressive, degenerative neurological disorder in an older adult not likely to live in the community again. Whether or not the use of these agents reduces hospitalizations or prevents pressure ulcers, unintended weight loss, infections, or other complications is not known.

Clinicians are divided on whether to continue therapy as long as the person is verbal and able to eat somewhat independently. For some, recognizing family members may be a sufficient criterion to continue therapy. For residents with moderate to severe Alzheimer dementia who tolerate donepezil, adding memantine maybe beneficial as long as treatment is compatible with previously stated wishes

TABLE 21-11

## Treatment Objectives in Advanced Alzheimer's Dementia

OBJECTIVE	POTENTIAL MEANINGFUL OUTCOMES OF CHOLINESTERASE INHIBITORS
Stabilize cognition	Recognize family Continue to talk
Maintain function	Continue to eat independently
Stabilize behaviors	Facilitate bathing and continence care
Decrease caregiver stress	Reduce hitting, kicking, screaming and yelling.
Reduce utilization of healthcare resources	Reduce hospitalizations
Prevent complications of functional decline	Prevent pressure ulcers Prevent infections Maintain swallowing function

and known goals. A safe approach for treating behavioral symptoms with pharmacotherapeutic agents is to start with a cholinesterase inhibitor, add memantine and/or citalopram if behaviors escalate, and reserve the atypical antipsychotic agents as a last resort for documented psychotic behaviors.

### Urinary Incontinence

Affecting slightly more than half of all nursing facility residents, urinary incontinence is an independent predictor for nursing facility admission and is associated with irritant dermatitis, pressure ulcers, falls, significant sleep interruptions, and urinary tract infections. Given that 82% of nursing facility residents require assistance or are dependent on caregivers for toileting assistance, it is not surprising that urinary incontinence is viewed as normal. The intent of F-Tag 315 is to ensure that incontinence is recognized, appropriately assessed, and managed so that the resident can achieve as normal a level of continence as practical. Physicians, geriatric advanced practice nurses, or certified continence nurses are valuable assets to the physical assessment team in identifying the cause and determining the appropriateness of bladder rehabilitation, toileting assistance, or check and change routines.

Residents who are only intermittently incontinent may benefit the most from an evaluation and management plan. For most residents with daytime continence as a goal, performing a focused physical examination that includes a rectal and genitourinary examination is reasonable. A cough test for stress incontinence, postvoid residual determination, urinalysis, and urine culture maybe helpful in guiding treatment in selected residents. Medical justification is required for indwelling catheters, including urinary retention or comfort in dying. As a cognitive screen, residents with advanced dementia who do not respond to their name or cannot state their name are unlikely to benefit from either a toileting program or bladder rehabilitation. Other incontinent residents should be given a 3- to 5-day trial of a systematic daytime toileting program such as prompted voiding. Bladder training is best reserved for ambulatory residents who are occasionally incontinent, are aware of the need to urinate, are able to learn and retain new information and are motivated to stay dry. Bladder training generally consists of teaching different techniques, including pelvic floor muscle exercises and scheduled voiding with systematic delay of voiding. Residents are taught distraction techniques to reduce urgency and delay toileting so that they can reach a goal to void continently every 2 to 4 hours during the day.

Toileting assistance programs may be resident-centered or caregiver-driven. Cognitively impaired residents who retain the ability to state their name or point to common objects respond favorably to prompted voiding. This resident-centered approach teaches the resident to recognize bladder fullness or the urge to void, to ask for assistance, and to accept or decline assistance when offered. Scheduled toileting depends on caregivers to toilet residents on a schedule that closely matches the resident's daily voiding pattern. Some residents may achieve daytime dryness without needing to wear incontinent briefs during the day. Residents who require two or more persons for assistance and are unable to respond to or consistently resist toileting assistance will need a schedule by which they are periodically checked for wet or soiled briefs and changed as necessary in order to maintain comfort and dignity.

### Polypharmacy and Medication Errors

Medication-related adverse events are common in the nursing facility population. Factors that increase the risk of adverse consequences include complex medication regimens, the large number and types of medication used, physiological changes accompanying the aging process, and the resident's multiple comorbidities. Inappropriate prescribing and inadequate monitoring are the most common errors in medication management. The AMDA and the American Society of Consulting Pharmacists have identified the top 10 particularly dangerous drug interactions in nursing facilities, and this list is shown in [Table 21-12](#).

The federal regulation F-Tag 428 states that the drug regimen of each resident is to be reviewed monthly by a licensed pharmacist. The pharmacist must report any irregularities to the attending physician and the director of nursing, who are to respond appropriately. The intent is to prevent or minimize adverse consequences that may impede residents reaching their highest level of functioning. According to F-Tag 329, each resident's drug regimen must be free from unnecessary drugs, which includes any drugs used in excessive dose (including duplicate therapy), for excessive duration, without adequate monitoring, without adequate indications for its use, or in the presence of adverse consequences. Following a few simple recommendations may reduce inappropriate prescribing and simplify the drug regimens ([Table 21-13](#)).

Common medication errors originating at the nursing facility include transcription errors, problems in drug administration, delay in obtaining medications, inadequate symptom management, and using as needed (prn) medications inappropriately. Asking the nurse to read orders before the physician leaves the building or to repeat a telephone order reduces transcription errors. Although most nursing facilities do not have pharmacies on site, facilities have policies and procedures to notify the attending physician or other practitioners if they encounter difficulties in obtaining medications promptly and may have an emergency medication supply. Practitioners can inquire about available antibiotics if urgent administration is required.

Following a few common procedures simplifies the drug regimen, encourages timely notification of a change in condition, and avoids adverse effects. Pain is more easily managed if analgesics are ordered around the clock. For convenience, many practitioners order a list of as-needed medications, where these include laxatives, mild analgesics, antipyretics, antitussives, topical antifungals, and antiemetics. Use of these medications, especially antipyretics in the absence of a documented infection, may result in a delay in notification of a significant change in condition and are best avoided. Limiting as needed medications to one mild analgesic for pain only and one laxative minimizes the problem. Regular laboratory assessment of drug levels, renal function, liver function, and blood counts is appropriate to monitor therapeutic responses and adverse effects of medications (see [Table 21-10](#)).

### Falls

Falls are a cause of significant morbidity and liability in the nursing facility. Age-related changes, disease-specific pathology, and environmental factors contribute to falls. Falls maybe an atypical presentation of an acute change in condition, as a result of poor judgment, related to an adverse medication event or physical deconditioning. Osteoporosis, anticoagulation, and slowed reaction time contribute to the risk of serious injury, including bone fractures and subdural hematomas. Although totally eliminating falls is unrealistic, practitioners can significantly minimize falls and reduce the risk of serious injury.

Adopting a consistent approach to the management of falls across the spectrum of aging from the physically frail, the person with

**TABLE 21-12**

#### Top 10 Dangerous Drug Interactions in Nursing Facilities

MEDICATION 1	MEDICATION 2	ADVERSE EVENT
Warfarin	NSAIDs such as ibuprofen, naproxen, COX-2 inhibitors	Potential for serious gastrointestinal bleeding
Warfarin	Sulfonamides such as trimethoprim/sulfamethoxazole	Increased effects of warfarin, with potential for bleeding
Warfarin	Macrolides such as clarithromycin, erythromycin	Increased effects of warfarin, with potential for bleeding
Warfarin	Fluoroquinolones such as ciprofloxacin, levofloxacin, ofloxacin	Increased effects of warfarin, with potential for bleeding
Warfarin	Phenytoin	Increased effects of warfarin and/or phenytoin
ACE inhibitors such as benazepril, captopril, enalapril, and lisinopril	Potassium supplements	Elevated serum potassium levels
ACE inhibitors such as benazepril, captopril, enalapril, and lisinopril	Spironolactone	Elevated serum potassium levels
Digoxin	Amiodarone	Digoxin toxicity
Digoxin	Verapamil	Digoxin toxicity
Theophylline	Fluoroquinolones such as ciprofloxacin, levofloxacin, ofloxacin	Theophylline toxicity

Data from the American Medical Directors Association; [www.amda.com](http://www.amda.com).

**TABLE 21-13****Strategies to Avoid Medication Related Problems**

POTENTIAL PROBLEM	RECOMMENDATION
Delay in obtaining medications	The nursing facility will have an “emergency drug box” If urgent administration of antibiotics is necessary, ask what is available at the facility
Inadequate symptom management	Prescribe pain medications around the clock
Delayed notification of change in condition	Limit prn medications to one over-the-counter laxative and acetaminophen for pain only Order acetaminophen for fever only during active illness and only for 2–3 days.
Inadequate monitoring for psychoactive medications	Utilize standardized tools to periodically evaluate depression, mental status, behavioral symptoms, e.g., Geriatric Depression Scale
Simplify the drug regimen	Utilize extended release medications Work toward once or twice a day dosing for all medications
Inadequate monitoring of medical conditions	Order weekly monitoring of blood pressure [antihypertensives], pulse [beta-blockers, digoxin], weight [megestrol acetate], monthly PT/INR [warfarin]
Duplicate medications	Specify the diagnosis for each medication. This may need to be written as a physicians order, e.g., “add diagnosis of seizure (resident is on phenytoin)” When original order is written put diagnosis after the drug, e.g., “warfarin for deep vein thrombosis”
Medications commonly over prescribed	Histamine—2 blockers, proton pump inhibitors: treat peptic ulcer disease or document gastroesophageal reflux disease Vitamin C and zinc: no good evidence for use in pressure ulcers Ferrous sulfate: rarely necessary more than once a day Multiple laxatives: choose one and order on a regular basis, stool softeners are generally ineffective

Data from the American Medical Directors Association; [www.amda.com](http://www.amda.com).

dementia, and to the individual who is dying, is reasonable. The AMDA suggests a structured interdisciplinary approach to falls including recognition, assessment, intervention, and assessment. A comprehensive approach to fall management (“The Fall Management Program”) is available at [www.medqic.org](http://www.medqic.org) (under “Nursing Homes, Restraints, Tools”).

A prior history of a fall is the single most potent predictor of future falls; fear of falling also imposes substantial risk. For newly admitted residents, interviewing the resident, family, or other caregivers is important in identifying these risk factors. Conditions that increase the risk for falls include chronic medical problems (such as cardiovascular disorders and degenerative joint disease), medications, impaired functional status, vision, dementia, and depression. Some conditions place residents at higher risk for severe injury in the event of any fall. These include anticoagulants that may cause excessive blood loss at a lower impact. Frequent fallers have a higher rate of significant injury as opposed to those who fall infrequently. Fractures of the hip, spine, and wrist are more common in persons who lack sufficient subcutaneous fat and muscle bulk to absorb the impact of a fall. Residents with visual impairment also are a higher risk for injurious falls. Most facilities contact the practitioner immediately after any fall, injurious or not. While the merits of immediate notification continue to be debated, residents who fall need a prompt nursing assessment for injury and then reassessment for at least 72 hours for any delayed appearance of injury. The AMDA recommends an additional interdisciplinary assessment to define the scope, frequency, causes, and complications of falls. Recurrent falls often have an identifiable cause. Falling maybe the presenting sign for a urinary tract infection, hypovolemia from dehydration, or postural hypotension following a medication adjustment. It is reasonable to rule out temporary conditions before assuming that a chronic condition such as dementia or Parkinson’s disease is the cause.

Resident autonomy and safety are important aspects of fall management. Residents and families may accept some risk to maximize

autonomy and promote dignity. Until recently, physical restraints were used to limit mobility. The intent of F-Tag 222, as shown in [Table 21-14](#), is to promote the highest practicable well-being for each resident and to specifically prohibit physical restraints for discipline

**TABLE 21-14****Physical Restraints**

The resident has the right to be free from any physical or chemical restraints imposed for purposes of discipline or convenience, and not required to treat the resident’s medical symptoms.

The intent of this requirement:

- assist the resident to attain and maintain highest level of function
- prohibit using restraints for discipline or convenience
- limit restraint use to medically indicated circumstances

A physical restraint is a device the resident cannot remove easily and restricts freedom of movement including leg restraints, arm restraints, hand mitts, soft ties or vests, lap cushions, and lap trays. Also:

- side rails that keep a resident from voluntarily getting out of bed
- sheets, fabric, or clothing used to restrict movement
- chairs with trays, tables, bars or belts, that the resident cannot remove easily
- placing a resident in a chair that prevents a resident from rising

*Alternatives to Physical Restraints*

- Restorative care to enhance strength for mobility
- Meaningful engagement in activities and interests
- Place the bed lower to the floor
- Soft floor mats next to the bed
- Monitoring devices to alert staff
- Frequent staff monitoring, hourly room rounds
- Consistent, frequent, assistance with toileting
- Call bells or visual reminders to ask for assistance, if appropriate

CMS. State Operations Manual: Appendix PP. 2006. [http://cms.hhs.gov/manuals/Downloads/som107ap\\_pp\\_guidelines\\_ltf.pdf](http://cms.hhs.gov/manuals/Downloads/som107ap_pp_guidelines_ltf.pdf). Accessed March 12, 2007.

**TABLE 21-15****Interventions to Prevent Falls in the Nursing Facility**

INTERVENTION	STRATEGY
Exercise	Screen with “Get Up and Go Test” Physical therapy Restorative nursing programs Walk to dine, walk to commode, walk to the outside, etc. Emphasize mobility during daily care Group exercise activities
Sensory impairment	Screen for visual acuity and contrast sensitivity Wear corrective lenses Appropriate referral to ophthalmology
Medication	Inform caregivers of dosage adjustments in medications, especially psychoactive medications, antihypertensives, diuretics, and antiepileptics Reduce the total number of medications
Footwear	Rubber sole, high collar, sturdy upper, and good fit Make shoes available within 24 hours of admission
Cognitive impairment technology	Redirection and diffusion for aggressive behaviors. Rigid hip protectors, if ambulatory Alarm systems Walkers and canes Scoop mattresses Split side rails, half rails, or no bed rails Raised toilet seat. Low beds with padded floor mats Close fit between bed mattress and any bed rail

Data from Bonner AF. *Falling into place: a practical approach to interdisciplinary education on falls prevention in long-term care. Annals Long-Term Care* 2006;14(6):21–29. Also see “The Fall Management Program”; [www.medqic.org](http://www.medqic.org), (under Nursing Homes, Restraints, Tools).

or convenience and limit restraint use to circumstances in which the resident has medical symptoms that warrant restraint use.

Physical restraints are associated with accelerated physical decline, depression, and anxiety, contribute to hip and knee contractures, and may contribute to falls and injuries rather than reduce them. Families may unrealistically ask that falls be prevented. Educating families about the steps to assess and reduce risk may be helpful. Examples of specific interventions are noted in Table 21-15. Monitoring the resident’s response to the interventions allows practitioners to determine if the interventions are effective.

### Altered Nutritional Status

Citizen advocacy groups, the community, and health care providers often equate weight loss to the quality of care in a nursing facility. While over half of nursing facility residents either gain or lose weight over 2 years, weight loss is most closely related to inadequate intake or altered utilization of nutrients. Nursing facilities are bound by federal regulation to maximize nutritional status for residents (Table 21-16). As weight changes that occur quickly may have significant negative consequences, federal guidelines mandate an assessment when a resident loses 5% or more of body weight in 30 days. Some facilities adopt a stricter parameter, intervening when a resident loses more than two pounds in 1 month. A significant unintended weight loss accompanied by protein–calorie malnutrition

**TABLE 21-16****Nutrition**

The facility must ensure that each resident

- Maintains acceptable parameters of nutritional status, such as body weight and protein levels, unless the resident’s clinical condition demonstrates that this is not possible and
- Receives the appropriate diet when there is a nutritional problem

The intent of this regulation is to assure that the resident maintains acceptable parameters of nutritional status, taking into account the resident’s clinical condition or other appropriate intervention, when there is a nutritional problem.

#### Managing Unintended Weight Loss

Obtain weight on admission and weekly for 4 weeks

Admission assessment

- Albumin
- Cholesterol
- Complete blood count
- Ideal body weight and body mass index
- Establish goals of care; cure, restoration, maintenance, or comfort.

Assess early when weight loss is identified

Interval	Significant Loss	Severe Loss
1 month	5%	Greater than 5%
3 months	7.5%	Greater than 7.5%
6 months	10%	Greater than 10%

Identify common or potentially reversible causes when weight loss occurs

- Adverse drug effects
- Complete blood count
- Comprehensive metabolic panel
- Thyroid stimulating hormones
- Fecal occult blood testing

CMS. *State Operations Manual: Appendix PP. 2006.* <http://cms.hhs.gov/manuals/Downloads/som107ap.pp.guidelines.ltcf.pdf>. Accessed March 12, 2007.

often precedes worsening health status. Protein–calorie malnutrition increases susceptibility to infections and pressure ulcer risk, delays wound healing, and increases mortality from comorbidities. With the exception of weight gain due to fluid retention from heart failure, chronic kidney disease or liver failure, the outcomes for weight gain are usually favorable and do not require intervention.

As with other clinical practice guidelines, the AMDA recommends a systematic approach to the evaluation and management of altered nutritional status in nursing facility residents including recognition, an assessment based on appropriate goals, treatment, and ongoing monitoring. The registered dietician calculates the resident’s ideal body weight and body mass index. Obtaining weekly weights for 4 weeks and ordering basic laboratory testing identifies most newly admitted residents at highest risk for under nutrition. Eating preferences and functional abilities are generally components of the admission interdisciplinary nutrition evaluation. If appropriate, a skilled clinician may perform a bedside eating evaluation (Table 21-17) to differentiate a swallowing disorder from other medical conditions. If a swallowing problem is identified, discussions with the resident or family lets practitioners determine if further testing falls within the goals of care.

Other conditions may precipitate nutritional problems, increase nutritional requirements, or mask potential nutritional problems.

**TABLE 21-17****Bedside Eating Evaluation**

## Assess:

- oral cavity for ulcers, dental caries, poorly fitting dentures
- gag reflex, tongue movement
- ability to handle saliva
- ability to eat independently

## Administer in order:

- thickened liquids; nectars, milkshakes
- pureed foods; pudding, yogurt, ice cream
- soft foods requiring chewing; cake, rice, bread
- firm texture foods; sliced meats, fruits
- clear liquids

## Observe for:

- coughing before, during, or after swallowing
- multiple swallows with each portion
- frequent throat clearing
- hoarse or wet voice after swallowing
- drooling
- pocketing
- protruding tongue movements

Data from Taler G, Rapp MP, Brandt N, et al. *Altered Nutritional Status: Clinical Practice Guideline*. Columbia, MD: American Medical Directors Association; 2001.

Nutritional requirements are increased in residents with pressure ulcers, healing surgical wounds, and infections. The consulting pharmacist can identify medications that alter taste, decrease appetite, precipitate dysphagia, or cause gastrointestinal complaints. Residents with agitation behavioral symptoms or movement disorders may need extra calories to maintain their weight. Infections may present with anorexia, malaise, or weight loss and should be ruled out.

A gradual, persistent weight loss is a more sensitive trigger for nutritional problems than the RAP and MDS. A common practice is to evaluate the resident's weight during each required visit and compare the current weight to that of the previous 3 to 4 months. It is helpful to establish notification parameters that identify residents who demonstrate an abrupt change in food and/or fluid intake as this frequently signals an acute condition or medication effect.

Treatment for weight loss is guided by the resident's goals and plan of care. Interventions may involve several disciplines, especially nursing, dietary, and medicine. As few residents return to earlier adult weights or regain weight lost during an acute event, stabilization at a lower weight may be appropriate. Facility interventions addressing the eating environment, tailoring meals for resident personal and cultural preferences, and providing adequate eating assistance are critical. Medical interventions listed in [Table 21-18](#) are low cost and often effective.

Disease-specific diets for hyperlipidemia, heart failure, and diabetes mellitus are not as palatable as unrestricted diets and probably do not control symptoms in nursing facility residents. However, restricting protein in late-stage chronic kidney disease may delay the need for dialysis. A more effective dietary intervention is to increase the food's nutrient density by adding milk powder, butter, or oil. Offering liquid dietary supplements at time of medication increases the likelihood that these supplements will be consumed.

It is reasonable to address artificial nutrition and hydration early in the admission evaluation, at least annually and if a significant change in condition occurs. Family members may have unrealistic

**TABLE 21-18****Medical Interventions for Altered Nutrition**

- Identify under-nutrition at the time of admission
- Treat depression aggressively
- Reassess all medications
- Order regular diets
- Consult with dietician to increase the nutrient density of foods
- Order 2 kcal per cc liquid supplements with medication passes
- Consider a daily vitamin supplement

## Managing artificial nutrition with tube feeding

- Tube feeding is consistent with resident advance directives
- Establish clear goals
- Discuss the probable lack of benefit for end stage dementia
- Withdraw tube feeding when goals are no longer met
- Consult with dietitians for calorie and fluid needs
- Order feedings for 16–20 hours a day to encourage out of bed activities

Data from Taler G, Rapp MP, Brandt N, et al. *Altered Nutritional Status: Clinical Practice Guideline*. Columbia, MD: American Medical Directors Association; 2001.

expectations regarding artificial nutrition and hydration, especially in dementia. Artificial nutrition and hydration has a limited effect on the natural course of dementia and further diminishes the resident's interaction in the facility environment. For persons in a persistent vegetative state, tube feeding extends life without an effect on functional status. Aspiration is a common problem with progressive dementia, and artificial nutrition does not reduce aspiration risk. Ongoing discussions with the family are necessary until the acute need for aggressive intervention is resolved, or the prognosis and goals are clearly understood. These conversations should be documented in the medical record.

**Pressure Ulcers**

Pressure ulcers are caused by external pressure usually due to in-bed immobility and out-of-bed inactivity. The intensity and duration of pressure interrupts blood flow over a bony prominence and causes tissue damage. Other risk factors include poor nutrition, impaired cognition, urinary and fecal incontinence, and friction and shear. Short-stay residents admitted for skilled nursing services are at the highest risk of developing a pressure ulcer, and this pressure ulcer usually develops within 3 weeks of admission. An acute change in the medical condition of a long-stay resident, such as an acute infection, is associated with an increased risk.

Topical treatment for pressure ulcers is based on the characteristics of the pressure ulcer, the treatment goals, cost, efficiency for nursing, and patient comfort. Limiting topical treatments to a facility-based formulary reduces variability and error in application. If allowed per facility policy and the state nursing practice, standing orders or protocols for Stage 1 and/or Stage 2 pressure ulcers facilitate prompt intervention ([Figure 21-7](#)). The "Tool Kit for Implementation of Clinical Practice Guidelines" from the AMDA is a valuable resource in developing a comprehensive pressure ulcer prevention and treatment program.

**Palliative Care**

Palliative care has become increasingly important in the nursing facility where currently 30% of persons admitted die within the first year, a number that is expected to increase as the population ages. Despite this reality, F-Tag 309 specifically states that each resident

## PRESSURE ULCER TREATMENT PROTOCOL

The intent of this protocol is to provide registered nurses [RN] and licensed vocational nurses [LVN] with a procedure to follow to initiate treatment of a stage 1 or stage 2 pressure ulcer. The nursing staff may not deviate from this protocol without prior consultation with the physician or nurse practitioner.

Check the appropriate boxes in each section. When complete, place the form in the physician order section of the chart.

## Assessment:

- Stage 1: Change in temperature, tissue consistency, and/or sensation in a defined area of persistent redness in lightly pigmented skin, or persistent red, blue, or purple hues in darker skin over an area prone to pressure ulcers
- Stage 2: Shallow, clean wound base with light to moderate exudates, color red to yellow
- Location \_\_\_\_\_
- Describe any pain associated with the pressure ulcer.  
\_\_\_\_\_

## Treatment Orders:

- Cleanse with normal saline
- Apply a hydrocolloid dressing and change every 7 days and prn
- Observe and document daily that the dressing is intact and in place.

## If there is pain:

- Acetaminophen 325 mg two tablets po or per tube twice a day until the ulcer heals
- Notify the physician or nurse practitioner if there is pain associated with the pressure ulcer is present and there are no treatment orders for pain

**FIGURE 21-7.** Pressure ulcer treatment protocol. Geriatric Associates of America (GAA) Order Set. (*Clinical Practice Guideline: Pressure Ulcer Therapy Companion. American Medical Director's Association 1999. Clinical Practice Guideline # 15: Treatment of Pressure Ulcers. Agency for Health Care Policy and Research 1994. Used with permission from Geriatric Associates of America, PA.*)

must receive care and services to attain or maintain the highest practicable physical, mental, and psychosocial well-being. The intent is to ensure residents receive optimal health care and do not deteriorate within the limits of a recognized pathology and the normal aging process. No F-Tag specifically addresses the quality of care in dying or dealing with symptoms such as pain or the emotional distress that may accompany the dying process. Although efforts have been made to use MDS items to predict death, there is neither a RAP for assessing a dying person nor is there currently a RAP for chronic pain.

The trajectory of dying occurs over months to years and can be characterized by exacerbations of chronic illnesses or a gradual global decline in health and function. Most often, an acute episode of illness such as a myocardial infarction, cerebral vascular accident, or pneumonia precedes death. In the absence of advance directives to the contrary, this acute event often precipitates a transfer to the hospital. Staff at nursing facilities are often more capable of caring for dying residents with as much if not more dignity and comfort than staff at hospitals. To help assure a resident's death according to their wishes, practitioners should discuss preferences (Figure 21-8). Improving palliative care in the nursing facility includes educating caregivers and families, managing the resident's pain, increased utilization of hospice services or palliative care plans, close attention to advance care planning, and better communication between the resident and family, staff, and physician.

## MANAGING THE ACUTE CHANGE OF CONDITION

Nursing facility residents are at high risk for acute illness and hospitalization. Hospitalization is both costly and disruptive and exposes residents to risks of fragmented transitional care and iatrogenic complications, including delirium, malnutrition, pressure ulcers, and adverse drug reactions. Residents most frequently hospitalized are those with preexisting pulmonary and/or cardiovascular disease, diabetes mellitus, swallowing dysfunction, and genitourinary tract disorders. The most common admitting diagnoses are pulmonary conditions, urinary tract and skin infections, heart failure, and dehydration/malnutrition syndromes. The primary issues contributing to preventable hospitalization include lack of early recognition of change in condition, absence of an appropriate assessment by the nursing staff, a delay in notification of the change in condition to the medical provider, and lack of appropriate monitoring and follow-up by both nursing and medical provider when a change is recognized.

Determining the underlying cause of a change in condition enables the staff to assess the situation appropriately. The staff must know residents who are at highest risk of hospitalization, be aware that when the residents become ill, symptoms may differ from those in younger persons, and be able to evaluate whether or not the resident can be cared for at the facility. Atypical presenting signs and symptoms compromise early detection of an acute change in condition. As residents with cognitive or communication deficits do not often report physical complaints, common presenting signs, which includes sleepiness, lethargy, and fatigue, are frequently not recognized until the resident is moribund. Direct care staff may not have a mechanism to report observations or fail to appreciate the significance of early, subtle changes in condition. Personnel from other departments, such as dietary or housekeeping, who do recognize a change may assume they are not qualified to make such an observation and fail to report it. Practitioners responding to multiple nonurgent or notification-only calls often fail to respond appropriately to the urgency of the condition.

The F-Tag 157 states that a facility must immediately consult with the resident's physician in the event of an accident with injury, deterioration in health, a need to discontinue a treatment due to adverse consequences or start a new treatment, and request transfer or discharge resident to another level of care. The regulations allow for consultation prospectively for minor frequently occurring events, such as skin tears or noninjurious falls. Protocols, such as the example for skin tears (see Figure 21-3) developed in consultation with the nursing facility team and used to manage commonly occurring events, may reduce the burden of communication.

Due to their knowledge of residents ADL habits, nursing assistants are often the first to observe a change in condition. Nurse assistants utilizing an instrument (Figure 21-9) or procedure to facilitate reporting permits LVN/LPNs and RNs to assess, monitor, and convey the appropriate information to the practitioner. Once a change is reported, the LVN/LPN or RN verifies the report to determine the change's nature, severity, and possible cause. At a minimum, the LVN/LPN or RN personally obtains the vital signs, performs a pain assessment, verifies food and fluid intake, evaluates the level of consciousness and weakness, and reviews fall history. The LVN/LPN or RN can ask the nursing assistant about changes in elimination, behavioral symptoms, and the ability to perform ADLs. The next step is to determine the resident's stability and, based on the urgency of the symptoms, call the practitioner.

## Palliative Care Form

The information on this form assists in documenting the reasons for palliative, or comfort care. The resident will continue to receive nursing, dietary, social, and medical services that will provide comfort.

Diagnoses to support the Palliative Care Plan

---

---

The physician, nurse practitioner, or physician's assistant has identified conditions or procedures that may be unavoidable for the resident. The nursing facility staff will talk to you about the procedures that may be used to decrease the occurrence of these conditions.

- Weight loss
- Skin breakdown and/or pressure sores [bedsores]
- Dehydration
- Severe constipation
- Gradual or rapid loss of the ability to move about independently
- The resident may not be able to get out of bed
- An indwelling bladder catheter may be necessary for comfort
- Medications to control symptoms may be necessary including but not limited to narcotics for pain or breathing symptoms, anti-anxiety medications, and sleeping medications.

The nursing facility wants to understand what heroic measures you would like to avoid. At your request the nursing facility will follow your instructions for the procedures listed.

**Specifically**

- DO NOT** Hospitalize unless symptoms cannot be controlled in the facility
- DO NOT** Attempt cardiopulmonary resuscitation
- DO NOT** Administer medications to cure a condition [antibiotics]
- DO NOT** Use artificial nutrition [tube in the nose or stomach]
- DO NOT** Use artificial hydration with fluids in the veins [intravenous or IV]
- DO NOT** Use artificial hydration with fluids under the skin [hypodermoclysis]

Adopting a standardized mechanism for reporting information promotes accurate and timely communication. The SBAR (situation–background–assessment–recommendation) is one such process to enhance communication between practitioners and fa-

cility nurses (Figure 21-10). Editing the format for the facility to initiate the call serves as a reminder to the nurses to collect the appropriate assessment information. The mnemonic is easy to remember, familiar to both nurses and practitioners, and encourages communication of critical information.

Regardless of the severity of the change noted in the initial report, it is critical for the nurse to follow-up and monitor the resident for a period of time. Three days is usually sufficient to assess trends and changes in vital signs, including pulse oximetry, the level of alertness, and appetite and fluid intake. During this time, the practitioner may make a visit to further assess the situation and intervene appropriately.

Medical conditions that usually warrant hospitalization include acute abdominal pain with vomiting, chest pain not due to stomach pain or musculoskeletal pain, a fall with pain and signs of fracture, hypertension with systolic BP over 230 mm Hg, signs of stroke, vomiting blood, low blood pressure, tachycardia, or respiratory distress with rate over 28 and not relieved with oxygen, nebulizers, or suctioning. In the absence of these conditions, the practitioner ascertains whether or not the facility has adequate support for the resident to remain in the facility (Figure 21-11).

### Acute Care/Nursing Facility Interface

Transitions between the hospital and the nursing facility are commonplace for residents with serious acute illnesses and exacerbation of chronic conditions. Relocation may lead to detrimental effects on residents, including delirium, adverse drug events, and undesirable

#### Early Warning Illness Report

Please answer these questions about your resident. If you answer **NO** to any of the following questions, please **tell the charge nurse as soon as possible**, no later than the end of your shift.

- Seems like herself/himself?
- Ate the same amount of food?
- Talked to you in usual way?
- Looked at you in usual way?
- Participated in usual leisure activity?
- ADL activity the same

Please check for the following. . .

- Nervous or Agitated
- Weak
- Drowsy or Tired
- Confused
- Need help with dressing, toileting, transfers

If any of these conditions seem **WORSE** than other days, or if she/he or anyone else tells you she/he had a health problem today **report it to the charge nurse as soon as possible!**

**FIGURE 21-9.** Early warning illness report. (Adapted and used with permission from Boockvar K, Brodie HD, Lachs M. Nursing assistants detect behavior changes in nursing home residents that precede acute illness: development and validation of an illness warning instrument. *J Am Geriatr Soc.* 2000;48(9):1086–1091.)

**FIGURE 21-10.** Receiving notification of change in condition. [Data from Permanente, K. *SBAR Technique for Communication: A Situational Briefing Model*. December, 2004. <http://www.ihl.org/IHI/Topics/PatientSafety/SafetyGeneral/Tools/SBARTechniqueforCommunicationASituationalBriefingModel.htm>. Accessed January 6, 2007.]

- Reporting mechanisms to ensure that changes in condition are reported appropriately
- Ability to start treatment, e.g., antibiotics, pain medication in a few hours
- Ability to start intravenous or hypodermoclysis therapy for hydration within 2 hours of the order
- Sufficient RN coverage to over see appropriate monitoring over 24 hours
- Sufficient RN staffing to ensure daily RN assessment until the acute change has resolved or stabilized
- Sufficient RN staffing to recognize and report possible complications of treatment within 24 hours of their identification

**FIGURE 21-11.** Criteria for managing an acute change in condition in the facility. [Data from Levenson S, Rapp MP, Barnett AM, et al. (2003). *Acute Change in Condition in the Long Term Care Setting*. Baltimore, MD: American Medical Directors Association; 2003.]

interventions. Effective communication and efficient transfer of information will ease the transition of nursing facility residents to and from the emergency department and hospital. The point of transfer for nursing facility residents to hospitals is usually the emergency department, where residents are admitted for evaluation of a change in condition frequently complicated by delirium, dehydration, and frailty.

Each setting presents a unique set of challenges for critical information exchange. Urban hospitals often depend on multiple medical disciplines to manage one admitted patient, and teaching hospitals regularly rotate medical residents and students each month. In the nursing facility, changes in administration, ownership, nursing leadership, and staff nursing further complicate communication between the hospital and the facility. Emergency departments (Figure 21-12) and nursing facilities (Figure 21-13) have different information

Long Term Care.* 2005;13(5):25–32.)

needs on point of transfer. Processes including standardized forms and checklists can improve the bidirectional communication.

## Infections

Diagnosing infections in nursing facility residents is difficult because of the limited availability of diagnostic tests, the variable assessment skills of the facility nurses, and lack of practitioners on site 24/7. Clinical presentation of illness in nursing facility residents is often subtle or atypical. Guidelines and standards appropriate to acute care or community-based settings may not be appropriate to the nursing facility. Provided there are no advance directives to the contrary, nursing facility residents suspected of an infection should be diagnostically evaluated and treated as is appropriate.

The most common infections among nursing facility residents are urinary tract infections, respiratory infections, skin and soft tissue infections, and gastroenteritis. The usual clinical clues to infection may or not be present, e.g., change in the characteristics of urine, fever, cough, and yellow sputum. Noted more often is a change in mental or cognitive function, falling, or an inability to perform usual activities in daily living. An indicator of pneumonia is that the resident may have tachypnea (> 25 breaths per min). In the absence of laboratory diagnostics, the respiratory rate effectively differentiates respiratory infections from urinary tract and soft tissue infections. Because of high mortality within 24 hours of presentation, blood

cultures should not be performed in suspected bacteremia. As long as transfer is compatible with the plan of care admit residents to the hospital who are likely to have bacteremia.

Recommended criteria for recognizing fever in the nursing facility resident are (1) an oral temperature of 100°F (37.8°C) measured once or (2) an oral temperature of 99°F (37.5°C) on repeated measures (or an increase of 2°F (1.1°C) above baseline). As most facilities obtain vital signs providing a baseline, including temperature, at least monthly, either method should suffice.

Clinical evaluation of residents includes measuring vital signs and performing an initial assessment at the facility. Using the SBAR (see Figure 21-10), the nursing staff should communicate information regarding the resident's status to the practitioner on the same shift the assessment is made. The evaluation and management plan is documented and, if applicable, the rationale for withholding any diagnostic or treatment measures noted. Before administering antibiotics, practitioners should consider assessment parameters, diagnostic tests, and minimum criterion outlined in Table 21-19.

## ROLE OF THE MEDICAL DIRECTOR

To ensure compliance with Medicare and Medicaid regulations under F-Tag 501, nursing facilities appoint a physician to serve as

TABLE 21-19

## Management of Common Infections

INFECTION	SIGNS AND SYMPTOMS	DIAGNOSTIC TESTING	MINIMUM CRITERIA FOR ANTIBIOTICS
Urinary tract	Specific: Fever, dysuria, urgency, frequency, nocturia, increased incontinence Nonspecific: new or increased confusion, anorexia, functional decline	Urinalysis and if positive for pyuria, urine culture Complete blood count with differential	1. No indwelling catheter: acute dysuria alone or with fever plus one of the following; new or worsening urgency, frequency, suprapubic pain, gross hematuria, costovertebral angle tenderness, or urinary incontinence 2. With and indwelling catheter: fever, new costovertebral tenderness, rigors, or new onset delirium
Pneumonia	Respiratory rate >25, pulse oximetry < 90, cough, fever, purulent sputum, positive auscultory findings, or pleuritic chest pain	Pulse oximetry Chest radiograph Complete blood count with differential	1. Temperature >102°F (38.9°C) plus one of the following: respiratory rate >25 or productive cough 2. Temperature >100°F (37.9°C) and cough plus one of the following, pulse >100, delirium, rigors, respiratory rate >25 3. Afebrile with chronic obstructive pulmonary disease (COPD): new or increased cough with purulent sputum production 4. Afebrile without COPD: new cough with purulent sputum production and one of the following: respiratory rate >25 or delirium
Skin	Erythema, tenderness, warmth, new or increased swelling, new or increased pain, failure of wound to heal	Complete blood count with differential For pressure ulcer cultures, deep tissue sample via biopsy	New or increasing purulent drainage at the site or at least two of the following: fever >100°F (37.9°C), redness, tenderness, warmth, new or increased swelling at the site (pressure ulcers, vascular wounds, percutaneous gastrostomy or jejunostomy sites, tracheostomy sites)
Gastrointestinal	More than one isolated diarrhea stool, fever, abdominal cramps	1. No workup if there is low-grade fever, new-onset diarrhea, no clinical change, and no outbreak in the facility 2. If on antibiotics in the past 30 days, obtain <i>C. difficile</i> toxin assay 3. If no antibiotics recently and fever, abdominal cramps, bloody diarrhea, or white blood cells, obtain stool culture for other enteropathogens	Presence of diarrhea with fever >100°F (37.9°C) and the onset of delirium or rigors

Data from Loeb M, Bentley DW, Bradley S, et al. Development of minimum criteria for the initiation of antibiotics in residents of long-term-care facilities: results of a consensus conference. *Infect Control Hosp Epidemiol*. 2001;22(2):120-124.

medical director. Most medical directors are independent contractors who devote 2 to 4 hours weekly of administrative time to a particular facility. Although the regulations concerning a medical director's function are brief, the potential impact is significant. Key components of the medical director's role include implementation of resident care policies and coordination of medical care in the facility. The unique needs and perspectives of each nursing facility dictate how the medical director's role is operationalized. The medical director functions in a similar manner to the chief of the hospital medical staff and as such, participates in the development of policies and procedures relevant to medical care delivery, coordinates a medical quality improvement program, and represents the facility to the community.

The nursing facility medical director works closely with all disciplines and is constantly cognizant of the interplay between laws, ethics, regulations, and the organization of medical care. Medical directors perform most effectively when they report directly to the facility administrator and work collaboratively with the Director of

Nursing. It is helpful to also have a line of communication with governance above the level of the administrator. A working relationship between the medical director and the medical staff ensures that quality standards set forth by the facility are instituted. The medical director is expected to be knowledgeable of current standards of care and proactively provide leadership while promoting adherence to standards.

As one of three required members of the nursing facility's quality assurance committee, the medical director meets at least quarterly with the facility administrator, DON, and any other appointed members. This committee reviews quality of care issues, develops strategies to improve quality, and provides a structure within the facility to correct negative outcomes and proactively enhance quality of care and quality of life for residents.

Certification for medical directors is offered through the American Medical Director's Association following completion of a formal course. However, as most medical liability insurance policies do not cover the role of the medical director, a physician acting as medical

director should seek an alternate source if the nursing facility is not able to provide liability coverage. Further information regarding medical director responsibilities, certification requirements, and relevant policies and procedures are available through the AMDA.

## SUMMARY

In summary, federal and state regulations serve to remind and guide practitioners regarding appropriate processes and expected outcomes of care. The approach to evaluating and managing syndromes (such as incontinence, pressure ulcers, falls, and weight loss) necessitates adaptation to the environment and differentiating the goals of care, where these goals often include maintenance, or comfort and palliation in addition to cure and restoration. Becoming familiar with the environment, learning to work with the interdisciplinary team, and managing the day-to-day practice efficiently facilitates establishing a successful satisfying nursing facility practice.

Unanswered questions and research for the future include studying collaborative models of care with physicians and nurse practitioners, clinical nurse specialists, and physician assistants. In addition, randomized controlled trials for pharmacological and nonpharmacological interventions for chronic illness and behavioral symptoms are needed as well as the need to know when to initiate and stop medications. In the future, a fully integrated electronic medical record may facilitate evaluation of medical care decisions which directly bears on the quality of care and quality of life.

# Community-Based Long-Term Care and Home Care

Jennifer Hayashi ■ Bruce Leff

In 2007, an estimated 7 million older Americans needed long-term care due to functional impairment, usually as a result of chronic medical conditions and illnesses. Most of these people choose to remain in the community, and require services to help them stay in their homes rather than enter an institution. These services constitute what is generally known as community-based long-term care (CBLTC). As the population ages and the number of functionally impaired older adults increases, so will the need for CBLTC. Unfortunately, no coherent national policy drives CBLTC in the United States, which leaves a “system” that is inconsistent, decentralized, difficult to access, bewildering to navigate, and unable to fully meet the needs of many patients. Much of what is actually done to meet these needs is provided by unpaid family caregivers at great personal and economic cost. This chapter addresses CBLTC for older adults in the United States. We outline the semantic challenges in understanding the scope and nature of CBLTC and the heterogeneity of care models that comprise CBLTC, describe who receives, provides, and pays for it, and review the evidence for its effectiveness. We also discuss important public policy issues and identify emerging innovations and trends in CBLTC delivery.

## SEMANTIC CHALLENGES OF CBLTC

The term “community-based long-term care” overlaps with several other terms in the medical and social sciences literature, including *home care*, *personal care services*, *home and community-based services*, *home visits*, and *house calls*. In general, these terms refer to nursing, personal care, or social services provided to older persons, with an explicit goal of filling unmet needs or maintaining them in the community. Most of this kind of care is provided by unpaid family members or friends, sometimes with support from a variety of formal caregivers. Home care may mean home-based rehabilitation or disease management after hospital discharge, preventive health interventions, geriatric assessment, primary care physician visits, or highly

technological care provided in individual patient homes. These services often overlap to such an extent that important aspects of a given intervention are not accurately reflected in a single label. For example, a program in which an interdisciplinary team provides comprehensive geriatric assessment followed by primary care home visits, inpatient management as needed, and continuing longitudinal care after hospital discharge does not fit neatly into any one category. Several forms of CBLTC integrate housing arrangements with personal and medical care, further blurring the distinction between CBLTC and institutional long-term care. [Table 22-1](#) depicts the heterogeneity and scope of services and settings that fall under the rubric of community-based long-term care.

Home health care usually comes in two forms: unskilled and skilled care. Unskilled care refers to services provided by unpaid caregivers, usually female family members. The estimated 26 million informal caregivers in the United States provide 45% to 70% of all home care and CBLTC services at an estimated economic value of \$196 billion—far greater than national spending on formal home care (\$32 billion) and nursing home care (\$83 billion). Skilled home health care refers to formal services delivered by professional providers, such as nurses or physical, occupational, or speech therapists. Medicare certifies and reimburses home healthcare agencies (HHAs) to provide this type of care when a patient is homebound and has a skilled need (see “Who Provides and Pays for CBLTC” later in the chapter). HHAs may also provide formal personal care services (bathing, dressing, etc.) under the Medicare home health care benefit while a patient is receiving skilled care. Although hospitalization is not required by Medicare to initiate home health care, postacute hospital skilled needs and rehabilitation are common reasons physicians refer patients for these services. For example, an older patient who suffers an acute exacerbation of chronic obstructive pulmonary disease may spend several days in bed (at home or in the hospital), and may need nursing to monitor her respiratory status and physical therapy to help her regain her baseline functional mobility. It is important to note that the effectiveness of skilled home care often

TABLE 22-1

## Types of Community-Based Long-Term Care and Home Care

TYPE OF CBLTC	DESCRIPTION/SERVICES	FUNDING
<i>CBLTC services provided at home</i>		
Home health care	Home health agency or client provides and pays personnel	Medicare or private long-term care insurance
Formal (agency or consumer-directed)		
Skilled care	Nursing, occupational and physical therapy	Private pay (if no skilled need)
Personal care	ADL assistance	"Cash and counseling" (Medicaid)
Informal	ADL/IADL assistance as needed	None/opportunity cost of caregivers
Physician house calls	Medical visits in patient's home	Medicare, private insurance, private pay
Preventive home visits	Health maintenance visits by health care providers (physicians, nurses, social workers) or trained "health visitors"	National insurance (Europe/UK), research grants (US)
Home-based geriatric assessment	Multidisciplinary evaluation of medical, social, functional, and cognitive issues	Variable depending on evaluator and context
Hospital at Home	Acute-level care at home with daily nurse/physician visits	Variable depending on system implementing the model
Case management	Disease-specific teaching and support provided by nurses	Medicare (as part of skilled care) or private insurance
<i>CBLTC services requiring temporary or permanent relocation</i>		
Program of All-Inclusive Care for the Elderly (PACE)	Comprehensive medical, functional, and social care for dually eligible, nursing home-eligible patients	Medicare and Medicaid capitated payments
Adult day care	Supervised congregate activities, 1–7 d/wk for several hours a day	Private pay, Medicaid
Medical		
Social	Includes medication administration and basic monitoring	
Assisted living	Limited to social interaction Apartment-style living with unskilled and/or skilled services available on-site	Long-term care insurance, private pay
Sheltered housing	"Senior apartments" with varying social services on site (e.g., friendly visitors, congregate meals, transportation)	Private pay, subsidized by federal and local governments
Adult foster care	Older adult who needs assistance or supervision moves in with "foster" family	Private pay, subsidized by federal and local governments
Group home	Group of adults who need assistance or supervision lives in one building with unskilled and/or skilled services available on site (can be similar to assisted living)	Private pay, subsidized by federal and local governments
Continuing care retirement communities (CCRCs)	Geographically localized and self-contained spectrum of living arrangements from independent housing to nursing home care	Private pay
Life care at home	Spectrum of care from minimal assistance to nursing home-level care provided in patient's own home	Private pay

relies on services provided by an informal caregiver who, if available, can implement a home exercise program, clean and dress pressure ulcers, or bathe, dress, and toilet a dependent patient.

Two related models of formal home medical care include physician house calls and hospital-at-home. Physician house calls, in which physicians (and, increasingly, nurse practitioners and physician assistants) provide ongoing longitudinal medical care at home, can play an important role in providing access to routine and urgent care for older adults who have difficulty getting to a medical office. Physician house call programs have been increasing in prevalence in recent years, though they are not yet widespread. Hospital-at-home is an emerging care model that provides hospital-level care in a pa-

tient's home as a substitute for an acute hospital admission. Other forms of CBLTC involve intermittent assessment and monitoring over time. Preventive home visits and home-based geriatric assessment typically aim to identify older adults in the community who have hidden risks for developing illness or functional decline, and modify those risks to prevent poor outcomes. Disease management targets patients known to have specific diseases or conditions that require significant care coordination, such as diabetes or heart failure, for formal support in managing those conditions, with the goal of delaying disease progression and avoiding hospitalization.

Still other forms of CBLTC entail temporary or permanent changes in location of care. Adult day care generally includes

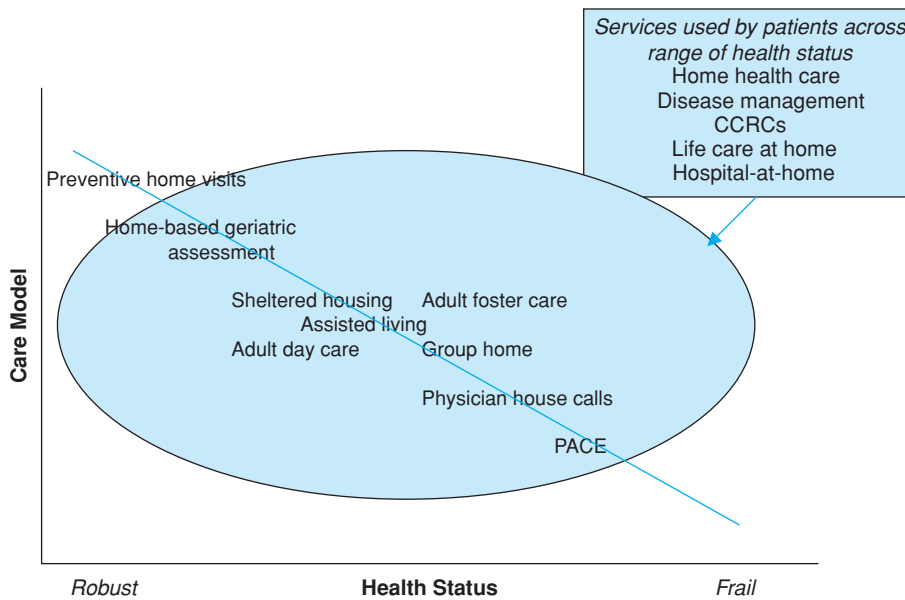

FIGURE 22-1. CBLTC continuum of care.

transportation to a day care center, and can provide both structured social activities and basic medical monitoring and treatment. The Program of All-Inclusive Care for the Elderly (PACE) relies heavily on a “day health center” in which dually eligible (i.e., Medicare and Medicaid eligible) nursing-home eligible participants receive comprehensive medical, hygienic, social, and rehabilitative care. For patients who cannot continue to live in their own homes, assisted living, sheltered housing (also known as senior apartments), adult foster care, and group homes all provide varying levels of functional assistance and access to some medical services. Continuing care retirement communities (CCRCs), as the name suggests, are self-contained organizations that allow people to move within the community to increasing levels of care as their needs dictate. At one end of the continuing care spectrum, a fully independent older adult lives in a single-family home or apartment, but over time may transition first to an assisted-living apartment, then to the skilled nursing facility within the same CCRC. There are several variations on this model, but most charge an entrance and monthly fee that provides lifelong care in the event that the participant develops some kind of functional impairment. Finally, some continuing care models, called life care at home, provide a similar range of care but do not require purchasers to move from their own homes.

This array of services and settings can be framed as a quasicon- tinuum of care services for older adults, as shown in Figure 22-1. While some forms of CBLTC are designed to address the needs of older adults through a variety of health or disease states, such as home health care, CCRCs or postacute disease management programs, others are targeted to specific populations based on levels of impairment or disability, such as preventive home visits or PACE. Again, many patients and programs do not fit neatly into a single category and patients do not usually move across the continuum in a straight line, as the use of services depends not only on the fit between the needs of an older adult and the care model, but also on the preferences of older adults and local availability of care models. For example, skilled home health care may be used by a healthy older adult after elective joint replacement surgery, or by a frail chronically ill patient recovering from a recent episode of community-acquired

pneumonia treated at home by a physician house call program. However, the concept of a continuum is a useful construct for organizing categories of CBLTC.

### WHO RECEIVES CBLTC?

As Figure 22-1 demonstrates, CBLTC services may be used by older adults over a wide range of health status. Health maintenance strategies such as preventive home visits and geriatric assessment tend to target patients who are relatively robust and functionally independent, while PACE and physician house calls address the needs of patients who are more frail and impaired. CCRCs and life care at home explicitly transition patients from the robust state through functional decline. Postacute home health care, physician house calls, and hospital at home may be used by both robust and frail older adults in specific circumstances, but the primary intended users of most CBLTC remain those who have chronic and complex medical illness accompanied by some level of functional disability, and thus require care for a prolonged or even indefinite time. The likelihood of receiving formal care is lower for men, minorities, married individuals, those with lower socioeconomic status, and those who are less dependent for assistance with activities and instrumental activities of daily living.

### WHO PROVIDES AND PAYS FOR CBLTC?

The role of unpaid informal caregivers cannot be overemphasized. The work they perform is not directly reimbursed or financially rewarded by the health care system. The indirect costs are enormous when lost wages, productivity, and future social insurance losses are calculated for caregivers who may sacrifice paid employment to provide informal care for a parent or other relative. For formal care, the provider varies with the type of CBLTC. In the most common model of home health care, a home health care agency (HHA) certified to provide care under Medicare reimbursement rules employs nurses,

therapists, aides, and social workers, and assigns them to individual patient cases. A physician must certify that the patient is homebound and has a skilled need in order for a Medicare-certified HHA to provide care for a 60-day “certification period.” By definition, a skilled need requires care that is part-time, intermittent, and must be provided by a person with special training (e.g., a nurse or therapist). Personal care assistance with ADLs such as bathing and dressing is covered during the certification period, but Medicare does not pay for it in the absence of a skilled need.

The HHA must catalog each patient’s medical, functional, and socioeconomic characteristics in the Outcome and Assessment Information Set (OASIS), which then determines in the Prospective Payment System the Medicare reimbursement the agency will receive for the certification period. PPS was implemented in 2000 in response to a period of extraordinary growth in medical home health care expenditures in the 1990s, which was unfortunately accompanied by inefficient or even fraudulent fee-for-service (FFS) billing. A patient can be “recertified” for multiple 60-day periods as long as a skilled need exists. HHAs can also be privately paid by the care recipients. Additionally, an emerging “consumer-directed” or “cash and counseling” model allows selected patients to choose, train, and pay their personal care providers directly with designated state funds (usually from Medicaid programs), instead of using an agency as an intermediary. In these programs, care providers can be family members or other previously unpaid caregivers. This model has had positive results, showing increased patient empowerment and satisfaction, and fewer unmet needs.

Interdisciplinary teams are critical in coordinating and delivering care in home health care, home-based geriatric assessment, PACE, and home hospital (see Chapter 26). Such teams typically include physicians, although the physician role may vary in different settings depending on the medical complexity of the patient and the setting. For example, in PACE, the physician provides primary care services, manages acute illness during hospitalization, and coordinates the activities of the interdisciplinary team. In postacute and home rehabilitation care, the interdisciplinary team drives most of the management with a focus on restoring function and following up medical issues, with the physician acting largely in an administrative role. In hospital-at-home interventions, the physician actively manages acute illness at home, so that physician house calls complemented by close coordination of the interdisciplinary team are crucial in this setting. Improvements in Medicare reimbursement for physician house calls have contributed to a recent growth in academic and private sector house call programs.

Other forms of CBLTC rely less on physicians and more on specialized nurses or trained lay visitors. Disease management, postacute home health care, and medical day care are often based on protocols driven by nurses. Home-based geriatric assessment is usually performed by geriatric nurses or nurse practitioners and then discussed as needed with physicians, while preventive home visits have been successful in using “health visitors,” or specially trained community residents, in screening for health risks. Medical care in ALFs, sheltered housing, and group homes is generally limited to medication administration and vital signs monitoring and may include relatively easy access to physicians when needed, such as domiciliary care visits or a clinic housed within a senior apartment building. A small number of older adults carry privately funded long-term care insurance, and in recent years, some businesses have added this option to their employee benefit packages. Ultimately, many peo-

ple exhaust their retirement savings and home equity to pay for CBLTC.

## IS CBLTC EFFECTIVE?

Studies of CBLTC are challenging to interpret because of the semantic difficulties outlined above, the heterogeneity of home care interventions, difficulties in controlling for severity of disability or illness of patients, patient attrition issues, changes in regulation over time, and examination of a disparate range of outcome measures. However, key studies and their findings are summarized in [Table 22-2](#). The National Long Term Care Demonstration project (also known as the Channeling Demonstration) in the early 1980s was a large study that evaluated the effect of adding comprehensive case management and a broad array of other purchased services to existing community care networks. It served an extremely frail population with unmet service needs, but did not show overall cost savings or decrease hospitalization, nursing home placement, or functional decline. However, it did improve in-home care, unmet needs, and quality of life of patients and caregivers. This landmark study set a pessimistic tone for home care research: that home care may be preferred by patients and caregivers, but difficult to justify in terms of clinical and economic effectiveness. Similarly, the Social Health Maintenance Organization demonstration projects (S/HMO I and II) that expanded case management services within Medicare managed care organizations (MCOs) failed to demonstrate any patient care or cost advantages over usual managed-care practices, and in 2003 reverted back to standard Medicare MCOs.

On the other hand, two recent outcomes-based quality improvement (OBQI) Medicare demonstration programs collected, encoded, and transmitted patient-level health status information to provide a risk-adjusted outcome report, which was then used to implement action plans to change Medicare-certified home health care agency behaviors. Each demonstration agency focused on reducing rehospitalization rates and one other targeted outcome (e.g., functional status or medication self-management) based on its performance report. With over 260 000 patients in 73 home care agencies in 28 states, the OBQI intervention achieved a more than 20% reduction in hospitalization and a 5% to 7% improvement in other targeted outcomes. In addition, the comprehensive management strategies of PACE programs appear effective at reducing institutionalization of at-risk patients, and postacute hospital disease management programs for conditions such as congestive heart failure, deep venous thrombosis, and diabetes mellitus improve patient outcomes such as hospital readmissions and self-management skills. Finally, hospital-at-home experiments, especially those that substitute entirely for an acute hospital admission, have reduced total days in care and geriatric clinical complications such as confusion and incontinence, with health outcomes and health-related quality-of-life measures comparable to usual care.

The evidence on the effects of other CBLTC interventions is less consistent and may result from issues related to model design and targeting of models to the appropriate patient population. A recent meta-regression analysis on the effects of home visits to prevent adverse outcomes found a 24% risk reduction in mortality for “young-old” (younger than 80 years) rather than “old-old” (older than 80 years) populations, while multidimensional assessment was associated with better functional outcomes compared with single-clinician

**TABLE 22-2****Evidence for Effectiveness of CBLTC**

<b>AUTHOR, YR</b>	<b>STUDY</b>	<b>SETTING</b>	<b>TARGETED POPULATION</b>	<b>MAJOR FINDINGS</b>
Kemper, 1986	National Channeling Demonstration	United States	Frail older adults at risk of nursing home placement	Improved patient/caregiver quality of life, in-home care, and unmet needs No decrease in costs, hospitalization, nursing home placement, or functional decline
Thompson, 2002	SHMO I and II	U.S. Medicare HMOs	Frail older adults	No improvement in quality of care, institutionalization, or hospital utilization compared with usual capitated care
Shaughnessy, 2002	OBQI	Medicare-certified home health agencies	Homebound older adults with skilled needs	Reduced hospitalization and improved other targeted outcomes
Eng, 1997	PACE	Eleven PACE sites in 9 US states across United States	Dually eligible, nursing home-eligible frail older adults	Decreased hospital length of stay Fewer nursing home days Less outpatient subspecialist utilization Decreased polypharmacy No increase in mortality Cost savings of 5%–15% relative to nursing home
Abt Associates, 2001	PACE	Eleven PACE sites in 8 U.S. states	Dually eligible, nursing home-eligible frail older adults	Increased life expectancy Decreased use of NH/hospital Improved (self-rated) health status Improved satisfaction with care and with life in general Decreased Medicare costs Increased Medicaid costs
Naylor, 1999	Post-hospital disease management	Two urban U.S. academic hospitals	Older adults hospitalized for 1 of 8 medical or surgical diagnoses	Decreased readmission rate Lengthened time between discharge and readmission Decreased Medicare costs
Caplan, 1999	Hospital at home	Australia	Acutely ill older adults randomized to hospital admission or hospital-at-home services	Significantly reduced incidence of geriatric complications (confusion, falls, urinary and bowel problems)
Weissert, 1988	Home care	Systematic review	N/A	Targeting was uneven and best accomplished when accompanied by a mandatory nursing home preadmission-screening program Cost savings on institutional care did not offset costs of intervention Hospital use increased in some studies
Stuck, 2002	Preventive home visits	Meta-analysis	N/A	Functional decline reduced in trials using multidimensional assessment with follow-up and in trials with control group mortality in lowest tertile Nursing home placement reduced in trials with >9 home visits during follow-up Mortality reduced in younger (<77.5 yr) but not older populations (>80 yr)
Hughes, 2000	Team-managed home-based primary care	Veterans' Administration	Elderly veterans with CHF, COPD, terminal illness, or impairments in 2 or more ADLs	Increased patient and caregiver satisfaction but also increased overall costs
Hedrick, 1993	Adult day care	Veterans' Administration	Elderly veterans with dependency in one or more ADLs	Increased costs and use of home care without improving health outcomes or caregiver satisfaction

assessment (relative risk 0.76), and risk of nursing home placement decreased by 34% as the number of follow-up visits increased from <4 to >9. Similarly, some physician house call programs have been shown to reduce hospital or emergency department utilization, and a large Veterans Administration study demonstrated significant improvements in patient health-related quality of life and caregiver satisfaction for patients receiving team-managed home-based primary care. In an important VA study of adult day care, there was no difference in health outcomes between patients who attended adult day care in the VA or in the community and those who did not attend day care, except in a subgroup of intervention patients with severe disabilities who had lower nursing home, clinic, home care, pharmacy, and laboratory costs, while the rest of the intervention group had generally higher costs. As Table 22-2 indicates, an extensive home care literature includes a wide variety of interventions and target populations. While this heterogeneity creates significant difficulty in drawing conclusions about the effectiveness and cost-effectiveness of home care, the overall body of evidence suggests that specific models when appropriately targeted are probably effective.

This issue of targeting care to appropriate patient populations is a major determinant of the cost-effectiveness of specific interventions. A related factor that complicates discussions of cost-effectiveness is the notion of paid care inappropriately substituting for informal care at a cost to society, or the “moral hazard” or “woodwork” effect. In theory, if CBLTC services are made widely available, functionally impaired patients will “come out of the woodwork” to utilize them, even though most of these patients will never enter an institution even without using CBLTC. Thus, the cost of providing care will overwhelm the potential savings of avoiding institutionalization. As one expert notes, “if you spend too much it’s hard to save money.” Targeting services to patients who are at high risk for institutionalization is generally accepted as an important way to optimize cost-effectiveness, but no practical, precise, and accurate targeting tools have been developed and tested. A recent systematic review and analysis of predictors of nursing home placement, hospitalization, functional impairment, and mortality identified 22 risk factors that consistently predicted two or more of these outcomes, including three factors that predicted all four outcomes: worse non-ADL physical function, illness severity, and previous hospital use. These factors have not been validated prospectively. Cost-effectiveness also depends upon the economic features of the health systems in which various forms of CBLTC have been studied; findings from European programs in which the government is the payer for CBLTC, institutional LTC, and acute care are difficult to apply to the U.S. fee-for-service environment with multiple public and private payers and complex cost-shifting pressures.

## INNOVATIONS

Recent technological and social advances have the potential to improve access to care, quality of care, and coordination of care for medically complex community-dwelling older adults. Telemedicine is a small but growing field with particular relevance to rural or homebound populations with chronic diseases that cannot otherwise access specialized care; dermatology, ophthalmology, and wound care have been widely studied in small clinical trials and appear to allow accurate diagnosis and management through both real-time inter-

actions and “store-and-forward” applications in which clinical data including video images are collected and stored for later review by a clinician. Other specialties relying heavily on verbal interactions, such as psychiatry and neurology, appear to effectively diagnose and treat patients via interactive video conferencing. Similarly, home-based telemedicine interventions in chronic diseases probably enhance communication between patients and providers and facilitate closer monitoring of overall health when conducted in settings with specialized equipment and dedicated staff. Although the evidence is limited by methodologic variability, lack of comparison with in-person evaluation, and absence of clinical outcome measures, a recent systematic review by the Agency for Healthcare Research and Quality (AHRQ) concluded that in some situations, the use of telemedicine might be warranted even if the evidence is inconclusive, including “remote rural areas or other locations where medical care is not available locally and the patient is for whatever reason unable to travel to a setting where it can be obtained.” Additional small or methodologically weak trials are unlikely to significantly add to the evidence base for telemedicine, and larger, well-designed comprehensive trials that include clinically meaningful outcome measures are needed in light of the increasing advocacy for health care payers to cover its use.

Like telemedicine, point-of-care diagnostic and therapeutic technology including electrocardiography, ultrasound, blood analysis, and intravenous treatment holds promise for health care delivery in home care and house calls. Wireless telephone and Internet applications that allow secure, high-speed broadband connections between portable electronic medical records (EMR) systems and acute care or office information systems can provide safe and seamless continuity of care with immediate data access and entry for providers caring for complex older patients with multiple medical issues, medications, sites of care, and consultants.

A third important innovation in caring for community-dwelling functionally impaired older adults is not based on technology, but on social, medical, and financial support. Medicaid waiver programs, authorized in section 1915(c) of the Social Security Act, allow states to shift funds for extensive home-based services for older or disabled people. Since much nursing home care is paid for by state-administered Medicaid programs, Medicaid has a major stake in financing CBLTC that can substitute for nursing home care without increasing costs, unmet needs, or adverse outcomes. Hence, 1915(c) waiver programs lower the income and asset thresholds for Medicaid, and provide a combination of traditional medical services (i.e. dental services, skilled nursing services) and nonmedical services (i.e. respite, case management, environmental modifications) with the goal of avoiding relatively expensive institutionalization for at-risk older adults with functional disabilities. Family members and friends may be providers of waiver services if they meet standard provider qualifications. Approximately 287 waiver programs are currently active in 48 states and the District of Columbia as government struggles to mitigate the costs of institutional care. A recent analysis showed that 58% of patients in these programs were elderly or disabled. A relatively small proportion of Medicaid waiver spending went toward this group (23.8% or \$3.4 billion) compared with the amount expended on patients with mental retardation or developmental disability (74% or \$10.5 billion).

Finally, a 2005 Medicare demonstration project, Care Management for High-Cost Beneficiaries (CMHCB), awarded 3-year contracts to several health care provider organizations across the nation

to “test the ability of intensive management for high-cost beneficiaries with various medical conditions to reduce cost as well as improve quality of care and quality of life.” These organizations are using a variety of care management tools such as increased provider availability (including physician house calls), structured chronic care programs, restructured physician practices, and expanded flexibility in care settings in an attempt to demonstrate overall cost savings and care improvement. Results from this demonstration should be available beginning in 2008.

## TRENDS

Several emerging trends in CBLTC will undoubtedly affect the future health care of the aging U.S. population. Interdisciplinary team-based models of care providing medical care, nursing, and social work at home for older adults with multiple chronic illnesses, once seen only in academic medical centers, are being developed by private sector companies and hospitals. These teams focus not on single-disease management, but on coordination of care, integration of patient goals and preferences, and improvement of patient outcomes relevant to this particularly frail and vulnerable group. At the same time, an increasing number of physicians are withdrawing from the current Medicare fee-for-service system as the reimbursement schedule continues to decline relative to the costs and risks of medical practice. This “opting out” trend, combined with the already grave shortage of primary care physicians including geriatricians, may, over time, drive a demand-based shift toward private insurance, health savings accounts, and concierge practices, further depleting the supply of physicians. The current interest in “pay-for-performance” (P4P) is aimed primarily at discrete, disease-specific measures such as hemoglobin A1C levels, which are not consistently applicable to a frail geriatric population. A recent effort to establish performance standards for home-based primary care adapted the Assessing Care of Vulnerable Elders (ACOVE) quality indicators for ambulatory geriatric and nursing facility patients to create a comprehensive framework for quality evaluation and future comparative research. The care of medically complex older adults will also require evaluation of events such as hospital admissions, intensive care stays, or nursing home placement for high-cost populations. Health systems that care for these high-cost populations should receive support for lowering the overall costs rather than for documenting the results of specific elements of single-disease management programs or discrete quality indicators. Finally, the growing recognition that patient empowerment and involvement improves quality and satisfaction will ideally translate into systems that value, support, and pay informal family caregivers for their essential and indispensable work.

## CONCLUSION

CBLTC is a varied collection of services aimed at allowing functionally impaired older adults to age in place according to their wishes. Although decades of research have resulted in some evidence of cost-effective benefit, this evidence is limited by semantic

and methodological issues. Overall, CBLTC is effective when appropriately targeted; older adults continue to prefer living in the community over living in institutions, and social pressures from an aging generation will only increase demand for CBLTC in the future. The current fragmented system of CBLTC will be untenable in the coming years as the number of older adults with complex multimorbidity and functional disability increases. Emerging models of CBLTC including physician house calls, team-based primary care coordination, and population-based pay-for-performance hold promise for improving health care for these patients, although systematic barriers exist to their widespread implementation. Creative economic, technological, and clinical solutions that focus on quality and cost-effectiveness will be critical in reforming the system to affirm and fulfill the public trust.

# Rural Aging

*Kenneth Brummel-Smith*

Over 51 million Americans live in areas classified by the U.S. Office of Management and Budget (OMB) as nonmetropolitan, or “rural.” They comprise one-fifth of the U.S. population. The rural life holds great value in the history of the United States. For most of our country’s history, rural living was practically the only way of life. Throughout the years, rural living has been seen as a noble and pure form of existence. Getting “back to the land” has long been viewed as a dream for many city dwellers. Unfortunately, when it comes to being old in a rural setting, there are many aspects which are not so sanguine.

Rural aging reflects many of the attitudes held toward older people in our society. Some, for instance, have questioned whether very high health care expenditures on persons at the end of life are worthwhile. Similarly, when viewed from an economic sense, rural residence is expensive for both society and individuals. The costs of distance, inefficiencies of spatial dispersion, and absence of economies of scale mean that health care has difficulties supplying specialty care and services. Forty years ago, William Myernick wrote that it does not make sense for society to expend resources in supporting small, dispersed, economically challenged communities. Yet the fact is older people make up a large percentage of the population of people living in rural settings.

The Kellogg Foundation conducted interviews with over 200 persons from different communities to assess views of rural living. Respondents viewed rural life as being primarily agricultural, as emphasizing family values with a strong sense of self-reliance, as having beautiful landscapes with animals and family farms, and as having a relaxed and friendly way of life. Interestingly, aging, or growing older and frailer, were not mentioned as common perceptions.

Rural life is also connected to prominent American values—the dual values of self-reliance and interdependence with one’s neighbors, freedom from governmental control, a slower pace of living, and the back to nature philosophy. As will be discussed, a significant movement, or “in-migration” of older people back to rural areas is occurring in part because of these values. However, the long trend of

younger people moving away from rural areas and poorer and sicker older people remaining also continues. What society may be facing in the next few decades is a population of primarily older people living in large portions of the country—a population made of two subgroups, healthy active and politically motivated baby boomers who have returned to the land, and a larger group of frail elders who have lived all their lives in that environment. This development will challenge health care service providers, as well as Medicare and Medicaid.

## DEMOGRAPHY OF RURAL AGING

One of the problems in discussing rural aging is the definition of “rural.” The two most frequently used definitions used in research and policy development are the U.S. Census Bureau’s use of community size and density and the OMB’s designation of counties as “nonmetropolitan.” The U.S. Census Bureau defines as “urban” any incorporated city, town, village, or borough with a population of at least 2500 people. Any area not defined as urban is defined as rural. Previously, the OMB used the terms Metropolitan Statistical Areas and Nonmetropolitan Statistical Areas to categorize populations. Recently, the OMB released a new classification system using Core Based Statistical Areas (CBSA). These are areas with at least 10 000 people with adjacent territories that have a high degree of social and economic integration (Table 23-1). Those areas that do not meet CBSA numbers are called Outside Core Based Statistical Areas, which equates with rural living. This change has significant implications. First, it reduced the number of people living in nonmetropolitan areas from 55 million to 49 million. More importantly, the OMB definitions are used to assign eligibility and reimbursement for a number of federal programs, including Medicare. In addition, the two definitions do not overlap, creating difficulties in planning. As it is, most counties contain a mixture of rural and urban living.

**TABLE 23-1****OMB Classifications of Rural and Urban Areas**

## Core-Based Statistical Areas

- Metropolitan—urbanized areas with a population of 50 000 or more
- Micropolitan—urban areas, population 10 000–49 999

## Outside Core-Based Statistical Areas

- Rural

There are many myths about rural aging. Krout outlined many stereotypes of rural elders, including that they

- live on farms and are a homogenous group,
- are in better physical and mental shape because of hard work, good food, and living in the country,
- are more active,
- better able to take care of themselves and make ends meet,
- are not homeless and have better housing,
- are surrounded by large families who are available and willing to help,
- have less need for health and social services, and
- can get what they need in the local stores.

The realities of rural aging are far different and much more diverse. Rural populations are vastly different—rural Florida is not the same as rural Minnesota, or even rural Mississippi. Americans 65 years and older make up 12.4% of the total population. However, nonmetropolitan areas have a higher percentage of older people—14.6% compared to 11.9% in metropolitan areas. The reasons for greater concentration include (1) aging in place, (2) younger persons migrating out for better jobs, and (3) in-migration of older adults after retirement. The percentage of women and those who are widowed reflects similar numbers to the general population of metropolitan areas. Ethnic diversity is increasing, but the current cohort is less diverse than in urban areas. Whites comprise 92.4%, African-Americans 6.2%, Hispanics 2.6%, and less than 1% are American Indian, Alaska Native, or Asian.

Although poverty rates in rural areas are the lowest they have been since 1980, persistent poverty is predominantly a rural problem. Of the 382 counties with poverty rates greater than 20% since 1952, 95% are rural. Fourteen percent of the rural older population is poor, compared to 10.8% in urban areas, and 50% are considered low income versus 38% of urban elders. Socioeconomic status is probably the strongest factor affecting health and health care services so the implications of this fact cannot be overstated.

Another important aspect of aging that affects health care is the availability of caregivers. Nationally, one out of four families is providing assistance to an older family member. Informal caregiving is the primary source of long term care in this country, and that is certainly true for the rural population. Unfortunately, rural elders appeared to be trapped between their higher expectations for care from a family member, and the decreasing availability of younger family members. A larger percentage of rural elders receive assistance from “fictive kin”—friends and others in the rural community. This probably is a main contributor to the fact that long-term institutional care is more common in rural areas than urban areas.

Finally, an important dynamic in the demographics of rural aging is the resettlement of rural areas by retirees, which is termed “in-migration.” In the 1970s, a net in-migration to rural areas followed decades of out migration. This was caused by a combination of some manufacturing jobs moving to more rural areas for cheaper land and labor and a “back-to-the-earth” movement following the tumultuous 1960s. Some of these residents are now the rural elders who have aged in place. However, this in-migration was short-lived, and in the 1980s, almost 2 million persons aged 20 to 29 years moved away from rural areas. More recently, wealthier and healthier elders have been moving back into rural areas after retirement, in order to seek a lower cost of living and the amenities afforded by recreational and cultural opportunities. A recent study of this development has revealed a number of interesting outcomes:

- Although in-migration encourages job growth, it does not increase per capita income or contribute to economic stability in host communities.
- Retired migrants contribute their fair share of taxes but they also bring added costs to rural governments with increased demands for public and health care services.
- Rural in-migration is likely to accelerate with the retirement of the baby boomers.

Less than 11% of the nation’s physicians are practicing in rural areas. Over 20 million rural residents live in areas that have a shortage of physicians to meet their basic needs. The majority of physicians (54%) in rural areas are in the primary care specialties of family or general practice, general internal medicine, pediatrics, and obstetrics/gynecology, compared with 38% of metropolitan physicians. In 1995, there were 56 635 office-based physicians practicing in rural areas. Family physicians are far more likely to practice in rural areas than all other specialties.

However, maintenance of a rural practice has been difficult. Medicare does offer a 10% bonus payment to physicians practicing in Health Professions Shortage Areas. Yet many physicians do not make use of the bonus and some who are not eligible have used it extensively. A recent study of rural physicians in Florida revealed that many were considering dropping Medicare or some services because of reimbursement problems.

Like the rest of the country, rural America is aging. However, it started out being the primary place of living of older people. While rural living still reflects strongly held American values, the aging of rural society will create significant challenges for the provision of health care to a population that is already at-risk.

## HEALTH STATUS OF RURAL ELDERS

Contrary to the myth of healthy, clean living older adults in the country, elders in rural areas have high rates of illness and disability. Populations living in rural areas have higher rates of heart disease, diabetes, hypertension, depression, emphysema, cancer, and arthritis than those in metropolitan areas. Some studies have shown diabetes to be 17% higher in rural areas. Compounding these high rates is the difficulties that older adults have in accessing specialist care and even primary care providers in some areas.

According to Rural Healthy People 2010, rural populations lag behind metropolitan populations in many health status indicators.

These include higher rates of heart disease, respiratory disease, diabetes, stroke, mental diseases, malnutrition, obesity, substance abuse, and cancer, as well as reduced rates of having insurance, and access to primary care. In addition, recommended screening practices also occur at lower rates.

While recent studies have documented a declining rate of disability among older Americans, the rate of frailty and dependency in activities of daily living (ADL) and instrumental activities of daily living (IADL) continues to be high in rural communities. Almost three-quarters (73%) of the rural older population has activity limitations, compared to approximately 50% in those living in metropolitan areas, and is also complicated by the relative lack of services, especially for rehabilitation. In addition, access to personal care by physical and occupational therapists, or in-home services are limited as well.

Higher rates of mental illness and substance abuse are particularly problematic in rural areas, where providers are few and special services are limited. The MoVIES Project, a 10-year prospective study of dementia in rural elderly showed that the incidence rates of Alzheimer's and other dementias was higher than in urban populations, with particularly high rates in men. Self-reported hopelessness, helplessness, worthlessness, and lethargy were reported at higher rates by older people in the National Health Interview Survey. Depression rates have been reported as high as 40% in women in rural areas, compared to 13% to 20% in urban older women. Rural Hispanic women have been found to rates of depression two times higher than white women.

Polypharmacy is always a risk in geriatrics but has special implications among rural elders. The use of multiple health care providers, who are often at great distance from one another, and limited access to pharmacies and knowledgeable pharmacists, makes polypharmacy even more risky for rural elders. In one study of falls among rural elders, four of five significant risk factors were drugs: analgesics, sedatives, antiarthritic medications, and antihypertensive medications.

Nutritional problems are very common among rural elders. Both overnutrition (obesity and overweight) and undernutrition are common (Table 23-2). In addition, rural elderly women consume lower amounts of recommended protein, vitamins A, C, E, B-6, B-12, riboflavin, and folate, as well as some minerals (calcium, phosphorus, and magnesium). Many rural elders consume a diet of low-nutrient value, including a high intake of bread, cereal, rice, pasta, fats, oils, and sweets. This pattern leads to high calorie consumption and low intake of essential vitamins and minerals. In addition, many older rural residents consume limited amounts of fruits and vegetables. In one study of 50-year-old and older residents in six rural communities, 45% ate less than one serving of fruit or vegetable juices per

week, 33% consumed less than one serving of fruits, and 21% ate less than one serving of any vegetable per week. Substantial numbers of rural elders report not having enough to eat or not having enough money to purchase quality foods. Rural minorities are at substantially increased risk for food insecurity.

Options for improvement in nutrition for elders are food stamps and home-delivered meals. Unfortunately, a smaller percentage of rural elders participate in the food stamp program than urban older persons (7.9% vs. 9.4%) and the majority of elders get the minimum benefit (U.S. Department of Agriculture Web site). Similarly, home-delivered meals, such as Meals on Wheels Programs, are much less commonly located in rural areas.

## ETHNIC AND MINORITY RURAL AGING

The well-known presence of health care disparities among ethnic groups is present, and in some cases, magnified in rural areas. For instance, African-Americans in rural areas are less likely to receive specialized medical care, to adhere to long-term preventive drug regimens, and are less likely to use more complex health care services. Unfortunately, there is little hard data on individual ethnic groups in rural settings because they have not been sufficiently studied.

Over 90% of rural African-Americans live in the South, and three-quarters of these live in just seven states (Louisiana, Mississippi, Alabama, Georgia, South Carolina, North Carolina, and Virginia). There are fewer home- and community-based services available to them, and consequently the rate of nursing home utilization is higher among rural African-Americans than those in urban areas.

Rural Hispanic elders have a higher prevalence of ADL and IADL deficits, and cognitive impairments than comparable non-Hispanic white elders. However, rural Hispanics are twice as likely as nonrural Hispanics to use nursing home care. Still, because over 60% of rural Hispanic elders were born outside the United States, their access to care is limited and they are often underserved. In part, this is due to lack of Medicare, lack of knowledge of available services, and language barriers. In addition, Hispanic elders have high expectations that their children will provide assistance when needed.

There are approximately 300 000 older American Indians and Alaskan Natives (AI/AN), according to the 2000 U.S. Census, which is 26% greater than 10 years before. There are 562 federally recognized tribes, who speak over 200 languages. Although American Indians live in all 50 states, approximately one-half of them live in three states: Oklahoma, California, and Arizona. Older American Indians have often lived their whole lives in one community. According to the Indian Health Service (IHS), the incidence of chronic diseases is increasing rapidly, substantially raising health care costs. Disability is extremely common among AI/AN elders with 30% having at least one ADL deficit (compared to 17% of whites).

Although there has been a movement toward independent and self-administered health care for many AI/AN tribes, the IHS continues to provide care to many older persons. However, funds have never been appropriated to the IHS for long-term care. Hence, most elders in need of LTC use tribal support, Medicaid and Administration on Aging funded services. Many go without services. There are only 20 tribally funded nursing homes in the United States. Many providers involved in caring for older American Indians and Alaskan Natives have been advocating for expansion of home and

**TABLE 23-2**

N/A, data not available.

community-based waivers through the state's Medicaid programs or funding at a national level.

## RURAL HEALTH CLINICS

The federal government authorized Public Law 95-210, the Rural Health Clinic Services Act, in 1997, which assures Medicare and Medicaid reimbursement to certified clinics staffed by physician assistants (PAs) and nurse practitioners (NPs) working with physician supervision. The purpose of the rural health clinic (RHC) program is to increase primary care medical services in rural, physician-shortage areas by utilizing PAs and NPs. Financial stability was promoted by providing cost-based compensation for care of Medicare and Medicaid patients. RHC are now paid under a special prospective payment system designed for them. The program failed to thrive for 10 years until Congress made a series of changes that reduced burdensome paperwork, increased payment levels, and enhanced technical assistance and awareness. Modifications to state PA laws, such as relaxation of onsite supervision requirements and the delegation of prescriptive authority, have also contributed to the program's success. As a result, the number of certified RHCs has grown from less than 600 in 1990 to approximately 3600 in 2003.

Because of changes in the Medicare law authorizing Medicare Part B coverage for PAs and NPs in all practice settings, the original incentive for utilizing PAs and NPs was diminished. However, because an RHC gets reimbursed the same amount from Medicare and Medicaid regardless of whether the patient is seen by a mid-level provider such as a PA, NP, or a physician, the facility continues to have a strong incentive to utilize these practitioners whenever it is clinically appropriate.

RHCs care for large numbers of Medicare, Medicaid, and uninsured patients. A 2003 national survey revealed that approximately 56% of patient visits in RHCs are covered by Medicare or Medicaid and approximately 15% are uninsured. Unlike a fee-for-service practice where Medicare and Medicaid payment is based on the cumulative charges for all services provided, a RHC is paid on a clinic-specific, all-inclusive rate that is adjusted annually and, in a majority of cases, subject to a limit set by the government. Challenges continue including questions about reimbursement models, the requirement for use of PAs and NPs, and the impact of managed care programs.

## RURAL HOSPITALS AND LONG-TERM CARE

Rural hospitals service nearly 54 million people, including 9 million Medicare beneficiaries. Like many hospitals, Medicare payments present some challenges. However, they also face other significant pressures—continued shortages of trained staff, rising health care liability premiums, and access to capital for investments in new technology or information systems. Rural hospitals are more at risk due to their small size, modest assets, and limited financial reserves. They also serve a higher percentage of Medicare patients since rural populations are typically older than average urban populations. Hence, Medicare margins are the lowest for rural hospitals, with the smallest hospitals having the lowest margins.

Rural hospitals have undergone many changes in the last two decades. With the advent of prospective payment in the 1980s, and

managed care in the 1990s, many rural hospitals diversified by developing a variety of postacute services. These included in-hospital skilled nursing facilities and home health programs. Some also developed assistive living facilities and adult daycare programs. However, the Balanced Budget Act of 1997 decreased payments to rural hospitals for skilled nursing and home health services, so many of the hospitals reduced or closed down these programs. There have been, however, a number of other Medicare policy decisions that have supported rural hospitals in maintaining a diverse service line. This is important, as rural communities usually have only one health center (if at all). In addition, unlike urban communities where physicians now specialize in a site of practice (hospitalists, office, or nursing home) rural health care providers usually practice in all settings.

Because of these challenges, the federal government has developed some special programs to support rural hospitals. Critical Access Hospitals (CAH) are rural community hospitals (RCHs) that receive cost-based reimbursement. To be designated a CAH, a rural hospital must meet defined criteria. As of March 2006, there are 1279 certified CAHs located throughout the United States. A list of CAH can be viewed online at [http://www.flexmonitoring.org/documents/CAHlist\\_current.xls](http://www.flexmonitoring.org/documents/CAHlist_current.xls).

The Rural Community Hospital Demonstration Program was created as part of the Medicare Modernization Act of 2003 to test the advisability and feasibility of establishing RCHs to provide Medicare-covered inpatient hospital services in rural areas. Medicare inpatient services are paid based on reasonable costs of providing such services to Medicare beneficiaries. After a period of time, the reimbursement process is modified to account for increased costs. In order to participate in the demonstration, the hospital must be located in a rural area, have fewer than 51 acute care beds, have 24-hour emergency care services available, and not be eligible for CAH designation. For this demonstration, hospitals had to be located in one of the 10 least densely populated States: Alaska, Idaho, Montana, Nebraska, Nevada, New Mexico, North Dakota, South Dakota, Utah, or Wyoming. Thirteen small rural hospitals in seven sparsely populated states are program participants.

The Social Security Act permits certain small, rural hospitals to enter into a swing bed agreement, under which the hospital can use its beds, as needed, to provide either acute or skilled nursing facility (SNF) care. Approximately 95% of rural hospitals operate swing beds. As defined in the regulations, a swing bed hospital is a hospital or CAH participating in Medicare that has CMS approval to provide posthospital SNF care and meets certain requirements. Medicare Part A (the hospital insurance program) covers posthospital extended care services furnished in a swing bed hospital. Swing bed facilities must be incorporated into the SNF prospective payment system by the end of a statutory transition period. CAHs with swing beds are exempt from the SNF PPS under more recent legislation. To qualify for SNF-level services, a beneficiary is required to receive acute care as a hospital inpatient for a medically necessary stay of at least 3 consecutive calendar days.

The Health Resource Services Administration has the Rural Hospital Performance Improvement (RHPI) project focuses on strengthening rural hospitals in the Mississippi delta as the cornerstone to preserving health care access. It is a source for technical expertise and business tools to help rural hospitals achieve performance improvement goals. The first contract in 2001–2004 yielded 71 applications and provided 59 consultations to small rural hospitals. Forty-six hospitals throughout the Delta Region have been served during

2004–2006 including 25 performance improvement assessments, 19 targeted consultations, and seven balanced scorecard consultations.

Nursing home care is the mainstay of long-term care services in rural areas. Home care and assisted living are far less common than in urban areas. Nearly 40% of the nation's nursing homes are in rural areas, and nursing home beds per 1000 population are higher than urban areas. However, skilled beds and special care units are less common. A large number of rural hospitals still offer a variety of postacute and long-term services. Approximately 50% of rural hospitals operate an SNF.

Rural hospitals are involved in operating home health agencies, though the number has been declining. Approximately 35% of CAH have home health programs. However, after the BBA of 1997, home health care in rural areas dropped by 26%, compared to a 19% decline in urban areas. Many rural hospitals are finding it difficult to maintain these programs and 52% of programs are operating at a loss. Those units that are part of a multihospital system tend to offer both skilled nursing unit services and home health at a higher rate than independent hospitals.

Integration of acute and long-term services has been promoted as a method to improve quality, reduce errors in transitions in care, and lead to reduced costs. Care integration is more difficult in rural areas for a number of reasons. Limited financial resources are the main hindrance. Rural hospitals do not operate high-volume, high reimbursement business lines, such as transplant or cardiac surgery programs. They also serve a larger proportion of Medicare and Medicaid clients. However, some states such as Wisconsin and Minnesota have developed successful integrated rural programs. Perhaps the quintessential integrated program is the Program of All-inclusive Care of the Elderly (PACE). This model uses capitated Medicare and Medicaid funding to provide services to nursing home eligible clients. The BBA of 1997 allowed the development of two rural PACE sites. Progress was initially slow, in part due to the \$1 million to \$2 million start-up costs for a PACE site. In 2005, the Center for Medicare and Medicaid Services announced \$7.5 million in competitive grants to 15 rural health care provider organizations to support development of PACE across rural America. More on rural PACE programs can be found at [www.npaonline.org](http://www.npaonline.org).

## TECHNOLOGY AND RURAL AGING

Because of the problems of distance, and the lack of providers, facilities, and economies of scale, technology holds great promise to expand the services provided to older adults living in rural areas. A wide variety of technologies exist for this use, and the technology is rapidly changing and becoming less expensive.

Interactive televideo can be used with telephone or special lines. A video camera, monitor, and connection system are all that is needed. Such a system can provide video and audio information, gathered by an in-home visiting nurse and projected to a consultant physician at a distant site. Real-time consultations can be made, or the data can be saved for later (asynchronous) interactions. The Telemedicine Research Center reported in 2004 that there were 88 telehealth networks across the United States providing over 85 000 patient-provider teleconsultations in 2003.

Telemedicine may be particularly useful when using interdisciplinary teams in rural geriatric care. NPs, PAs, and rehabilitation

therapists can communicate with one another, and a physician to optimize care for frail older persons. Kansas University has been using telemedicine to enable speech and language pathologists to conduct swallowing evaluations from remote sites. It has also been used in rural nursing homes for monitoring and directing wound care. Comprehensive geriatric assessment has been conducted in rural areas using telemedicine to link with a geriatrician at a remote area.

Finally, it is particularly useful in home care, where a wide variety of health assessments, such as blood pressure, temperature, monitoring of heart and lung sounds, oximeters, spirometers, and laboratory determinations can be made. Patients of family caregivers can be trained to administer the assessments and transmit the results to treatment of team members. This is particularly useful in chronic disease management programs.

The use of the Internet will expand the options for telemedicine even more. Videos can be transmitted live or asynchronously. Web cameras are inexpensive and Voice over Internet Protocol (VoIP) allows audio transmission. The major obstacle is the speed of transmission but high-speed lines are being expanded into rural areas and a number of cell phone companies provide wireless transmission.

The challenges of instituting widespread use of interactive televideo medicine are numerous. They include limitations of reimbursement, the absence of or antiquated technical infrastructure, interstate telemedicine license questions, privacy concerns, and the fact that the present cohort of elders, and particularly those in rural areas are not particularly technologically savvy. However, in spite of these barriers, rural physicians who recognize the benefits to both themselves and to their patients are likely to implement a telemedicine strategy when offered.

## SUMMARY

Rural aging provides both significant challenges and special opportunities. The number of elders in rural settings is not likely to decline soon. Primary care physicians will always provide the bulk of care to older persons in rural areas. The advent of new technologies, particularly the Internet, should allow expansion of services and greater access to high-quality geriatric care.

# Appropriate Approach to Prescribing

*Paula A. Rochon ■ Jennifer Tjia ■ Sudeep S. Gill ■ Jerry H. Gurwitz*

Prescribing for older patients offers special challenges. Older people take about three times as many prescription medications as do younger people, mainly because of an increased prevalence of chronic medical conditions among the older patient population. Taking several drugs together substantially increases the risk of drug interactions and adverse events. Many medications need to be used with special caution because of age-related changes in pharmacokinetics (i.e., absorption, distribution, metabolism, and excretion) and pharmacodynamics (see Chapter 8). For some drugs, an increase in the volume of distribution (e.g., diazepam) or a reduction in drug clearance (e.g., lithium) may lead to higher plasma concentrations in older patients than it does in younger patients. Pharmacodynamic changes with aging may result in an increased sensitivity to the effects of certain drugs, such as opioids, for any given plasma concentration. The pharmacokinetic and pharmacodynamic changes with aging are discussed in Chapter 8.

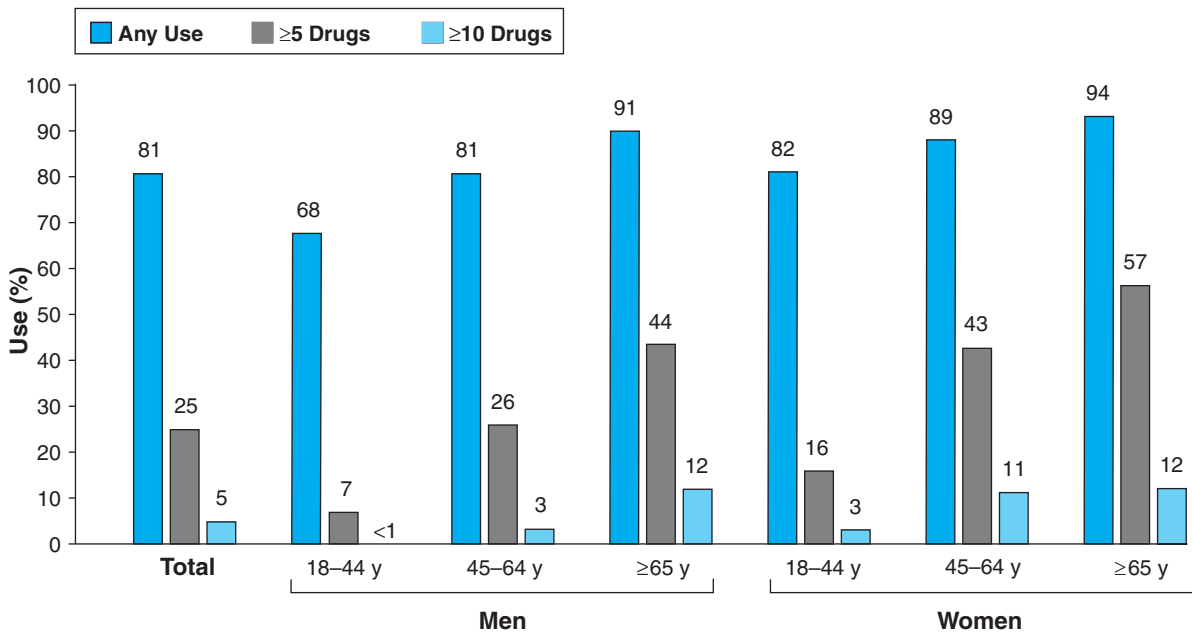

While a physician can usually do little to alter the characteristics of individual older patients to affect the kinetics or dynamics of drugs, the decision whether to prescribe any drug, the choice of drug, and the manner in which it is to be used (e.g., dose and duration of therapy) are all factors that are under control of the prescriber. This chapter discusses ways to optimize prescribing of drug therapy for older adults.

## EPIDEMIOLOGY OF DRUG THERAPY

Writing a prescription is the most frequently employed medical intervention. Yet, creating optimal drug regimens that meet the complex needs of older persons requires thought and careful planning. Multiple factors contribute to inappropriate drug prescribing, including lack of adequate training of doctors in safe prescribing behavior and in prescribing for geriatric patients. Further, a lack of a routine use of safe medication prescribing behaviors such as checking drug allergies, double checking drug doses, adjusting doses for

renal impairment, and potential drug–drug interactions also contribute to prescribing errors. Avoidable adverse drug events (ADEs) are the most serious consequences of inappropriate drug prescribing. The possibility of an ADE should always be borne in mind when evaluating an elderly individual. A maxim from one wise geriatrician recommends: “In evaluating virtually any symptom in an older patient, the possibility of an ADE should be considered in the differential diagnosis.” Advanced age, frailty, and increased drug utilization are all factors that contribute to an individual patient’s risk for developing a drug-related problem. In the ambulatory setting, 25% of patients may have ADEs. When an ADE is identified in the ambulatory setting between 11% and approximately 25% are considered to be preventable. In the nursing home setting, the incidence is higher and approaches 10 ADEs per 100 resident-months, of which over half were preventable. These estimates are probably low because preventable ADEs were strictly defined and assumed that, in many cases, the prescription of the offending drug was indicated and the ADE was therefore not preventable. As many as 28% of hospital admissions among older patients result from drug-related problems. Up to 70% of these drug-related admissions are attributed to adverse drug reactions. Perhaps the most compelling explanation for the prevalence of ADE in older patients is that we lack methods for determining the harms associated with the multiple medications consumed simultaneously.

A random sample of 2590 noninstitutionalized older adults in the United States during the years 1998 and 1999 provides information on the use of prescription and over-the-counter medications in the community. This survey demonstrated that use of all medications (prescriptions, over-the-counter drugs, vitamins/minerals, and herbals/supplements) (Figure 24-1) and the use of prescribed drug therapies (Figure 24-2) increases dramatically with advancing age. The highest prevalence of medication use was among women aged 65 years and older. Among these women, 12% took 10 or more medications and 23% took at least five prescribed drug therapies. The use of a larger number of drugs is associated with an increased

**FIGURE 24-1.** Use of medications during the preceding week, by sex and age. (Adapted from Kaufman DW, Kelly JP, Rosenberg L, et al. Recent patterns of medication use in the ambulatory adult population of the United States: the Slone survey. JAMA. 2002;287:337.)

likelihood of inappropriate prescribing, ADEs, and risk for geriatric syndromes including cognitive impairment, falls, hip fractures, and urinary incontinence. The widespread use of over-the-counter drug therapies indicates the importance of routinely inquiring about their use when evaluating a drug therapy regimen.

Herbal medicines are frequently used by older adults; physicians often do not question patients about such use. An estimated 14% of the U.S. population takes an herbal medicine or supplement such as ginseng, ginkgo biloba extract, and glucosamine. The use has increased from among adults who are 50 years of age or older, from 28% in 1991 to 39% in 1997. In one survey, almost 75% did not inform their physician that they were using unconventional treatments including herbal medicines. Herbal medicines may interact with prescribed drug therapies leading to adverse events, underscor-

ing the importance of routinely questioning patients about their use of these unconventional therapies. Examples of herbal–drug therapy interactions include warfarin in combination with ginkgo biloba extract leading to an increased risk of bleeding and serotonin-reuptake inhibitors in combination with St. John’s Wort leading to serotonin syndrome in older adults.

### MEASURING THE QUALITY OF DRUG PRESCRIBING IN OLDER PERSONS

Various criteria have been developed by expert panels in Canada and in the United States to assess the quality of medication use in elderly patient populations. The most widely used criteria employed

**FIGURE 24-2.** Use of prescription drugs during the preceding week, by sex and age. (Adapted from Kaufman DW, Kelly JP, Rosenberg L, et al. Recent patterns of medication use in the ambulatory adult population of the United States: the Slone survey. JAMA. 2002;287:337.)

for the assessment of inappropriate prescribing are based on the Beers criteria. These criteria were developed in 1991 by a consensus panel of experts in geriatric medicine, geriatric psychiatry, and pharmacology to evaluate inappropriate prescribing in nursing home residents. This expert group identified a list of medications considered inappropriate for older patients, either because they are ineffective or because they pose a high risk for adverse events. The list included long-elimination half-life benzodiazepines (e.g., diazepam) and hypoglycemic agents with long half-lives (chlorpropamide), antidepressants with strong anticholinergic properties (e.g., amitriptyline), and ineffective dementia treatments (e.g., cyclandelate). The Beers criteria were revised in 1997 and again in 2003 to make them more relevant to current prescribing issues and to generalize them beyond the nursing home setting. The 1997 revision recategorized the 33 medications deemed inappropriate according to the Beers criteria into three groups: (1) drugs that should always be avoided (e.g., barbiturates, chlorpropamide); (2) drugs that are rarely appropriate (e.g., diazepam, propoxyphene); and (3) drugs with some indications, but that are often misused (e.g., oxybutynin, diphenhydramine). The 2003 reorganization acknowledged that precise information to evaluate appropriateness may be lacking; two categories were generated: (1) medications or medication classes that should generally be avoided in persons 65 years or older because they are either ineffective or they pose unnecessarily high risk for older persons and a safer alternative is available and (2) medications that should not be used in older persons known to have specific medical conditions.

Use of drug therapies considered inappropriate according to the Beers criteria has been identified as an ongoing problem among community-dwelling older adults. The prevalence of inappropriate drug use remained steady between 1995 and 2000. Using the subset of the 20 drug therapies from the original Beers criteria that should be entirely avoided, 23.5% of community-dwelling older adults in the United States, as identified using the 1987 National Medical Expenditure Survey, were found to be taking one or more of the inappropriate medications. Three percent used at least one of the 11 drug therapies that the panel determined should always be avoided by older adults. Data from other surveys showed that the risk of hospitalization, emergency department visits, and death were greater for nursing home patients who had been prescribed potentially inappropriate medications.

The Health Care Financing Administration (now called The Centers for Medicare and Medicaid Services) expert consensus panel drug utilization review criteria have also been used to evaluate inappropriate prescribing in community-dwelling older adults. These criteria target eight prescription drug classes (i.e., digoxin, calcium channel-blockers, angiotensin-converting enzyme (ACE) inhibitors, histamine-2 receptor antagonists, nonsteroidal antiinflammatory drugs (NSAIDs), benzodiazepines, antipsychotics, and antidepressants) and focus on four types of prescribing problems: (1) use of an inappropriate dosage; (2) duplication of therapies; (3) potential for drug–drug interactions; and (4) inappropriate duration of therapy. Based on the criteria, almost 20% of 2508 community-dwelling older adults were found to be using one or more medications inappropriately. NSAIDs and benzodiazepines were the drug classes identified with the most frequent potential problems.

Unfortunately, the vast majority of medications that are commonly implicated in preventable ADEs are not identified by these widely used “bad drug” lists. Inappropriate prescribing is often more

subtle, more pervasive, and often unrecognized. “Good drugs” prescribed in an inappropriate manner may be far more common and problematic. Very few drugs that cause difficulty for older adults are inherently bad. To address these concerns, a more comprehensive approach to evaluating the quality of pharmacologic care for older adults was developed by the Assessing Care of Vulnerable Elders (ACOVE) project. These include 12 quality indicators for appropriate medication use identified by Knight and Avorn. [Table 24-1](#) describes each of the 12 indicators and summarizes the rationale for its need. These indicators start with the need to document the indication for a new drug therapy, to educate patients on the benefits and risks associated with the use of a new therapy, the need to maintain current medication lists in patient medical records, the importance of documenting response to therapy, and the need for a periodic review of drug therapies. In addition, these indicators specify seven drug therapies that either should not be prescribed for older adults (i.e., hypoglycemic agent chlorpropamide, drugs with strong anticholinergic properties, barbiturates, and meperidine) or that warrant careful monitoring after they have been initiated (i.e., warfarin, diuretic, and ACE inhibitor therapy).

Underprescribing of potentially useful medications is at least as problematic as overprescribing of potentially harmful medications. Using a subset of ACOVE quality indicators and a sample of 372 vulnerable older adults in two managed care organizations, investigators determined the proportion of patients who met criteria for underprescribing potentially useful medications and overprescribing potentially harmful medications. Of nine quality indicators measuring the overprescribing of harmful medications, eight had a pass rate of 90% or greater. Of 17 quality indicators measuring the underprescribing of useful medications, only 1 had a pass rate of 90% or greater; eight had a pass rate of less than 60%. In another study, investigators found coexistence of both the inappropriate use of harmful medications and the under use of beneficial medications in 42% of study patients; 13% had neither. The complexity of safe and effective prescribing for older adults with multiple chronic conditions makes the determination of appropriate prescribing difficult to assess. Defining over- and underprescribing outside the context of individual measures of disease burden, total medication use, and preferences may be misleading and fraught with unintended consequences. These estimates of over- and underprescribing should, therefore, be interpreted cautiously.

## PRESCRIBING CASCADES

A particularly concerning aspect of suboptimal medication use in older adults relates to the occurrence of prescribing cascades. A prescribing cascade begins when an ADE is misinterpreted as a new medical condition. An additional drug therapy is prescribed, and the patient is placed at risk for the development of additional ADEs relating to this potentially unnecessary treatment ([Figure 24-3](#)). Prescribing cascades and other risks associated with drug therapy are particularly important for older adults with multiple chronic diseases who are likely to be prescribed multiple drug therapies. Selected examples of prescribing cascades are described below.

### Drug-Induced Parkinsonism

Among 95 new cases of Parkinson’s disease from community-dwelling older adults referred to a geriatric medicine department

**TABLE 24-1****Quality Indicators for Appropriate Medication Use in Older Adults**

INDICATOR TITLE	DESCRIPTION	RATIONALE
Indication	When prescribing a new drug, the therapy should have a clearly defined indication documented in the medical record.	The medication may have been prescribed for an indication that was unclear or transient.
Patient education	When prescribing a new drug, the patient or caregiver should be educated about the optimal use of the therapy and the anticipated adverse events.	Education may improve adherence, clinical outcomes, and alert patients or caregivers to potential adverse events.
Medication list	Medical records (outpatient or hospital) should contain a current medication list.	Allows identification and elimination of duplicate therapies, corrects drug interactions, and streamlines the drug regimen to improve adherence.
Response to therapy	Every new drug prescribed on an ongoing basis (e.g., for a chronic condition) should have documentation of response of therapy within 6 months.	Provides a rationale for continuation of the therapy if effective, or change or discontinuation if ineffective.
Periodic drug review	Annual drug regimen review.	Provides an opportunity to discontinue unnecessary therapy or to add needed drug therapies.
Monitoring warfarin therapy	When warfarin is prescribed, international normalized ratio (INR) should be evaluated within 4 days and at least every 6 weeks.	Older adults are at high risk for drug toxicity that can be identified earlier if there is close monitoring for agents with a narrow therapeutic range.
Monitoring diuretic therapy	When a thiazide or loop diuretic therapy is prescribed, electrolytes should be checked within 1 week after initiation and at least annually.	Risk of hypokalemia because of diuretic therapy.
Avoid use of chlorpropamide as a hypoglycemic agent	When prescribing an oral hypoglycemic agent, chlorpropamide should not be used.	This therapy has a prolonged half-life that can result in serious hypoglycemia and is more likely than other agents to cause the syndrome of inappropriate secretion of antidiuretic hormone.
Avoid drugs with strong anticholinergic properties	Do not prescribe drug therapies with a strong anticholinergic effect if alternative therapies are available.	These therapies are associated with adverse events such as confusion, urinary retention, constipation, and hypotension.
Avoid barbituates	If older adult does require the therapy for control of seizures, do not use barbiturates.	These therapies are potent central nervous system depressants, have a low therapeutic index, are highly addictive, cause drug interactions, and are associated with an increased risk for falls and hip fracture.
Avoid meperidine as an opioid analgesic	When analgesia is required, avoid use of meperidine.	This therapy is associated with an increased risk for delirium and may be associated with the development of seizures.
Monitor renal function and potassium in patients prescribed angiotensin-converting enzyme inhibitors	If angiotensin-converting enzyme inhibitor therapy is initiated, potassium and creatinine levels should be monitored with 1 week of initiation of therapy.	Monitoring may prevent the development of renal insufficiency and hyperkalemia.

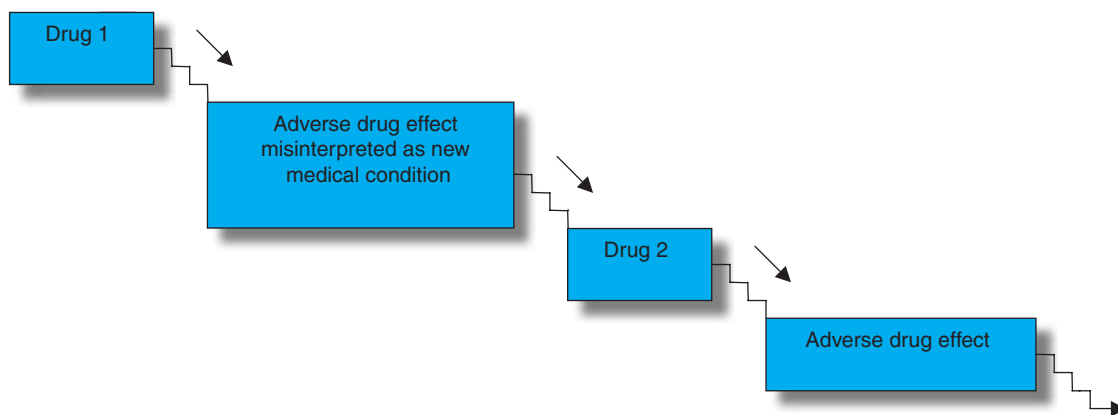

Data from Knight E, Avron J. Quality indicators for appropriate medications use in vulnerable elders. *Ann Intern Med.* 2001;135(Pt 2):703.

in the United Kingdom, more than half were found to have drug-induced Parkinsonism. Conventional antipsychotic medications such as haloperidol, prochlorperazine, and thioridazine were among the major drug therapies implicated.

The association between antipsychotic drug exposure and subsequent treatment of Parkinsonism was identified among 3512 adults aged 65 to 99 years who were enrolled in a Medicaid program and initiated on a drug therapy for the treatment of Parkinsonian symptoms. Patients dispensed a antipsychotic therapy in the 90 days prior to the initiation of anti-Parkinson's therapy were more than five times

more likely to begin anti-Parkinson's therapy relative to control patients who were not dispensed antipsychotic therapy. Furthermore, a dose-response relationship was demonstrated.

Antipsychotic therapy is widely used in older adults for the management of behavioral problems associated with dementia. Antidopaminergic-related adverse effects associated with these agents have long been recognized, including the development of extrapyramidal signs and symptoms. This drug-related symptom may be potentially misdiagnosed as a new medical condition (i.e., Parkinson's disease). A recent study has demonstrated that even the newer

**FIGURE 24-3.** Prescribing cascade. (Adapted from Rochon PA, Gurwitz JH. *Drug therapy. Lancet.* 1995;346:32.)

“atypical” antipsychotics can be associated with Parkinsonism in a dose-related fashion. Patients who are placed on anti-Parkinsonian therapy then become vulnerable to the adverse events associated with this new therapy, including hypotension and delirium. A better approach is to discontinue or reduce the dose of the antipsychotic therapy. If an antipsychotic is deemed essential, it is prudent to select a therapy with a more favorable adverse effect profile and to use this therapy at the lowest feasible dose. Even newer agents have adverse effects at higher doses.

Drug-induced Parkinsonism has also been reported with other drug therapies, including metoclopramide. A case-control study of adults aged 65 years and older in the New Jersey Medicaid Program demonstrated that metoclopramide users were three times more likely to begin drug treatment for Parkinson’s disease as compared with nonusers. Risk increased with increasing daily metoclopramide dose such that the odds ratio was 1.19 for up to 10 mg/day, 3.33 for 10 to 20 mg/day, and 5.25 for >20 mg/day. Thus, drug-induced Parkinsonism may lead to the initiation of anti-Parkinson drug therapy. Such drug-induced symptoms in an older person can be misinterpreted as indicating the presence of a new disease or be attributed to the aging process rather than to the drug therapy. This misinterpretation is particularly likely when the symptoms are indistinguishable from an illness, such as Parkinson’s disease that is seen in greater frequency in older persons.

#### Acetylcholinesterase Inhibitors and Anticholinergic Therapy

Cholinesterase inhibitors (such as donepezil, rivastigmine, and galantamine) are often prescribed to manage the symptoms of Alzheimer’s disease and related dementias. Through their effects on the autonomic nervous system, cholinesterase inhibitors can sometimes precipitate urge urinary incontinence. However, new-onset or worsening urge incontinence is also commonly seen as part of the natural history of dementia. Thus, clinicians may misinterpret incontinence in patients with dementia as an unavoidable progression of their underlying disease, when it may in fact represent a potentially reversible drug-related adverse event. A population-based cohort study demonstrated that cholinesterase inhibitor use was associated with an increased risk of receiving anticholinergic medications to manage urinary incontinence. This study suggests the use of anticholinergic drugs in patients with dementia may sometimes represent an unrecognized ADE related to cholinesterase inhibitor

use. The use of anticholinergic drugs by older adults with dementia may expose them to anticholinergic adverse effects (such as urinary retention and postural hypotension) and may also dilute the benefits of cholinesterase inhibitor treatment.

Other prescribing cascade scenarios, such as the association between the use of hydrochlorothiazide therapy and the initiation of antigout therapy or the use of NSAID therapy and hypertension, have been identified. Many more potential prescribing cascades will become apparent as physicians carefully consider the relationship between the initiation of a new drug therapy, the adverse event profile of that therapy, and the development of a new medical condition. The increased recognition of similar prescribing scenarios hopefully will reduce the occurrence of inappropriate prescribing decisions.

#### UNDERUSE OF BENEFICIAL THERAPY

Prescribing strategies that seek to simply limit the overall number of drugs prescribed to older adults in the name of improving quality of care may be misdirected. For example, a patient with a myocardial infarction may be prescribed three essential drug therapies: a beta-blocker, an ACE inhibitor, and acetylsalicylic acid. If this patient has elevated lipid levels and diabetes, three or more additional medications may be required. Accordingly, many elderly persons may benefit from taking six or more essential medications. Under use of beneficial drug therapy by older adults may be associated with increased morbidity, mortality, and reduced quality of life. This suggests a need for a more complex model for assessing the quality and appropriateness of prescribing for older persons than simply counting the number of different medications that a patient is receiving. This complex model should be directed toward assessing the potential benefit versus harm of the patient’s total medication regimen. One proposed model for the initiation or discontinuation of medications for older adults in late life considers remaining life expectancy, time until benefit will be achieved, the patient’s goals of care and whether the medication can meet treatment goals. For example, if a patient’s life expectancy is short and the goals of care are palliative, then prescribing a prophylactic medication requiring several years to realize a benefit may not be considered appropriate.

For patients of advanced age with multiple medical problems, secondary prevention may not be given a high priority. Among patients 65 years of age or older who have a chronic condition, unrelated

diseases often go untreated. Similarly, patients with psychotic syndromes, as indicated by use of haloperidol, were significantly less likely to be dispensed arthritis therapy relative to patients without psychoses (18% relative to 27%,  $p < 0.001$ ). While an understanding of the logic behind these decisions for individual patients remains uncertain, potential explanations for under treatment include “a belief that treatment of the patient’s primary problem is enough; a judgment that the adverse effects of additional medications are too great and the benefits insufficient; or a patient’s preference for taking fewer medicines.” Selected examples of under prescribing of beneficial therapy are described below.

### Example of Underuse of Beneficial Therapy: Hypertension

Despite the availability of guidelines to facilitate hypertension management, this condition is inadequately treated even when physicians are monitoring their patients in a clinic. For example, among 800 men with hypertension with a mean age of 65 years receiving care in Veterans Affairs outpatient clinics in New England, approximately 40% had a blood pressure of 160/90 mm Hg despite an average of more than six hypertension-related visits in a year. At visits in which a diastolic blood pressure of  $<90$  mm Hg and a systolic blood pressure of  $>165$  mm Hg were recorded, increases in the antihypertensive regimen occurred only 22% of the time. The Systolic Hypertension in the Elderly Person (SHEP) study demonstrated that treating isolated systolic hypertension in people 60 years of age and older reduced the risk of stroke by 36% ( $p = 0.0003$ ) and also reduced major cardiovascular events relative to the placebo condition.

### Example of Underuse of Beneficial Therapy: Beta-Blocker Therapy Postmyocardial Infarction

Studies demonstrate that older adults, including those at high-risk for poor outcomes, benefit from beta-blocker therapy postmyocardial infarction. The relation between beta-blocker use and subsequent mortality was evaluated among New Jersey Medicare recipients sustaining an acute myocardial infarction between 1987 and 1992. Among those dispensed beta-blocker therapy, mortality was decreased by 43% relative to nonrecipients of this agent (aRR = 0.57). In a sample of “ideal” beta-blocker therapy candidates in the Cooperative Cardiovascular Project’s cohort of myocardial infarction survivors between 1994 and 1995, being discharged from hospital with a prescription for beta-blocker therapy was associated with a 14% mortality reduction (aRR = 0.86).

Withholding beta-blocker therapy maybe most harmful to seniors of advanced age and with potential contraindications to beta-blocker therapy. Among 201 752 seniors participating in the Cooperative Cardiovascular Project, patients at high-risk for beta-blocker-related complications (i.e., patients with heart failure, pulmonary disease, and diabetes) obtained substantial mortality reduction when prescribed beta-blocker therapy relative to those who were not prescribed this treatment. For example, patients with congestive heart failure treated with beta-blocker therapy had a 40% mortality reduction relative to nonrecipients. While it is impossible to eliminate unmeasured confounding as at least a partial explanation for this survival benefit in recipients versus nonrecipients, observational studies suggest continued under prescribing of beta-blocker therapy

to seniors some 20 years after these agents were proven effective in randomized control trials (RCTs).

### Example of Underuse of Beneficial Therapy: Osteoporosis

Osteoporosis is a common condition, particularly among older women. Guidelines are available for the management of the condition (see Chapter 117). To treat osteoporosis, it must first be diagnosed. Despite increasing attention, this condition continues to be underdiagnosed. The findings obtained from the National Osteoporosis Risk Assessment (NORA) study illustrate this problem. The NORA study is a longitudinal observational study of more than 200 000 postmenopausal women to evaluate the relationship between bone mineral density and the risk for fractures. Ambulatory, postmenopausal women with no previous diagnosis of osteoporosis and not on osteoporosis therapy (i.e., bisphosphonate, calcitonin, or raloxifene) were eligible. Of the patients evaluated 39.6% were classified as having osteopenia and 7.2% with osteoporosis. Among the individuals with follow-up information at 1 year, those with osteopenia were almost twice as likely to develop a fracture relative to those with normal bone mineral density. Those older women with a diagnosis of osteoporosis were four times as likely to develop a fracture during the 1 year of follow-up relative to those with a normal bone mineral density. These findings suggest that undiagnosed low bone mineral density is very common in postmenopausal women and is associated with a high rate of fractures. Improved measures aimed at primary prevention in combination with better diagnosis could lead to better outcomes for older women.

### Example of Underuse of Beneficial Therapy: Opioid Analgesia and Cancer Pain

Opioid analgesia reduces pain and improves quality of life for cancer patients. Underprescribing of analgesia for cancer pain means that older patients may suffer needless discomfort. Pain guidelines are available to assist physicians in managing pain associated with metastatic cancer. In a study of 1308 outpatients with metastatic cancer being followed by oncologists, 769 patients reported experiencing pain, which 62% described as being substantial. Furthermore, older patients were more likely than younger patients to report that their pain was not being adequately managed. Older persons may be at risk of undertreatment because of a reluctance to prescribe opioid analgesics to older cancer patients. If analgesics are prescribed, the dose may not be adequate to achieve pain control. Efforts to address underprescribing of beneficial therapy in the elderly population must focus on educating health care providers, improving the adherence to prescribed drug regimens by older patients, and reducing the financial barriers to access to essential medications.

### Example of Underuse of Beneficial Therapy: Warfarin in Atrial Fibrillation

Warfarin is recommended in evidence-based guidelines for stroke prevention for older adults with atrial fibrillation, but is often inappropriately prescribed to older adults in long-term care setting. Among 429 residents of long-term care facilities with atrial fibrillation, 42% were prescribed warfarin therapy. Of the 83 older adults who were classified as being “ideal” candidates for warfarin

therapy (i.e., no known risk factors for hemorrhage), only half (53%) were prescribed this therapy. Furthermore, international normalized ratio (INR) readings were often found to be either below or above the therapeutic range. In fact, INR values were maintained in the therapeutic range only 51% of the time, placing patients at unnecessary risk for an adverse event despite long-term care residents residing in a supervised setting.

The American Geriatrics Society and the ACOVE project introduced guidelines to address the need for a more systematic approach to decision-making regarding the use of warfarin for stroke prevention in frail older persons. The proposed strategy guides the consideration of appropriate use of warfarin therapy and encourages more frequent monitoring until INR is stable in older adults because of the increased risk of hemorrhage. More widespread use of specialized anticoagulation clinics in order to provide coordinated anticoagulation care may offer an option to improve the effectiveness and safety of warfarin therapy in this particularly high-risk group of patients.

### SPECIAL CONSIDERATIONS REGARDING DRUG THERAPY IN THE LONG-TERM CARE SETTING

Long-term care residents include a disproportionate number of women, people of advanced age, and those with multiple medical problems, in particular dementia. Of all types of therapeutic interventions, medications are the most commonly used in the nursing home setting. The average U.S. nursing home resident uses six different medications; more than 20% use 10 or more different drugs, placing this group at increased risk of ADEs.

#### Antipsychotic Therapy in the Long-Term Care Setting

In long-term care facilities, excess use of antipsychotic therapy for the management of behavioral problems is an area of concern. Atypical antipsychotic medications are among the drugs most frequently associated with adverse events in long-term care facilities. Use is widespread and a study of 19 780 older adults with no history of major psychosis prior to long-term care admission found that antipsychotic therapy was prescribed for 24% within 1 year. Further, there is marked variation in the use of antipsychotic therapies in the nursing home. A study of antipsychotic therapy use in 47 322 residents of 485 provincially regulated nursing homes found that the mean rate of antipsychotic prescribing ranged from 20.9% in facilities with the lowest mean prescribing rates and 44.3% in facilities with highest mean prescribing rates. Compared with individuals residing in nursing homes with the lowest mean antipsychotic prescribing rates, those residing in facilities with highest rates were three times more likely to be dispensed an antipsychotic therapy irrespective of their potential clinical indication. There is recent evidence that the benefit from atypical antipsychotics for management of behavioral and psychological symptoms in Alzheimer's type dementia may be offset by the risk of ADEs. There is also evidence about the risk of death with both conventional and atypical antipsychotic medications warranting careful monitoring. Health Canada and the Food and Drug Administration have issued warnings about their use. Given these important safety concerns, use of antipsychotic therapy should generally be reserved for situations where the benefit

outweighs the risk. Specifically, antipsychotic therapy is potentially indicated to manage psychoses and for situations where the behavioral problems pose a risk to the resident or others.

An Institute of Medicine report on improving the quality of care in nursing homes in the United States determined that excessive use of antipsychotic therapy was evidence of poor quality of care. Concern about overuse of antipsychotic therapy led to the introduction of guidelines and legislative action in the United States designed to reduce antipsychotic therapy use in long-term care. As a result of these U.S. federal regulations implemented in 1990, the indication for treatment with antipsychotic therapy now has to be documented, nonpharmacologic approaches must be tried first, and a record of gradual reduction of therapy has to be on file after 6 months of treatment. Following the institution of these federal guidelines, antipsychotic therapy in nursing homes decreased by 27% with no compensatory increase in use of other psychoactive medications.

#### Risk of Adverse Drug Events in the Long-term Care Setting

The occurrence of ADEs that may have been prevented is among the most serious concerns regarding suboptimal medication use in the nursing home setting. Few studies have systematically examined the incidence of ADEs in the nursing home population. A retrospective review of incident reports relating to adverse and unexpected events in an academically oriented, 700-bed, long-term care facility identified 50 reports of adverse drug reactions over a 1-year period. Skin rashes were the most frequently reported events, and antibiotics were the most commonly implicated medication category. The limited number of reports of drug-related events suggests that voluntary reporting systems in the nursing home setting lead to very low reporting rates of only a very narrow spectrum of events.

In recent cohort study of two academic long-term care facilities in Ontario and Connecticut over a 9-month period, drug-related incidents were detected by computer-generated signals from a computerized physician order entry system, clinical pharmacist investigators, and periodic review of medical record. Incidents were classified by physician reviewers according to whether they represented an ADE, and if so, the severity (significant, serious, life-threatening, and fatal) and preventability of the event. During this study 815 ADEs were identified (9.8 ADEs per 100 resident-months). Of these, 42% were judged preventable. Of all ADEs, 4 (<1%) were fatal, 33 (4%) were life-threatening, 188 (23%) were serious, and 590 (72%) were less serious.

In this study, residents using anticoagulants, atypical antipsychotic agents, diuretics, antiinfectives, and antiepileptics were at the greatest risk of ADE. Psychoactive drugs (i.e., antipsychotics, antidepressants, and sedatives/hypnotics), cardiovascular and anticoagulants were the most commonly implicated drug categories associated with the occurrence of preventable ADEs (Table 24-2). Confusion, oversedation, delirium, and hemorrhagic events were the most commonly identified preventable ADEs (Table 24-3). Errors resulting in preventable ADEs occurred most often at the stages of ordering and monitoring. Among the prescribing errors, the most common were wrong dose, wrong drug choice, and known drug interaction. Dispensing and administration errors were less commonly identified. Independent risk factors for experiencing a preventable ADE included using medications in several drug categories, including antipsychotic agents, anticoagulants, diuretics, and antiepileptic. Extrapolating

TABLE 24-2

## Frequency of Adverse Drug Events and Potential Adverse Drug Events by Drug Class\*

DRUG CLASS	ADVERSE DRUG EVENTS		PREVENTABLE ADVERSE DRUG EVENTS		NONPREVENTABLE ADVERSE DRUG EVENTS	
	NO.	(%) (n = 815)	NO.	(%) (n = 318)	NO.	(%) (n = 497)
Atypical and typical antipsychotics	110	(11)	52	(16)	58	(12)
Antibiotics/antiinfectives	106	(13)	5	(2)	101	(20)

Syncope/dizziness	16 (2)	8 (2)
Anticholinergic <sup>‡</sup>	9 (1)	3 (1)
Ataxia/difficulty with gait	9 (1)	5 (2)
Hematologic	8 (1)	3 (1)
Respiratory	6 (1)	4 (1)
Anorexia/weight loss	3 (<1)	2 (<1)
Functional decline <sup>§</sup>	3 (<1)	2 (<1)
Hepatic	1 (<1)	1 (<1)

\*Adverse drug events could manifest as more than one type.

<sup>†</sup>Neuropsychiatric events include over sedation, confusion, hallucinations, and delirium.

<sup>‡</sup>Anticholinergic effects include dry mouth, dry eyes, urinary retention, and constipation.

<sup>§</sup>Adverse drug event manifested only as decline in activities of daily living without any other more specific type of event. Other types of events may have been associated with functional decline.

Adapted from Gurwitz, JH, Field TS, Judge J, et al. The incidence of adverse drug events in two large academic long-term care facilities. *Am J Med.* 2005;118:251.

from the results of this research, 1.9 million ADEs per year may occur among the 1.6 million U.S. nursing home residents and more than 40% maybe preventable. There are almost 86 000 fatal or life-threatening ADEs per year, of which 70% maybe preventable. Drug-related morbidity and mortality is an important area to target in efforts to both improve the quality of medical care for older persons and reduce the costs of health care for this population.

Failures in the design of systems of care often contribute to the occurrence of medical errors, as well as the injuries that result from some of those errors. Enhanced surveillance and reporting systems for ADEs occurring in the nursing home setting are required as are continued educational efforts relating to the optimal use of drug therapies in the frail elderly patient population. However, as Leape et al. (1995) concluded in regard to the occurrence of serious medication errors in the hospital setting, “preventive efforts that focus solely on the individual provider or which rely on inspection alone have limited impact. Analysis and the correction of underlying systems faults is much more likely to result in enduring changes and significant error reduction.” Ordering and monitoring errors in the nursing home setting maybe particularly amenable to prevention strategies that use systems-based approaches. The benefits of such an approach to error reduction in the hospital setting that uses computerized order entry have been reported. For example, a computer-based decision aid reduced in-hospital inappropriate dosing of psychotropic medications for geriatric inpatients. Successes in the hospital setting pave the way for similar efforts in the nursing home setting aimed at reducing drug-related injuries and disability and improving the quality of care provided to the frail elderly patient population. At least one large Canadian academic long-term care facility has adopted a computerized order entry system with decision aids for prescribing to improve the quality of medication prescribing. Figure 24-4 is an example of the kind of decision support, which provides drug therapy dosing recommendations in patients with renal impairment.

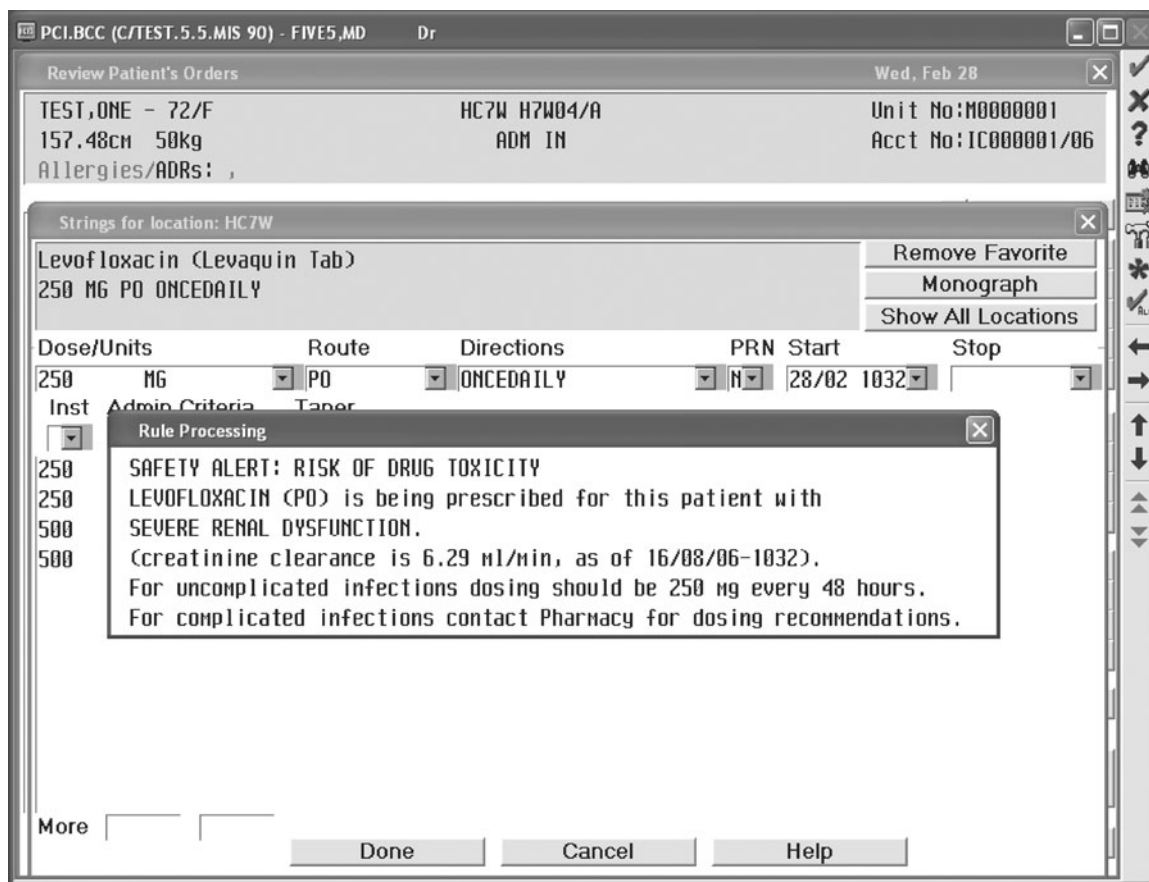

FIGURE 24-4. Example of computerized physician order entry.

## DEFICIENCIES IN INFORMATION ABOUT DRUG THERAPY IN OLDER ADULTS

Selecting the right medication and the right dose to prescribe for an older person is difficult because so little evidence is available to guide choices. Decision-making often has to draw on information obtained from the experience of patients very different from those encountered in clinical practice, where patients often have several medical conditions and are taking more than one drug. The findings of clinical trials of treatments for conditions commonly affecting older people cannot directly be extrapolated to that age group, as older persons, particularly frail persons and those with multiple illnesses, have often been excluded from participation in such studies. This poses challenges to the adoption of clinical practice guidelines developed to improve the quality of health care for many chronic conditions. A review of clinical practice guidelines for nine common chronic diseases promulgated by national and international medical organizations found that most clinical practice guidelines did not modify or discuss the applicability of their recommendations for older patients with multiple comorbidities. Most did not comment on burden, short- and long-term goals, and the quality of the underlying scientific evidence, nor give guidance for incorporating patient preferences into treatment plans. But clinical practice guidelines have important implications for medication prescribing. This study describes an example where, if the relevant guidelines were followed, a hypothetical 79-year-old patient with osteoporosis,

osteoarthritis, type 2 diabetes mellitus, hypertension, and chronic obstructive pulmonary disease would be prescribed 12 medications. There are several ways in which the quality and availability of information about the use of drugs in older persons might be improved. These include enhancing the inclusion of older persons in drug trials, and using observational studies and systematic reviews to provide information to guide clinical decision making.

## Inclusion of Older Persons in Clinical Trials

Approximately two decades ago, the United States Food and Drug Administration published “Guidelines for the Study of Drugs Likely to be Used in the Elderly.” The guideline was intended to encourage routine and thorough evaluation in elderly populations of the effects of new drugs being proposed for federal approval so that physicians would have sufficient information to use such drugs properly in their older patients. The guidelines state “there is no good basis for the exclusion of patients on the basis of advanced age alone, or because of the presence of any concomitant illness or medication, unless there is a reason to believe that the concomitant illness or medication will endanger the patient or lead to confusion in interpreting the results of the study.” In short, drug trials should include subjects that reflect the group that would eventually be prescribed the therapy.

Despite these guidelines, older adults continue to be underrepresented in clinical trials. For example, while almost 50% of older people report some form of arthritis, RCTs of NSAID therapy include

few older people and hardly any older than age 85 years. National funding agencies, particularly the National Institutes of Health in the United States, have also developed guidelines to ensure that the trials they fund adequately represent women. These guidelines are very important for older adults because women outnumber men in the older age groups. While these guidelines have been received with enthusiasm, their impact on the inclusion of older women in clinical trials is less encouraging. For example, despite the fact that 80% of deaths caused by acute myocardial infarction occur in persons aged 65 years and older, older patients continue to be excluded from clinical trials. In a review of 214 randomized trials of treatments for acute myocardial infarction, 60% were found to exclude patients older than 75 years of age (Gurwitz et al., 1992). Similarly, it was found that women represented, on average, less than a quarter of participants in trials evaluating the benefit of drug therapy for myocardial infarction. In a comparison of the inclusion of elderly persons and women in trials of acute coronary syndromes (myocardial infarction, unstable angina, or acute coronary syndromes) published between 1966 and 1990 relative to those published between 1991 and 2000, trials with explicit age-related exclusion criteria were noted to decrease from 58% to 40% in more recent years. The inclusion of older patients (i.e., 75 years of age and older) increased from 2% between 1966 and 1990 to 9% between 1991 and 2000. The inclusion of women in these trials increased from 20% from 1966 to 1990 to 25% in the more recent years. However, this number remains below the number of women presenting with myocardial infarction. These findings suggest that federal guidelines have not yet met their expectation.

### Using Alternative Study Designs to Study Drug-Related Risks and Benefits

Using alternative study designs as a complement to clinical trials may help to improve the quality and availability of information about the use of drug therapy by older persons. RCTs have long been considered the gold standard for evaluating the efficacy of a drug therapy. Ethical concerns may prevent the inclusion of the very impaired and the very old in RCTs and it maybe unrealistic to expect these studies to include adequate numbers of all relevant subgroups in the elderly population. In addition, there is mounting concern that such clinical trials are not the optimal way to evaluate ADEs in older adults. Drug trials are of relatively short duration. Drug-related problems that present months after initiating therapy may not be identified during the course of these relatively short trials. In general, drug trials focus on the efficacy of the therapy and give less emphasis to the potential risks associated with the use of the therapy. For example, in a survey of 192 randomized drug trials, the severity of clinical adverse events was adequately defined in fewer than 40% of the published trials. The amount of text devoted to the discussion of the adverse events was similar to that given to the listing of contributor's name and affiliations, suggesting underreporting of adverse events. Furthermore, the older persons included in RCTs have fewer comorbid illnesses than their age-matched peers. Thus, RCT results may not reflect the benefits or adverse effects of medications in frailer older persons or persons with multiple chronic illnesses.

Well-designed observational studies provide a promising approach for evaluating the relative risk and benefit of new drugs among subgroups of older persons who were not represented in clinical trials. Observational data may detect rare adverse events that

become of major public health importance when a drug therapy is taken by very large numbers of people. For example, a study of adults 60 years and older from the Tennessee Medicaid program found that patients currently dispensed an NSAID were almost five times more likely as those not dispensed an NSAID to die from a peptic ulcer or a gastrointestinal hemorrhage. This study made an important contribution to alerting health care providers to important risks associated with commonly used therapy. Following the reporting of heart attacks, strokes, and deaths associated with the COX-2 inhibitor, rofecoxib (tradename: Vioxx), the Institute of Medicine Report of Reducing Medication Errors recommended that the United States Food and Drug Administration mandate drug manufacturers conduct postmarketing surveillance and risk assessments.

Observational data may also provide information about the benefits of drug therapy at doses that were not evaluated in clinical trials. The major RCTs demonstrating the benefit of beta-blocker therapy post myocardial infarction evaluated doses of beta-blocker therapy that are higher than those generally used in clinical practice. Using linked Ontario provincial databases, 10 991 myocardial infarction survivors were identified who were dispensed one of the evaluated beta-blocker therapies (i.e., atenolol, metoprolol, propranolol, or timolol). Almost 90% received a lower dose of a beta-blocker than have been evaluated in a clinical trial. Among 13 623 older myocardial infarction survivors in the province of Ontario, relative to those not dispensed beta-blocker therapies, the adjusted risk ratios for mortality were lower for all three doses (low, standard, or high) of beta-blocker therapy. In a study from the United States, myocardial infarction survivors dispensed beta-blocker therapy at doses less than half of that evaluated in clinical trials received substantial benefit from the therapy. These findings support the strategy of initiating beta-blocker therapy at low dose and titrating the dose as tolerated.

While there are many challenges in using observational data, careful attention to design and methodological issues maximize the likelihood of obtaining high-quality usable data. Inception cohorts using strict criteria ensure the identification of the populations at risk and the time of exposure. Risk-adjustment techniques enable the modeling of outcomes controlling for observed differences between exposed and unexposed groups. Despite their limitations, observational studies provide valuable information on the benefits and harms of medications when prescribed to actual patient in a real-world setting.

### Systematic Reviews to Guide Therapeutic Decision Making

A systematic review provides another important source of information. Systematic reviews can be a useful way to organize and synthesize the vast amount of information available from clinical trials, which individually may include relatively small numbers of older people. By combining the information from older individuals obtained from a series of trials, useful information can be retrieved. Standardized reporting of trial data by age would make such analyses easier. The high-quality systematic reviews produced and maintained by the Cochrane Collaboration provide important information to improve the care of older adults with a specific medical condition. For example, in a systematic review of the evidence for pharmacotherapy for hypertension treatment in elderly persons, 15 hypertension trials involving 21 908 adults who were at least 60 years of age or older were evaluated. This review demonstrated that treating hypertension in elderly persons, at least the spectrum of elderly persons included

in RCTs, reduces coronary heart disease and cerebrovascular morbidity and mortality. Systematic reviews can be used to summarize data and inform clinical decisions that clinicians have had to make empirically.

Better representation of older and frailer adults in clinical trials, the evaluation of the risks and benefits of drug therapy through the use of observational data, and the use of high-quality systematic reviews are examples of ways to improve the quality of information available to clinicians in making prescribing decisions for older patients. In the meantime, limitations on what is known about drug treatments for many common conditions in older persons suggest the need for special care in prescribing and extra caution in considering use of new products in older patients.

## POLICY ISSUES RELATED TO DRUG THERAPY IN OLDER ADULTS

### Cost-Related Adherence

A prescription maybe written but not filled, or filled and not taken regularly, because of financial considerations. The use of drug therapy has been shown to be directly related to coverage of drug costs. It is estimated that more than 40% of all Medicare enrollees in the United States had no coverage for outpatient drug expenditures prior to the implementation of the 2003 Medicare Modernization Act. In the United States, cost has been identified as an important reason that patients did not take medication that was prescribed by their health care provider. Specifically, among older adults, 13% of a national sample of 13 869 noninstitutionalized Medicare enrollees reported cost-related underuse of medications. Those in fair to poor health, with multiple comorbidities, and without coverage were most at risk.

Enhanced drug coverage for elderly persons may encourage the use of beneficial treatments. Among two groups of Medicare patients with heart disease, statins use ranged from 4.1% in those without coverage to 27% in those with employer-sponsored drug coverage ( $p < .001$ ). Significant differences were also seen for use of relatively inexpensive beta-blocker therapy (20.7% vs. 36.1%;  $p = .003$ ) and nitrates (20.4% vs. 38%;  $p = .005$ ). This study suggests that older adults without drug coverage are less likely to be dispensed inexpensive life-saving drug therapy relative to those with drug coverage. Whether this difference is caused by the differences in drug coverage or to differences in characteristics of persons with and without such coverage is not clear.

### Limited Manufacturing of Low-Dose Formulations of Recommended Drug Therapy

Limited manufacturing of low-dose formulations of drug therapy may make it more difficult for patients to take their prescribed drug therapy. Low-dose therapy is often recommended for older adults. For example, there is considerable evidence supporting the efficacy and greater safety of low doses of thiazide diuretic therapy in the treatment of hypertension in the older patient population. The Joint National Committee on Detection, Evaluation and Treatment of High Blood Pressure Guidelines (JNC VII) suggest starting antihypertensive therapy at low doses in all patients. Specifically, these guidelines suggest that therapy be initiated with a 12.5 mg dose of

**TABLE 24-4**

### Five Steps of Medication Reconciliation

- (1) Develop a list of current medications.
- (2) Develop a list of medications to be prescribed.
- (3) Compare the medications on the two lists.
- (4) Make a clinical decision based on the comparison.
- (5) Communicate the new list to the patient and appropriate caregivers.

*Adapted from JCAHO Web site. <http://www.jointcommission.org/SentinelEvents/SentinelEventAlert/sea.35.htm>.*

a thiazide diuretic. Low doses of thiazide diuretics (e.g., 12.5 mg of hydrochlorothiazide) often produce as large an antihypertensive effect as larger doses, with a reduced risk of metabolic abnormalities. In fact, there is evidence that a dose of hydrochlorothiazide as low as 6.25 mg can be as efficacious in treating hypertension in many older patients, when combined with a low dose of another antihypertensive medication.

### Medication Reconciliation

In the United States, the Joint Commission on Accreditation of Healthcare Organizations recently required accredited facilities to implement a system of medication reconciliation to reduce medication errors at transitions of care. Medication reconciliation is the process of comparing a patient's medication prescriptions to all the medications that the patient has been taking (Table 24-4). Patients, and responsible physicians, nurses, and pharmacists should be involved in the medication reconciliation process. This reconciliation is done to avoid medication errors such as omissions, duplications, dosing errors, or drug interactions. Changes in medication (different dose, discontinued therapies, additional therapies), common during transitions between hospital and nursing home or institutional setting and home, are a common source of medication errors and confusions. ADEs attributed to medication changes occurred in 20% of patients on transfer from hospital to a nursing home, occurring most commonly for patients being readmitted to the nursing home. One study found that discharged patients understood the potential side effects of their medications less frequently than their attending physicians believed. One Canadian multisite study found that 25% of 325 older adults experienced an ADE after discharge home from the hospital; half of these events were considered preventable. Medication reconciliation systems and processes have successfully reduced medication errors in many health care organizations. Pharmacy technicians at one hospital reduced potential ADEs by 80% within 3 months by obtaining medication histories of patients scheduled for surgery.

## PRACTICAL APPROACH TO PRESCRIBING MEDICATIONS TO OLDER PERSONS

### Review Current Drug Therapies

A periodic evaluation of the drug regimen that a patient is taking is an essential component of the medical care of an older person. Such a review may indicate the need for changes to prescribed drug therapy. These changes may include discontinuation of a therapy prescribed for an indication that no longer exists, substitution of a

**TABLE 24-5****Practical Steps to Consider in Optimizing Drug Regimens for Older Adults**

Review current drug therapy
Discontinue unnecessary therapy
Consider adverse drug events as a potential cause for any new symptom
Consider nonpharmacologic approaches
Substitute with safer alternatives
Reduce the dose

*Modified from Rochon PA, Gurwitz JH. Drug therapy. Lancet. 1995;346:32.*

required therapy with a potentially safer agent, reduction in dosage of a drug that the patient still needs to take, or an increase in dose or even addition of a new medication (Table 24-5). Randomized controlled trials examining the effect of medication reviews report mixed results. All studies reported that medication review leads to recommendations for different types of changes, including elimination of drugs, increasing the number of drugs, therapeutic substitutions, or better dosing. However, few reported statistically significant changes in patient drug use and drug expenditures. Studies that involved direct contact between the consulting pharmacist and the patient appeared to be more effective than interventions aimed at recommending drug changes to the patient's physician. One intervention study found that patients were resistant to reducing medications to recommended levels, particularly psychoactive drugs. To conduct a medication review, the physician should ask the patient to bring to the visit all the bottles of pills that they are using. For example, patients may not consider over-the-counter products, ointments, vitamins, ophthalmic preparations, or herbal medicines to be drug therapies. Patients need to be specifically told to bring these therapies to the visit. In addition, patients should be instructed to keep a complete, accurate, and up-to-date medication list including over-the-counter medications and herbal preparations. This list should be brought to every physician visit. A patient-generated list is particularly important as patients are prescribed medications from several physicians and receive their medications from several pharmacies. Although there are an increasing number of effective medications for preventing or controlling a range of illnesses and for alleviating many symptoms, several studies show that adherence decreases, and adverse medication effects increase, with the complexity of the medication regimen. The goal should thus be the simplest regimen that controls the patient's symptoms and illnesses, and optimizes disease prevention. A medication grid, which displays each medication with dosage and frequency, has been found effective at facilitating the reduction in medication complexity.

### Discontinue Potentially Unnecessary Therapy

Physicians are often reluctant to stop medications, especially if they did not initiate the treatment and the patient seems to be tolerating the therapy. Sometimes, however, this exposes the patient only to the risks for an adverse event with limited or no therapeutic benefit. The use of chronic digoxin therapy among older adults with normal systolic function is one such example. Use of digoxin therapy by older adults is not without risk. Renal impairment that progresses over time or dehydration associated with a gastrointestinal or respiratory illness, or urinary tract infection, may predispose older adults to

digoxin toxicity. Often digoxin therapy has been prescribed for years for reasons that were not well documented. In a small study of 23 nursing home residents with normal sinus rhythm, normal ejection fraction, and no clinical evidence of heart failure, digoxin was discontinued in 14 residents. One patient developed a decreased ejection fraction (from 60% to 50%) and digoxin therapy was restarted even though the patient remained clinically asymptomatic. At 2 months following the discontinuation of digoxin therapy, all patients with digoxin therapy discontinued remained clinically stable. These findings suggest that digoxin can be safely discontinued in selected nursing home residents. Other investigators, however, have found that discontinuation of digoxin therapy in patients with impaired systolic function can have a detrimental effect.

Physicians should carefully consider whether the development of a new medical condition could be linked to an existing drug therapy before adding a new drug therapy to the patient's drug regimen. For example, tricyclic antidepressants such as amitriptyline are used for a variety of indications in elderly patients, from depression to the relief of chronic pain. The tricyclic antidepressants tend to have especially strong anticholinergic properties with the potential for side effects including constipation. A patient started on a strongly anticholinergic antidepressant may develop constipation. As a result, laxative therapy may be prescribed. A better alternative may be to discontinue the anticholinergic therapy.

### Consider Nonpharmacologic Approaches

Physicians should limit prescribing of a new drug therapy to situations in which benefits clearly outweigh risks and to use drug therapy only after potentially safer alternatives have been attempted. For example, NSAIDs may be extremely useful in treating patients with rheumatoid arthritis. However, the use of this medication to manage pain in older adults with osteoarthritis may be inappropriate because safer options are available. Epidemiologic and clinical studies have characterized the adverse consequences of NSAID use in older persons, particularly the association between NSAID use and gastrointestinal bleeds and renal impairment. Thus, alternative approaches should be considered before NSAIDs are prescribed for indications such as osteoarthritis. Possible nonpharmacologic approaches, such as gentle exercise and weight reduction, may be beneficial alternatives to treatment with NSAIDs. When pharmacologic therapy is required, a drug therapy with a less-adverse event profile, such as acetaminophen, should be used.

Hypertension is another example of a condition for which nonpharmacologic treatments may be beneficial. Drug therapy is beneficial in reducing the risk of stroke and coronary heart disease associated with hypertension in older adults. However, use of drug therapy is associated with the potential for drug-related adverse events and can be costly, particularly when the therapy is required long-term. Nonpharmacologic approaches are an attractive option. The benefit of dietary sodium reduction and weight loss in the treatment of hypertension was recently examined. Three months following the intervention, a withdrawal of hypertension therapy was attempted and patients were followed for the combined outcome measure (i.e., occurrence of high blood pressure, treatment with an antihypertensive medication, or the occurrence of a cardiovascular event). Among 585 obese older adults, participants assigned to reduced sodium intake, weight loss alone, or to a reduced sodium intake and weight loss intervention were significantly more likely to remain free of an

outcome relative to those participants assigned to usual care without a lifestyle intervention. This trial indicates restricting sodium intake and weight reduction are beneficial nonpharmacologic therapies for hypertension management in older adults.

Often when drug therapy is deemed necessary for the patient, a safer alternative to the current regimen is available. For example, if a patient is taking a long elimination half-life benzodiazepine such as diazepam and continued therapy is required, a shorter half-life agent may reduce risks associated with drug accumulation with repeated dosing especially in the context of age-related pharmacokinetic changes. Longer half-life agents are more likely to produce central nervous system adverse events such as daytime somnolence, confusion, and impaired motor coordination. The evidence remains inconclusive as to whether long-acting benzodiazepines are associated with an increased risk of hip fractures relative to shorter-acting preparations. Another study suggests that the benzodiazepine dose is a more important risk factor for hip fracture than the elimination half-life. Given this information, a prudent approach would be to avoid using both long elimination half-life and high doses of benzodiazepine therapy in older adults.

## Reduce the Dose

Many ADEs are dose-related. A classic example of dose-related adverse events is the association between use of long elimination half-life hypnotic-anxiolytics, antipsychotics, and tricyclic antidepressants and the development of hip fracture. A dose-related association has been found for each class of drug. Many studies have illustrated dose-related ADEs. When prescribing drug therapies, it is important to use the minimal dose required to obtain clinical benefit.

## SUMMARY

Optimizing drug therapy means achieving the balance between overprescribing of inappropriate therapy and underprescribing of beneficial therapy. Particular attention should be given to using all drug therapies only when required and at the minimum effective dose. Beneficial therapy should be prescribed when indicated. Financial pressures need to be recognized and strategies developed to make sure that older adults have access to drug therapies when needed. ADEs are common and system-level approaches need to be developed to minimize their impact.

# Complementary and Alternative Medicine

*Joseph T. Hanlon ■ Marc R. Blackman ■ Ronald M. Glick*

## INTRODUCTION

Complementary and alternative medicine (CAM) modalities constitute a diverse group of consumer-driven medical and health care practices outside the realm of conventional medicine, which are yet to be validated using scientific methods. Considered as such, CAM practices are ever changing. Most CAM use is complementary, that is, as an adjunct to conventional practices, and only a minority is used as an alternative to mainstream medical care. A main tenet of CAM therapy is that it stimulates and strengthens the body's own natural defense systems to prevent and treat diseases. Thus, elderly as well as nonelderly individuals use CAM practices with the hope of improving wellness and for relief of symptoms attributable to chronic, "stressful," degenerative, or fatal conditions.

From a conceptual perspective, the panoply of CAM modalities can be divided into five major groupings: alternative medical systems, mind–body interventions, manipulative and body-based methods, energy therapies, and biologically based treatments (including dietary supplements) (Table 25-1). A dietary supplement is defined as: (1) a product that contains one or more of the following ingredients: vitamin, mineral, herb, botanical, amino acid, or a substance to increase total daily intake; (2) ingested orally; (3) not a conventional food or sold as a meal or diet, and (4) labeled as a dietary supplement (Food and Drug Administration (FDA) Web site).

In the United States, CAM practices are widely available (Table 25-2), but are largely unregulated. Among CAM practices, only five (acupuncture, chiropractic, massage, naturopathy, and homeopathy) are licensed in multiple states, whereas several others (art therapy, traditional Chinese medicine, reflexology) are licensed in only a few states, and still others (biofeedback, hypnosis) require only certification. Moreover, the scope of practice may vary from state to state (e.g., acupuncture). The American public spends more out-of-pocket for CAM practices than for all other health care needs. Most consumers believe that their health plans should pay for CAM

treatments, and an increasing number of insurers and Health Maintenance Organizations are now doing so.

The reasons for CAM use are multiple, but include dissatisfaction with conventional medicine because of its ineffectiveness in producing cures, cost, adverse effects, and depersonalization. CAM use also empowers the individual to take control over personal health decisions, and focuses on the individual's values, spiritual and religious philosophy, and beliefs regarding the nature and origins of illness. The fragmentation of care by busy specialists, and provision by CAM therapists of "touch, talk, and time," as well as media reports of dramatic results, all contribute to the increasing interest in CAM therapies.

## CURRENT USE AND CONCERNS WITH CAM MODALITIES

In recent years, the use of CAM has steadily increased among adults of all ages. In the largest U.S. study to date, nearly 29% of 30 801 respondents to a 1999 National Health Interview Survey reported using at least one CAM modality in the prior year (Barnes, et al., 2004). This prevalence of CAM usage is somewhat less than that reported in other surveys. According to Eisenberg's (1998) follow-up of his earlier national survey, the probability of an adult American visiting a CAM provider increased by 30% during the 1990s, to 46.3% in 1997, accounting for approximately \$27 billion in out-of-pocket expenses. It was estimated that nearly 60% of CAM use was not disclosed to health care providers. Alternative therapies were most frequently pursued for chronic conditions including back problems, anxiety, depression, and headaches. The therapies of escalating usage included botanicals, massage, vitamins, self-help group, folk remedies, energy healing, and homeopathy.

The use of dietary supplements in older adults is substantial. The Slone Survey reported that 40% of U.S. older adults take at least

**TABLE 25-1****CAM Domains**

Alternative medical systems	Complete systems that evolved independent of and often prior to conventional medicine, e.g., traditional systems <ul style="list-style-type: none"> <li>• Traditional Chinese medicine</li> <li>• Ayurveda</li> <li>• Native American medicine</li> <li>• Homeopathy</li> <li>• Naturopathy</li> </ul>
Mind–body interventions	Application of techniques designed to facilitate the mind’s ability to affect one’s body symptoms and functions. <ul style="list-style-type: none"> <li>• Meditation or guided imagery</li> <li>• Dance, music, and art therapy</li> <li>• Prayer</li> <li>• Biofeedback</li> </ul>
Biologically based treatments	Natural and biologically based practices, interventions, and products <ul style="list-style-type: none"> <li>• Herbal therapies</li> <li>• Dietary supplements</li> <li>• Special diets</li> <li>• Orthomolecular therapies</li> </ul>
Manipulative and body-based methods	Modalities based upon manipulation and/or movement of the body <ul style="list-style-type: none"> <li>• Chiropractic</li> <li>• Osteopathic manipulation</li> <li>• Therapeutic massage</li> </ul>
Energy therapies	Focus on energy fields believed to originate within the body or from other sources <ul style="list-style-type: none"> <li>• Biofields (internal), e.g., reiki, qi gong, therapeutic touch</li> <li>• Bioelectromagnetic based (external), e.g., electroacupuncture, magnetic fields</li> </ul>

one vitamin/mineral and one in seven older adults take at least one herbal supplement (Kaufman, et al., 2002). A study using data from the 2002 National Health Interview reported that 12.9% of the elderly reported the use of a herbal product in previous 12 months (Bruno, et al., 2005). The most common products used included glucosamine/chondroitin, saw palmetto, ginkgo, and St. John’s Wort.

The use of dietary supplements is of concern because the manufacturers are not responsible for proving efficacy or safety for these products before marketing (Anon, 2002). The FDA has however recommended that manufacturers stop selling several products due to concerns about toxicity (e.g., kava, ephedrine). They have also cautioned about drug interactions with St. John’s Wort, a potent

**TABLE 25-2****CAM Practitioners and Their Utilization**

- *Chiropractic*: 55 000 licensed, \$8 billion estimated market for services
- *Massage*: 1 million, 150 000–200 000 certified. \$6 billion market.
- *Acupuncture*: 5000–8000 licensed (1000 MD’s) \$0.5–1 billion
- *Homeopathy* – 3000 (500 MDs), \$0.2 billion
- *Naturopathy* – 1000–3000 licensed; \$0.2 billion.

**TABLE 25-3****Potentially Clinically Significant Herbal–Drug Interactions**

OBJECT DRUG	INTERACTING HERB	OUTCOME
Antidepressants	St. John’s Wort	Serotonergic syndrome
Anticonvulsants	Shankpushpi	↓ Seizure threshold
Anticonvulsants	Wormwood	↓ Seizure threshold
Anticonvulsants	Ginkgo biloba	↓ Seizure threshold
Cyclosporine	St John’s Wort	Transplant rejection
Digoxin	Hawthorn	↑ Digoxin activity
Digoxin	Siberian ginseng	↑ Digoxin levels
Digoxin	St John’s Wort	↓ Digoxin levels
Indinavir	St John’s Wort	↓ Indinavir levels
Theophylline	St John’s Wort	↓ Theophylline levels
Warfarin	Ginkgo biloba	↑ Risk of bleeding
Warfarin	Dong quai	↑ Risk of bleeding
Warfarin	St. John’s Wort	↓ Warfarin activity
Warfarin	Ginseng	↓ Warfarin activity

inducer of certain hepatic cytochrome P450 isoenzymes (Xie and Kim, 2005). [Table 25-3](#) lists clinically important drug interaction with St John’s Wort and other dietary supplements with prescription medications (especially narrow therapeutic range drugs) and their impact on patient outcomes (Xie and Kim, 2005; Holbrook, et al., 2005; Williamson, 2003; Tyagi, et al., 2003).

Recently, new FDA regulations have been passed regarding dietary supplements. As of December 2007, manufacturers will now be required to report serious adverse events to the FDA (Morrow, 2008). Moreover, starting June 2008, a new FDA rule will be implemented entitled “Current Good Manufacturing Practice in Manufacturing, Packaging, Labeling, or Holding Operations for Dietary Supplements.” Essentially what this rule does is assure that what is on the label of a dietary supplement is what is contained in the product itself (Morrow, 2008).

## USE OF CAM MODALITIES FOR DISORDERS OF THE ELDERLY PATIENT

While CAM modalities may be used for a number of conditions experienced by the elderly, evidence-based data supporting their use is limited. We describe in the following sections what is known for six common conditions, depression, anxiety, insomnia, osteoarthritis, dementia, and benign prostatic hypertrophy.

### Depression, Anxiety Disorders, and Insomnia

Of the domains of CAM listed on [Table 25-1](#), the modalities most commonly used for mental health conditions fall under the headings of biologically based treatments and mind–body interventions. Of the herbal agents and supplements, St. John’s Wort or Hypericum is in (wide) use by the general population. Studies have shown only modest efficacy over placebo for mild–moderate depression and favorable side effect profile as compared to standard antidepressants [Table 25-2](#) (Schulz, 2006). As mentioned previously, St. John’s Wort

can interact with numerous prescription medications. Consequently, this herbal product is best reserved for patients who are otherwise healthy with few other prescription medications.

A common measure that has made it into the lay media is the importance of the dietary balance between omega-6 and omega-3 fatty acids with the former being proinflammatory and seen as contributing to many health conditions including depression. Consequently, there has been a push to modify our diets with a reduction in red meats, fried foods, and trans-fats, all of which contribute to the omega-6 side of the equation. On the omega-3 side consumption of fish, using olive or canola oil for cooking, and eating nuts—particularly walnuts in moderation are seen as beneficial. There is a moderate level of evidence supporting a connection between this balance and depression, including the observation that dietary intake and blood concentrations of omega-6 over omega-3 correlates with the incidence of depression (Kiecolt-Glaser, et al., 2007). While the circumstantial evidence is strong, the clinical trial data is inconclusive (Severus, 2006). Nonetheless, the addition of a fish oil supplement is a reasonable measure as an adjunct in the treatment of depression or bipolar disorder. Pharmaceutical grade fish oil supplements concentrate the two essential fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) while removing contaminants, particularly mercury. One thousand milligrams appears to be a safe dose at which there does not appear to be a significant concern of drug–drug interaction or platelet inhibition in most individuals.

Other supplements have been used or studied for depression. S-adenosylmethionine (SAM-e) has good support of efficacy (Mischoulon & Fava, 2002). However, given the dosage requirement of 800 to 1600 mg/day to see the effect, the cost is roughly 5 to 10 times higher than a generic selective serotonin reuptake inhibitor antidepressant (SSRI). This limits the potential utility of this agent, although it should be considered when patients do not tolerate an SSRI. Another agent, 5-hydroxytryptophan (5-HTP), is a direct serotonin precursor and has the potential to serve as a weak antidepressant itself or to augment the classical antidepressants (Turner, 2006). In clinical practice, this dietary supplement appears to have the advantage of fewer of the classical serotonin side effects (e.g., nausea, sexual dysfunction). One option is to use this well-tolerated agent as an adjunct (e.g., if someone continues with moderate anxiety symptoms or insomnia while being treated with an antidepressant). When using serotonergic medications in combination, it is prudent to advise patients as to the potential for serotonin syndrome, with physical or psychological symptoms of hyperarousal as well as cardiac symptoms such as tachycardia or palpitations.

Valerian root may work by being a benzodiazepine receptor agonist. Its use may have benefit for anxiety and insomnia but studies have not shown a consistent benefit over placebo (Taibi, et al., 2007). The most common patient complaint is of the bitter taste or after-taste and mild dyspepsia. Melatonin appears to be a logical treatment for geriatric insomnia. Paralleling the drop-off in sleep efficiency and hours of sleep with age is the decline in production of melatonin by the pineal gland. Trials of melatonin, with a half-life ( $t_{1/2}$ ) of just under 1 hour, find benefit for falling asleep. However, as a majority of insomnia patients have difficulty remaining asleep, the overall benefit on sleep patterns has been disappointing. In one study of insomnia in older adults 2 mg of a sustained-release form of melatonin was found to be of significant benefit to sleep (Wade, et al.,

2007). Sustained-release melatonin can be ordered from several nutritional supplement companies and 3 to 6 mg taken 1 to 2 hours before bed can be tried.

Mind–body approaches have been used extensively for mental health disorders as well as for chronic pain and other general health conditions that may have a stress-related component. Depression, anxiety, and insomnia are associated with a sympathetic nervous system predominant pattern. Mind–body approaches have been shown to result in a shift of autonomic reactivity to a more parasympathetic pattern. In geriatric medicine, in addition to the direct effects of these primary psychological conditions on quality of life, we are greatly concerned about the potential impact on general health, morbidity, and mortality. Some potentially helpful mind–body approaches are: yoga, meditation, rhythmic breathing, and biofeedback. These are not recommended in lieu of traditional therapies. Rather, as an adjunct, they can be of benefit for enhancing mood, decreasing anxiety, and improving sleep. In addition to benefit for mood, they may help with comorbid medical conditions such as hypertension or coronary heart disease. Mindfulness-Based Stress Reduction (MBSR) is a meditation-focused program that was developed by Dr. Jon Kabat-Zinn of the University of Massachusetts in the late 1970s. MBSR's central concept is the development of mindfulness, or present moment nonjudgmental awareness (Grossman et al., 2004). The program includes formal meditation practices such as body scan, sitting and walking meditation, and mindful movement (simple yoga) as well as mindfulness practices for coping with everyday life stressors. This 8-week program is currently taught worldwide. Mindfulness-Based Cognitive Therapy, a variant of MBSR, combines meditation practice with a cognitive-behavioral approach for individuals with recurrent depression in remission to help prevent future recurrences (Smith, et al., 2007).

There is moderate support in the traditional Chinese medicine (TCM) literature for the use of acupuncture in the treatment of insomnia, but this remains to be examined in a carefully designed randomized-controlled trial (RCT) (Kalavapalli & Singareddy, 2007). One commonality to seemingly different treatments, acupuncture and massage therapy, both have an impact on autonomic stress reactivity and result in a shift from sympathetic to parasympathetic predominance. This may explain the potential benefit of these modalities for anxiety symptoms, insomnia, and other hyperarousal states.

Several therapeutic modalities or practices fall outside of the realm of CAM but are included here because they are often omitted from the discussion. With greater recognition of the presence of seasonal affective disorder, the use of bright light therapy has come into common psychiatric practice and many insurance companies will cover the cost of the light boxes. Similarly, while we have always known that exercise is health-promoting, there is greater recognition of the mood-enhancing effect of aerobic exercise such as walking half-hour per day at a brisk pace (Motl, et al., 2005). Obviously for individuals whose mobility is limited, it can be helpful to find some other means of exercise, such as a pool aerobic class, arm ergometry, or seated exercise classes. Social isolation is seen as a major risk factor for cardiovascular and all-cause mortality as well as for depression and it goes without saying that isolation is a major concern for older adults. It may be that social interventions can have the greatest impact for many of our patients (Greaves & Farbus, 2006). Such interventions include CAM programs such as yoga or Tai Chi classes, but can

also involve adult education, exercise—such as with Silver Sneakers programs or regular religious observance.

### Osteoarthritis, Degenerative Disk Disease, and Chronic Pain

Glucosamine and chondroitin sulfate have been used extensively to treat knee osteoarthritis (OA) pain with a moderate level of literature support. An elegant multicenter study with over 1500 subjects examined the effects of glucosamine and chondroitin individually and in combination as compared with celecoxib versus a placebo finding no advantage of the supplements over placebo (Clegg, et al., 2006). Compared to placebo, glucosamine and chondroitin sulfate were not significantly better in reducing knee pain. Concerns about the study include the placebo response rate as high as 60% and the use of glucosamine hydrochloride, given that all prior positive studies were of glucosamine sulfate. This leaves us without clear guidance from the literature, but if patients elect to try these agents it is advised to use glucosamine sulfate at 1500 mg and chondroitin sulfate at 1200 mg/day both divided into twice or thrice daily dosing, depending on the preparation. Additionally, patients should be advised to stick with the supplements for at least 3 months to see an effect.

SAM-e may be the unsung hero in the management of OA. In RCTs, SAM-e has demonstrated a comparable level of improvement in pain and functioning as nonsteroidal anti-inflammatory drug (NSAIDs), also showing a better side-effect profile with doses ranging from 400 to 1200 mg/day (Soeken, et al., 2002). As noted above, it also has the potential benefit of enhancing mood, which can be affected by OA pain.

While OA has classically been considered a noninflammatory disorder, mounting evidence supports the importance of inflammation in its pathogenesis. Elsewhere in the literature anti-inflammatory effects have been seen with omega-3 fatty acids and fish oil. While fish oil has shown a benefit for lupus and rheumatoid arthritis, the research on OA and degenerative disk disease (DDD) is very preliminary (Maroon & Bost, 2006). Nonetheless, fish oil supplementation may be a reasonable adjunct in the management of OA for several reasons: it is generally safe and well-tolerated; it offers the potential for a direct benefit for OA-related pain; it may result in a reduction of NSAID use, with concomitant decrease in adverse effects; and it has the potential to decrease comorbidities of chronic pain including cardiac disease and depression. Dosing recommendations are as noted above, using 1 gram combination of EPA and DHA of a concentrated pharmaceutical-grade fish oil supplement.

For years, we have been puzzled by the disparity between the apparent benefit of acupuncture for many chronic pain conditions noted in practice and in open trials versus the observation that RCTs did not support a significant difference over placebo. Many factors go into this discussion including the possibility that superficial needling commonly used as a control condition may have a physiological analgesic effect. Several recent well-designed RCTs have shown a significant benefit of acupuncture over control needling for knee osteoarthritis and stronger evidence is emerging supporting efficacy in low back pain and other chronic pain conditions (Berman, et al., 2004; Manheimer, et al., 2005; Witt, et al., 2005). Future studies are needed to confirm these findings, highlight specific acupuncture protocols that can be readily reproduced in clinical practice, and address the issue of durability of the treatment on pain and func-

tioning. While acupuncture is not likely to take the place of surgery, for patients electing a nonsurgical option, this treatment has the potential to decrease pain, increase functioning, and allow patients to limit NSAID and opioid medications.

Among older adults, pain is the most commonly cited reason for seeking CAM treatments and chiropractic is the most commonly used modality (Foster, et al., 2000). There is moderate support of the use of chiropractic manipulation for the treatment of low back pain with benefit for pain, functioning, and medical and indirect costs, although effects appear to be comparable to other interventions such as physical therapy and massage (Hurwitz, et al., 2006). Theoretically by alleviating nerve root pressure with manipulation, this modality could be beneficial for the radicular pain associated with cervical and lumbar spinal stenosis and this improvement is described widely in clinical practice. Unfortunately, chiropractic research is limited in the treatment of spinal stenosis or treatment of older adults in general. To their credit, many chiropractors have extended their practice from the passive manipulative treatment to include more active rehabilitation measures which can potentially help patients to recondition and maintain the enhanced range-of-motion.

Although the most visible changes for our patients with OA and DDD can be seen radiologically, it is quite common to have prominent secondary myofascial pain. Treatments directed at this component, including massage therapy and physical therapy involving stretching of the tight muscles, can result in a dramatic improvement. In addition to or in lieu of formal physical therapy, yoga classes can provide an interesting social setting in which participants experience a number of benefits including total body stretching, core stabilization, a mild aerobic workout, and relaxation response associated with the exercise and breathing techniques. It is important that the class be geared for older adults or that the instructor be knowledgeable in modifying activities for individuals with OA. Although Tai Chi is commonly discussed in the setting of prevention of falls, this approach can also provide similar benefits including core stabilization, stretching, aerobic activity, and relaxation.

As noted above, some of the benefit of yoga and Tai Chi relate to a mind–body effect. Meditation programs, specifically MBSR, have the potential to greatly help our patients experiencing chronic pain (Morone, et al., 2008). Pain has both sensory and affective components. Through mindfulness training and meditation practice, patients describe two significant changes. The mindful awareness can allow them to attend to the sensory component of the pain without this automatically eliciting a reactive affective response. Additionally, with this uncoupling of sensory and affective components, they describe that the common pain–stress cycle seems to be circumvented. Consequently, many describe greatly reduced pain intensity and associated distress, as well as improved function.

### Dementia

The two most common types of dementia in the elderly are vascular and Alzheimer's disease. Ginkgo biloba extract, EGb 761, is widely used to increase memory and cognitive ability. There is a lack of convincing evidence that ginkgo may be beneficial for enhancing cognitive function for patients with both vascular and Alzheimer's dementia (Birks et al., 2007). Adverse effects of ginkgo biloba are generally mild. The NIH is currently sponsoring a large, multicenter study to examine the efficacy and safety of EGb 761 in the treatment of dementia caused by Alzheimer's disease.

## Benign Prostatic Hyperplasia

Symptomatic benign prostatic hyperplasia (BPH) affects more than 40% of men older than 70 years of age. During the past several years, men have increasingly begun to self-treat this condition with the herbal compound *Serenoa repens*, known as saw palmetto. A recent meta-analysis that included patients with moderate benign prostatic hypertrophy who averaged 65 years of age and were studied for at least 3 months (Wilt, et al., 1998). Saw palmetto was found to be superior to placebo and to exhibit similar efficacy to the standard pharmacologic treatment. Few side effects were reported other than intermittent slight abdominal distress. However, the rigor of the experimental design of these trials has been questioned. Recently, a large, multicenter, NIH-sponsored clinical trial to assess the effect of saw palmetto extract in men with moderate to severe BPH was published (Bent, et al., 2006). They found that saw palmetto was not effective in treating BPH.

## CONCLUSION

The escalating use of CAM modalities by the U.S. public, including the elderly population, and the paucity of information supporting the safety, efficacy, and mechanisms of action of these diverse modalities, argue strongly for increasing the scope and rigor of CAM-related research. To address important public health needs in the elderly population, including those who are underserved, it would seem prudent to investigate the basic biology and potential clinical utility of selected CAM modalities that may allay or attenuate a variety of a life “stressors,” including depression, cognitive decline, chronic pain, musculoskeletal frailty, and sleep disorders. Of particular note is that the aforementioned conditions are disproportionately more problematic in older persons than in younger persons, often coexist in the same individual, and account for substantial use of one or more CAM modalities. Moreover, from a pathophysiologic perspective, each of these age-related stressors exhibits derangements in the interrelationships among endocrinologic, neurologic, and immunologic functions. Thus further research efforts might profitably be directed towards unraveling the interactions among these three important physiologic systems, particularly as they affect aged individuals.

Identifying an appropriate agenda for future CAM studies in the elderly population poses significant challenges. To select among the myriad CAM modalities that are currently being used by consumers, several considerations appear warranted, including the extent of use by aged persons; the public health importance of the diseases or conditions being treated; the quality and quantity of reported data, which allows for determination of whether to emphasize preclinical versus clinical studies; and the feasibility and cost of conducting the research. Integrating allopathic and CAM approaches in the design of the next generation of CAM studies represents another exciting yet daunting opportunity to advance the discipline of CAM in the twenty-first century.

# Team Care

*Ellen Flaherty* ■ *Kathryn Hyer* ■ *Terry Fulmer*

Geriatric interdisciplinary team care has been shown to be essential to manage the complex syndromes experienced by frail older adults. Providing comprehensive care to geriatric patients with multiple illnesses, disabilities, increased social problems, and fragmented care requires skills that no one individual possesses. Older adults are, therefore, best cared for by a team of health professionals. Outcomes associated with effective geriatric interdisciplinary team care include the improvement of functional status, perceived well-being, mental status, and depression. Geriatric interdisciplinary team care has also been shown to be cost effective by reducing patient readmission rates and numbers of physician office visits. Specialized interdisciplinary teams focusing on specific diseases such as congestive heart failure, stroke, or myocardial infarction have also demonstrated improved patient outcomes. The purpose of this chapter is to outline the benefits of interdisciplinary geriatric team care. The current and projected health care workforce shortage, coupled with the aging of the population dictate that care models be as efficient and effective as possible. Managing the complex syndromes experienced by frail older adults requires skills beyond the training of one discipline and multiple clinicians to communicate with each other regularly in order to coordinate services. These needs have resulted in the growth of geriatric interdisciplinary teams.

In 1993, the Pew Health Professions Commission predicted that health professionals would need 17 competencies to practice health care in 2005. Anticipating a shift toward population-based medicine, increasing use of technology, and managed care, the competencies included an emphasis on primary care, participation in coordinated care, involvement of patients and families in decision making, and ensuring cost effectiveness. While regulators and policy makers, almost a decade later, seem less enthralled with managed care, the forces driving managed care—increasing costs, concerns about cost effectiveness, and a focus on prevention—have not slowed.

The Joint Commission on Accreditation of Healthcare Organizations stated that shared decision making and an interdisciplinary health care team approach are essential to reduce medical errors and

to provide improved patient safety in all health care organizations in America. The Institute of Medicine of the National Academies made a similar plea in the *Quality Chasm* report, strongly urging that all health professionals receive interdisciplinary team training to ensure the delivery of patient-centered care. More recently, additional reports from the Institute of Medicine of the National Academies specifically point to the need for interdisciplinary care for geriatric patients.

In 1995, The American Geriatrics Society developed a position statement on interdisciplinary care for older adults, which supports the interdisciplinary care model for the following reasons:

1. Interdisciplinary care meets the complex needs of older adults with multiple, interacting comorbidities.
2. Interdisciplinary care improves health care processes and outcomes for geriatric syndromes.
3. Interdisciplinary care benefits the health care system as well as caregivers of older adults.
4. Interdisciplinary training and education effectively prepares providers to care for older adults.

Studies of the clinical effectiveness and cost effectiveness of teams generally demonstrate that patients are helped by an initial comprehensive geriatric assessment conducted by multiple disciplines. Team management and internal performance also seem to matter. In a study of the 26 Program of All-Inclusive Care for the Elderly (PACE) sites, teams that ranked themselves as performing better had patients with better 3- and 12-month outcomes in Activities of Daily Living (ADL) performance and better urinary incontinence rates. It appears that coordination of services, ability of team members to communicate well, and agreement from the multiple providers over how to implement complex care improve patient outcomes in both the short and the long terms. While there was no difference in mortality owing to team performance, changes in patient outcome were risk adjusted. Teams require management skills, leadership, and

well-honed communication skills. Coordinating care, leading group discussions, and managing conflict are the key team skills that are discussed below.

Studies focusing on patient satisfaction have demonstrated that the presence of a team champion and the involvement of the physicians on the team are positively associated with greater perceived team effectiveness. Maintaining a balance among culture values of participation, achievement, openness to innovation, and adherence to rules and accountability also appeared to be important.

## COLLABORATION AND THE IMPORTANCE OF "INTERDISCIPLINARITY"

Collaboration implies a process of shared planning, decision making, accountability, and responsibility in the care of the patient. In collaborative practice, providers work together. They demonstrate effective communication, trust, mutual respect, and understanding of others' skills. While skills and services may overlap, most skills and services are complementary and reinforce each other.

With advanced technology and the growth of community-based care, providers frequently provide home treatments or treatments in the nursing home that were previously delivered exclusively in the hospital setting. Monitoring older adults in these community settings requires good communication skills, because providers need to understand and correctly implement complex plans of care. It is crucial to recognize when to alert other providers of change in status. It is also important to learn what information other team members require to make decisions about treatment.

With the advent of managed care, there is an emphasis on efficiency and appropriate use of resources. Skills in coordinating care and being responsive to older adults increase in importance. Physicians, nurses, social workers, and other providers must recognize when referrals to other providers are necessary and know what outcome to expect. Understanding the skills of other health providers is increasingly important for all patients but is critical in the care of frail older adults.

Transitions from one health care setting to another are particular periods of risk for elders, and programs designed to smooth those transitions result in better patient outcomes. Patients have benefited from programs designed to improve the transition between hospital and home. A study in which nurse practitioners followed elders after hospital discharge for heart failure at home demonstrated the effectiveness of these clinicians in reducing rehospitalizations and improving the confidence and comfort of the caregiver at home.

For almost a decade, the John A. Hartford Foundation of New York City has supported an effort to incorporate team training into graduate medical, nursing, and social work education. The program, Geriatric interdisciplinary Team Training (GITT), has trained more than 1800 health care students and professionals across the country and developed training materials to encourage the development of effective geriatric teams. Two important principles were realized in the development of curriculum and programs. Effective teams require a structure and an understanding of group process, skills that can be taught and should continue to evolve during professional development. However, teams must focus on the outcome of the team process, the creation of an interdisciplinary care plan, or the management of the complex patient. While structure and process increase the efficiency of teams, assessing the team's effectiveness

must be based on the outcome of team meetings and the ability of the team to address and improve the patient's and the family's needs.

To be effective in managing the complex care of older adults, team knowledge and skills must emphasize multidimensional geriatric assessment, interdisciplinary team care planning, maximization of self-care and function, self-determination in the care plan, and improving quality of life. Future health professionals providing care to older individuals will be expected to apply knowledge and skill in practice. Clinical care managers will need to evaluate providers on patient satisfaction, cost effectiveness, productivity, and quality of care. Geriatric teams of the future will be expected to identify individuals at greatest risk of functional limitations and manage groups of older persons with similar problems in a cost-effective manner. In this context, the task for educators of future health professionals and practice-based managers becomes one of ensuring that providers are knowledgeable about the principles and practices of team care.

According to the American Congress on Rehabilitation Medicine, a team is capable of achieving with patients what individuals who constitute the team cannot achieve in isolation. Simply forming a team comprised of several disciplines does not, however, guarantee that the team will function well or that the outcome of the process will be the desired one. Effective teaming as an interdisciplinary group requires structure, the use of agendas, agreement upon ground rules and process, attention to issues of leadership, communication, and respect for one another's expertise.

## PRINCIPLES OF SUCCESSFUL TEAMWORK

To provide the important benefits of team care, team members must know their functions and how to interact to make the team effective. The essential elements of teamwork are coordination of services, shared responsibility, and communication. Effective teams must work across settings and have well-organized mechanisms to share information. Geriatric assessment is often shared among two or more providers who administer various tests and other components of the assessment. Because the focus of the team is on the older person, the team shares a common goal. Effective teaming requires rules to govern the team and team member behavior, plans to make meetings run efficiently, clarity about the skills and boundaries for the roles and responsibilities of each team member, team communication skills, and mechanisms for managing team conflict.

### Teams and Team Member Rules

Team rules, both for team governance and for member behavior, are needed in the early stages of team development. [Table 26-1](#) provides an overview of the eight principles of successful team work. Not having these rules is a primary cause of team problems later on and can slow or stop team development completely. Rules for team governance should include some or all of the following:

- Share a clear understanding by all members (and the larger organization within which it operates) about the overall purpose of the team and the goals for each meeting.
- Determine the composition of the team, including which disciplines are needed as members and the number of members (enough to get the job done; not so many that the work cannot

**TABLE 26-1****Eight Principles of Successful Team Work**

1. All team members share a common purpose and work together to establish explicitly stated patient care goals.
2. The patient and family are at the center of all team activities and are active team members.
3. The full scope of the professional capabilities of each team member is clearly understood by everyone on the team; professional roles are dynamic and are determined by the needs of the team, individual experience, and the knowledge and skills of team members.
4. All team members should contribute to team function through constructive individual behaviors, including rotating leadership.
5. There must be effective team communication across all work and care settings.
6. The team must have tools or strategies for the effective management of conflict.
7. The team should have explicit rules about participation and decision making.
8. The team must be adaptable, responding to new challenges and conditions as these develop over time.

get done). Allow the problem to define the composition of the team, not vice versa.

- Determine how often the team needs to meet and specify attendance requirements. (Is there a core team of physician, nurse, and social worker? Are other disciplines asked to participate on cases that require their expertise?)
- Identify time, place, and duration of team meetings.
- Determine a system by which cases are to be presented and by whom. Identify how care plans and action will be carried out and documented. (Is one member chosen to write down the care plan or does this responsibility rotate?)
- Identify opportunities or requirements for team building meetings and/or team training.
- Create mechanism for enforcing both governance and behavior rules through ongoing evaluation of the effectiveness of the meeting (if rules are made and not enforced, the team can quickly become ineffective and be a negative experience for everyone involved).

People are usually more willing to spend time and energy if there is a clear understanding of what is going to occur and why it is needed. The time spent with participants clarifying rules and getting a commitment for involvement will prevent team problems and support the development of an effective and efficient team.

While the above governance rules provide a structure for team interaction, behavior rules are also needed for each team. They can include some or all of the following:

- Ensure clear understanding by all team members of what an interdisciplinary team is and what members should bring to the group.
- Promote understanding and respect for others' expertise.
- Recognize the implications of idioms by the professionals involved. Learn how to articulate information clearly to others. (Do "client" and "patient" mean the same thing in different professional groups?) Health care goals will come from different perspectives and from different disciplines.

- Share information and expertise openly.
- Identify and follow a decision process when roles overlap. Resist setting rigid boundaries on roles. Instead, promote effective ways of sharing responsibilities and tasks.
- Define acceptable behavior (willingness to work with other professionals to develop a care plan, active participation, and respect for others' roles).

## THE WELL-PLANNED MEETING

Teams with poorly planned and organized meetings become ineffective and inefficient. This cultivates negative attitudes toward teams and leads to poor attendance and less than enthusiastic participation by the team members. Elements essential to the structure of an effective meeting include the following:

1. Agenda (what do we expect to accomplish?).
2. Estimated timeline for completing agenda (reasonable time frames).
3. Establishment of meeting roles. Members can and should rotate the following roles but every meeting should include
  - a. leader (calls meeting to order, has agenda, and sets expectations),
  - b. timekeeper (keeps group on task),
  - c. recorder (keeps track of agreements about the care plan and modifications and is responsible for recording changes to care plan).
4. Summary of agreements (recorder reports agreements).
5. Evaluation/reflection on team process (both team process and outcome of the meeting are discussed).

### Suggested Structure for Regular Health Care Team Meetings

Creating a structure and format for health care team meetings standardizes the meeting process and assists in making teams more efficient and effective. By using a standard agenda, health care team members are more prepared for meetings and the flow of the meeting is predictable. [Table 26-2](#) provides tips on how to facilitate a team meeting. Key elements are an agenda item, a timekeeper to encourage

**TABLE 26-2****How to Facilitate a Team Meeting**

1. Ensure that goals and objectives of the meeting are clear to all members.
2. Observe and value the participation of each member.
3. Acknowledge both verbal and nonverbal communication and address dysfunctional behaviors within the team.
4. Identify conflict, exploring thought processes that lead to differing conclusions.
5. Seek mutual understanding.
6. Assure shared decision making.
7. Suggest tools/techniques to enhance meeting flow, information gathering, decision making, and future planning.
8. Give constructive feedback.
9. Encourage team to evaluate its progress.

the group to stay on track, and a recorder who captures the group decisions and delineates the responsible person for specified tasks. Evaluating meetings is important and improves the quality of the structure and process, especially if evaluation is a routine part of the regularly scheduled meetings. The following format should work for most meetings:

1. Review meeting objectives to ensure that all members understand and are in agreement with the meeting objectives.
2. Review agenda and order of items. Add, reorder, or delete items as the group decides. Ensure that all team members agree with the agenda items.
3. Assign timekeeper, recorder, and leader roles. Confirm time intervals timekeeper will use to cue group.
4. Report follow-up from last meeting.
5. Discuss issues or patients as listed on the agenda.
6. Summarize action items from this meeting. Decide who will do what before the next meeting.
7. Decide what the objectives and agenda items will be for the next meeting.
8. Evaluate the meeting. Ask each member to evaluate the meeting. Evaluation can be written or verbal, but the questions should focus on: What did the team do well that it should continue doing? What could the team do differently to improve the meeting?

## SKILLS OF DIFFERENT PROFESSIONALS ON TEAMS

Team members from different disciplines bring a unique set of skills (Table 26-3), but those skills also overlap. Understanding the skills and education of various team members contributes to respect but also allows team members to refer elderly clients appropriately to other professionals. Because each profession trains its members in a culture that reflects a common language, professional behaviors, values, and beliefs, disagreement between professionals may occur because of different expectations and language. Most professionals recognize the training of others and learn what other professionals do only after being in professional practice. Although a range of individuals serve as members of an interdisciplinary team in geriatrics,

the core professional members are typically the physician, nurse, social worker, and pharmacist. The extended professional members of the team might include nonphysician providers (nurse practitioners and physician assistants), physical therapist, occupational therapist, speech pathologist, dietitian, and psychologist or psychiatrist. The older patient and the patient's family are also important members of the team.

Knowledge about the preparation, expertise, and scope of practice affects individual team member performance, in that it can

- reduce tension that occurs around who is doing what;
- help members accept role overlap as necessary and positive;
- foster positive views toward the efforts of several disciplines; and
- increase the ability to solve problem beyond a single discipline.

## EFFECTIVE TEAM COMMUNICATION

Communication is the foundation for all team functioning. It requires that all team members cooperate to establish ongoing communication with each other, with the patient, and with the family for the sole purpose of developing an integrated care plan that addresses each aspect of care.

Barriers to communication range from the lack of a shared language, born of differences in core values and terminology used by different disciplines, to systems and organizational barriers. Moreover, in a busy health care organization, a major hurdle is finding the time for a team meeting and developing methods for effective team communication. In an organization where care is being provided in multiple locations and settings, informal communication often occurs in hallways and elevators, and by telephone, voice mail, and e-mail. The provision of effective coordinated care requires the team to have a clear mechanism for the exchange of information. At the simplest level, this requires the time, space, and regular opportunity for members to meet and discuss patients. An ideal system for interdisciplinary team communication includes

- a well-designed record system;
- a regularly scheduled forum for members to discuss patient management issues;
- a regularly scheduled forum to discuss and evaluate team function and development, and to address related interpersonal issues;
- a mechanism for communicating with the external system (e.g., hospital administration) within which the team operates.

Effective communication also relies on listening, explaining perceptions, acknowledging, and discussing the differences and similarities in views, recommending appropriate treatment, and negotiating agreement. In our increasingly diverse workplaces, language and cultural barriers can exist among members of a team. These barriers can make it difficult for one member to understand the finer points in the meanings, intentions, and reactions of other team members. Our cultural heritage, our gender, our socioeconomic status, and our stage of life all influence our use of language and our perception of others. Some degree of cultural competency must be in place for team members to effectively communicate with each other as well as with patients and family members. Additional barriers to effective communication and teamwork can include

**TABLE 26-3**

### Helpful Questions in Eliciting Patient and Family Goals and Values

What are you expecting?
What do you most want to accomplish?
What is most important in your life right now?
What are you hoping for?
What do you hope to avoid?
What do you think will happen?
What are you afraid will happen?
What gives your life joy or meaning?
What would be left undone, if you were to die soon?

Data from Emanuel LL et al: *Goals of Care. EPEC Participants Handbook. EPEC Project [Module 7]. Chicago, IL: American Medical Association; 1999:pM7.*

- lack of a clearly stated, shared, and measurable purpose;
- lack of training in interdisciplinary collaboration;
- role and leadership ambiguity;
- team too large or too small;
- team not composed of appropriate professionals;
- lack of appropriate mechanisms for timely exchange of information.

Even among team members of similar cultural backgrounds, members need to recognize and value the different competencies and approaches of different disciplines. People do not need to think the same to be unified. The key to team success is to value the differences on the team and use such diversity to achieve the team's common purpose.

## VALUING DIVERSITY

Values are a major source of conflicting and competing communication patterns among health professionals. The education and training of health care professionals vary according to different modes and methods of practice. For example, a patient who is being seen by a team may have a problem with depression. A pharmacist might see a patient with no drug therapy, a social worker might see a patient who is socially isolated, and a physician might see a patient with possible dementia. Furthermore, if members of an interdisciplinary team do not possess at least a basic understanding of each other's knowledge and values, then it is likely that misunderstandings will result. For example, most physicians equate quality of life with mental status or freedom from mental impairment, while many nurses relate quality of life to physical strength, seeing, hearing, and having someone who cares.

The following tips may be helpful for valuing diversity on a team:

- Reasonable people can—and do—differ from each other. No two people are the same. Diversity among team members enhances creativity.
- Learn as much as you can from others. Learning the various backgrounds, cultures, and professional values of others can enrich your own skills and abilities.
- Evaluate a new idea based on its merits. Avoid evaluating ideas based on who submitted them or how closely these mirror your own personal preferences.
- Avoid comments and remarks that draw negative attention to a person's unique characteristics. Humor is a key factor in a healthy team environment but should never be used at the expense of another's identity or self-esteem.

Differences among team members should be honored and utilized to advance the goals of the team. Decision making and conflict resolution are also components of the communication process that must be acknowledged by teams. The group process must integrate openness and confrontation, support and trust, cooperation and conflict, sound procedures for solving problems and getting things done, and good communication. Establishing a planned process for decision making is essential. The process must also take resolution of conflicts into account, because conflict is inevitable.

**TABLE 26-4**

### Common Approaches to Negotiation and Conflict Resolution

1. Welcome conflict and use it as potential for change. Address data, facts, assumptions, and conclusions.
2. Clarify the nature of the problem as seen by all parties.
3. Try to identify areas of agreement. Focus on common interests, not positions.
4. Deal with one problem at a time, beginning with the easier issues.
5. Listen with understanding. Reflect and clarify when communicating.
6. Brainstorm.
7. Use objective criteria when possible.
8. Invent new solutions where all parties gain.
9. Evaluate and review the problem-solving process after implementing the plan.

## TEAM CONFLICT

Conflict is a natural and unavoidable part of human affairs, especially in such groups as interdisciplinary health care teams that seek to grow and develop. The various health professionals on a team have underlying differences in their modes and methods of practice that affect their relationships with each other, as well as with their patients. For example, various professionals may differ in their logic of geriatric clinical assessment or how to define a patient's problem.

Differences may be characterized by two different styles of practice. One, a "ruling-out problem" approach, systematically eliminates possibilities until only one problem and a corresponding solution remain. The other, a "ruling-in problem" approach, relies on expanding the range of professional view to encompass an increasingly long list of potential factors. For example, physicians are trained in diagnostic techniques that narrow the range of options, relying heavily on such objective data as laboratory tests in the process. Social workers, on the other hand, are taught to go beyond the narrow presenting problems to view it within larger, encompassing psychosocial issues, such as income, family relationships, and environment. In addition to the diverse professional perspectives, team members also have different personalities, which influence interactions among team members. Other factors that may lead to conflict in team care include scarce resources and organizational or professional changes that threaten guidelines for using conflict to promote interdisciplinary problem solving.

The discussion of different points of view promotes growth and development, which in turn leads to improved outcomes. This sort of discussion often leads to conflict, a natural and unavoidable part of human affairs. Successful resolution of conflict requires the ability to communicate effectively as well as to confront issues, not people, focusing on the search for win-win solutions in which both sides achieve a benefit. [Table 26-4](#) lists common approaches to negotiation and conflict resolution.

## EMPHASIZING CARE GOALS AND INTERDISCIPLINARY CARE PLANNING

The concept of goals is essential on at least two levels within interdisciplinary geriatric care teams. Teams are generally organized to

achieve specific programmatic goals. Health care teams work with patients, families, and others to achieve patient-specific goals. For an interdisciplinary team to function effectively, the team's purpose and goals should be understood clearly and agreed on by all members. With the increasing cost consciousness in health care, the goals of teamwork and the products of interdisciplinary collaboration are of paramount importance. In managed care, the measurement of outcomes is an important and widely accepted way of demonstrating that adequate care is being provided. Goals established—whether long- or short-term—need to be feasible and take into account that interdisciplinary teams function in a variety of settings (e.g., home care, inpatient) and that the team membership, types, and intensity of services provided vary. One step toward establishing goals is to have the team answer the questions, “What do we want to achieve with this patient?”

### Interdisciplinary Care Planning

After programmatic goals are determined, team members next must agree on what they mean in reality. For example, if “improve patient outcome” is a goal used by a team, successful outcome will need to be defined case by case. The process of interdisciplinary team care planning is the means of achieving consensus on desired patient outcomes. One discipline might want to save the patient's life at all costs, while another discipline might want comfort and less aggressive medical care. For example, when a patient shows signs of confusion and an inability to care for self, a physician might want the patient hospitalized for the patient's own safety, while a social worker might want to bring social services or health care into the home first. These choices can keep the team in a conflict mode, without reaching a decision on the care plan unless the purpose and goals are clear and the patient or a surrogate is meaningfully involved in the decision about care.

An interdisciplinary team developing care plans and treatment goals for patients must be able to conceptualize patients broadly, incorporating all relevant information and knowing how different pieces of information relate. The ability of each discipline to add to the overall care plan will depend on team member's understanding of the linkages between the problems. A general treatment outcome goal of optimum health for the patient can be easily agreed on by team members, but the best means of obtaining that goal will be considered differently by the various disciplines represented on the team. Professionals will share their views of plan initiatives based on their professional knowledge or previous experience. This exchange will lead the team into areas that might not be considered if it were not for the team expertise available. Team members must communicate their own professional opinions, and all members need to respect the different kinds of expertise each brings to the group in order to optimize care planning.

For all the great effort put into developing a care plan, a plan cannot work unless the team has a system for documenting it and indicating clearly who will be responsible for what and by when. This documentation should be completed before the end of the meeting and available to all team members to remind them of their responsibilities. In addition, there must be in place a system (formal and informal) for communicating and continuing with the next steps of the care plan between team meetings. This is most often done informally with the different disciplines, talking with each other as needed.

## SUMMARY

Good interdisciplinary care teams can enhance management of the complex syndromes experienced by older adults. Good teams require team members with excellent clinical skills who are schooled in the knowledge and skills of teaming. Good teaming does not happen by accident but is a function of well-developed team structure. This includes rules to govern the team and team member behavior, plans to make meetings run efficiently, clarity about the skills and boundaries for the roles and responsibilities of each team member, team communication skills, and mechanisms for managing team conflict. Fulfilling these requirements can lead to care goals and care planning that emphasizes the particular needs of an individual older adult. The demographic imperative and the workforce demand for the future necessitate fresh approaches to team care, as well as new research from which to build the science of efficient and effective team care.

# Social Work

*Ruth E. Dunkle* ■ *Mary Catherine Dennis*

Social workers provide services to older patients across a continuum of care needs that range from supporting community living to providing palliative care services at the end of life. This occurs in many different health care arenas including institutional settings, such as acute care hospitals, chronic care settings, and nursing homes, as well as in patients' homes in the community. Social workers support and enhance the adaptive capacities of patients within their living environments and are knowledgeable about interviewing, assessment, and intervention in social problems faced by individuals, couples, families, and groups. Using negotiating skills, social workers mediate conflicts and obtain resources for clients and their families. Knowledge of group process makes social workers effective in forming natural helping networks and serving as members of interdisciplinary teams. Their expertise in coordinating services within a single organization or across different agencies or settings helps to ensure appropriate and adequate care for older patients.

While 76% of social workers in a health care settings work with older patients, not all social workers have specialized training in geriatrics. This is changing rapidly, primarily through training efforts sponsored by the Hartford Foundation's initiative established in 1999. Such training enhances social workers' awareness of older people's needs and subsequently leads to better quality of care by helping social workers provide the appropriate services at the right time. Proper care provided by gerontologically trained professionals including social workers can reduce the cost of care by 10% each year in hospitals, nursing homes, and patients' homes as well as improve psychosocial outcomes and reduce mortality.

This chapter describes the key roles for geriatric social workers, the practice issues they face, and the settings in which they work.

## KEY ROLES FOR GERIATRIC SOCIAL WORKERS

The roles social workers play vary within health care settings (Tables 27-1 and 27-2). Social workers provide direct service to elders as well as facilitate linkages between service workers and agencies.

## Direct Service Provision

Social workers meet face to face with patients and consumer groups to provide services as caseworkers, marital or family therapists, and group worker or educators. Individual casework and counseling services help elders who have mental health problems or need help with resolving issues in such areas as housing, finances, or interpersonal problems. Marital and family therapies include meeting with individual elders, with marital partners, as well as with groups of elders who are experiencing concerns related to their families. This could involve helping elderly grandparents be more effective in raising their grandchildren, aiding families in coping with an elderly parent with a dementing illness, or supporting elderly couples as they struggle with debilitating health problems, which strain the emotional resources necessary to maintain their marriage bonds. Group work services include support groups for elders with a variety of health concerns, such as those who have cancer, low vision, or early-stage dementia. Support groups have been particularly helpful to caregivers of patients with such diseases as Alzheimer's. These groups run by social workers help caregivers better understand the disease process and provide information that helps them deal with the problems of caregiving more effectively and thus improve the disease outcome. Groups also focus on self-help issues, where elders learn to deal with such problems as alcoholism or smoking. Psychotherapy groups work to resolve such concerns as abuse (as victim or perpetrator), depression, and marital problems. Social workers also work directly with older adults and their families as educators and disseminators of information. For instance, they provide educational sessions on caregiving, stress management, and various aspects of mental and physical health care.

## Linkage Roles

Social workers link elderly individuals to the services they need. This may be because agencies are not meeting the older person's needs, because elders themselves lack knowledge of available resources or

**TABLE 27-1****The Roles Social Workers Perform**

ROLES	DESCRIPTION	EXAMPLES
Group worker	Social worker plans and conducts group activities for clients to help understand themselves better through a variety of methods; can be therapeutic, educational, social, or for support	Worker organizes a group for grandparents raising grandchildren to share information and provide support
Advocate	Social worker fights for, defends, and promotes patient's perspectives and rights	Social worker helps a patient destined for a nursing home receive home health care rather than be institutionalized
Case manager	Social worker assesses patient needs, connects patient to resources, and coordinates and oversees delivery and participation of services	The case manager coordinates the services. A patient might need rehabilitation therapy, psychotherapy, and home health care as well as transportation services
Educator	Social worker offers knowledge regarding health care information, processes, and procedures with patients and provides knowledge of patient with the team	In hospice, the social worker provides information regarding the dying process, pain management, stages of grief, and option for burial services
Discharge planner	Social worker prepares patient for next phases of departure from facility by designing a course of action	When patient leaves the hospital and goes home, the social worker may arrange transportation services, meal delivery, home care services, and assessment of home for safety
Therapist	Social worker engages clients in interpersonal interactions regarding client's behavior, feelings, attitudes, and perceptions	Social worker works with an older couple who is having marital problems resulting from stress of caregiving
Team member	Social worker collaborates with health professionals to provide efficient delivery of services	Social worker shares information with physicians and nurses and provides insight into the patient's cultural and personal life
Broker	Social worker connects patients to most relevant resources	Social work brokers help African-American elders overcome the racial and ethnic disparities they face in receiving health care, by building trust between the patient and health care professionals
Information and referral	Social worker has knowledge of community resources and offers connection to these agencies	Social worker has knowledge of respite care services and links caregiver of Alzheimer patient to the respite care agency
Mediator/arbitrator/advocate	Social worker facilitates conflict resolution	The social worker advocates for the older patient in a guardianship hearing

**TABLE 27-2****The Setting Where Social Workers Work and the Roles They Perform**

SETTINGS	ROLES
Home	Support patients' adjustment to health status, provide emotional support, address barriers in access to medical care (i.e., transportation), provide education so that patient can make informed decisions, assess social support and referral to resources, and case management
Hospital	Assessment; discharge planning; prevention and treatment of mental and physical health; promotion of psychosocial health, advocacy in relation to aspects of human diversity; mediate between patients, families, and the health care team; group work; psychotherapy
Nursing home	Financial planning; psychosocial assessment and addressing emotional needs; care planning; mediation between residents, staff, and family; linking residents and families to resources
Assisted-living facility	Negotiate placement and transition, support in navigating decision-making and emotions regarding changes in autonomy, financial planning, and fostering communication
Senior center	Administration, program planning, case management, facilitate group and individual therapy, address life transitions, and organize advocacy groups
Dept of Public Welfare	Case management, oversee and evaluate programs, community outreach, advocacy, development of services, income assistance, protective services, support parents raising grandchildren
Community mental health setting	Perform client assessments, conduct support groups, provide emergency and crisis services to older mental health clients and their families; referral to other resources in the community such as adult day care, respite services, and partial day treatment programs
Hospice	Liaison between care settings; case manager; address psychosocial needs of families and patients; support for adjustment to setting, treatment, illness, and death; educator, advocate, broker, and mediator between family members, patient, and medical professionals; team member; information and referral; group worker; and counselor
Adult day care/respite program	Assess clients' mental and physical abilities, plan and facilitate activities to maximize physical and cognitive functioning, facilitate support groups, provide information and support for Alzheimer's and other disease processes, and referral to community resources
Primary care	Plan and implementation of safety and illness prevention programs, identify social factors that support prevention of illness and cause of disease, provide emotional and social support, facilitate support groups around a specific disease or mental illness, and provide education, information, and referral

ability to access those resources, or because elders and their families need help in overcoming fears and concerns they might have about using services. For instance, family members who are struggling to provide home care to their mother with Alzheimer's disease may be reluctant to use a support or educational group of other family members in similar circumstances for fear of revealing the personal problems their mother faces. Social workers can help overcome these fears by helping family members realize that all families where a family member has a dementing illness face similar problems and have similar reactions to their circumstances. Social workers also work as case managers to help elders receive services in a timely fashion. In general, case management involves screening, assessment, care planning, implementation, monitoring, and reassessment to evaluate ongoing service needs. Case management meets a variety of goals in numerous settings. The social worker assesses the elder's problems and needs to determine eligibility for services as well as financial resources and links elders to the needed services. Family and friends may provide collateral information to help the social worker determine their capacity for support. Goals for a care plan are set by discussing the elderly patients' perception of their needs. Interventions are then designed to meet these goals. Resources are identified to this end. Subsequently, the social worker monitors the delivery of the services. When care is needed over a longer period of time, the needs of elders are reevaluated. Ultimately, an outcome evaluation is conducted to determine if the patient's goals were achieved.

Social workers also work as mediators and advocate for their clients/patients. As mediators, social workers determine the issues behind a conflict. Social workers facilitate family discussion of issues identified by the family and elders as important. For example, adult guardianship mediation can be used to discuss how the family can best help elders to preserve autonomy (or to maximize his/her greatest level of independent functioning). When advocating for their clients, social workers often form partnerships with lawyers to aid victimized elders who need legal redress. For example, social workers and lawyers can aid gays, lesbians, bisexuals, and transgendered (GLBT) elders who face housing and service delivery discrimination in accessing benefits to which they are entitled.

## PRACTICE ISSUES WITH POPULATIONS SERVED

Geriatric social workers strive to meet the basic human needs of all elders, with a particular emphasis on those who are vulnerable owing to oppression and poverty. With health care provided in a myriad of public and private settings, the social worker acts as a broker, a mediator, and an advocate for clients.

This section reviews key populations served by social workers and the practice issues that come into play with elders in these groups.

### Cultural Diversity

Social workers are uniquely situated to respond to the needs of older adults across racial-ethnic groups and sexual orientation because of their skills in training and cultural awareness in service delivery. Attention to cultural diversity includes sensitivity to differences in cultural history, language, values, religion, ethnicity, nationality, regionality, immigration status, and sexual orientation as well as recognition of within-group variation. For example, cultural assessment strategies are used to understand the clients' definition of

their problem. During the assessment process, social workers working with culturally diverse groups evaluate attitudes toward health care and the clients' belief about the causes of illness and benefit of health care services. As social workers attempt to understand the clients' problems, they evaluate the language skills, educational level, and degree of acculturation of the patients. In addition, determining which family member has the authority to make care decision is important for the health care professional to know. For females, in some cultures, a male decides how care proceeds. In Native American culture, generational standing comes into play in decision-making for care. The patient's use of language to label and categorize a problem, the availability and use of indigenous community resources, the decision-making involved in problem intervention strategies, and the patient's cultural criteria for determining problem resolution are important issues for the social worker and other health care workers to consider in working effectively with older patients and their families.

While there are common themes that are relevant to people of color, and other minority elders such as lesbians, bisexuals, and transgender persons, each group has its own cultural history relevant to care. Social workers identify barriers to seeking help, such as stigma, denial, and financial and access barriers resulting from service fragmentation and gaps in health care. For some older minorities, health problems are rooted in historic experiences of discrimination that prevent access to the social service system. Therefore, culturally specific interventions consider the unique background and resources of the individual. Initial contact with a patient requires understanding of the individual's identity, including their degree of acculturation, generational status, immigration/refugee status, as well as sexual orientation. Nonverbal cues may be more meaningful than verbal expressions. These may provide information about knowledge or problems and ways of handling them. Knowing the client's sense of ethnic identity, attitudes toward formal services, and service preferences helps the social worker sort out cultural values and traditions and family beliefs and practices relevant to care.

### The Poor

While government programs such as Social Security, Medicare, unemployment insurance, and welfare have reduced the extent of poverty in the older population, it is still a significant problem, resulting, in part, from the cumulative effects of lifelong discrimination, particularly for elders of color, those older than 75 years, those residing in rural areas, and women. Underutilization of health and mental health services by elders in poverty makes these groups a target for social work intervention. One significant barrier to meeting the needs of elders in poverty is lack of knowledge about their problems and needs. Gerontological social workers are aware of the barriers that impede the development and delivery of appropriate services and are aware of formal as well as informal resources to aid elders in rural communities, women, and racial/ethnic minorities.

### Immigrants and Refugees

Since the early 20th century, rising numbers of elders have arrived from South America and Asia. The majority of older immigrants to the United States has a median length of residence of 14 years and has close relatives who are U.S. citizens. The diversity in this population is reflected in race and ethnicity, as well as age, length of residence

in the United States, English language proficiency, and reasons for immigration. These elders are more likely to live in households with extended family and nonfamily than are nonimmigrants and, if they come from developing countries, to live with their children. Families are central to the provision of care to their aging relatives. Demand for family caregiving often occurs in the context of limited coping resources, inadequate knowledge of services, misperceptions of eligibility requirements of government programs, and the elders' beliefs that children will be their care providers. Unfortunately, the multiple roles result in greater caregiving strain and increased neglect and abuse of elderly family members. Social workers educate elders and their families about the available services and how to obtain transportation and financial resources to access these services. More importantly, through a culturally competent assessment, social workers can identify negative attitudes toward formal services, culturally specific definition of illness and healing, and religiously acceptable perceptions of services for these families.

### Abused and Neglected

The abuse or neglect of elders is often identified in a health care setting. Many types of mistreatment, such as physical abuse, sexual abuse, and neglect (including self-neglect), result in injury, pain, and physical and psychological impairment. Other types of abuse such as financial and identity theft are more difficult to detect. The assessment of mistreatment, which may require several contacts, involves an interview with the elder to review the risk of abuse and the elder's cognitive ability and level of independent functioning. While all states have mandatory or voluntary reporting laws, the elderly victim's willingness to receive help is voluntary. Social workers help in the assessment process for elder abuse by providing education about the nature of abuse and prevention strategies. Social workers can be instrumental in helping the elder recognize the power imbalance in abusive relationships and devise strategies for protection. The biggest challenge that health professionals face is identifying and helping abused or neglected elders who do not realize that they are victims of mistreatment.

### Mentally Ill

The incidence of mental illness among the elderly ranges from 15% to 25% across all care settings. Approximately 4% receive assistance for their problems, with half of the help coming from primary-care physicians. Many elders are reluctant to seek help because of stigma, language barriers, or the lack of culturally appropriate services. Social workers work with a health care team to assess the mental health issues and to identify appropriate treatment and services. They can provide structured cognitive-behavioral, interpersonal, and problem-solving treatments that are effective mental health approaches, often in conjunction with prescribed medication. Pharmacological interventions and psychosocial treatments are both effective in the elderly.

### Cognitively Impaired

Social workers are involved with the assessment of older adults with dementia and their caregivers. Such an assessment considers the client's social and medical history, including a physical and mental status examination, an assessment of the individual's living environ-

ment, a functional ability assessment of both instrumental activities of daily living and activities of daily living, social service needs and family dynamics, service and resource needs, legal issues such as power of attorney and health care proxy, advance care planning, and end-of-life planning. Social workers also play a variety of roles on the interdisciplinary team used when an elder and his/her family experience a dementing illness. In the early stages of the dementing illness, social workers can support the elder with dementia and provide cognitively stimulating programs. In some cases, the elder is able to plan for his/her own future physical and financial needs, which the social worker can facilitate. Social workers are also helpful to family members who are struggling with the acceptance of physical and emotional changes in their loved one as the dementing illness progresses. Finally, social workers may function as case managers for individuals experiencing cognitive impairment.

### Older GLBT

This is often an invisible population, but one that has special needs and has experienced a history of discrimination leading to barriers in service delivery. Few organizations offer specialized services to GLBT patients or are sensitive to their needs. Unfortunately, stigma and hatred toward homosexuals limit access to services as well as the scope of available services provided to people in these populations. Without the protection of legal marriage, GLBT persons and their children do not have access to Social Security survivor benefits, employee health benefits, inheritance, or housing and hospital visitation. When confronted with institutional care, elders in these communities worry that their partnerships will not be honored. Social workers connect GLBT clients to services and service providers who do not discriminate against them and respect their identity. In addition, social workers help establish GLBT-friendly resources such as providing a list of physicians and elder-friendly living facilities and facilitating completion of power of attorney, advanced directives, and other health care documents to secure access to financial and health care decisions for GLBT partners.

### Substance and Alcohol Abusers

This problem often is unrecognized by health care professionals as symptoms are often mistaken for other age-related problems such as depression and dementia. Risk factors for the substance and alcohol abuse include social isolation, living-alone, chronic pain, and a variety of losses such as retirement, widowhood, and mobility. Six percent to 11% of elders seen in health care settings show symptoms of alcoholism, and this increases to 14% in emergency departments and 20% in psychiatric settings. Treatment for these problems in older people is more successful than in younger adults. Social workers aid other health care professionals in assessing the problem and providing the necessary treatment. Social workers provide successful educational interventions with older patients who are not aware that they are consuming too much alcohol or misusing over-the-counter medications. Counseling can also aid the older person in changing their behaviors and reducing stress that leads to overuse of alcohol and medications. Counseling that uses motivational interviewing to help clients desire a change in their behavior has been effective with older people. Group and individual interventions using a cognitive-behavioral approach as well as self-help and psychoeducation groups are effective approaches to these problems. Social workers provide

couples and family interventions, which also aid in reducing the stress that may trigger the overuse of alcohol and medications.

### HIV/AIDS Victims

Many older people come into contact with HIV/AIDS either as patients with the disease or as caretakers for loved ones with this disease. Currently, approximately 10% to 12% of people with AIDS are older than 50 years, but, with treatments that prolong life, this is expected to increase. The isolation of elders with HIV/AIDS is greater than for younger people, as they are more likely to live alone. They are also more reluctant to seek social service and mental health support. This same resistance is evident with caretakers of persons infected with this disease as a result of concerns about being stigmatized, adding additional stress to the caregiving situation. Social workers can help identify elders with HIV and help improve access to services and social networks with older people who have HIV concerns. Social workers offer educational information about HIV as well as case management services that coordinate the raft of services that many patients with HIV and their families need, such as caregiver respite services, home health care and hospice care, individual and group supportive counseling, and financial assistance.

## WHERE SOCIAL WORKERS PRACTICE

Social workers are employed in a variety of settings that older persons use for their health care. Several of the central practice arenas are reviewed below.

### Nursing Homes

Social workers are employed in nursing homes of all sizes but when the size of the facility is 120 beds or larger, their employment is mandated under the Omnibus Budget Reconciliation Act of 1999. The number of elders using nursing homes has declined during the last 20 years because of a reduction in disability among elders as well as an increase in home health care and the expansion of assisted living facilities. Because these facilities are residences where people live, social workers have the responsibility of helping in all aspects of life, including the resident and their family, facility staff, and the overall institutional environment. Their assistance begins with the transition into the facility. Adjustment to a new living environment is faced by not only the older person but their family as well. The social worker provides direct services to residents and their families as part of an interdisciplinary team. They assess the psychosocial needs of the resident and aid in the development of a care plan under the government requirements of maintaining a Minimum Data Set. The Minimum Data Set is part of the U.S. federally mandated process for clinical assessment of all residents in Medicare or Medicaid-certified nursing homes. This process provides a comprehensive assessment of each resident's functional capabilities and helps nursing home staff (physicians, social workers, and nurses) identify health problems and develop strategies to address them. Social workers also facilitate psychosocial well-being among residents and their families, linking the resident and family members to services inside and outside the facility, helping with discharge planning for the elders who are discharged, and serving as advocates for appropriate care and treatment for all patients and their families. Because social workers are often the

only staff members focused on the psychosocial needs of residents and their families, they are in the best position to identify and address mental health issues. Often they complete the cognitive, mood, behavioral, and psychosocial portion of the Minimum Data Set and the resident assessment protocol and can readily identify the mental health needs of the residents.

### Community Mental Health Facilities

Twenty percent of elders experience mental health disorders, and almost 70% of them live in the community. Unfortunately, older persons are underrepresented in community mental health facilities, as mental health symptoms are sometimes mistaken for issues of aging by family, friends, and health professionals. When elders seek treatment, they usually have more severe symptoms. Social workers are part of a team of mental health practitioners, which includes nurses, psychologists, and psychiatrists, who work in these settings. Social workers do client assessments, conduct support groups, provide emergency and crisis services to older mental health clients and their families, and refer these people to other resources in the community such as adult day care, respite services, and partial day treatment programs. They often provide therapeutic interventions in the form of brief psychotherapy and behavior modification to individuals or groups. They also provide indirect services through community education and consultations in long-term care facilities.

### Hospitals and Health Care Facilities

Social work practice with older adults in health care settings is focused on adaptation and coping with chronic illness, adjustment to disability and physical limitation, decisions about end of life, compliance with medical regimens, wellness, long-term care, and quality of life. Social workers also provide mental health services that address depression, substance abuse, management of long-term mental health issues, cognitive deficits, suicide prevention, and adjustment to changes in life by patients and families.

In hospital settings, social workers are members of an interdisciplinary team (consisting of physicians, nurses, social workers, and chaplains, among others), providing services to patients and families regarding assessments of a patient's cognitive, emotional, and behavioral status, as well as social support network. Social workers counsel patients and families, assisting them in adjustment to illness and providing crisis intervention and connection to community resources. Additionally, social workers identify interpersonal aspects of patients' lives that contribute to positive outcomes in relation to their chronic illnesses, such as addressing obstacles to medical compliance and environmental and financial obstacles, by acquiring information and accessing support resources for geriatric patients. Social workers advocate for the cultural, language, sexual orientation, ethnicity, religious, class, and other aspects of diversity by affirming and addressing these aspects of patients' lives. Social workers also advocate on behalf of patients with the health care team when patients face barriers to receiving care. For example, social workers can aid in the care of abused and neglected elders by documenting and reporting instances of abuse and neglect and can testify in court with regard to these matters.

In acute care settings, where patient stays are very short, social workers focus on high-risk screening, brief counseling, bereavement

services, discharge planning, collaboration, information, referral, follow-up, and emergency services on call programs. Social workers are typically assigned to specific medical or psychiatric departments in hospitals. Patients are screened to determine whether they need social work services. Need for services is also conveyed to other health care professionals by having social workers attend team meetings and discharge planning conferences, by referrals from nurses or physicians, or by requests from patients and families. A social worker's presence, when a diagnosis, death, or other unpleasant news is communicated, can ease shock and help individuals address the emotion loss and face forthcoming decisions. Additionally, the social worker can provide information regarding aspects of diseases, care options, and assistance in meeting the patient's needs.

Discharge planning is particularly important for older adults who are transitioning from the hospital to other facilities or their homes. Addressing older adults' needs during discharge is necessary, in order to allow the older adult the best possible scenario for recovery from illness. The social worker assesses caregiving needs, and availability of social supports, family support, and home and community environment, as well as financial supports when the patient leaves the hospital.

## Hospice

Hospice social workers practice in a variety of end-of-life settings, such as palliative care centers in hospitals, nursing homes, assisted living facilities, outpatient practices, and residential hospice facilities, and in homes. Palliative care requires an interdisciplinary team, where the social worker is a crucial member providing psychosocial support and referral to resources, easing transitions between settings, and addressing issues of loss for patients and families.

The role of the social worker begins before patients enter into hospice or palliative care and continues with families and loved ones after end-of-life care ends. Social workers provide a variety of services to address the needs of patients, families, and caregivers in end-of-life care. Social workers in end-of-life care fulfill a variety of roles such as liaison, educator, mediator, advocate, broker, and counselor. As patients face debilitating illness in palliative care, social workers help with the transition between care facilities, assessing readiness for palliative care and beginning to address the emotional and psychological aspects of end of life. Social workers are pivotal in assessing and supporting patients, families, and caregivers in their psychological, spiritual, social, financial, and cultural needs at the end of life. Addressing loss in patients and families is essential, as individuals and families may have difficulty communicating and accepting their feelings regarding the losses they face. Identifying social support for patients and families is important, as they may reconcile their relationships with family and friends and find support in these relationships. Discord may arise when families are brought together at the end of life, and, therefore, social workers assist families to communicate and understand decisions that are made, emotions that are expressed, and relationships that are negotiated.

As an educator and mediator, the social worker provides information regarding the plan of care, the illness, and the process of dying; communicates with the health care team; informs the patient of their rights; provides information regarding medical rights to accept or refuse medical interventions; and provides information regarding the grieving process for families and caregivers. Additionally, educating the health care team regarding the specific needs of

a particular patient or family and providing information regarding cultural and spiritual accommodations that may be made are important aspects of hospice care. Social workers act as brokers for resources and services to address the needs of patients who are dying and their families, arrange services, facilitate communication among family members, provide services to fulfill last wishes, and provide assistance with funeral plan arrangements. As an advocate, the social worker supports and represents the patients' and families' needs, wishes, and desires to the health care team; recognizes the dying person as a social person during the end-of-life stages; and works toward fulfilling end-of-life wishes. As a counselor, a social worker addresses the psychological, emotional, and spiritual needs of the family in addressing losses, illness, and reconciling relationships. Also, grief support to families, friends, and caregivers is provided after death through individual counseling sessions with family members, support groups, grief camps for children, and formal ceremonies and services for families who have lost loved ones.

## Home Care

Home care is a term that encompasses a variety of services, including home health agencies, homemakers, home health aides and assistance, medical equipment and supplies, visiting nurses, caregiver respite, and other medical services that are provided in the home. One agency may provide one or several of these services to older adults.

Social workers in home care address a wide range of issues that are similar to and unique from other settings. These fall into several areas including adaptation to illnesses and chronic conditions; decisions regarding end of life, dementia, and behavior management; caregiving; issues of abuse, neglect, and prescription drug misuse and handling theft; family discord; and connecting family members who live long distances from the older adult. In addition, financial management, addressing unsafe living conditions, connecting to resources to provide safe living quarters, social support, mental health, legal issues, and compliance to medical treatments are part of the social worker's job in home care for older people.

In order to address these diverse issues, home care social workers employ a case management approach, where interventions are crafted for individuals and their unique needs. Also considered in these situations are the families, caregivers, the environment, and the community resources that are available. Key aspects of these services include assessment, planning, management and coordination of resources, and advocacy. Social workers are equipped to communicate with older adults and assess their preferences, wishes, desires, emotional states, coping styles, needs, and cultural diversity issues involved in service delivery. When older adults continue living in their homes, social workers arrange and monitor services, such as meals on wheels or grocery deliveries. As caregivers are often involved, caregivers' burden is evaluated along with the need for respite services in case of illness or hospitalization. A holistic approach is employed, where psychological, spiritual, and cultural needs are met. For example, religious services can be arranged so that the older adult can continue practicing their faith.

Social workers provide a unique psychosocial perspective that allows for assessment and monitoring of older adults' ability to make decisions. Social workers can advocate on behalf of the older adult to the members of the home health team regarding termination of

services and understand patients' perspectives and unique needs. Finally, social workers assist with discharge planning and transition from home to other medical providers when needed.

## SUMMARY

Geriatric social workers are integral members in the health care team serving older patients. Their wide range of skill, as well as their knowledge of available services in a variety of settings, makes social workers valuable members of the team serving older patients.

# Self-Management of Health Behavior in Geriatric Medicine

W. Jack Rejeski ■ Lawrence R. Brawley ■ Mary E. Jung

## INTRODUCTION

A significant development in medicine is the recognition that patients should be treated as active agents in their health care. Contemporary consumers show increased interest in becoming more personally involved in decisions about their health, as evidenced by the popularity of such resources as WebMD and the marketability of health-related products and services. In the context of the traditional office visit, self-management is an inevitable part of treatment, since patients ultimately decide when to initiate the process and to what extent they will adhere to recommended courses of action prescribed by health care professionals.

Geriatric medicine is no exception to this trend. A guiding assumption of this chapter is that older adults' self-management of health behaviors is central to understanding the etiology, treatment, and downstream consequences of illness, chronic disease, and disability. An appropriate model for 21st-century geriatric medicine will focus on creating a partnership between health care professionals and their patients and will require that health care professionals have a working knowledge of what motivates older adults to initiate health behaviors and the potential reasons for success or failure in self-management. The early sections of this chapter will define and provide a conceptual framework for self-management; later sections will review key studies in the area and offer guiding principles and suggestions for incorporating patient self-management into practice. Mastering this knowledge will enable geriatric health care professionals to deliver state-of-the-art care to their patients.

## DEFINING SELF-MANAGEMENT

In 2003, Noreen Clark noted important distinctions among terms such as self-care, disease management, self-regulation, and self-management. Establishing clear definitions is an important first step

in ensuring that health care professionals understand how to integrate self-management with clinical practice.

Using Clark's distinctions as a guide, *self-care* involves actions taken by an older adult to maintain a desired health status without the interaction or assistance of a professional. Examples might include taking herbal supplements or participating in a yoga class at the YMCA independently, without any advice or monitoring by health care professionals.

Although self-care is important in the lives of older adults, in this chapter, we are interested in health behaviors that either do or should directly involve health care professionals. Such behavior falls under the rubric of either *disease management* or *self-management*. Clearly, older adults managing chronic disease and disability must frequently consult health care professionals and adhere to the various therapies they prescribe. Adherence implies that the older adults perceive that they have an active role in making decisions about, and carrying out, a particular regimen. It implies a collaborative relationship between patient and health provider. In contrast, compliance suggests an unquestioning and passive response by the patient and a provider-patient relationship that is one-way and top-down. Adherence has been shown to be better in promoting persistence and motivation than compliance, underscoring the necessity for collaboration in health care.

How, then, does disease management differ from self-management? *Disease management* involves both the health care system and the individual. At the system level, disease management refers to what the provider and health care system do to manage chronic disease and disability; for example, making available necessary services and prescriptions. At the individual level, disease management refers to the strategies implemented by patients and their families to manage both the disease and its consequences.

The individual level is the arena of *self-management* within disease management; it involves a partnership among the older adult, family and caregivers, and the health care professional. Ideally, the patient who self-manages effectively learns to use these human

resources toward the goal of minimizing symptoms and optimizing function while living with the chronic disease or disability. In Clark's view, *self-regulation* refers to the way that patients derive strategies to handle their chronic disease; it is a process embedded in the larger context of self-management. While we agree that self-regulation is at the core of the self-management process, we contend that it will be strongly influenced by the health care provider. It should not be limited solely to patient-derived strategies, which are in the domain of self-care. In fact, the provider must educate patients about the self-regulation process if they are to understand and use it to manage their health behavior.

In summary, we define self-management as *a process that involves self-regulatory strategies taken by patients, who use their personal skills as well as those of health care professionals and supportive others to detect and manage their symptomatology and improve function*. While learning about and maintaining self-management of chronic disease require a partnership, the partners' responsibilities may vary over time, and the eventual goal is for the patient to achieve as much independence as possible. These partnerships must strive to help older adults acquire the self-regulatory skills essential to effective self-management of health behavior.

## HEALTH BEHAVIORS EMBODIED IN SELF-MANAGEMENT

To explain self-management in geriatric medicine, we must clarify what is meant by health behavior. Generally speaking, older adults' self-management may involve three broad classes of health behavior: detection, promotion, and prevention. These behaviors must be distinguished because the motives and strategies to encourage each of them differ. Further, the extent of adherence to each class can be influenced by both positive (taking action) and negative (avoiding action) responses. Self-management encompasses both responses. For example, one older adult might attempt to adopt and maintain a therapeutic regimen of physical therapy for a frozen shoulder, yet another may decide not to go to the therapist to avoid the pain and discomfort of treatment. While avoidance by patients is rarely effective in managing symptoms in the long run and contributes to nonadherence, health care professionals must recognize that self-management does not always involve what they may view as the "correct" response.

Detection behavior, performed by the individual or the provider, provides information about the presence or absence of unhealthy or potentially unhealthy chronic conditions, for example older women performing breast self-examinations or health care professionals ordering mammograms. Promotion behavior is intended to maintain or improve an older adult's current state of relatively good health, for example healthy eating, regular exercise, and meditation when used proactively to manage stress. Often, health promotion behaviors do not involve the health care provider and are best conceptualized as part of self-care than self-management. On the other hand, prevention behavior is performed either to reduce or prevent the risk of future health problems or to facilitate recovery from a health event. Examples of preventive self-management include reducing saturated fat in the diet to lower cholesterol and the risk for cardiovascular disease (primary prevention) or engaging in exercise therapy to facilitate recovery following a myocardial infarction (secondary prevention) (Table 28-1).

**TABLE 28-1**

### Examples of Self-Management Behaviors

DETECTION	PROTECTION	PROMOTION
Performing breast or testicular self-examination	Using sunscreen every day	Eating a healthy diet
Scheduling regular checkups with the dentist, optometrist, and physician	Flossing and brushing teeth each day	Exercising regularly
Checking blood pressure regularly	Getting an influenza shot	Meditating regularly to maintain a healthy state of psychological well-being
Testing home for safe radon and carbon monoxide levels	Wearing seat belt every time you drive	Maintaining a healthy social network

In geriatric medicine, health providers must encourage and actively facilitate older adults' development of self-management skills. They must also work to build the adherence of older adults toward desired detection, prevention, and promotion behaviors and thus strengthen and reinforce older adults' related self-confidence for managing those behaviors. Later in the chapter, we will discuss the research literature in self-management, which holds promise for successful collaborations between older adults and health care professionals in achieving these goals.

## CONCEPTUAL FRAMEWORK FOR SELF-MANAGEMENT

Having defined self-management and discussed different classes of health behavior, the next logical step is to ask the following questions: What motivates older adults to engage in self-managing health behaviors? What causes success or failure in effective self-management? In answering these questions, we offer a conceptual framework that will serve two important roles. First, it will be used to examine evidence from research on self-management. What are the features of successful programs designed to promote self-management? What are important gaps in the knowledge? Second, it will provide health care professionals with a template for examining current practices or designing new initiatives that target self-management of health behavior for older adults.

Older adults engage in self-management in response to a conscious goal or to remove barriers in the path toward goals. For geriatric medicine, health-related goals most often stem from concerns related to detection or prevention behavior; that is, older adults want to identify and to alleviate or avoid a specific physical or psychological symptom/condition. If the symptom is new to them, then older adults' self-management behavior is frequently encouraged by a family member and begins with seeking a diagnosis.

However, in many instances, patients seek treatment for chronic disease, and a diagnosis is not needed. Here, prevention of the symptom becomes the goal. A common example among older adults is the pain associated with osteoarthritis. Quite often, they may not view pain management as self-management because they may perceive

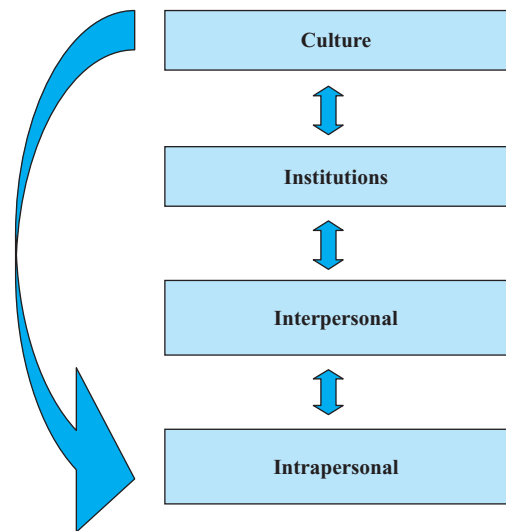

chronic pain as beyond their control. They believe that the health care provider has the sole remedy to fix their problem and prevent it in the future. For example, they might expect to obtain new medication or an increased dose of their current medication to alleviate arthritic pain. The physician's actions may reinforce this passive solution to the pain. The physician may feel that pain from osteoarthritis is rooted in some underlying pathology and that it is a biological problem and immediately rule out collaborative self-management. Such a decision and subsequent behavior either knowingly or unwittingly discourage self-management, reinforcing patients' notion that they have no role to play in treating their chronic condition. This example illustrates that both patients' understanding of their medical conditions and the behavior of health care professionals contribute to the motivation to self-manage health behavior. Active partnerships between patients and their health care professionals develop the motivation to take action and are essential in shaping patients' self-management behaviors.

### Commonsense Model of Self-Regulation

Howard Leventhal and his colleagues have been instrumental in promoting a "commonsense" model of self-regulation for health behavior and have conducted considerable research on what motivates people to seek treatment. Their model also has relevance to adherence to self-management over time. A critical feature is its bottom-up, as opposed to top-down, organization. The focus begins with an older adult's perceptual experiences (feeling off-balance or weak) and physical symptoms (pain and fatigue)—the raw sensory experience that something is wrong. Moods and emotions related to this raw sensory experience as well as feelings of competence in being able to manage the problem are also important in determining higher-order reasoning, such as, "I'm in trouble and need help."

The model identifies five features of health events that motivate people to act: label/symptom, timeline, consequences, cause, and perceived control. The following scenario provides an explanation of how these features operate. Fred has noticed that he seems to have weakness and some mild discomfort in his upper legs when getting out of the car or rising from a kneeling or sitting position: the perceptual experience/symptom. Originally, he thought that these might be the result of an overuse injury, the inevitable effects of aging, or a complication related to the tension he has been experiencing with his younger son: the suspected cause. However, the symptoms have persisted for 8 weeks, and he long ago resolved the conflict with his son: the timeline. He has also noticed that friends of his age are not reporting this problem. He reasons that if aging were the cause, more of his friends would have the same symptoms. The symptoms are very frustrating because those have all but stopped him from working around the house and seem progressively worse because he now has discomfort when rising from his chair after watching TV. Consequently, Fred questions his original, suspected causes and now concludes and worries that he may have nerve damage in his spine or a musculoskeletal disease: loss of control.

Fred's initial cause-and-effect explanations of his symptoms are consistent with his personal reasoning about the relationship between stress and illness and age and illness and may have delayed his seeking treatment. However, when their duration and their absence among his peers suggest that these are not a normal problem of aging or stress, these become prompts to seek treatment. Leventhal and his group have found that, in addition to these five factors, fear is

**FIGURE 28-1.** Multiple levels of influence that can affect older adult self-management.

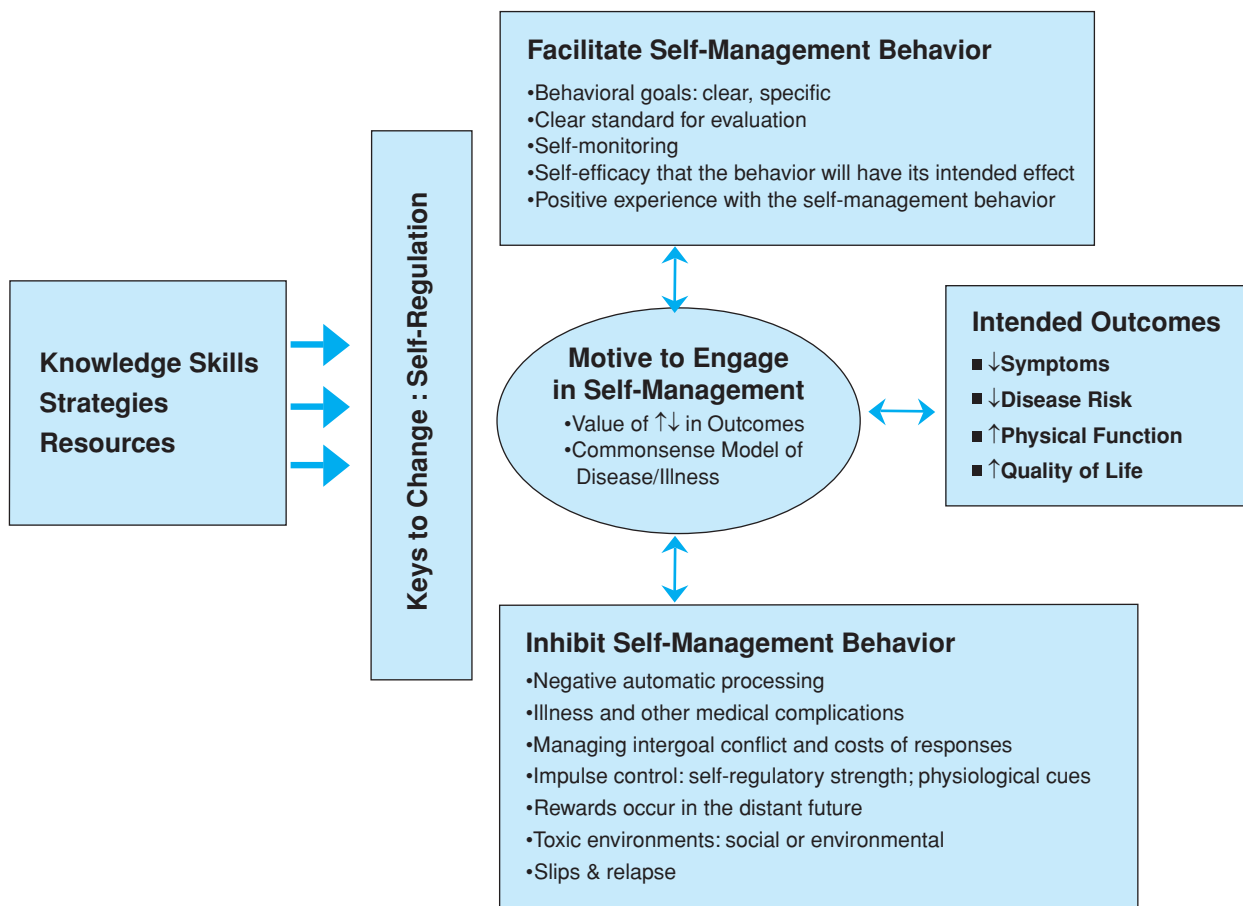

Note that culture indirectly influences all levels in self-management but can especially influence the individual (intrapersonal) because of prevailing ageist stereotypes.

an important motive for action, but that without an action plan, fear does little to promote constructive behavior. For Fred, an action plan might consist of intending to call his physician tomorrow morning after breakfast to make an appointment for the following week.

Of course, older adults' commonsense models are not created in a vacuum; they are influenced by the social system. Individual health behavior is influenced by factors at interpersonal, institutional, and cultural levels, and our understanding of self-management has to be considered from a systems-based perspective (Figure 28-1).

Factors from multiple aspects of the system can both facilitate and inhibit older adults' actions. For example, a wife's insistence may result in her husband going for a prostate examination for potential detection of cancer (interpersonal influence). TV documentaries on the biology of aging may lead older adults to adopt a regimen of vitamin supplementation (institutional influence). Grown children may openly verbalize an emotional objection to their elderly parents seeking treatment for a symptom, being convinced that physicians are just trying to collect money on procedures for benign aches and pains, in effect "ripping off" Medicare (cultural influence). Other powerful cultural stereotypes in our society can discourage physical activity among older adults.

Symptoms do not always lead older adults to seek a solution, even when they are severe and persistent. In many instances, older adults self-manage their symptoms through avoidance. For example, a woman ignored rectal bleeding for more than a year until acute pain forced her to visit the emergency department, where colon cancer was diagnosed. She knew that something was seriously wrong long before this event, but she was afraid that once she went for a diagnosis, she would be hospitalized, and that would be the end of her life as she knew it. Such avoidance can also be triggered by older adults' beliefs about specific health behaviors. For example, older adults may have adopted stereotypes that support their position that they are too old to be physically active or that losing weight is unhealthy for them.

**FIGURE 28-2.** Blueprint for self-management.

### Conceptual Framework for Understanding the Complexities of Self-Management

We will elaborate on three features in the following sections: (1) facilitating factors, (2) inhibitory factors, and (3) knowledge, skills, strategies, and resources (Figure 28-2).

#### Facilitating Factors in Self-Management

More than two decades of research in psychology have identified several factors that promote effective self-management of health behavior. Consider the following example. Helen is an obese, physically compromised older adult. She is frustrated by several consequences of her poor health, including the fatigue she experiences when moving, the loss of some of her functional independence, and a recent confirmation by her physician that she has type-2 diabetes. In collaboration with her physician, Helen decides to join a research study that is treating physical disability and diabetes in older adults using a combination of caloric restriction and increased physical activity. When she first enters the study, the intervention team evaluates her diet and activity patterns, and, based on these data, she and an interventionist together establish goals for modifying them over the next month. In addition, they discuss the importance of establishing weekly behavioral goals related to self-monitoring and evaluation of her progress. Together, they decide that, each month, Helen will time herself while walking four laps at the local YMCA track (~400 m)

and also record her fatigue on a simple 10-point scale (0 = no fatigue whatsoever and 10 = as tired as she has ever felt). Helen's progress and her confidence in being able to complete the prescription are checked weekly. Her goals are adjusted as necessary. On a monthly basis, Helen is asked to reflect on what she has done and to notice what effects, if any, the program is having on various aspects of her life (Table 28-2). As a result of this self-evaluation and a number of successes in pursuing the goals that she helped to set, Helen gained confidence in the skills necessary to make progress in changing her behavior. She could see the change happening as she engaged in these self-regulatory processes to manage her chronic health condition (see Table 28-2).

The scenario and the description provided in Table 28-2 illustrate how self-regulation generates effective self-management. The skills inherent in this process warrant repeating, since they are part of the tools that health care professionals must share with older adults in self-managing health behavior. They include:

1. setting clear, specific, and reasonably challenging goals for behavioral change;
2. monitoring personal behavior and how it influences reaching goals and the rate of change;
3. providing feedback and information on each health behavior goal that has been collaboratively established between the health care professional and the older adult;

TABLE 28-2

## Factors that Promote Effective Self-Management

SELF-REGULATORY SKILL	EXAMPLE
Establishing proximal and distal goals	Helen and her HCP* discuss her current diet and activity patterns in order to develop realistic, challenging goals together. In addition to a long-term, monthly goal, weekly proximal goals are also created.
Self-monitoring progress toward goal	Helen writes down specifics about her diet and her exercise workouts each day. She also “tests” herself each month by walking around a track four times and seeing how much this tires her out.
Attaining feedback	Helen meets with her HCP weekly to discuss her log book. The HCP provides constructive feedback on how Helen is doing.
Self-evaluating progress toward goal	Helen looks back and reflects on her previous log entries to make note of any progress she is making toward her goals and whether she is noticing any changes in other areas of her life. She sees that it now takes less effort for her to walk around the track four times and that she can now ride the bike 10 min longer than she could 2 weeks ago. Both of these improvements are seen as progress toward her goal of increasing her physical activity level.
Making corrections to goal-directed behavior	The HCP helps Helen think of ways in which she can progress. She suggests, for example, that Helen work toward increasing her fruit and vegetable consumption gradually just as she has increased gradually the number of minutes of continuous physical activity. Helen brainstorming on practical tips that she can do to reach her short-term goals, such as buying precut vegetables and adding sautéed vegetables to all of her entrees.
Raising self-efficacy beliefs	Helen is encouraged to dote on the progress she has made—to see all of the workouts and positive changes she has made to her diet. This increases Helen’s confidence in her abilities to successfully change her health behaviors, regardless of barriers that she encountered along the way.

\*HCP, health-care professional.

- self-evaluating progress related to the goal—collecting the older adults’ personal judgments and emotional reactions about their pursuit of goals and making or not making progress;
- correcting behavior as a result of feedback and self-evaluation, leading to more effective and persistent change in the direction of established goals;
- encouraging belief in their ability to organize and to take actions associated with the specific circumstances that they are trying to change, in order to achieve specific goals. These beliefs foster the persistence necessary to increase behavioral change, despite the setbacks, difficulties, or rate of progress (self-efficacy beliefs).

The interaction of these multiple factors influences the success that older adults will have with health behavior change. However, their collaboration with health care professionals as their partners influences the entire self-regulatory process. The partners can make informed judgments about expectations and outcomes. In the example above, consequences could include not only Helen’s reduced calorie consumption and increased walking but also compliments from family and friends, and the personal satisfaction with her own accomplishments. Regular reflection on progress (feedback) and comments about how it has affected life (outcome information) by both parties characterize a self-evaluative process and influence the desire of older adults to adhere to the collaborative prescription for change. The health care professional’s comments about change in Helen’s outlook and persistence and Helen’s pleasure in being able to stick with reduced caloric consumption for more than a month jointly contribute to her self-efficacy (confidence) to adhere to their plan over the next month.

### Inhibitory Factors in Self-Management

For some older adults, behavioral practices that reflect effective self-management of chronic disease are well learned and help to resist threats, such as competing behaviors and events. Many older adults

consistently visit their physicians when they encounter novel physical symptoms, schedule screening examinations and vaccinations as recommended by health care professionals, and take recommended supplements and daily walks without fail. However, health care professionals must often ask older adults dealing with chronic disease or disability to adopt new remedial or preventive behaviors or to change dysfunctional patterns of behavior. Under such circumstances, a number of factors inhibit effective self-management.

**Operating on Automatic Pilot** Clearly, a major threat to self-regulation and effective self-management is operating automatically. The self-regulation needed to adopt a new behavior or to change an old pattern requires conscious control of thought and action. If an older adult behaves without thinking, opting for the easier, routine path that allows dysfunctional behavior, hope for change is futile. Why do older adults persist in automatic patterns? According to Walter Mischel’s research, strong emotions, which are common in older adults, shut down their rational thinking and derail attempts at conscious behavior change. In our studies with older adults, these emotions have a variety of causes, including the frustration with failed treatments, the concern that they are a burden for their caregivers, and the acute illness or injury that disrupts the action plans that they use to self-manage their behavior change. The important lesson from Mischel’s research is that self-management planning cannot ignore these emotions and their related causes.

In addition, decades of eastern writings and recent research in western psychology on mindfulness convincingly argue that North American society encourages automatic responding. Many individuals find it difficult to pay attention in the present moment to where they are headed and whether or not the direction of their path is consistent with what they value. It has been suggested that we have this difficulty because we spend much of our young and middle adult years striving to get somewhere or to complete the next task. This behavior pattern continues into old age. Some customary routines

do not require that older adults consciously monitor what they are doing, and their inclination is not to alter what seems to be working for them in day-to-day situations. The problem, of course, is that many customary routines run counter to the strategies or prescriptions that health care professionals hope to make a part of older adults' health self-management: "I always have a doughnut with my coffee." More will be said about how health care professionals can counter the phenomenon of "operating on automatic pilot" later in the chapter.

**Slips, Relapses, and Intergoal Conflict** A second general threat to effective self-management is the occurrence of slips and relapses in behavior and intergoal conflict. The failure to remain true to personal goals is often distressing, and older adults are no exceptions to this experience. For this reason, slips and relapses often spark negative emotions, which contribute to giving up the adoption or maintenance of new self-regulatory behavior that can facilitate self-management. For example, Byrne, Cooper, and Fairburn conducted a qualitative study comparing obese women who were either successful or unsuccessful in maintaining weight loss after an initial intensive treatment. They found that relapse was related to (1) the failure to achieve weight goals and dissatisfaction with the weight achieved, (2) the tendency to evaluate self-worth in terms of weight and shape, (3) a lack of vigilant weight control, (4) a dichotomous (black-and-white) thinking style, and (5) the tendency to use eating to regulate mood. The theme that emerges is that relapse is often triggered by negative thoughts and feelings about self-management, which can arise from (1) unrealistic expectations about outcomes, (2) eliminating a behavior that is used to cope with life stress, or (3) having zero-tolerance for slips.

We have also found that slips in self-management are often related to competing events—intergoal conflict. A common example for older adults is vacation or family gatherings, which compete for time and priority with preventive actions. In these situations, self-management behavior takes a back seat and can even lead to negative thoughts, such as: "I just don't have time for this program on vacation," or "I don't like the feeling of guilt that I am suddenly experiencing; something's got to give." The black-and-white thinking style posits that vacation and active self-management of health behavior are incongruent. However, with the development of appropriate self-regulatory skills, the two goals need not be in conflict.

**Toxic Environments** Poor physical and social environments as well as lack of resources for effective self-management can interfere with diagnosis, prevention, and promotion. According to Marcia Ory and her colleagues, barriers often evolve from negative stereotypes related to six common myths of aging. These ageist stereotypes are reflected in the media and social and health care services. Expert witnesses who testified before the U.S. Senate Special Committee on Aging reported that the media and marketing depict older adults as helpless, feeble, and ineffective. In the realm of health care, Ory and her colleagues found that physicians tend to provide less aggressive treatments to older patients and that self-management programs typically target younger populations. Furthermore, behavioral and lifestyle interventions are believed to have only minimal impact on older adults, despite accumulating evidence to the contrary (Table 28-3).

TABLE 28-3

## Popular Myths of Aging

MYTH	REALITY
1 To be old is to be sick	Although chronic illnesses and disabilities do increase with age, the majority of older people are able to perform functions necessary for daily living and to manage independently until very advanced ages. The effects of population aging are mediated, in part, by declining disability rates.
2 You can't teach an old dog new tricks	Older people are capable of learning new things and continue to do so over the life course. This relates to cognitive vitality as well as the adoption of new behaviors.
3 The horse is out of the barn	The benefits of adopting recommended lifestyle behaviors continue into the later years. It is never too late to gain benefits from highly recommended behaviors, such as increasing physical activity.
4 The secret to successful aging is to choose your parents wisely	Genetic factors play a relatively small role in determining longevity and quality of life. Social and behavioral factors play a larger role in one's overall health status and functioning.
5 The lights may be on, but the voltage is low	While interest and engagement in sexual activities decline with age, the majority of older people with partners and without major health problems are sexually active, although the nature and frequency of their activities may change over time.
6 The elderly don't pull their own weight	The majority of older adults who do not work for pay are engaged in productive roles within their families and/or the community at large.

**Costs and the Problems of Distant Benefits** Research from multiple theoretical perspectives illustrates that the anticipated costs of behavior weigh heavily on the decision to seek or to persist with a treatment. For example, research has shown that the fear of a medical procedure, without a plan to deal with the fear, is a significant barrier to treatment. In our own work on lifestyle behavior, we find that negatively interpreted physical symptoms during activity are barriers to older adults' continued involvement with exercise programs, and having to eliminate favorite foods in caloric and fat restriction prescriptions for weight loss is, at times, difficult for older adults to accept.

Another common challenge for older adults is what researchers have described as temporal discounting or the delay of gratification necessary to reach some outcomes. Willingness to persist with treatment for weeks, and sometimes months, before any major outcome is realized may wane. Many older adults may be faced with delayed gratification both in achieving desired outcomes and in the heavy costs of day-to-day treatment. No wonder self-management can be perceived as complex and stressful and lead to avoidance or nonadherence.

### Knowledge, Skills, and Strategies

The final component of our conceptual blueprint for self-management addresses the knowledge, skills, and strategies that

**TABLE 28-4****Six Key Questions Concerning Traditional and Collaborative Care**

QUESTION	TRADITIONAL CARE	COLLABORATIVE CARE
What is the relationship between patient and health professionals?	Professionals are the experts who tell patients what to do. Patients are passive.	Shared expertise with active patients. Professionals are experts about the disease and patients are experts about their lives.
Who is the principal caregiver and the problem solver? Who is responsible for outcomes?	The professional	The patient and professional are the principal caregivers; they share responsibility for solving problems and for outcomes.
What is the goal?	Compliance with instructions. Noncompliance is a personal deficit of the patient.	The patient sets goals and the professional helps the patient make informed choices. Lack of goal achievement is a problem to be solved by modifying strategies.
How is behavior changed?	External motivation	Internal motivation. Patients gain understanding and confidence to accomplish new behaviors.
How are problems identified?	By the professional, e.g., changing unhealthy behaviors.	By the patient, e.g., pain or inability to function; and by the professional.
How are problems solved?	Professionals solve problems for patients.	Professionals teach problem-solving skills and help patients in solving problems.

inform self-regulation and, in turn, promote effective forms of self-management. Knowledge about illness, chronic disease, and disability is important from at least two perspectives. First, patients must know about the origin and course of the disease itself. For example, it has been well documented that adults are better at managing diabetes when they understand the importance of self-monitoring their blood glucose level and have specific action plans to implement when values are below or above the target. Second, consistent with Leventhal's commonsense model of illness and disease, older adults' concepts of their health conditions must be explored and expanded. As we saw in [Figure 28-1](#), important areas include (1) symptoms, (2) perceived causes, (3) anticipated consequences, (4) degree of perceived control over the process and course of the disease, and (5) the timeline for disease progression and achieving symptom management.

Skills and strategies refer to intervention methods that have been proven effective in promoting the self-regulation of positive and negative factors toward health behavior change. As we review selected examples from the literature, we will identify elements that are consistent markers of success and indicate how the methods fit into our self-management blueprint.

## LESSONS FROM THE LITERATURE ON SELF-MANAGEMENT

Self-management is good medicine. If the huge benefits of these few habits were put into a pill, it would be declared a scientific milestone in the field of medicine. (Bandura A. Health promotion by social cognitive means. *Health Education & Behavior* 2004;31:143.)

### Partnerships in Self-Management: A Description and Conceptual Rationale

A central position of this chapter that is reinforced in the contemporary literature on self-management is the importance of establishing partnerships between patients and health care professionals. An inherent quality of any effective self-management program is that the patient is an active partner in treatment. What is actually meant by

the term partnership? How does traditional care differ from collaborative care? How do these two approaches influence the approach a health care professional should take to patient education? What is the conceptual significance of partnerships?

### Traditional Versus Collaborative Patient Care

Bodenheimer and his colleagues have recently offered an excellent description of traditional and collaborative care paradigms in chronic disease management and explained the impact of this distinction on patient education. [Table 28-4](#) identifies their six key questions about patient care together with answers based on each of these paradigms. Note that in a traditional medical model, patients tend to take a more passive role in the interaction with the health care professional. Health care professionals identify the problem, provide solutions, and expect that patients will comply with recommendations and prescriptions; noncompliance is viewed as a dysfunctional patient problem. In contrast, when partnerships are established in collaborative care, patients are allowed to define their problems, and patient and professional share responsibility for the creation of treatment plans. Health care professionals facilitate and guide rather than dictate treatment, and noncompliance is viewed as a shared problem to be solved. Indeed, in some instances, most obviously involving side effects from pharmacological therapy, noncompliance may be a wise and rational step, indicating that treatment plans should be either modified or expanded (see [Table 28-4](#)).

In suggesting that patients be allowed to help to define problems, we do not mean that they should supplant health care professionals as diagnosticians. Rather, health care professionals must listen carefully to what patients are saying about their health status and treatment. Consider the example of an older male patient in cardiac rehabilitation. His main concern was his impotence, not the condition of his heart. After considerable dialogue, close examination of his medications, and consultation with his cardiologist, his beta-blocker was changed. Within a very brief time, his erections improved, and his entire attitude toward treatment changed. He was now emotionally able and willing to consider how he could prevent further disease. In fact, what motivated him to exercise, take lipid-lowering medication, and watch his diet was the realization that the vessels that

**TABLE 28-5****Contrasts Between Traditional and Collaborative Medicine**

	<b>TRADITIONAL PATIENT EDUCATION</b>	<b>SELF-MANAGEMENT EDUCATION</b>
What is taught?	Information and technical skills about the disease	Skills on how to act on problems
How are problems formulated?	Problems reflect inadequate control of the disease	The patient identifies problems he/she experiences that may or may not be related to the disease
Relation of education to the disease	Education is disease specific and teaches information and technical skills related to the disease	Education provides problem-solving skills that are relevant to the consequences of chronic conditions in general
What is the theory underlying the education?	Disease-specific knowledge creates behavior change, which in turn produces better clinical outcomes	Greater patient confidence in his/her capacity to make life-improving changes (self-efficacy) yields better clinical outcomes
What is the goal?	Compliance with the behavior changes taught to the patient to improve clinical outcomes	Increased self-efficacy to improve clinical outcomes
Who is the educator?	A health professional	A health professional, peer leader, or other patients, often in group settings

served the penis were also subject to atherosclerosis. The benefit of listening to the patient's concerns and then collaborating on a solution provided huge gains in adherence to the traditional goals of cardiac rehabilitation. This process also contributed to his understanding of the system-wide impact of both disease and adherence on the rehabilitation prescription.

Traditional and collaborative medical care lead to different sets of goals and strategies for patient education. According to Bodenheimer and colleagues, the traditional model is delivered by health care professionals and reinforces patients' ability and need to follow "what the physician orders." By contrast, in a partnership model, education is synonymous with the concept of self-management (Table 28-5). Geriatric health care professionals are part of a larger network of services and individuals that promote the health of older adults. Thus, an important goal of geriatric medicine is to teach patients to leverage resources in their communities and within the health care system. Using such resources enables older adults to reach effective solutions for their current problems and compress their future disability, morbidity, and mortality into the last few months or years of life. This perspective is at the heart of what the healthy aging research network concluded: Healthy aging is most easily achieved when two sets of conditions are operating. The first is when physical environments and communities are safe and support the adoption and maintenance of attitudes and behavior known to promote health and well-being. The second is through the effective use of health services and community programs to prevent or minimize the impact of acute and chronic disease on function (see Table 28-5).

### The Conceptual Importance of Partnerships in Health Care

Partnerships have immense significance to the development and maintenance of effective self-management and health in older adults for several reasons. First, older adults' commonsense models of their disease and illness play a key role in determining health behaviors. In the absence of a partnership between patients and their health-care professionals, these commonsense models go unnoticed. A recent paper by Halm and his associates illustrates the significance of such oversight among minority inner-city adults with persistent asthma. They found that many patients—53% of their sample—believed that they only had asthma when they were having acute symptoms.

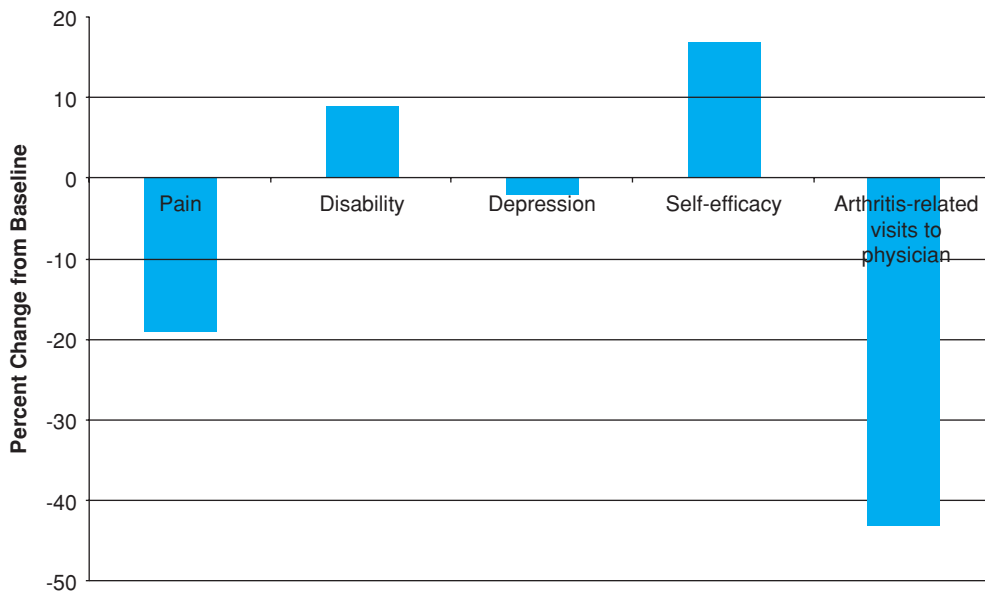

The authors termed this phenomenon the no symptoms, no asthma belief. Men older than 65 years and those who had no consistent health care provider were most likely to hold this belief, which was related to lower use of flowmeters, poorer adherence to inhaled corticosteroids, and the belief that using inhaled corticosteroids in the absence of symptoms was less important. Rates of morbidity and mortality from asthma are highest among these minority inner-city populations.

The importance of partnerships is also supported by epidemiological studies, indicating that physician advice can strongly enhance older adults' desire and confidence in their ability to perform specific health behaviors. Many older adults choose not to discuss health-related self-care with physicians because they are unsure whether the physicians will approve of what they are doing. Thus, geriatricians are often unaware of whether or not their patients are in counseling or dieting or exercising or receiving other forms of health-related treatment, which severely compromises the process of self-management. When health care professionals engage their older patients as partners in a health care plan, discussions are more likely to be open and mutually enlightening.

Finally, through partnerships, health care professionals are in a good position to teach patients effective self-regulation of health behavior. Communication and buy-in occur when goals are clearly specified and action plans are articulated, monitored, and evaluated on a regular basis to enhance patients' motivation and confidence in various treatment regimens. The remainder of this chapter will demonstrate the promise that various programs of self-management have in encouraging health behavior. Although some of the research does not directly involve physicians, these programs work best when physicians understand and support their goals.

### Chronic Disease Self-Management Program

Kate Lorig has published widely on the Arthritis Self-Management Program (ASMP), which has since evolved into a generic Chronic Disease Self-Management Program (CDSMP). ASMP and CDSMP are led by individuals with chronic health conditions who receive 20 hours of training, based on detailed manuals for group facilitation. ASMP is disease specific, emphasizing the management of arthritic pain. It is delivered in 2-hour group sessions (10–15 individuals), meeting once a week for 6 weeks. Major topics include

**FIGURE 28-3.** Twelve years of research on the Arthritis Self-Management Program. (Adapted with permission from Lorig K, Holman H. *Arthritis self-management studies: a twelve-year review.* *Health Educ Q.* 1993;20:17).

pain and stress management; exercise; problem solving; communication skills, especially for physician/patient interactions; nutrition; medications; and nontraditional treatments. CDSMP is designed to treat people who have a range of chronic diseases and is delivered in 2.5-hour sessions every week for 7 weeks. Topics include managing physical symptoms and negative emotions, exercise, problem solving and decision making, communication skills, nutrition, medication use, and the use of community resources. In both programs, leaders function as facilitators, rather than lecturers, actively engaging participants to develop personal goals and specific action plans for each week. Regular feedback is a crucial component, and the objective is to enhance patients' confidence in their ability to acquire specific behaviors or skills in each area of content.

Despite the limited time allotted to address such a broad range of complex health behaviors, data from randomized clinical trials of both ASMP and CDSMP have been encouraging. Figure 28-3 summarizes 12 years of research on ASMP, as reported by Lorig. Note that the 6-week ASMP interventions led to enduring positive changes in self-efficacy, level of pain, and frequency of physician visits (see Figure 28-3).

In a 6-month randomized trial of CDSMP, intervention patients experienced statistically significant increases in weekly minutes of exercise, frequency of cognitive symptom management, improved communication with physicians, and enhanced self-reported health, as compared to control patients. Other improvements favoring intervention patients were lower levels of health distress, fatigue, and disability, and fewer limitations in social/role activities. They also had fewer hospitalizations and days in the hospital. However, they did not differ from controls in their pain or physical discomfort, shortness of breath, or psychological well-being.

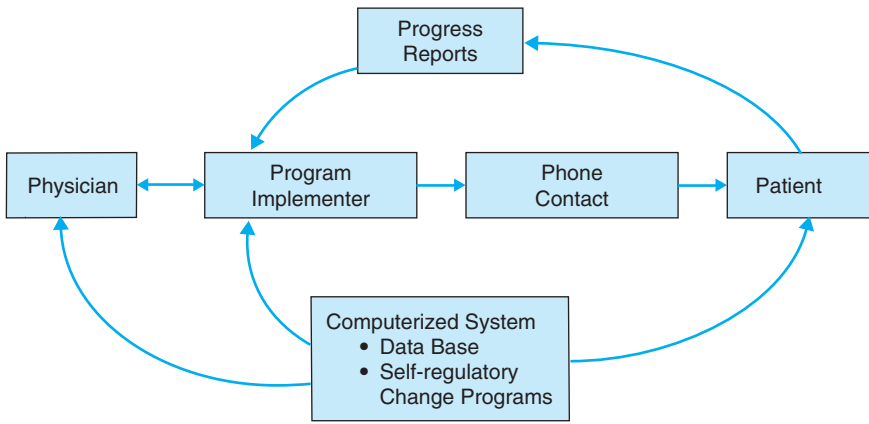

While self-efficacy beliefs appear to play an important role in the apparent success of ASMP and CDSMP, establishing proximal goals and providing feedback on goal attainment are also important. These latter steps help to create short-term incentives and to guide behavior in the desired direction. Moreover, to sustain efforts in the face of inevitable barriers and to assist with problem solving, the

interventions encourage participants to enlist support from health care professionals, peer groups, and significant others.

### Other Programs from Stanford University

The same self-regulation principles that facilitate self-management can be found in other types of interventions that employ an individual, as opposed to a group format, yet are designed to reach large segments of the population. One example of this approach is the case-management system for health care, originally developed by DeBusk and his colleagues at Stanford University—to modify and reduce coronary risk factors. The program is conducted by nurses who receive 80 hours of special training by multidisciplinary experts to deliver interventions for smoking cessation, exercise training, and dietary-drug therapy for hyperlipidemia. Scheduled interventions during a 1-year period include: (1) questionnaires that patients complete and then mail to the nurse case manager; (2) computerized progress reports mailed to patients, based on those questionnaires; (3) 14 nurse-initiated phone contacts; (4) four one-on-one patient visits to the nurse case manager; and (5) eight patient visits to the blood chemistry laboratory. Figure 28-4 illustrates the interdependence of physician, case manager (implementer), and patient using phone contacts and the computerized system to facilitate self-management. Note that the computerized system serves a dual role: one for data management and another in providing knowledge and information on self-regulatory skills that are essential to health behavior change (see Figure 28-4).

The initial study using this system was conducted on adults with a mean age of 57 years who were hospitalized for acute myocardial infarction. Patients were randomized to this treatment or usual care and then followed for 1 year. At the 1-year assessment visit, biochemically determined rates of smoking cessation were significantly higher in the case-managed group (70%) than in the usual care control group (53%), and on a treadmill test performed at 6 months, patients in the case-managed group had higher cardiovascular fitness. At 1 year, lipid-lowering drugs had been prescribed to ~80%

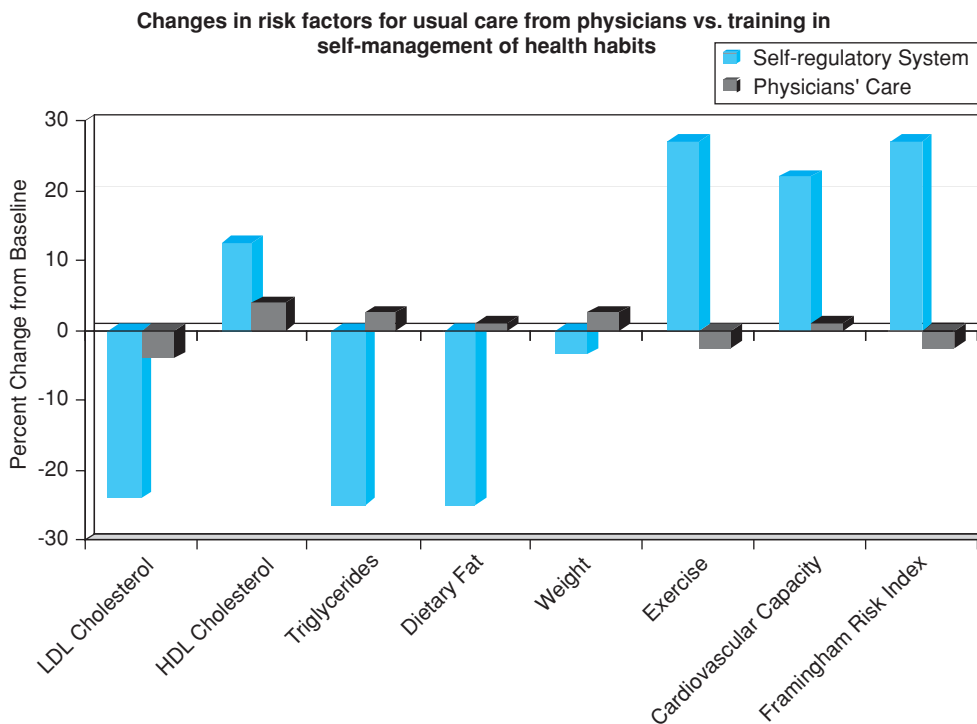

**FIGURE 28-4.** Case management model for coronary risk modification. (Adapted with permission from DeBusk RF, Miller NH, Superko HR, et al. A case-management system for coronary risk factor modification after acute myocardial infarction. *Ann Intern Med.* 1994;120:721.)

of patients in the case-managed group but only 21% in usual care. While corresponding differences in plasma cholesterol favored those in the case-managed group, patients in both groups experienced decreasing levels of dietary cholesterol and fat from baseline to the 1-year assessment.

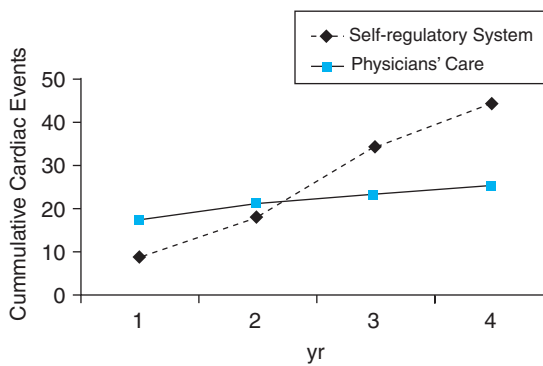

Haskell and his colleagues at Stanford conducted a related study of risk reduction in middle-aged to older adults who had coronary atherosclerosis. Their study was a randomized trial with two groups: usual care and intensive risk management. Their trial design had an objective measure of disease progression and 4 years of follow-up. Patients were provided with short- and long-term goals and an individualized action plan for risk reduction. Progress was tracked, and short-term goals were adjusted using telephone and mail contacts as well as face-to-face clinic visits every 2 to 3 months across the 4 years of the study. The staff included experts in the content areas of interest, such as nutrition, exercise, smoking, and lipid management.

After 4 years of treatment, patients who were randomly assigned to usual care showed little or no change in study outcomes. By

comparison, those in intensive risk management showed dramatic changes in their health, improving their cholesterol profile, lowering saturated fats, losing weight, increasing their physical activity, and improving the functional capacity of their cardiovascular system (Figure 28-5). This shift in health behavior was reflected in significant reductions in cumulative cardiac deaths at the 4-year assessment visit (Figure 28-6). As in the case management study by Debusk, at some point during the course of this study, 93% of those in the intensive risk management condition were placed on drugs for lipid management, compared to only 30% in the usual care condition. Since patients in both studies improved in areas unrelated to blood lipids, not all of the observed effects were contaminated by the introduction of lipid-lowering drugs into treatment. The superiority of results for the intervention groups in both studies implies that even drug therapy can be enhanced by being embedded in a program that establishes clear goals for therapy and provides more frequent evaluation of patients' health status (see Figures 28-5 and 28-6).

**FIGURE 28-5.** A comparison of a self-regulatory system for self-management with usual care. (Data from Haskell WL, Alderman EL, Fair JM, et al. Effects of intensive multiple risk factor reduction on coronary atherosclerosis and clinical cardiac events in men and women with coronary artery disease: the Stanford Coronary Risk Intervention Project (SCRIP). *Circulation.* 1994;89:975.)

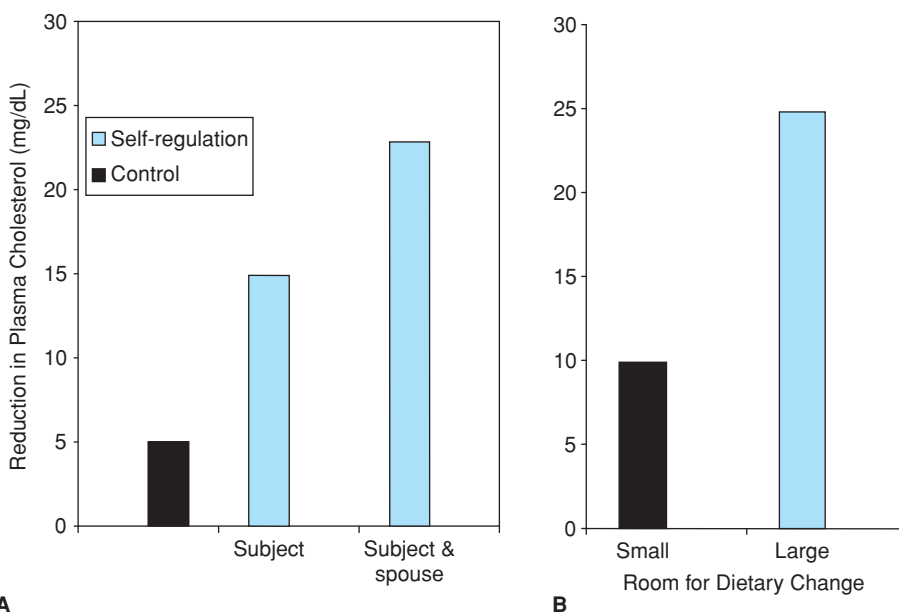

**FIGURE 28-6.** Four-year cumulative cardiac events with a self-regulatory intervention as compared to usual care. (Data from Haskell WL, Alderman EL, Fair JM, et al. Effects of intensive multiple risk factor reduction on coronary atherosclerosis and clinical cardiac events in men and women with coronary artery disease: the Stanford Coronary Risk Intervention Project (SCRIP). *Circulation*. 1994;89:975.)

One other study that deserves mention is a workplace project described by Bandura. Although it was not conducted on older adults, it underscores the potential value of social support in self-management. The goal of this project was to lower cholesterol in workers by reducing foods high in saturated fats. A nutritionist supervised the self-management system that was conceptually similar to the previously described programs conducted at Stanford. At the 3-month assessment, plasma cholesterol between those assigned to an experimental group dropped approximately 10 mg/dL as compared to a control group; however, this difference increased to ~17 mg/dL when spouses participated in the program (Figure 28-7). The effects of the intervention appear to have been compromised somewhat by the inclusion of individuals who had relatively low plasma cholesterol at the onset of the program (panel B, Figure 28-7). However, these data are worth mentioning because they suggest that self-managing lipids is particularly beneficial to those who need it most—those with more severe disease or disability (see Figure 28-7).

## Individual Versus Group-Based Interventions

The work at Stanford and elsewhere indicates the benefits of incorporating groups into programs to instill self-management of health behavior for older adults when appropriate and possible. In our research, we have compared the effects of group-mediated cognitive-behavioral self-management among older patients who qualify for cardiac rehabilitation with a standard model. Both interventions involved center-based exercise therapy. In the standard therapy, patients met three times a week for exercise only. For the group-mediated cognitive-behavioral self-management treatment, patients met less often for exercise at the center, in order to promote home-based exercise, but, when they did exercise at the center, they also met afterward in small counseling groups, designed to provide the knowledge, motivation, self-regulatory skills, and resources, to be more physically active and to reduce self-perceived mobility disability (Table 28-6). At 3 months, after both groups had been heavily involved in their respective treatment plans, older adults who had been more compromised at entry into the study achieved greater reductions in self-perceived mobility disability under the group-mediated cognitive-behavioral condition than those who had been randomly assigned to standard exercise therapy (Figure 28-8). In addition, at 12 months, those in the group-mediated treatment group made greater improvements in their MET capacity (a measure of cardiovascular fitness), physical activity habits, and confidence to perform a timed walk test than those in standard treatment (see Figures 28-6 and 28-8).

This successful example shows that groups are useful in developing participants' self-regulatory skills. The group is developed to foster an active, collaborative learning of rehabilitation and self-regulation. Over the course of the group intervention, patients are encouraged to integrate the skills they learn and, with mutual input, test and evaluate their successes and failures in using these skills in their home-based activity. Belonging to a group whose members' goal is active involvement and collective change is a powerful agent that creates the impetus for, and, eventually, the practice of, effective self-management. The approach differs markedly from the use of

TABLE 28-6

## Self-Regulatory Skills Taught in Group-Mediated Cognitive-Behavioral Interventions

WEEK IN PROGRAM	SELF-REGULATORY GOAL	EXAMPLE ACTIVITY
Week 1	Promote and develop group identity	Participants created and adopted group name.
Week 2	Learn how to self-monitor effort, symptoms, and behavior	Participants were taught how to log physical activity bouts and gauge perceived effort expended during the bout.
Week 3	Set individual and group goals	Participants were taught how to set specific, realistic, yet challenging goals for themselves and as a group.
Week 4	Planning how to exercise independently	Participants were paired with a “buddy” and asked to brainstorm solutions to possible barriers that one may encounter when attempting to exercise alone.
Week 5	Foster social support for individual and group goals	Each participant stated their individual goal to the group and indicated how it would help the group achieve the group goal, and fellow group members offered suggestions on how to attain that goal.
Week 6	Same as week 5, only for decreasing sedentary behaviors	
Week 7	Encourage self-reinforcement and self-evaluation	Participants were taught how to use self-reinforcement to achieve similar future goals.
Week 8	Increasing exercise independence	Participants worked in pairs to design individualized exercise plans for the next week.
Week 9	Recognition of environmental cues	Participants were asked to brainstorm on what cues they could use to facilitate their home-based activity.
Week 10	Develop coping strategies	Feedback was given by group members to each participant’s report of success/failure with self-planned activity. Members were encouraged to suggest ways in which others could improve or avoid barriers encountered during the next week.
Week 11	Learn how to prevent and deal with relapses	The group identified signs of relapse and suggested strategies for overcoming relapse.
Week 12	Increasing self-efficacy	Participants were reminded of all the success and improvements and then created their first week of totally independent home-based activity, as well as a general plan for their first month of independent activity.

Note: All weekly plans were integrated such that goals were continually assessed and revised. From week 8 to 12, participants continued to plan and try their programs when away from the center. In summary, participants gradually weaned themselves from the group toward independent exercise.

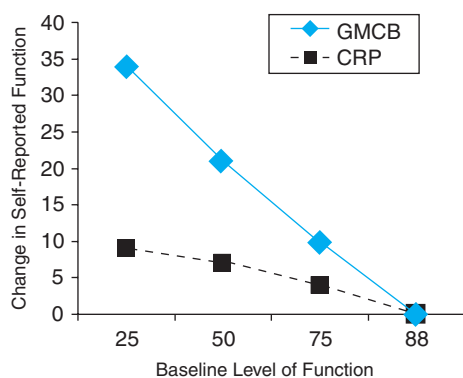

the group as a simple forum of convenience, in order to deliver standard therapy to multiple participants where they primarily follow direction provided by a trained leader. Results from cancer research have shown that it is not group contact per se but how the group is leveraged that promotes effective self-regulation.

How can group potential for health care improvements be maximized? As Yalom noted in his classic text on the use of groups for

psychological therapy, group cohesiveness must be developed. In the preceding example on cardiac rehabilitation, we used classic formative techniques to optimize the dynamics of these small groups ( $n = 7-10$  members). Older adults who have chronic diseases have a common motivation for uniting in a group. Older adults best suited to groups are receptive to the concept of therapy and (1) discussing their disease, (2) learning from other members, (3) developing group goals, and (4) interacting with other members in practicing self-regulatory skills. Within this receptive context, group goal-setting and social support can emerge. Health care professionals can assist in enhancing these properties during the limited life of the group. For example, a group norm of strong attendance is essential. Occasional absences must be expected; however, general sporadic attendance makes a group difficult to manage. This failure is more likely when patients are passively carrying out their therapy, group mission and identity are not emphasized, and the partnership between health care professional and patient members is minimal.

This kind of therapeutic group must also aim for its members’ eventual departure so that they can become more independent in their self-management, although they may later require additional training and education sessions to help them to adhere to their program. The group or alumni group can be the magnet that draws former members back for “re-inoculation” sessions to assist in long-term maintenance of self-management behavior.

Although the group can be used to foster self-management and the learning of self-regulatory skills, practitioners should be mindful

**FIGURE 28-8.** Three-month changes in self-reported physical function in traditional versus a group-mediated cognitive-behavioral intervention. (Adapted with permission from Rejeski WJ, Foy CG, Brawley LR, et al. *Older adults in cardiac rehabilitation: a new strategy for enhancing physical function. Medicine and Science in Sports and Exercise.* 2002;34:1705–1713.)

of caveats. First, as Bandura and others have noted, groups can create dependency, and older adults may quickly revert to their old ways when their group terminates. Cancer research suggests that if groups have no specific purpose other than to allow patients to meet with their peers, then the effects on self-management are nil.

## Challenges to Active Self-Management

### Heterogeneity in Health Status and Health Goals

Self-management programs frequently target chronic diseases, such as diabetes, asthma, COPD, or arthritis, which require managing medications and lifestyle in response to specific symptoms. In such instances, the outcomes of effective self-management are often clear and reinforcing to patients. They realize that their active involvement in disease management makes a difference. They experience increased confidence in managing their symptoms, and enhanced perceptions of personal control become a central part of their commonsense model of the disease process.

Unfortunately, this success does not come to everyone with a chronic disease. For example, if the disease or symptom becomes worse and/or they experience a considerable loss in function, older adults may perceive a loss of control that understandably inhibits the motivation for active self-management. Ample research has shown that when doubt surrounding the effectiveness of behavior is strong, the impetus either to expend effort on action plans or to pursue goals for change is weak.

Before we discuss possible solutions to such challenges, it is useful to recognize that goals exist in a hierarchy. In the current context, a common goal for older adults is “to maintain a healthy state.” However, its pursuit is not necessarily conscious and active until it is threatened by either the loss of function or the emergence of physical symptoms. Once this occurs, then older adults are inclined to institute “do goals,” such as taking medication to relieve symptoms or participating in physical therapy to improve their balance. Because such “do goals” are more specific than the global goal of a healthy state, their achievement requires an action plan or a sequence of steps to follow. If medication is prescribed, it may involve going to the medicine cabinet at a specific time of day, opening the bottle, and taking the medication as well as monitoring medication use and impact over time. In the case of physical therapy, it involves making appointments, scheduling transportation to the appointment, clarifying the physiotherapist’s teaching of exercises for balance improvement, trying the exercises at home at a specific time of day, and monitoring the impact of the regimen on personal balance control.

### Need to Change Health Goals as Health Declines

With a better understanding of goal hierarchy, we can propose ways to help older adults whose motivation to engage in self-management has been depleted. Scheier and Carver have emphasized that western culture frowns on giving up on goals, yet they argue that, in some contexts, goal disengagement is an important coping process. Aging inevitably presents some insoluble problems. Our physiological systems deteriorate, yielding predictable declines in mental and physical functioning. From a self-management perspective, detaching from an unrealistic goal allows the health care professional and patient to recalibrate less ambitious goals that still point the patient in the same persistent direction, while enhancing their sense of part-

nership. For example, a physical activity goal of 150 minute/week may be trimmed to 80 minute/week. Experts believe that following this principle of partial disengagement—moving from an unrealistic to a more realistic and achievable goal without totally abandoning a particular behavioral domain—is essential because it keeps the person engaged with life and may well delay the onset of further health problems.

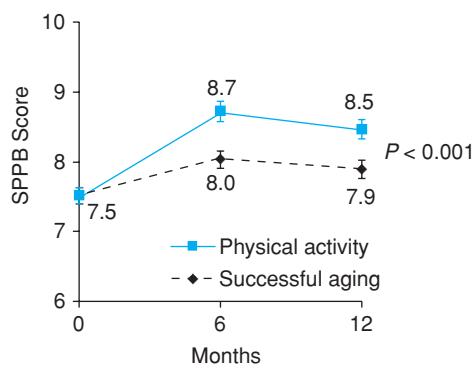

Unfortunately, some circumstances may dictate total elimination of activities that provide older adults with a purpose for living. We have seen many older individuals with chronic diseases who eventually have to give up valued activities owing to a variety of impairments in the later stages of functional decline. In these instances, some older adults disengage and cope effectively by redirecting their energies into other domains, such as spirituality. In effect, they redefine or reprioritize their higher-order goals to accommodate their limited health state. Others fail to cope. They cling to old concepts, are unwilling to let go, and create suffering for themselves and their families. Indeed, contemporary research suggests that failing to disengage from past goals that are no longer feasible creates intense regret among older adults and predisposes them to depression and physical symptoms like constipation and skin disease. Health care professionals may be frustrated in attempting to pursue a partnership on a treatment path that is unacceptable to the patient.

Mindfulness-based interventions may be particularly beneficial in this realm of self-management for older adults, and they are being offered as part of hospital, outpatient, and community outreach programs. These interventions teach centering skills, designed around breathing, for controlling negative thoughts and emotion; they foster insights designed to promote acceptance of life experiences that are not subject to personal control. Although further discussion of this topic is beyond the scope of this chapter, interested readers may consult the end of chapter reference by Baer (Baer, 2006).

## Evidence of Effectiveness of Interventions that Facilitate Self-Management

To date, several hundred studies have been conducted in the area of self-management. The set of adequately designed experiments is smaller. Chodosh et al. (2005) reviewed 53 randomized trials of chronic disease management programs for older adults. The authors concluded that programs targeting diabetes and hypertension produced clinically important benefits. However, determining which elements of the interventions were responsible for the observed effects proved impossible. Although this review did not find a beneficial effect of self-management in patients with osteoarthritis, a more focused literature review suggests a small but statistically significant effect on pain and function.

The results of self-management programs that target objective measures of physical disability among older adults with multiple chronic diseases are more encouraging. Several critical reviews have shown that strength training and walking programs produce robust improvements in physiological functioning and small-to-moderate clinical effects on various functional tasks, such as rising from a chair, climbing stairs, and walking 400 m. For example, in a recent study of adults older than 70 years who had compromised function at baseline, we demonstrated a clinically significant change in scores on the Short Physical Performance Battery (SPPB), a well-validated measure of physical functioning that includes very basic tests of balance, strength, and mobility disability (Figure 28-9). Other studies

**FIGURE 28-9.** Comparison of a physical activity intervention with a successful aging intervention on SPPB scores. Means estimated from repeated measures ANCOVA adjusted for gender, field center, and baseline values. (Pahor M, Blair SN, Espeland M, et al. Effects of a physical activity intervention on measures of physical performance: results of the lifestyle interventions and independence for elders pilot (LIFE-P) study. *J Gerontol A Biol Sci Med Sci.* 2006;61A:1157.)

demonstrate that training older adults for balance has noticeable effects on preventing falls.

Thus, research findings on the topic of self-management vary considerably. Why do they differ so widely both within and between diseases? What conclusions can we draw for clinical practice?

First of all, the value of attributing clinical meaning to the strength of effects that are statistically averaged across studies, even after grouping them according to specific characteristics, such as tailored treatment or group versus individual treatment, is questionable. Among the many reasons for this concern, three stand out: (1) varying duration of intervention, from 6 weeks to 24 months; (2) targeting multiple outcomes; and (3) studying persons with a broad range of disease severity. These variable elements preclude making useful clinical generalizations. For example, we know from our extensive research in weight management that the intensity and duration of treatment are critical factors in the success of behavior change. Also, when studies target multiple outcomes, individual behaviors are rarely given the attention that is required for many participants to focus on their change. The clinical effectiveness of self-management on osteoarthritis pain is much greater in intensive studies of pain management than in short-term community programs that target multiple outcomes, such as the ASMP. While both programs have benefits, comparing them is not clinically appropriate; they are inherently different.

As for disease severity, both the chronic disease and the disability literature adduce good evidence that people with mild disease have less room for improvement in function than those with more severe disease or disability. Of course, for most health conditions, there comes a point where severity offers little room for hope, but this state represents only a minority of the older adult population. Reviews that include studies without controlling for the severity of patients' conditions are obviously misleading. Individuals who are severely ill or have disabilities require different treatments that may not be classified as self-management.

Perhaps more important for geriatric health care professionals is the clinical utility of the information presented both in this section dedicated to research and in the previous section on a conceptual blueprint for change. How does the geriatrician use the informa-

tion we have presented? Can specific principles and suggestions be proposed to optimize self-management in geriatric medicine?

## PRINCIPLES AND SUGGESTIONS FOR INTEGRATING SELF-MANAGEMENT INTO GERIATRIC MEDICINE

How do health care professionals best promote self-management in the context of their own practices? Are particular target behaviors of interest? Choices will vary with resources and personnel. Several fundamental principles that have evolved from the evidence presented in this chapter can and should be common to all self-management programs for chronic health problems. In addition, health care professionals might want to consider targeting several specific types of behaviors (see also Chapter 9).

### The Self-Management Partnership

A core principle in promoting effective self-management is establishing partnerships between health care professionals and their patients. Health care professionals can use the contrast noted between traditional and collaborative styles of interaction (see Table 28-1) as a guide to set concrete goals for themselves in establishing a consistent model of care with patients and then to formulate plans of action in conducting their practice. If these steps sound familiar, it is because these are identical to those we suggested earlier for patients. Because health care professional/patient interaction is bidirectional and bilateral, health care professionals should also examine their own behavior to ensure that they are contributing to, rather than detracting from, the partnership to promote self-management. The same factors that limit the patient's contribution to self-management also pose challenges for health care professionals trying to follow through on their own plans of action to contribute to the partnership's achievement of goals.

By definition, partnerships require cooperation between two or more people. An important facet of promoting partnerships in geriatric medicine is enlisting patients' support and educating them about the skills and commitment required of both parties. Clearly, a major challenge for health care professionals is that the common-sense model of medicine in our culture is one in which patients are relatively passive, expecting physicians and nurses to solve or to fix problems. While health care remains a problem-solving enterprise, the partnership model must (1) identify problems collaboratively; (2) specify options and choose a treatment together; (3) make detailed action plans; and (4) clarify for patients steps for evaluation, including feedback to the health care professional. Communication between health care professionals and patients should reinforce the patient's active role in health care, underscoring diverse behaviors that include adhering to medication regimens, monitoring symptoms, or altering lifestyle behaviors.

### Fostering Collaboration

Meichenbaum and Turk's classic text (Meichenbaum and Turk's 1987; p. 187), *Facilitating Treatment Adherence: A Practitioner's Guidebook*, offers health care professionals the following practical advice to facilitate collaboration in self-management:

1. Ascertain the patient's preference for each aspect of the treatment regimen.
2. Assess the patient's previous experience with self-management.
3. Ensure that the patient has the requisite skills and resources for implementation.
4. Introduce change gradually over the course of several visits to learn together how the patient is doing.
5. Break complex tasks that require more demanding adherence into actions that can be handled sequentially.
6. Begin the collaboration with a step that can be readily accomplished to foster immediate patient control and direction.
7. Enlist support of family or other strong allies.
8. As the patient assumes an increasing level of self-management, gradually reduce the health care professional's role in order to foster greater patient responsibility.

All of these suggestions imply frequent, ongoing contact with patients, a necessary aspect of managing chronic disease. Physicians and nurses must carefully plan how they use contact time with patients to most efficiently build the collaboration.

With the exception of smoking, physicians are not aggressive in giving patients advice about lifestyles, despite the profound effect that changes in lifestyle behaviors have in accruing, preventing, and treating chronic disease and disability. For adults older than 65 years who report on their physician's guidance, only 31.3% are told to get more exercise, 41.5% are given advice to eat more fruits and vegetables, 38.2% are instructed to reduce their dietary fat, 25.5% are advised to reduce stress, and 82.8% are advised to stop smoking. These statistics only concern one of the most prevalent forms of physician behavior—providing advice—not teaching or actively changing patient behavior. The number of older adults who are assisted in self-managing lifestyle behaviors remains low. Incorporation of counseling on health behaviors into clinical encounters is discussed further in Chapter 9: Preventive Gerontology.

### Implementing a Framework for Effective Self-Management

Self-management is heavily influenced by older adults' common-sense models of health-related problems and treatment options. When they are unclear about the meaning of their symptoms and conditions, they may experience anxiety and perhaps avoid important self-management behavior. Interpreting a symptom as "nothing to worry about—it's old age" can lead patients to be passive, and they may fail to take action that could prevent downstream morbidity. On the other hand, overreacting to the single occurrence of a symptom may result in overcompensation, for example resting, when a more helpful reaction should be increased activity. Clarifying and documenting the type, intensity, frequency, and duration of symptoms that older adults are experiencing should be a priority of any practice. These data should be updated on follow-up visits.

Any diagnosis should also be accompanied by information about both the disease/health state and the patients' role in managing the health event. Simply asking older adults whether or not they understand the problem they are encountering and then moving on if they answer affirmatively is insufficient for two reasons. First, they may be embarrassed to admit that they do not understand common disease states, such as hypertension or diabetes. Second, even if patients think

that they understand a specific diagnosis, components of their common-sense models may well be in error (see Figure 28-1) and detract from adherence to recommended and agreed-upon action. Health care professionals discussing self-management with older adults in relation to these diagnoses can underscore the importance of their partnership, using it as a platform for mutual understanding (1) to set concrete goals in specific areas, (2) to establish action plans, and (3) to discuss the importance and means of providing feedback about these action plans (Table 28-2).

Health care professionals should be able to link their older patients to resources in either their own network or the community that might be valuable in managing their health states. For example, someone who is obese and has elevated glucose should be referred for weight loss. Referrals should be proactive when possible; that is, if patients are receptive, health care professionals should arrange the initial contact with resource personnel. They must also be aware of whether or not patients have the economic means, time, and transportation required to take advantage of the proposed resources. This kind of matching and planning greatly increases the likelihood that older adults will follow-up on recommendations. Of course, health care professionals must monitor patients' progress with outpatient programs if they really are to function as active partners in self-management. However, as noted in Chapter 15, The Health Care System, these coordinating activities are not reimbursable under Medicare. This represents a significant barrier to health care professionals who wish to incorporate these important self-management activities into their practices.

### Targets for Self-Management: General Practices

Health care professionals must specify behavioral targets and have concrete goals for self-management that patients can understand and accomplish. For example, a number of screening behaviors should be a part of every geriatric practice (see Chapter 9). These include colon screens, breast examinations, skin cancer screening, prostate examinations, bone mineral density, and physical disability. Without having specific action plans in place to ensure participation in these screenings, adherence rates will suffer. Here are some suggestions, based on the framework we proposed earlier:

1. Underscore the threat of electing not to be screened.
2. Schedule visits for patients, as opposed to simply suggesting that screening be completed.
3. Systematically monitor screening tests for each patient and be certain that feedback is provided immediately.
4. Schedule follow-up visits immediately when test scores are abnormal.
5. Display rates of participation in screening tests by patients in your practice in highly visible areas and set goals of 100% participation.

With older adults, take time to evaluate and advise on health behaviors, such as (1) caloric consumption, (2) healthy eating practices, (3) smoking behavior, (4) level of physical activity, and (5) depression/anxiety. Simply telling the patient, "You seem to be doing fine," might be well intended, but that feedback lacks clarity and may be deceiving. For example, when older adults have two comorbidities, they are at risk of future decline in functional independence. If they consider this risk normative, and the health care professional says they "seem to be doing fine," they may not try to do anything to

TABLE 28-7

## The Short Physical Performance Battery (SPPB)

COMPONENT	SCORE RANGE	DESCRIPTION OF TASK
Balance tests	Either 0 (unable to hold for 10 s) or 1 (held for 10 s)	Side-by-side stand: participant stands with feet side by side and attempts to hold for 10 s without moving feet.
	Either 0 (unable to hold for 10 s) or 1 (held for 10 s)	Semi-tandem stand: participant stands with one side of heel touching the big toe of the other foot and attempts to hold for 10 s without moving feet.
	Either 0 (held for less than 3 s) or 2 (held for 10 s)	Tandem stand: participant stands with one heel directly in front of toes of other foot and attempts to hold for 10 s without moving feet.
Gait speed test	Between 0 (unable to do the walk) and 4 (took less than 4.82 s)	Participant walks 4 meters at their usual pace, while HCP times them with stopwatch.
Chair stand test	If cannot do, end test here. If can do, move to repeated chair stand test.	Participant folds arms across chest while sitting in a chair and then attempts to stand up without use of arms.
Repeated chair stand test	Between 0 (could not perform five in a row or took longer than 60 s to complete) and 4 (performed five in less than 11.19 s)	Participant folds arms across chest while sitting in a chair and attempts to stand up and sit back down as quickly as possible.

SPPB Score Between 0 and 12.

improve their condition. Feedback and guidance must be specific for individuals to understand their health status. General feedback can unintentionally reinforce a counterproductive commonsense model of older adults' health status. Patients can complete self-report tests, that evaluate their lifestyle behaviors either prior to their visits or while they are waiting to be examined. Results of these self-reports can provide a clearer picture for both partners and build the foundation for ongoing interaction that effective self-management requires.

### Targets for Self-Management: Assessing and Acting on Physical Disability

Because the loss of mobility is such a catastrophic health event for older adults, brief assessments with specific recommendations promoting active lifestyles should be performed on a regular basis (see Chapters 11 and 115). Increased physical activity has preventive value not only for mobility loss but also in managing multiple health problems. According to data from the Centers for Disease Control and Prevention (CDC), physicians ask 56.6% of 65- to 79-year-old adults about their level of physical activity, decreasing to 38.9% of those  $\geq 80$  years old. Physicians only give 12.6% of adults, older than 65 years, assistance in structuring an exercise program. Moreover, even when assistance is given, no information is provided on how to successfully self-manage it, and systematic follow-up is poor.

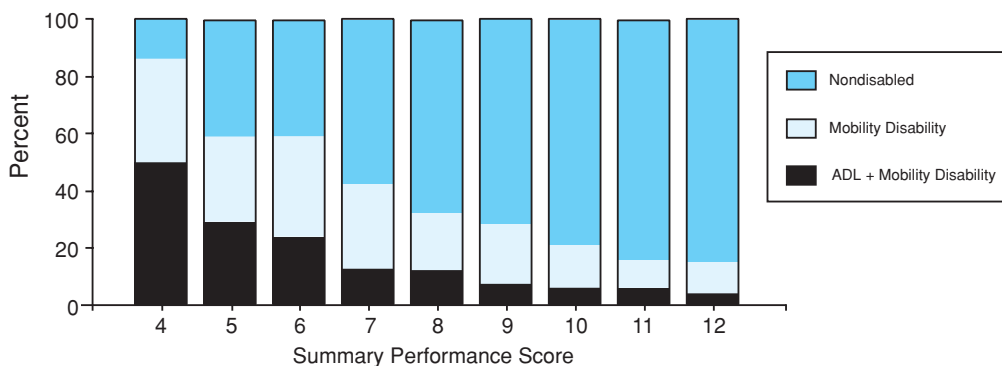

Physicians report that they do not counsel patients because they lack practical tools, time, reimbursement, and confidence that it will trigger the desired behavior change.

There are some simple tools for assessing physical capacities of older adults (Chapters 11 and 115). One is the SPPB, which takes approximately 10 minutes, can be conducted by a nurse or trained volunteer, and involves three tasks: walking 4 meters, completing a simple chair-sitting exercise, and performing two very brief static balance tests. Results from this test have been shown to predict both morbidity and rates of nursing home admissions (Table 28-7 and Figure 28-10).

Our own research has found that SPPB test results have a motivational effect on older adults. Given this specific feedback, they are more responsive to receiving and seeking information about remedial physical activity to enhance their basic performance. Fortunately, an increasing number of community-based programs offer physical activity for seniors.

As a closing guide, we offer additional practical suggestions on how to maintain adherence from the classic textbook by Meichenbaum and Turk (pp. 244–251).

1. *Anticipate nonadherence:* There are a variety of reasons for nonadherence; some of which neither the health care professional nor the patient can control. Do not treat it as a sign of failure on your part or typecast older adults who struggle with self-management

**FIGURE 28-10.** Disability status assessed 4 yrs later among those nondisabled at baseline based on baseline SPPS score. (Guralnik JM, Ferrucci L, Simonsick EM et al. Lower-extremity function in persons over the age of 70 as a predictor of subsequent disability. *The New England Journal of Medicine*. 1995;332:556–561.)

as nonadherers. Either response is destructive to the process of mutual problem solving.

2. *Consider self-management from the patient's perspective and establish a collaborative relationship:* Carefully study the inhibitory factors discussed earlier in this chapter. Understanding them can lead to a renewed appreciation of the challenges that patients face and result in renegotiating more realistic self-management goals. Meichenbaum and Turk remind us that: "An acceptable regimen that is carried out appropriately is better than an ideal one that is ignored" (p. 247).
3. *Be patient oriented:* Health care professionals should gain knowledge of their patients' commonsense understanding of their disease or functional problem and the proposed treatment. Listen carefully to what patients say and to what they do not say. For example, are patients really not listening when they say nothing? Perhaps they are embarrassed about their lack of understanding. In addition to clear instruction from the health care professional, patients should articulate their understanding of what the health care professional said.
4. *Customize treatment:* As part of self-management, the health care professional must be prepared to work with the patient to adjust and to modify standard protocols.
5. *Use family or significant other support:* Because other people can facilitate or hinder older adults' self-management, family and/or significant others must be included in the health care partnership. They should understand the chronic disease, the nature of the treatment, and the goals of self-management. The obvious benefit is their support for the approach being taken without eliminating or blocking the older adults' role in the self-management process.
6. *Provide accessibility and continuity of care:* If patients find difficulty gaining access to health care professionals, if your staff does not show the same interest and care as you, and if you do not draw on other health care professionals and community programs that could assist in treatment (for example, psychosocial specialists for depression; exercise rehabilitation specialists for older adults), self-management has a greater risk of failure. Developing an integrated, highly communicative group of health care professionals is essential for effective self-management, although challenging under the existing fragmented health care system and lack of reimbursement.
7. *Repeat everything and do not give up:* Intervention research in a variety of areas suggests that, for chronic problems, patients must

be "re-inoculated." Long-term maintenance requires repeating education and behavioral practice about treatment regimens and modifying the self-management approach to counter declines or lapses in adherence.

# Rehabilitation

Cynthia J. Brown ■ Claire Peel

## DEFINING REHABILITATION

The purpose of rehabilitation is to restore some or all of a person's physical and mental capabilities that have been lost as a result of disease, injury, or illness and to help achieve the highest possible level of function, independence, and quality of life. The techniques and modalities used to achieve these goals are numerous and typically do not differ for younger versus older persons. However, rehabilitation outcomes and approaches are frequently different for the older adult. For example, most young adults experience a single acute event that results in disability. Older adults are more likely to have multiple comorbid conditions that, over time, result in disability. Even if the older persons have acute events, like a hip fracture or a stroke, their underlying comorbid conditions may impact on the outcomes of rehabilitation. Older patients may also have subclinical physical or cognitive comorbidities, which become evident when challenged by a new disability. For example, mild cognitive impairment may be first recognized during rehabilitation after a hip fracture, when the patient has difficulty learning how to use a new assistive device.

Goals of rehabilitation for older adults usually focus on recovery of self-care ability and mobility, while for younger persons reentering the work force or returning to school may be the goal. In general, recovery for older adults requires a longer period of time to achieve, and functional outcomes are usually worse when compared with younger adults. It is important to discuss rehabilitation goals with all patients and focus therapy toward achieving those goals. For example, older persons may have been avid golfers or fishermen, and return to this activity may be important for their quality of life. Rehabilitation efforts and goals of care may also be impacted by a person's values and beliefs about exercise and social roles. For example, if a patient has never cooked and does not believe that this is an important task to learn, taking the patient to the kitchen to learn how to prepare a meal may be viewed as a useless task. Participation by the patient and family in the development of the goals of rehabilitation is critical to achieve a successful outcome.

Disability is common in older persons and can have a significant impact on function and quality of life. In order to better understand the process of disablement, a variety of theoretical models have been explored and are presented below.

## History of the Disability Framework

In an attempt to provide a framework for the discussion of the consequences of disease and injury, Nagi developed the first disablement model in the 1960s (Figure 29-1). The model uses four related yet distinct phenomena considered by Nagi to be the basis of rehabilitation and include active pathology, impairment, functional limitation, and disability. Active pathology was described as a disruption in the normal cellular function and the body's efforts to regain a normal state. Impairment, which usually results from active pathology, referred to an abnormality or loss at the tissue or organ level. Functional limitation described restrictions at the individual level, while disability described a physical or mental limitation in a social context. Nagi's view of disability was a product of the interaction between individuals and their environment. Importantly, individuals could have similar functional impairments that result in different patterns of disability, depending on the environment in which they function.

In 1980, the World Health Organization's (WHO) *International Classification of Impairments, Disabilities, and Handicaps* (ICIDH) was developed in Europe. Like Nagi's disablement model, the ICIDH characterized three distinct concepts related to disease and health conditions: impairments, disabilities, and handicaps. While the ICIDH was developed to classify function and disability, it failed to receive endorsement by the World Health Assembly. A major criticism of these early disablement models was that these presented the response to disease or illness as a static process with a linear progression through the disablement process. It was recognized that the interaction between disease and disability is more complex, particularly for older persons. Recognition of this complexity led to

**FIGURE 29-1.** Schematic of the Nagi disablement model with definitions. The first disablement model was described by Nagi in the early 1960s. The initial disablement model focused on a linear progression to disability and has been replaced over time with new models such as the International Classification of Functioning, Disability, and Health (ICF). Importantly, the Nagi model was the first attempt to describe the process of disability. (Jette AM. *Toward a common language for function, disability, and health. Phys Ther.* 2006;86(5):726.)

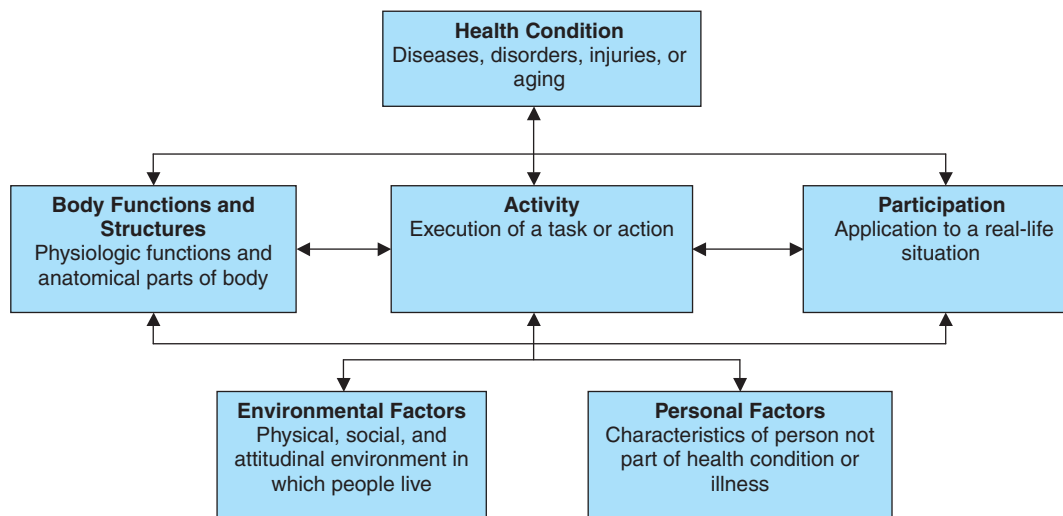

significant dialogue within the rehabilitation community and to a major revision of the ICIDH.

In 2001, the WHO released the *International Classification of Functioning, Disability and Health* (ICF) (Figure 29-2), which attempted to incorporate, from a biological, personal, and social perspective, a biopsychosocial view of health. The ICF characterizes decreases in function as the consequence of a dynamic interaction between various health conditions and contextual factors. Health conditions are described as diseases, disorders, injuries, or aging. Contextual factors are divided into two categories: environmental factors and personal factors. Environmental factors include the physical, social, and attitudinal environment in which people live. These might include individual environment like furniture placement in the home or societal environment like policies regarding access to buildings. Personal factors are characteristics of the individual, which are not part of the health condition or illness. These might include gender, fitness, or coping styles. Listed across the center of the model are the three domains of human function: body functions and structures, activities, and participation. Body functions and structures are the physiologic functions and the anatomical parts of the body. The execution of a task or action by a person is an activity, while participation is the application to a real-life activity. For each of these three domains of human function, there are several levels on which

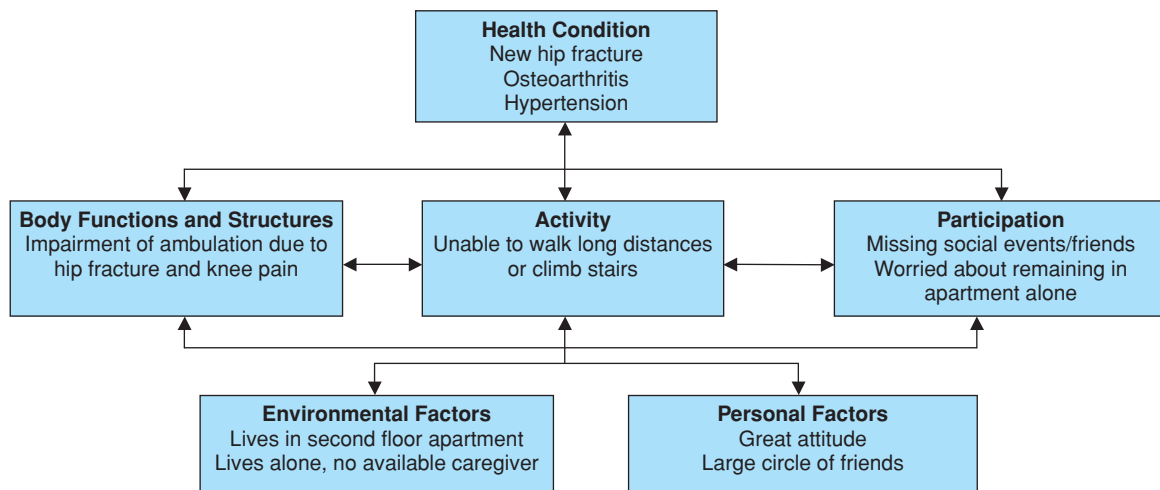

the function can be experienced. These include functioning at the level of the body or body parts and the level of the whole person and the whole person in their environment. Disability is defined as any decline at any of these levels.

Using the ICF model, we could describe an older woman who has a history of osteoarthritis of the knees and hypertension who presents to rehabilitation after a hip fracture. She lives alone in a second-floor apartment and has a daughter who lives at a distance 6 hours away. The patient has a large circle of friends and regularly attends social gatherings at the local senior center. Figure 29-3 demonstrates how this patient's problems might be placed in the ICF model, with the goal of generating hypotheses about the best treatment options. Important issues include not only improving the patient's strength and walking ability but also addressing where she will live after discharge and how to keep her active in her community. Understanding the relationships between the different components and addressing them is the key to a successful rehabilitation.

It is believed by many that the ICF framework has the potential to provide a standard disablement language, which could facilitate dialogue across disciplines. The ICF model attempts to reflect the interactions between different components of health and avoids the linear view of previous models. This framework also looks beyond

**FIGURE 29-2.** International Classification of Functioning, Disability and Health (ICF). The latest version of the ICF focuses on the interaction between various factors and the impact these factors have on health and functioning. Prior models focused on disability and portrayed the path to disability as a linear process. This model attempts to incorporate, from a biological, personal, and social perspective, a biopsychosocial view of health. (Reprinted with permission of the World Health Organization. *Towards a Common Language for Functioning, Disability and Health: ICF.* Geneva, Switzerland. 2002.)

**FIGURE 29-3.** Using the ICF model to describe patient function. This figure demonstrates how a patient's problems might be placed in the ICF model with the goal of generating hypotheses about the best treatment options. In the case of this patient with osteoarthritis and new hip fracture, the ICF model illustrates how addressing where the patient will live after discharge and how to keep the patient active in the community are as important as improving the patient's strength and walking ability. Understanding the relationships between the different components and addressing them is the key to successful rehabilitation. (Authors' own work using WHO ICF model.)

disease and mortality to focus on how people live with their disabling conditions.

## EVALUATION

### Goals of Evaluation

An important goal of evaluation is to identify the cause of the disability for which rehabilitation is required. While there is frequently a final common pathway for many disabilities, the cause may impact on treatment and outcomes. For example, a person's walking difficulty could be caused by osteoarthritis of the knee or a meniscal tear. For the patient with osteoarthritis, an exercise program focused on strengthening the musculature around the knee has been demonstrated to decrease pain and improve the ability to walk. For the patient with a meniscal tear, surgical intervention may be a better option. Evaluation prior to rehabilitation is also important to identify comorbidities that may directly or indirectly affect rehabilitation outcomes. While the older person may have osteoarthritis causing limited walking ability, they may also have poor cardiac or pulmonary function that further limit walking ability. Another goal of evaluation is to determine the best site for rehabilitation to occur. Several settings are available, including an inpatient rehabilitation facility, a subacute nursing home, or a home. The appropriate setting is usually determined through evaluation of the disability and comorbid conditions that may affect rehabilitation. The next section outlines the evaluation process and focuses on creation of an individual treatment plan that addresses the patient's unique disabilities.

### Disability-Oriented History and Physical Examination

During the initial evaluation, the history and physical examination can help characterize the disability and lead the clinician toward the most effective types of treatment. Determining if the functional

decline occurred suddenly or has taken a more slowly progressive course may be very helpful in determining the cause of the disability. Symptoms associated with a given activity may also help narrow the cause to a specific organ system. For example, while the impairment may be difficulty in walking, the limitation could be caused by shortness of breath or pain with weight bearing. Differentiating the causal pathway, in this case pulmonary versus musculoskeletal, helps to refine the workup required and assists the provider in targeting the appropriate therapy. Functional status and residence prior to the illness or injury may also help guide expectations of rehabilitation.

Table 29-1 lists several brief screening maneuvers, which can be done in the physician's office when evaluating a patient for disability. These assessment tools can be used to quickly assess baseline functional status as well as monitor progress during rehabilitation. If these screening tests are positive, additional testing should be performed, as the screening tests are often not as accurate as more detailed maneuvers. A variety of standardized measures are available to further test function during basic and instrumental activities of daily living.

For example, lifting a heavy book overhead tests shoulder range of motion and strength. If a person is unable to achieve this task, additional range of motion and muscle testing should be done to isolate the cause of the difficulty.

Many of the screening tests listed have normative values and have been well validated for the geriatric population. The short physical performance battery includes three of the screening tests gait speed, timed chair stands and static balance with worse scores being associated with falls, nursing home placement, and mortality. The University of Alabama at Birmingham (UAB) Study of Aging Life-Space Assessment is a validated instrument that measures a person's mobility in the home and community during the month preceding the assessment. Importantly, the Study of Aging Life-Space Assessment goes beyond measuring the individual's ability to perform specific tasks by assessing the person's actual pattern of mobility, which may help identify factors other than physical impairment, such as emotional or socioeconomic factors, which might be limiting mobility.

**TABLE 29-1****Physical Performance Tests Used to Assess Function**

SCREENING ACTIVITY	ATTRIBUTE ADDRESSED	FUNCTIONAL IMPLICATION
Put a heavy book on an overhead shelf	Upper extremity strength and range of motion	Ability to perform housework
Grasp a piece of paper and resist its removal	Pinch strength	Grooming and feeding self
Write a sentence	Fine motor coordination	Feeding self
Timed rise to standing five times*	Lower extremity strength	Ambulation and stair climbing
Gait speed*	Dynamic balance, predicts falls, and morbidity and mortality	Ambulation and general function with ADLs
Standing balance*; feet side by side, semitandem and tandem	Static balance	Balance with progressively smaller base of support
Life space assessment <sup>†</sup>	Mobility within the home and community in the 4 weeks prior to assessment	Addresses factors in addition to physical function that might impair mobility
Rhomberg; standing with eyes closed and assess sway or loss of balance	Proprioception	Ability to balance without visual input

Physical performance measures in the clinical setting. *J Am Geriatr Soc.* 2003;51(3):314; and <sup>†</sup>Peel C, Sawyer-Baker P, Roth DL, et al. Assessing mobility in older adults: the UAB Study of Aging Life-Space Assessment. *Phys Ther.* 2005;85:1008–1019.

In addition to the history and physical examination, an evaluation should include assessments of cognition, motivation, depression, social support, and financial resources, as these factors can have a significant impact on rehabilitation outcomes. A variety of validated assessment tools can be used to screen for cognition and depression, such as the Geriatric Depression Scale or the mini mental state examination. Assessment of current methods utilized by the patient for coping with disability, including use of assistive devices, level of assistance needed, and any limitation of activities, should also be explored.

### Determining Rehabilitation Potential

Many factors influence the choice of who would benefit from rehabilitation and the success of those rehabilitation efforts. Assessment for rehabilitation potential needs to be done when the acute medical illness has resolved. A patient with a hip fracture and concurrent delirium may do poorly on initial assessment but, once the delirium clears, may progress nicely with rehabilitation. At times, the medical condition will need to be treated concurrently with rehabilitation efforts. After a prolonged ICU stay, a patient may have significant orthostatic hypotension, which will resolve as they regain the upright position during rehabilitation. Table 29-2 lists a variety of acute medical illnesses that might delay referral to rehabilitation until these are resolved.

Other determinants of rehabilitation benefit include motivation, cognition, and prior functional status. Comorbid illness may have a significant effect on rehabilitation efforts and may even cause a change in rehabilitation approaches. For example, a patient with chronic obstructive pulmonary disease (COPD) on home oxygen who falls and fractures a hip may not be able to tolerate more than 5 minutes of therapy at one time. The rehabilitation approach might be changed to include frequent walks of short duration by therapy and nursing, as opposed to an hour-long therapy session twice a day. Table 29-3 lists a variety of factors that might influence either the use of rehabilitation or the goals of the rehabilitation. In some cases, like terminal illness with a short life expectancy, the goals of

care may need to be addressed with the patient and family, and palliative care may be a more appropriate option. For other factors, like lack of motivation, well-defined patient-centered goals that are easily measured may help overcome this potential obstacle.

After careful evaluation, including a disability-oriented history and physical examination, assessment of factors that may impact on rehabilitation outcomes, and the development of goals with the team, including the patient and the family, we are ready for the final step prior to initiation of rehabilitation, choosing the site for rehabilitation. Determining the optimal setting in which rehabilitation

**TABLE 29-2****Factors for Which Rehabilitation May Need to be Delayed Until Resolved**

FACTOR OF INTEREST	REASON FOR POSSIBLE DELAY IN REHABILITATION
Delirium or altered level of consciousness	Unable to cooperate or learn
Hemodynamic instability	May make it unsafe to carry out certain types of exercise
Occult fracture and bony metastasis	Weight bearing or resistance exercise could worsen fracture or cause fracture
Acute infections (e.g., bladder infection and pneumonia)	May cause confusion, fatigue, and/or hypotension
Acute skin or joint infection	May cause fatigue, pain, and/or muscle splinting
Acute inflammatory disease (e.g., certain rheumatologic and neuromuscular conditions)	Resistive exercises may impair recovery
Acute orthopedic conditions	Joint instability may preclude use of certain exercises, and functional goals may be limited

Adapted from Hoening H and Cutson T, *Geriatric Rehabilitation*. In: *Principles of Geriatric Medicine and Gerontology*, Ed. Hazzard WR, Blass JP, Halter JB, Ouslander JG, Tinetti ME. 5th edition, McGraw-Hill; 2003.

**TABLE 29-3****Factors That May Influence the Success of Rehabilitation Interventions**

Cognitive Impairment	Goals may be more limited. Take advantage of skills patient already has, use interventions that do not require carryover.
Disability has been present for many years	Goals may be more limited and directed to compensatory strategies or treatment of deconditioning.
Motivation is limited	Goals need to be well defined and reached in measurable steps.
Patient had prior rehabilitation for the same problem	Rehabilitation may be limited unless new functional decline has occurred.
Terminal illness	Intervention is directed toward reducing care giver burden and patient discomfort.
Severity of disability	Extremely mild disability may not require intervention. Extremely severe disability may have very limited potential for benefit.
Social and cultural circumstances	Absence of a caregiver, financial limitations, and cultural beliefs may preclude use of certain techniques or technologies.
Malnutrition	Unable to build muscle; rehabilitative interventions may be limited unless nutritional status is improved.

Adapted from Hoening H and Cutson T, *Geriatric Rehabilitation*. In: *Principles of Geriatric Medicine and Gerontology*, Ed. Hazzard WR, Blass JP, Halter JB, Ouslander JG, Tinetti ME. 5th edition, McGraw-Hill; 2003.

should occur is based on many of the factors previously evaluated, as well as patient preference.

## COMPONENTS OF REHABILITATION

### The Organization of Rehabilitation

#### Settings for Care

A variety of settings are available, both inpatient and community based, in which to receive rehabilitation services. It is important for the provider to understand the range of available settings and the advantages and disadvantages of each setting. While the provider may be responsible for helping match the patient to the optimal setting, insurance and cost also play a role. Rehabilitation services are available through Medicare Part A on a time-limited basis. Patients must demonstrate that they are making progress with rehabilitation in order to qualify for services.

Inpatient rehabilitation is offered in rehabilitation centers and Medicare-skilled nursing facilities. In order to qualify as a Medicare-certified inpatient rehabilitation hospital, a certain percentage of all admitted patients must have at least one of 13 conditions, which include diagnoses like stroke, burns, and neurological disorders. Patients must be managed by an interdisciplinary team of skilled nurses and therapists, be seen daily by a physician, and have 24-hour rehabilitation nursing care. Rehabilitation is intensive with patients receiving a minimum of 3 hours of therapy daily. As the rehabil-

itation center offers 24-hour-a-day medical care, patients in need of close medical supervision during therapy can receive it. However, the patient must be able to tolerate the intensity of therapy provided, which may be difficult for the older patient.

Like the rehabilitation center, Medicare-approved skilled nursing facilities must provide 24-hour nursing care. While physicians must be available 24 hours a day, they are just supervising care and can visit the patients less frequently. Multidisciplinary care may not occur, although therapy services, dietary, pharmacy, and social services are available. There are no requirements for intensity or duration of therapy sessions, or any required case mix. This setting allows for a slower rehabilitation pace, which may be necessary for some older patients with multiple comorbid diseases. The availability of 24-hour nursing care is also a benefit for persons who are unable to care for themselves or who do not have caregivers at home.

Home health benefits for rehabilitation are also available through Medicare to patients who are defined as “homebound.” This includes patients for whom leaving the home is difficult or who require help of another person to get out of the home. Part-time nursing and therapy services are available if prescribed by a physician, and these services must be recertified every 60 days. While the intensity of the rehabilitation is less and the nursing services are part time, many patients prefer rehabilitating in their own home. If the patient has the necessary support system, this can be an excellent option.

While a number of studies have examined the effect of the rehabilitation setting on outcomes, the results remain unclear. For patients with hip fracture, the setting of care does not appear to have an impact on outcomes. After a stroke, patients who are treated in inpatient rehabilitation hospitals or special stroke units are more likely to be discharged to home and with improved function. Ultimately, factors such as patient prognosis, level of medical and nursing care needed, and intensity of therapy the patient can tolerate will help determine the optimal setting for rehabilitation.

#### Rehabilitation Providers

An interdisciplinary team is often required to meet the complex rehabilitation needs of older patients. While team members have defined roles and functions, there is considerable overlap in the services provided. For example, while the physical therapist may focus on transfer and gait training, the occupational therapist may also encourage practice of transfers while performing self-care skills. In addition, there are different levels of education and licensure required for different providers. Table 29-4 outlines the types of rehabilitation providers and their usual methods of evaluation and treatment.

Key members of this interdisciplinary team are the patient and the family. An important component of chronic disease management is patient self-management, and patients must be active participants in the decision-making process. The team is responsible for establishing goals, in collaboration with the patient and the family, and developing a treatment plan to achieve those goals. In addition to teaching the patient, a key component of rehabilitation is training the caregiver or family. Specifically, caregivers must be taught how to assist with exercise programs ambulation and ADLs. The caregiver may need to know how to use adaptive equipment or even how to transfer the patient safely, if the patient is not independent with this task. Communication among all team members, including the patient and their family, is critical for success.

**TABLE 29-4****Rehabilitation Providers and Typical Methods Used for Evaluation and Treatment**

PROVIDER	PRIMARY METHODS OF EVALUATION AND TREATMENT
Physical therapist	<ul style="list-style-type: none"> <li>• Assessment of joint range of motion and muscle strength</li> <li>• Assessment of gait and mobility</li> <li>• Provision of appropriate assistive devices</li> <li>• Exercise training to increase range of motion, strength, endurance, balance, coordination, and gait</li> <li>• Treatment with physical modalities (heat, cold, ultrasound, massage, and electrical stimulation)</li> </ul>
Occupational therapist	<ul style="list-style-type: none"> <li>• Evaluate self-care skills and other activities of daily living</li> <li>• Home assessment</li> <li>• Self-care skills training; recommendations and training in use of assistive technology</li> <li>• Fabrication of splints and treatment of upper extremity deficits</li> </ul>
Speech therapist	<ul style="list-style-type: none"> <li>• Assessment of all aspects of communication</li> <li>• Assessment of swallowing disorders</li> <li>• Treatment of communication deficits</li> <li>• Recommendations for alterations of diet and positioning to treat dysphagia</li> </ul>
Nurse	<ul style="list-style-type: none"> <li>• Evaluation of self-care skills</li> <li>• Evaluation of family and home care factors</li> <li>• Self-care training</li> <li>• Patient and family education</li> <li>• Liaison with community</li> </ul>
Social worker	<ul style="list-style-type: none"> <li>• Evaluation of family and home care factors</li> <li>• Assessment of psychosocial factors</li> <li>• Counseling</li> </ul>
Dietician	<ul style="list-style-type: none"> <li>• Assess nutritional status</li> <li>• Alter diet to maximize nutrition</li> </ul>
Recreation therapist	<ul style="list-style-type: none"> <li>• Assess leisure skills and interests</li> <li>• Involve patients in recreational activities to maintain social roles</li> </ul>
Prosthetist	<ul style="list-style-type: none"> <li>• Makes and fits prosthetic limbs</li> </ul>
Orthotist	<ul style="list-style-type: none"> <li>• Makes a variety of orthotics including braces, ankle-foot orthoses, splints, and shoe inserts</li> <li>• Assesses fit of orthotics</li> </ul>

## Process of Care: Rehabilitation Interventions

A variety of interventions are available to treat physical impairments and disability. The selection of intervention strategy is determined by the results of the assessment. All interventions should either directly or indirectly lead to an improvement in function and/or quality of life. Major categories of interventions include (1) exercise/physical activity; (2) modalities including thermal agents, electrotherapy, and phototherapy; (3) adaptive aids such as walkers, canes, and devices to improve activities of daily living; and (4) orthotics (splints and braces) and prosthetics (artificial limbs).

### Exercise/Physical Activity

**General Principles of Exercise** Exercise, also referred to as physical activity, is the cornerstone of physical rehabilitation. Each exercise

prescribed for a patient should be related to achievement of a goal, and all goals should lead to improvement in function. For example, a common exercise for patients is elbow and shoulder flexion. Typical goals related to these exercises are feeding oneself, dressing oneself, or reaching over head to retrieve an item from a shelf. The expected functional outcome for each exercise should be shared with the patient and his/her family. The involvement of the patient and the family is important to maximize compliance.

In setting goals for exercise programs, it is important to consider any pathology that is present. If there is irreversible damage to the neuromuscular system, then the potential for improvement in muscle function is limited. Amyotrophic lateral sclerosis is an example of a pathology in which improvement in muscle function is limited. However, in most cases, decline in muscle strength results from a combination of pathology and deconditioning occurring secondary to inactivity. The deconditioning component is reversible, and therefore some improvement in muscle strength is possible.

A common question often asked is whether exercise is safe for older adults. The number of adverse events reported as a result of exercise in adults is relatively low, with adverse events being more common with vigorous exertion and in persons with atherosclerotic heart disease. To facilitate a safe response, close monitoring before exercise, during exercise, immediately after exercise, and 24 hours after exercise is important. In addition, prior to the initiation of an exercise program, it is important for medical conditions such as congestive heart failure and diabetes to be stable and under optimal medical management. Exercise should be supervised initially to assure appropriate changes in heart rate and blood pressure. There is an expectation that minor muscle soreness will occur with most types of exercise, and patients should be counseled to expect some discomfort. Some patients with osteoarthritis may actually experience a decrease in joint discomfort with exercise. Because increased activity typically has a positive effect on insulin resistance, patients with diabetes may experience a need for less medication to control blood glucose levels.

For exercise to cause a change in physical function, the body must be stressed greater than the usual stress of everyday life. Therefore, it is important that patients are challenged in their exercise programs. For example, when a patient achieves a specific goal, such as walking 30 m at 0.5 m/s, the goal needs to be increased to a greater distance and/or speed. In comparison to younger adults, older adults need a longer recovery time both during an exercise session (between bouts) and between sessions. Improvement may also take longer for older versus younger adults, which should be considered when setting timeframes for the achievement of goals.

There are many classification systems for types of exercise. In the following discussion, we will describe exercise types based on the anticipated outcome, including exercise to increase muscle strength, endurance, balance, flexibility, and motor control.

**Exercise to Increase Muscle Strength** A typical exercise program to increase muscle strength involves movements performed against resistance. The resistance can be weights, rubber tubing or bands, or the person's own body weight. To achieve optimal results, the resistance should be 60% to 80% of the person's maximal lifting ability. For the majority of older adults who are starting an exercise program, it is wise to begin at a lower level (approximately 40%–50% of maximal capacity) until the person has mastered the movement patterns.

Sarcopenia refers to the age-related decline in muscle strength, which naturally occurs as we age. At approximately 50 years of age, individuals begin to experience a decline in muscle strength. This decline in muscle strength typically does not interfere with function until persons are 70 years or older. The cause of the decrease in muscle function is thought to be multifactorial and may include changes in muscle metabolism, endocrine alterations, and nutritional factors. One of the most effective treatments is high-intensity resistance exercise training.

Adequate muscle strength is essential to both balance and gait. A positive correlation has been shown between lower extremity muscle strength and gait speed, demonstrating that persons with higher levels of muscle strength walk faster. Balance is determined both by sensory input and by motor output. Even if sensory input is appropriate and the person senses as if they are falling, without adequate muscle strength, the individual will fall.

Bone density can be positively affected by exercises designed to increase muscle strength. Prior to initiating a program to increase muscle strength, it is important to know the individual's bone status, or the extent and location of osteoporosis and/or osteopenia. In persons with osteoporosis, the amount of resistance may need to be modified to avoid overstressing bones and causing a fracture.

**Exercise to Increase Endurance** Exercise programs, designed to increase endurance, involve continuous activity (such as walking, cycling, and stair stepping), usually performed for at least 20 minutes at an intensity that is 50% to 80% of one's maximal oxygen consumption. Older adults who are beginning a program may need to start with 5 to 10 minutes of continuous activity at a lower intensity. In fact, several sessions of shorter duration (i.e., 10 minutes) per day have shown similar benefits as one session of 30 minutes. To achieve benefits, endurance training needs to be performed three to five times per week. For older persons in rehabilitation programs who have physical limitations, the specific activities may need to be modified. For example, cycling may not be possible for a person who has significant hemiparesis after a stroke. Adaptations, such as securing the person's foot to the pedal, may allow the individual to exercise. Moving to another venue, such as a therapeutic pool, may be another option.

A benefit of endurance training is an increase in maximal oxygen consumption, which is defined as the amount of oxygen consumed while performing the maximal workload that one can perform for 2 to 3 minutes. Improving the maximal amount of work that a person can perform is not necessarily a direct benefit because daily activities are performed at submaximal, rather than maximal, levels of exertion. However, with an increase in maximal oxygen consumption, a given amount of submaximal work is performed at a lower percent of maximal oxygen consumption. Consequently, as a result of endurance training, submaximal work expressed as a percent of maximal oxygen consumption is lower. From a functional perspective, activities such as dressing, bathing, and performing housework can be performed with less fatigue and for longer time periods.

Endurance exercise has positive benefits for persons with hypertension, hypercholesterolemia, and obesity. Regular endurance exercise has been shown to decrease resting blood pressure, resulting in either a decrease in the amount of or a need for medications. Although, endurance exercise often does not decrease total cholesterol, many studies have shown positive benefits for High Density Lipoprotein-cholesterol and triglyceride levels. For both treatment

and prevention of obesity, endurance exercise is a key component of a successful program.

Endurance exercise also has benefits for cardiovascular and pulmonary diseases. For persons with angina, participation in a regular endurance exercise program produces an increase in the "anginal threshold," allowing persons to exercise at higher levels prior to the onset of angina. Persons with chronic pulmonary disease typically experience less breathlessness with activities, as a result of a regular exercise program. One of the most effective treatments for claudication is walking to the onset of pain, which ultimately produces an increase in the distance walked prior to the onset of claudication.

**Exercise to Improve Balance** Balance, defined as the ability to remain upright as the body's center of gravity shifts relative to the base of support, declines as people age. The somatosensory, visual, and vestibular systems contribute to our ability to maintain balance. Balance is an essential component to walking because walking involves a continuous shift of the body's center of gravity relative to the base of support.

Balance exercises are important for persons who have fallen or who are at high risk of falls. Exercises are prescribed that are appropriate for the individual's current level of function. For example, low-level exercises may involve standing and shifting one's center of gravity. As the person progresses, he/she may practice standing on one extremity or walking on a balance beam. Exercises performed with eyes closed force the use of the vestibular and somatosensory systems. Exercises performed on altered surfaces, such as foam or carpet, force the use of the visual and vestibular systems. For persons with a specific abnormality of the vestibular system, such as benign positional vertigo, there are specific exercises that often are helpful.

**Flexibility Exercises** The goal of flexibility exercises is to increase range of motion of a body part by increasing muscle length and/or joint motion. The most effective and safe approach is a prolonged, low-intensity stretch of the muscle/joint with limited motion. Having a sufficient amount of motion is important for many functional activities. For example, going up- and downstairs using a reciprocal gait pattern requires at least 90 degrees of knee flexion. Reaching overhead requires 120 to 150 degrees of shoulder flexion and abduction. In addition, sufficient range of motion at the hip and ankle is important for maintaining standing balance. Excessive range of motion, however, decreases stability and can lead to pain, decreased mobility, and falls.

Parkinson's disease is an example of a common condition in older adults in which flexibility exercises are important. Persons with Parkinson's disease assume a flexed posture, resulting in loss of cervical and thoracic extension. Prescribing exercises early in the course of the disease may prevent the severity of the postural abnormalities. Maintaining spinal extension is important to prevent compromise of respiratory capacity, and to minimize gait and balance disorders.

**Task-Oriented Exercises to Improve Motor Control** Older persons may lose their ability to perform tasks because of abnormal tone (spasticity) and/or muscle weakness. Task-oriented exercises are used to improve coordination and motor performance. Constraint-induced movement therapy (CIMT) is one method used to improve motor function. With constraint-induced movement therapy, the stronger, less affected extremity is "constrained" using a cast or mitt. The person is forced to use the affected extremity and practice tasks

needed for daily living. This method typically involves participation in therapy for 4 to 6 hours per day. The approach is based on learning theory and assumes plasticity of the central nervous system with reforming of neural connections after injury. A recent report of a multicenter randomized controlled trial reported greater improvements in upper extremity motor function in persons post stroke with constraint-induced movement therapy compared to conventional treatment.

A second method used to improve walking performance and balance is treadmill training with partial body support. A harness is connected to an overhead system, which is mounted on a treadmill. By providing partial weight support in combination with a speed-controlled treadmill, patients can perform a greater amount of task-specific practice compared to traditional methods of gait training. A recent review of treadmill training with and without body weight support after stroke concluded that there was insufficient evidence at this time to determine if this intervention was more effective in improving walking performance compared to conventional therapy.

**Designing Exercise Prescriptions** Exercise should be prescribed in an individualized manner similar to prescriptions for medications. The components of an exercise prescription include mode (type of activity), frequency (number of times per day or week), intensity (level of exertion), and duration (time of each individual session). Sufficient research is not available to determine the ideal exercise prescription for older adults with the variety of comorbidities that are typically present. However, for some types of exercise, such as moderate- to high-intensity strength training, there is evidence that exercising every other day or every third day is optimal because of the need for recovery time. Because specific guidelines for persons with pathology are not available, pre- and postexercise monitoring is essential. Vital signs and blood glucose levels (if diabetes is present) need to be checked prior to and after exercise. Persons who are beginning an exercise program or increasing their current exercise level need to be asked how they are feeling 24 hours after exercise. Severe muscle soreness or general body fatigue are signs that the exercise stress was excessive.

### Physical Modalities

Physical modalities that are often used with older adults include heat and cold agents, aquatic or pool therapy, electrotherapy, and phototherapy (monochromatic infrared energy—MIRE). For most of these agents, there is limited evidence of effectiveness as a sole intervention. However, when used in combination with other therapies, especially exercise therapy, these modalities can enhance the effectiveness of the overall intervention. The most common indication for use of physical modalities is pain management. Because older adults may have reduced mental status, or impaired circulation and sensation, using modalities in older adults requires caution. Educating patients and their families on the rationale for use of modalities is essential, especially if these are to be used in the home environment.

**Thermal Agents (Including Aquatic Therapy)** Thermal agents include superficial and deep heating modalities and cryotherapy. Physiological effects of heat include increased blood flow and edema, increased extensibility of connective tissue structures, and decreased pain. Superficial modalities primarily increase the temperature of the skin and underlying subcutaneous tissue and include hot packs, heating pads, paraffin, and whirlpool baths. Superficial heat is beneficial

for persons with osteoarthritis, rheumatoid arthritis, and conditions resulting in cervical and low-back pain. The most popular deep heating modality is ultrasound, a form of acoustical energy, which when absorbed by tissues is converted into heat. Ultrasound is often used for tissue contractures, tendonitis, and pain resulting from musculoskeletal disorders. Ultrasound should not be administered close to the brain, eyes, reproductive organs, pacemakers, or arthroplasties.

Cryotherapy includes cold packs, ice massage, cold water immersion, and vapocoolant sprays. Physiological effects of cold include cutaneous vasoconstriction, decreased nerve conduction velocity, decreased spasticity, and increased joint stiffness. Cold therapy provides short-term analgesia and often allows patients to move when movement otherwise would be too painful. Cold therapy should be avoided in persons with arterial insufficiency, impaired sensation, cold hypersensitivity, and Raynaud's disease.

Aquatic or pool therapy is an alternative to physical modalities and/or exercise on land. A therapeutic pool provides a combination of heat and buoyancy for support of upright activities. Patients with muscle weakness and pain often can walk and exercise in a therapeutic pool when movement on land is limited. Because total body heating produces significant vasodilation, patients with cardiac insufficiency may experience chest pain. All patients need to be careful exiting the pool because of the possibility of postural hypotension.

**Electrotherapy** Electrotherapy can be used as an intervention for pain management, muscle activation, wound healing, and urinary incontinence. Transcutaneous electrical nerve stimulation (TENS), a popular treatment for pain, involves placing electrodes over peripheral nerves, nerve roots, or painful areas. The mechanism of action is unclear but probably involves the release of endogenous endorphins in the cerebrospinal fluid, which block pain by binding to opiate receptors. Adverse effects of TENS are minor and typically involve skin irritation secondary to sensitivity to the electrodes or gel. Contraindications to the use of TENS include persons with impaired sensation and/or cognition and persons with either a pacemaker or an implanted cardiac defibrillator. Studies have shown TENS to be effective in the geriatric population for persons with low-back pain, knee osteoarthritis, and carpal tunnel syndrome.

Neuromuscular stimulation is used to activate muscles addressing treatment goals in persons post stroke, spinal injury, or knee surgery. For persons post stroke, electrical stimulation can be used to enhance functional movement patterns, such as contraction of the anterior tibialis muscle to prevent foot drop during the swing phase of gait or contraction of the quadriceps at heel strike during gait. After knee surgery or injury, persons often “forget” how to contract the quadriceps muscle as a result of pain and/or joint effusion. Neuromuscular stimulation can be used to “retrain” the quadriceps muscle counteracting atrophy that occurs with immobilization.

An important difference between normal muscle contraction and electrically induced muscle contraction is the order of recruitment of motor units. With normal muscle contraction, the smaller fatigue-resistant motor units are recruited first, followed by larger, fatigable motor units. With electrical stimulation, the larger-diameter fatigable fibers are recruited first. The consequence is that fatigue occurs fairly quickly with neuromuscular stimulation. Providing adequate rest periods and limiting the duration and frequency of contractions are strategies to lessen fatigue.

Electrotherapy used for wound healing involves application of electric current either directly to a wound or to the skin surrounding the wound. Electrical stimulation is approved for Medicare coverage

for the treatment of stasis, arterial pressure, and diabetic ulcers that have not responded to conventional therapy. Animal and human studies have shown that electrical stimulation increases both DNA and collagen synthesis; directs epithelial, fibroblast, and endothelial cell migration into wound sites; inhibits the growth of some wound pathogens; and increases the strength of scar tissue. The effectiveness of electrical stimulation is demonstrated not only in case reports but also in randomized controlled trials, with the strongest evidence being demonstrated in the treatment of pressure ulcers.

**Phototherapy (MIRE)** Devices that deliver MIRE were approved by the FDA in 1994 to increase circulation and decrease pain. This treatment involves placing pads over the lower leg and foot. The pads contain diodes that emit light energy in the near-infrared spectrum (890-nm wave length). The typical treatment protocol involves 30-minute treatments, three times a week, for a total of 12 treatments. The infrared photo energy is thought to release nitric oxide from hemoglobin. Nitric oxide relaxes smooth muscle cells, dilating blood vessels and improving circulation.

MIRE recently has gained popularity for the treatment of peripheral neuropathy, with the goal to improve sensation and decrease neuropathic pain. Research studies are conflicting with one randomized controlled trial reporting that MIRE was no more effective than placebo in improving sensation. An interesting finding from this study was that both groups (treatment and placebo) showed significant improvements in plantar sensation. This finding may explain why noncontrolled studies have shown improvements in sensation using MIRE. Important implications of the demonstrated improvement in sensation shown in some studies are a lower incidence of falls and foot ulcers and an increase in activity level.

### Adaptive Aids

Adaptive aids include devices that allow persons with physical limitations to participate in activities, such as basic and instrumental activities of daily living, with greater ease and/or less pain. Categories of adaptive aids include mobility aids to assist people to move around within their home and community, bathroom aids to assist with bathing and toileting, and self-care aids that assist with dressing, personal hygiene, cooking, and other activities. It is not unusual for older persons to have devices that they do not need, often as a gift from a friend or relative. The opposite also occurs when older persons need devices that are not prescribed. The devices described below need to be prescribed by a professional, and the patient and family or caregiver need to be instructed in their use. Devices that are used incorrectly can lead to falls and other adverse events. It is often helpful for the professional (typically a physical or occupational therapist) to make a home visit to assess whether the prescribed adaptive devices can be used safely in the patient's home.

**Mobility Aids** Canes are the most popular mobility aid for older adults because they are lightweight and easy to use when space is limited. Canes are used to decrease weight bearing (and pain) in an extremity with an arthritic joint and to improve balance. When adjusted to the proper height, the handle of the cane is at the level of the wrist when the arm is fully extended. Canes should be used in the hand on the side opposite of the involved extremity. The base of support is increased, which improves stability, and the patient can shift weight to the cane when weight bearing on the involved side. Many people will incorrectly use the cane in the hand on the

side of the involved extremity. The cane then acts as a brace for the involved extremity, producing an abnormal gait pattern and limiting range of motion of both the hip and the knee of the involved side. To achieve a normal gait pattern, patients are instructed to hold the cane in the hand opposite the involved extremity and advance the cane and the involved extremity simultaneously. Patients then swing thru with the uninvolved extremity while bearing weight on the cane and, to a lesser degree, the involved extremity. For stairs, patients are taught “up with the good and down with the bad.” To ascend the stairs the uninvolved extremity is advanced up the stairs first, while the involved extremity and the cane remain on the lower step. To descend the stairs, the involved extremity and the cane are lowered first and then the uninvolved extremity descends to the same step. For persons with decreased sensation in the lower extremities, a cane can also provide proprioceptive input to the brain by transmitting information from intact proprioceptors in the hand.

Two major types of canes are straight canes and quad canes. Straight canes are usually made of aluminum or wood, with a variety of handles available. Quad canes are aluminum canes with a four-legged base. One advantage of a quad cane is that the cane does not fall if the person releases the handle. A disadvantage of some quad canes is that the base is too large to place on stairs, making stair climbing difficult.

Crutches are usually not used with older adults because a higher level of coordination and skill is required. The two major types of crutches are axillary and forearm crutches. If axillary crutches are used incorrectly, shoulder injury and/or axillary nerve damage can occur. Forearm crutches are more functional because a cuff secures the crutch on the patient's arm allowing use of the hand to manipulate objects. Crutches are usually used to provide bilateral support. However, a single crutch can be used instead of a cane if additional unilateral support is needed.

When a cane does not provide sufficient support, a walker usually is prescribed. Walkers provide bilateral support and are easier to use than crutches. Walkers should be adjusted so that the user maintains an erect posture and is not required to lean forward to reach the walker. There are several types of walkers that vary in stability and function. The standard four-point or “pick-up” walker provides the most stability. The walker is picked up with each step, requiring arm strength and endurance, and producing a slow walking speed. With a two-wheeled rolling walker, the person can use a more normal gait pattern and speed. Having two rather than three or four wheels provides more stability. A four-wheeled walker, called a “rollator,” has hand brakes so that it can be locked when the user is standing up and sitting down. This type also has a platform seat for resting, and a basket for carrying objects. The rollator requires greater skill because of the use of the hand brakes. It is preferred for outdoor use because the wheels are larger and move easier over sidewalks and slightly rough terrain. A final option is the Merry Walker<sup>®</sup>, which provides the maximal amount of support. This type of walker includes front, side, and back bars, and a seat for resting. Merry Walkers<sup>®</sup> are larger and more difficult to manipulate in homes. They are often used in institutional settings for persons with severe balance and coordination deficits.

A wheelchair should be prescribed when the person can no longer walk safely or when walking endurance is low. The wheelchair allows the person to continue to do activities such as shopping that require extended periods of standing and walking. Quality of life is maintained and social isolation is avoided. Two main types of wheelchairs are manual and power chairs. There are many options available

for customizing a chair for individual needs. In considering the optimal chair, both stability and mobility need to be considered. For example, a back height that is too high makes propelling the chair independently difficult, impairing mobility, whereas a back height that is too low may not provide adequate trunk support. There are a variety of manual wheelchairs available with many different features. The width of the seat can range from narrow to wide to accommodate larger persons. Removable arm rests and foot rests are available and make transfers easier and safer. Fixed foot rests are not recommended because they can contribute to falls. Consultation with the Occupational Therapist or Physical Therapist is recommended, as the therapist would know best how to order appropriate parts to maximize function.

Manual wheelchairs are lighter in weight than power chairs and are fairly easy to fold and load into a car for travel. Power chairs and scooters provide enhanced mobility outdoors and in the community. Most power chairs are difficult to maneuver in homes. In addition, a car carrier is needed for travel.

Prescribing a wheelchair for use is an important decision, and the advantages and disadvantages for each patient need to be considered. For patients who are able to walk, having a wheelchair may discourage walking, leading to decreased muscle strength and endurance and increasing the probability of falling. However, not prescribing a wheelchair as walking ability declines can negatively affect quality of life. Patients and families need to be counseled on appropriate use of a wheelchair based on their unique needs.

Table 29-5 illustrates some of the commonly prescribed types of canes, walkers, and power chairs and describes some of the benefits and risks of using the different mobility aids.

**Bathroom and Self-care Aids** For many older adults with physical disabilities, the bathroom is a challenging and unsafe place. Devices are available for use in a typical home bathroom to make activities easier and safer. Grab bars located close to the toilet and shower or tub should be considered for all older adults. Many older adults have

**FIGURE 29-4.** Canes (straight and quad). (Photograph by David T. Gadbois.)

difficulty rising from a regular toilet seat because of the low height. A raised toilet seat can be secured to a regular toilet. For persons who need more assistance, bedside commode chairs are available. Some bedside commode chairs have wheels, and can be rolled over a regular toilet. Tub benches are available for individuals who have difficulty getting out of a regular tub, and shower chairs are available for persons who cannot stand independently to take a shower.

Devices are also available to assist patients with activities of daily living. Occupational therapists can assist with identifying the most appropriate adaptive aids. Some examples for dressing include aids to assist with manipulating buttons, securing pants, and putting on/off shoes and socks. For eating, enlarged handles on utensils and modified plates are available. Having an appropriate aid often results in independence in performing a task versus needing to ask for assistance.

**Electronic Devices (Environmental Control Units/Augmentative Communication Aids)** Devices are available that use more sophisticated technologies to allow patients a greater degree of independence and enhanced communication. Environmental control units typically are used for patients with severe disabilities to allow turning on/off lights and controlling other electronic devices. Whatever voluntary motion is available is used to control the unit, usually through a joystick, mouth stick, or eye motion. Devices used to enhance communication include communication boards, voice amplifiers, and telephone adaptations. For strategies to enhance communication, consultation with a speech and language pathologist is recommended.

**TABLE 29-5**

**Commonly Prescribed Mobility Aids**

TYPE	EXAMPLE	DESCRIPTION
Canes: straight and quad	Figure 29-4	<ul style="list-style-type: none"> <li>• Easiest to use, provides the most mobility with walking</li> <li>• Provides unilateral support</li> <li>• Supports 15%–20% of body weight</li> <li>• May not provide sufficient support</li> </ul>
Walkers: rolling and rollator	Figure 29-5	<ul style="list-style-type: none"> <li>• Bilateral support</li> <li>• Supports more body weight than the cane</li> <li>• Gait is slower</li> <li>• More difficult to use on stairs and in smaller spaces</li> </ul>
Power chairs: wheelchair and scooter	Figures 29-6 and 29-7	<ul style="list-style-type: none"> <li>• Total body support</li> <li>• Provides community mobility but may be difficult to use in the home</li> <li>• May contribute to decline in strength and walking performance</li> </ul>

### Orthotics and Prosthetics

Orthotics and prosthetics are external devices used to enhance function. Orthoses typically are used to either restrict or assist motion and are named according to the joints or body parts that are affected. For example, ankle-foot orthoses include the foot and ankle, and knee-ankle-foot orthoses extend from the thigh to the foot.

The most commonly used orthoses for older adults are foot orthoses and ankle-foot orthoses. Foot orthoses include shoe inserts and other devices placed inside the shoe. Inserts can be used to relieve pain or to protect insensitve feet. Examples of commonly used foot orthoses include heel spur cushions, scaphoid pads to correct flattening of the arches, and metatarsal pads to transfer weight from the metatarsal heads to the metatarsal shafts. Ankle-foot orthoses are used for patients with either weakness or paresis of dorsiflexors to prevent foot drop during gait. These orthoses can be made of plastic or metal. Plastic orthoses can be interchanged between shoes but do not provide as much support as metal orthoses. Appropriate

**FIGURE 29-6.** Power wheelchair. (Photograph by David T. Gadbois.)

**FIGURE 29-7.** Power scooter. (Photograph by David T. Gadbois.)

use of foot and ankle orthoses can improve function by providing a safe, more comfortable gait.

Many older adults require prostheses because of amputation resulting from vascular disease. In prescribing prostheses for older adults, important considerations include ease of donning and doffing, stability during activities, and overall function. In persons with severe dementia or advanced cardiopulmonary disease, wearing a prosthesis may not be practical. Persons who are not independent in basic Activities of Daily Living (ADL) skills, such as transferring and dressing, typically are not good candidates for prosthetic use. To achieve the optimal outcome, the patient should be involved in a preprosthetic training program to improve strength and endurance. The physician should work closely with the physical therapist and prosthetist to assure that the prosthesis is evaluated for correct fit and that the patient receives training on use of the prosthesis.

## SPECIFIC CONDITIONS TREATED WITH REHABILITATION

### Pulmonary Rehabilitation

Patients with chronic respiratory diseases frequently experience disability owing to decreased exercise tolerance and symptoms like dyspnea and anxiety. The established benefits of pulmonary rehabilitation include improved exercise capacity, a decreased sensation of dyspnea, and overall improvement in quality of life. The cornerstone of most pulmonary rehabilitation programs is exercise, although other components may include education and behavioral modifications like energy-conservation techniques. As with other rehabilitation programs, pulmonary rehabilitation can occur in inpatient, outpatient, and home settings with equal success. Exercise programs are individually tailored to meet the patients' needs, and patients are usually encouraged to exercise three times a week or more to a level where they experience moderate dyspnea. Training regimens vary, depending on the goal of the rehabilitation. For example, many patients with COPD experience dyspnea with upper body activity, like bathing or grooming. An exercise program that targets strengthening of the arms with elastic bands or light weights helps decrease the dyspnea and work effort required for these tasks. Treadmill or track training will improve walking endurance but not strength, so a variety of training exercises are usually utilized.

The majority of studies have examined the benefit of pulmonary rehabilitation for patients with COPD, and a recent meta-analysis concluded that pulmonary rehabilitation showed both statistical and clinical improvements in dyspnea and disease-specific quality-of-life-measures. Supervised programs offered greater benefit than unsupervised ones, and patients with severe disease appeared to benefit the most when compared to those with mild-to-moderate COPD. However, many questions still remain about what components are essential and how to best assess outcomes after rehabilitation.

### Cardiac Rehabilitation

Cardiac rehabilitation (CR) is increasingly recognized as an important component of a multidisciplinary treatment strategy for patients with a history of myocardial infarction and stable angina and patients after coronary artery bypass graft (CABG) surgery. Many of

the benefits of CR occur through the exercise component of these programs. Exercise training has been found to decrease coagulability, increase fibrinolysis, improve endothelial function by moderating inflammation, and improve endothelium-dependent vasodilation. These beneficial effects can be demonstrated by the reduction in C-reactive protein seen with exercise and the improvement in hyperemic myocardial flow after CR. Disability or functional decline is often associated with a variety of cardiac conditions, and participation in CR can improve fitness and reduce the signs and symptoms of exercise intolerance. This can lead to improved functional independence. In addition to exercise training, CR provides a structured environment for risk factor management through patient monitoring plus support of compliance and adherence. However, despite evidence of the beneficial effects, CR remains underutilized, with a 15% to 25% participation rate among eligible patients.

CR after acute myocardial infarction has been an important component of patient management for several decades. The survival benefit of CR has been well documented by two meta-analyses. These studies demonstrated a reduction of 20% to 24% total mortality, with a 22% to 25% reduction in cardiovascular mortality at 3 years of follow-up. Importantly, CR is a cost-effective way to reduce health care expenditures and recurrent hospitalizations and compares favorably with other well-established therapeutic interventions like cholesterol-lowering and CABG surgery. Older patients with coronary heart disease frequently have a greater severity of disease, with more left ventricular dysfunction and more medical comorbidities leading to decreased exercise tolerance and higher rates of disability. One of the most predictable benefits of CR is improved exercise capacity, making it an ideal therapy for older patients. One randomized controlled study of resistance training in older women with a disability who has a coronary heart disease documented improvement in functional performance, including household activities and endurance tasks such as stair climbing and 6-minute walk distance.

After CABG surgery, most patients have significantly reduced exercise capacity, especially older patients. The goal of CR is to improve peak exercise capacity and return patients to functional independence. Studies have demonstrated that CR after CABG reduces hospital readmissions and can lead to a significant reduction in cardiovascular events when compared to the control group (18.4% vs. 34.7%). The improvements in exercise capacity with CR have translated into a decrease in long-term mortality rates.

For patients with congestive heart failure, randomized clinical trials conducted during the last decade have demonstrated that CR can improve exercise tolerance, quality of life, and disease-related symptoms, without adversely affecting left ventricular function. While there is no consensus regarding the optimal exercise program, guidelines support the use of regular aerobic and/or strengthening exercises. Exercise training induces peripheral and central adaptations, including improvement in vasodilation among active muscle, decreased sympathetic nervous system activation, and increases in peak cardiac output, heart rate, and stroke volume. These adaptations lead to a reduction in the commonly observed exercise intolerance because of fatigue and dyspnea. Using peak oxygen consumption (VO<sub>2</sub>) to measure exercise capacity, improvements have ranged from 15% to 30%. Other common symptoms associated with heart failure such as shortness of breath, ability to perform activities of daily living, anxiety, depression, and general well-being have all been improved with CR. The magnitude of improvement has ranged from 15% to 50% for each of these variables, and improvements in quality

of life can be seen as early as 2 months after initiation of the exercise program. In addition to improvements in symptoms and quality of life, reduction in mortality has also been demonstrated. Increased sympathetic nervous system activity and higher plasma and tissue cytokine concentrations are associated with worsening disease and poorer prognosis in patients with heart failure. Exercise training causes a down-regulation of these systems, with a resultant 28% reduction in total mortality and hospitalization and a 29% reduction in death rate. Prior to initiation of an exercise program, patients must be clinically stable with controlled fluid status for at least 3 to 4 weeks.

The literature demonstrates a beneficial effect of CR for a variety of cardiac diagnoses, including acute myocardial infarction, congestive heart failure, and after CABG surgery. Exercise training positively affects both the basic pathophysiology of coronary artery disease and the underlying disease process. This, in turn, minimizes the impact of disability, improves quality of life, and reduces mortality. Referral to CR increases the likelihood of participation and long-term compliance, which can have significant beneficial effects for the patient.

### Peripheral Arterial Disease

Lower extremity peripheral artery disease is common in older persons, with a prevalence of 16% to 34% in patients older than 65 years. Studies have demonstrated that the optimal exercise rehabilitation program for improving the distance walked prior to the onset of claudication uses intermittent walking to the onset of pain. The increased distance achieved occurs through improvements in cardiopulmonary function, peripheral circulation, and walking economy. Improvements require an exercise program of at least 6 months duration to be effective. Treadmill walking has been shown to be more effective than strength training.

### Amputation

In the United States, approximately 50 000 new major lower extremity amputations are performed each year. The majority of these amputations occur in patients older than 60 years, and peripheral vascular disease and diabetes mellitus account for more than 90% of these amputations. The estimated 5-year survival after amputation is 35% to 40%, and the risk of contralateral amputation in the subsequent 2 years can be as high as 20%.

During the initial postoperative period, goals include relieving pain, preventing medical complications, and preventing mobility problems, particularly muscle atrophy and contractures. Between 60% and 80% of persons undergoing a lower extremity amputation experience phantom limb pain. Approximately 10% of those who experience phantom pain rate the pain as severe enough to be disabling. Conflicting evidence exists regarding the success of adequate pain control preoperative or perioperatively on the incidence of phantom pain. However, there is little controversy regarding the importance of adequate pain control for persons undergoing amputation.

Common medical problems after amputation include poor wound healing, skin breakdown, and falls. Early mobilization with or without a prosthesis is critical for recovery of function. Older persons who already have decreased lean muscle mass are at risk of additional muscle atrophy. Joint contractures occur when patients

spend significant periods of time sitting in a chair or a wheelchair and can have a negative impact on their ability to ambulate with a prosthesis. Initially after amputation, older persons are instructed in the basics of self-care and mobility and then discharged to home. Rehabilitation occurs later after healing of the amputation site and can occur in a rehabilitation facility, in the home, or as an outpatient.

For the older adult, comorbid conditions and premorbid functional status impact the success of the surgery and subsequent rehabilitation. Prior to surgery, the older person should be medically stable, with special attention being paid to cardiopulmonary status. Level of amputation should also be considered. The energy expenditure required for a transtibial amputee is much less than for a transfemoral amputee and may predict a person's ability to regain ambulatory ability. However, while preserving the knee joint may be beneficial, preoperative evaluation should carefully assess the risk and benefit of knee preservation to avoid surgical revisions and longer lengths of stay in the hospital.

Prosthesis use can decrease energy expenditure with transfers and ambulation and should at least be considered, irrespective of age. Firm criteria for prosthesis use do not exist. Some authors suggest using functional status, medical status, and ability to learn as potential markers of success with prosthesis training. These measures would certainly be useful when developing goals for the patient after amputation. A variety of lower limb prosthetic devices are available. To date, studies have not included a large enough sample of older persons to determine the optimal socket or foot design for this population. This determination should be made with the input of the patient, physician, prosthetist, therapists, and insurance company.

### Stroke Rehabilitation

Rehabilitation after stroke begins once the patient is medically stable and initially focuses on prevention of medical complications like pressure ulcers or deep vein thrombosis, minimization of spasticity, encouragement of patients to resume self-care activities, and provision of emotional support to the patient and family. There appears to be a statistically significant and clinically important benefit from organized inpatient interdisciplinary rehabilitation in the postacute period. In several randomized controlled trials, either organized inpatient multidisciplinary rehabilitation or stroke unit care demonstrated improved outcomes, including reduced odds of death. Guidelines for the management of stroke were developed by Veterans Affairs and the Department of Defense and rate the quality of available evidence. The guidelines present algorithms for initial assessment as well as management after rehabilitation referral (<http://stroke.ahajournals.org/cgi/content/full/36/9/e100>).

Techniques used during stroke rehabilitation vary and are tailored to the needs and deficits of an individual patient. Strengthening and task-oriented approaches, like constraint-induced therapy, are common. Facilitation techniques that progress movement to higher-level control by suppressing primitive reflexes may also be used. The goal of therapy, no matter the approach, is improvement of function and quality of life.

After a stroke, patients may have a variety of impairments in addition to muscle weakness. Dysphagia places patients at risk of aspiration and can be silent in up to one-third of patients with dysphagia. Communication disorders including aphasia also occur in one-third of patients, with prognosis being worse for patients of advanced age, or with delayed treatment. During the first month

after a stroke, the incidence of bladder incontinence is 50% to 70%, although it returns to levels seen in the general population by 6 months. Treatment can include timed voiding schedules and monitoring of postvoid residuals. Hemiplegic shoulder pain is also a common occurrence, affecting 34% to 84% of patients post stroke. Major risk factors include advanced age and changes in muscle tone, which occur after the stroke. Treatment involves proper positioning to avoid joint subluxation and early range of motion exercises to prevent contractures and spasticity. There is some evidence that electric stimulation can improve hemiplegic shoulder pain for up to 6 months after treatment. Depression is another frequent complication after stroke, one that can have a significant negative effect on rehabilitation. Incidence ranges from 15% to 70% depending on the study, and several antidepressant medications have been associated with improvement. An organized, interdisciplinary team approach helps to address these common sequelae after stroke.

### Parkinsonism

Physical manifestations of parkinsonism include muscular rigidity, bradykinesia, postural instability, and gait disturbances. Muscle rigidity and bradykinesia are often manifested by difficulty initiating movement, which causes patients to have significant difficulty performing even simple activities of daily living. Owing to postural instability and gait disturbances, patients with parkinsonism are more likely to experience falls and are at risk of injury owing to slow reaction speed.

At this time, there are no guidelines or generally accepted rehabilitation techniques for persons with Parkinson's disease. Traditionally, therapy has focused on improving posture, range of motion, and gait. There is evidence that exercise programs including resistive and flexibility exercises can improve physical function. One meta-analysis demonstrated improvements in stride length, gait speed, and ADL performance with exercise. Another commonly used technique is an external cueing strategy where auditory pacing, use of a walking stick, or visual cues can help improve gait and decrease episodes of freezing for some patients. Because of the success of rhythmic cueing, studies are being done to explore the use of treadmill training as a method to improve the gait pattern of patients with parkinsonism. Early studies are promising, with a decrease in variability of stride length and swing time being seen. The long-term benefits of all the exercise interventions are still unknown.

### Osteoarthritis and Total Joint Replacement

Osteoarthritis is the leading cause of impaired mobility in older persons because of the associated joint pain, muscle weakness, and atrophy. In persons with osteoarthritis of the knee, the severity of the knee pain is directly correlated with the degree of muscle weakness. Several randomized trials have demonstrated the efficacy of strengthening exercises to lessen pain and improve function. Weight loss combined with strengthening exercises was shown to be more effective than weight loss alone for improving function and reducing pain. If pain occurs with an exercise, that exercise should be avoided, and monitoring by a physical therapist during the initial rehabilitation period is reasonable. Osteoarthritis of the hip is less amenable to exercise, probably because improving strength in the ball and socket hip joint does not provide the same support as strengthening the hinged knee joint.

Total joint arthroplasty is the most common elective surgical procedure done in the United States. The primary indications for arthroplasty are mobility limitation and progressive pain, despite conservative treatments like exercise and use of mobility aids. After total joint replacement, the principal goal is to attain the highest level of functional independence possible. Rehabilitation after a total hip replacement focuses on strengthening exercises and gait training. In the early stages of recovery, patients are taught to avoid crossing their legs and flexing their hips more than 90 degrees, to decrease the risk of hip dislocation. Raised toilet seats are also recommended to prevent excessive hip flexion during the first few months after surgery. After total knee replacement, rehabilitation is focused on pain control, reduction of swelling, improving range of motion, and strengthening the muscles around the knee. Recovery from total knee replacement requires the patient work hard to attain and maintain range of motion during the first few months after surgery, which is distinct from hip replacement surgery.

### Falls

A multicomponent strategy has been demonstrated in a series of randomized controlled trials to be highly effective in reducing falls in all older persons. These successful interventions have included strength and balance training as important components. In one meta-analysis, exercise programs alone have been demonstrated to reduce the risk of falling. Demonstrating a positive effect for environmental modifications has been more difficult, although a recent Cochrane analysis noted that two trials showed a reduction in falls with home hazard reduction.

### Hip Fracture

Hip fractures are common, with approximately 95% being caused by falls. Excess mortality of 12% to 20% has been documented after hip fracture and as much as 80% of those who survive fail to regain their prior level of function. One year after hip fracture, half of the patients who had been independent with walking were no longer independent.

The initial rehabilitation efforts are focused on early mobilization to prevent complications of bed rest, like deconditioning and deep vein thrombosis. Post repair, decreased weight bearing on the fractured limb is standard and patients are taught to walk with an appropriate assistive device. The amount of weight that can be placed on the repaired limb depends on fracture stability. If possible, patients should be allowed to weight bear as tolerated as opposed to "touch-down" weight bearing, which is often difficult for older patients to achieve. A meta-analysis examining outcomes of rehabilitation after hip fracture demonstrated that there was no measurable difference between inpatient rehabilitation and subacute care. The goals of care are the same despite the setting and include lower extremity strengthening, gait and balance training, and assessment of fall risk factors, which might be modifiable.

### Sarcopenia and Deconditioning

While there is considerable variation in the loss of muscle mass with aging, cross-sectional studies indicate that strength declines at a rate of 12% to 15% per decade after the fifth decade. This age-related loss of muscle strength and mass is termed sarcopenia. Sarcopenia leads

to losses of muscle strength, power, and endurance, which are all critical to daily function. The decline in power output, or the ability to contract a muscle quickly, may also be related to an increased risk of falls, as well as difficulty with functional tasks.

A variety of factors appear to impact on the loss of strength, in addition to age. Reduction in anabolic hormones and local growth factors may also contribute to the observed decline. There appear to be gender differences in response to the same exercise program, with older women showing a blunted response to muscle fiber hypertrophy when compared to older men. The most effective resistance programs for older women occur twice a week, suggesting that older women required longer recuperation periods between bouts of resistance exercise. It has been suggested that, in addition to these factors, the frequently observed decline in physical activity may be a significant mediator in the recognized strength and muscle mass loss.

This decline in physical activity, or deconditioning, is often associated with acute illness or chronic disease. Patients with osteoarthritis may limit activity because of pain. As a result, they lose muscle mass and strength, making daily activities more difficult to accomplish. Over time, the patient will tend to perform fewer activities, as they continue to lose strength and endurance. Bed rest during acute care hospitalization can also lead to loss of strength and muscle mass, even after only a few days. The adverse outcomes associated with this low level of activity include functional decline and increased nursing home placement, even after controlling for severity of illness and comorbidities. Early mobilization has been demonstrated to improve functional outcomes for a variety of patients, including those with a hip fracture or pneumonia.

While no consensus exists regarding the optimal training program, numerous studies have demonstrated resistance exercises to be very beneficial in the treatment of sarcopenia and deconditioning. Increased muscle mass and strength occur with loading the muscle at 60% to 80% of one repetition maximum (1RM), two to three times a week. Some researchers also recommend that at least once a week low-intensity, high-velocity resistance training should be done to address the loss of power that occurs with sarcopenia.

Improvement in muscle strength and power through endurance exercise can reduce the difficulty older adults may experience in performing daily functional activities and may promote spontaneous additional physical activity. While sarcopenia owing to aging may not be reversible, other components of the observed decline in physical activity can be ameliorated with exercise.

## Pain

For older persons, pain is common and frequently associated with adverse consequences such as depression, anxiety, and impaired ability to walk. In the community-dwelling older adults, 25% to 50% experience significant pain, and, in the nursing home, rates range from 45% to 80%. Having persistent pain may worsen the level of physical activity achieved, and the associated deconditioning can contribute to further pain and disability.

Many of the physical modalities, such as thermal agents (heat or cold) and electrotherapy, can be very beneficial in relieving pain.

There is evidence that participation in an exercise program can improve pain as well as improve function. The prescribed exercise program needs to be individualized for the patient and focused on improving range of motion, strength, and endurance. For additional information on pain management, the American Geriatrics Society has guidelines on the management of persistent pain in older persons (available at [www.americangeriatrics.org/education/cp\\_index.shtml](http://www.americangeriatrics.org/education/cp_index.shtml)).

## CONCLUSION

Because disability is common among older persons, rehabilitation is an important component of geriatric health care. Defining the cause or causes of disability will allow the rehabilitation team to provide treatment in the optimal setting for the individual patient. Much remains unknown about the most effective rehabilitation techniques for patients with multiple comorbidities; however, available literature supports the continued use of rehabilitation to improve function, independence, and quality of life for older persons.

# Pain Management

*Bruce A. Ferrell* ■ *Susan L. Charette*

## THE OLDER PATIENT IN PAIN

Pain is a common complaint among elderly persons. For ambulatory care visits, pain-related problems are more common than any other complaint. The intensity of pain often correlates with the severity of injury and indicates urgency for treatment. Unrelieved pain, pain that persists, or pain out of proportion to tissue damage, over time, often results in substantial disability and psychological distress.

Epidemiology studies of pain in general populations have suffered from the lack of standard definitions for what might be considered “significant” pain. Nonetheless, studies have suggested that the prevalence of pain in community-dwelling older persons may be as high as 25% to 56%. Sources of pain also vary from study to study. Prevalence of back pain has been reported from 21% to 49.5%; joint pain 20.5% to 71%; and headache 1.2% to 50% in persons older than 65 years. In general, the most common causes of pain in elderly persons are probably related to musculoskeletal disorders such as back pain and arthritis. Neuralgia is common, stemming from diseases such as diabetes, herpes zoster, and trauma such as surgery, amputation, and other nerve injuries. Nighttime leg pain (e.g., cramps and restless legs) is also common, as is claudication. Cancer, although not as common as arthritis, is a cause of severe pain. The distress of cancer pain has brought attention to the obligation that clinicians have to provide effective pain management especially near the end of life. Pain is also common in nursing homes. Between 45% and 80% of nursing home residents may have substantial pain. Many have multiple pain complaints and multiple potential sources of pain. Pain is associated with a number of negative outcomes in elderly people. Depression, decreased socialization, sleep disturbance, falls, adverse drug events, slow rehabilitation, and increased health care utilization and costs have all been associated with either the presence of pain or its treatment in older people. Older patients rely heavily on family and other caregivers near the end of life. For these patients and their caregivers, pain can be espe-

cially distressing. Caregiver strain and caregiver attitudes can have substantial impact on pain.

The approach to pain management is different in elderly versus younger persons. Older persons may underreport pain. They often present with concurrent illnesses and multiple problems, making pain evaluation and treatment more difficult. Elderly persons have a higher incidence of side effects to medications and higher potential for complications and adverse events related to many treatment procedures. Despite these challenges, pain can be effectively managed in most elderly patients. Moreover, clinicians have an ethical and moral obligation to prevent needless suffering and provide effective pain relief, especially for those near the end of life.

## HOW AGING AFFECTS PAIN PERCEPTION

The effect of aging on pain perception has been a topic of interest for many years. Elderly persons often present with altered presentation of common diseases. For example, older persons have been observed to present with apparently painless myocardial infarction and painless intra-abdominal catastrophes. The extent to which these observations are attributable to age-related changes in pain perception remains uncertain. Anatomical studies, as summarized in [Table 30-1](#), have observed some age-related changes in the nervous system that might alter pain perception. Some of these findings include decreased numbers of various pain receptors in the skin and other organs, altered nerve conduction, and some central nervous system changes that may affect sensory processing. Most of these studies were based on cross-sectional studies of animal and postmortem specimens, for which little or no data were actually available, or correlated with the premortem pain experiences.

Likewise, a large number of physiologic studies of pain perception also exist. These studies typically use a heat probe, electrical stimulation, or other methods to induce pain in volunteers in an effort

**TABLE 30-1****Age-Related Changes in Pain Perception**

COMPONENT	AGE-RELATED CHANGE	COMMENTS
Pain receptors	<ul style="list-style-type: none"> <li>• 50% decrease in Pacini's corpuscles</li> <li>• 10%–30% decrease in Meissner's/Merkles disks</li> <li>• Free nerve endings—no age change</li> </ul>	Few studies largely limited to skin
Peripheral nerves	<ul style="list-style-type: none"> <li>• Myelinated nerves               <ul style="list-style-type: none"> <li>◦ Decreased density</li> <li>◦ Increase abnormal/degenerating fibers</li> <li>◦ Slower conduction velocity</li> </ul> </li> <li>• Unmyelinated nerves               <ul style="list-style-type: none"> <li>◦ Decreased number of large fibers (1.2–1.6 <math>\mu</math>n)</li> <li>◦ No change in small fibers (0.4 <math>\mu</math>n)</li> <li>◦ Substance P content decreased</li> </ul> </li> </ul>	Evidence of change in pain function is lacking; findings are not specific to pain
Central nervous system	<ul style="list-style-type: none"> <li>• Loss in dorsal horn neurons               <ul style="list-style-type: none"> <li>◦ Altered endogenous inhibition and hyperalgesia</li> </ul> </li> <li>• Loss of neurons in cortex, midbrain, and brainstem               <ul style="list-style-type: none"> <li>◦ 18% loss in thalamus</li> <li>◦ Altered cerebral-evoked responses</li> <li>◦ Decreased catecholamines, acetylcholine, GABA, and 5HT</li> <li>◦ Endogenous opioids—mixed changes</li> <li>◦ Neuropeptides—no change</li> </ul> </li> </ul>	Findings not specific to pain

Data from Gibson SJ, Helme RD. Age differences in pain perception and report: a review of physiological, psychological, laboratory and clinical studies. *Pain Rev.* 1995;2:111–137.

to identify a pain threshold or pain tolerance level. These studies have shown mixed results, some showing increased, some showing decreased, and some showing no change in pain perception with aging in normal volunteers. Moreover, it has been difficult to conduct a formal meta-analysis using all of these studies because of flaws in many of these studies concerning sampling errors and methodological differences. In the final analysis, most investigators have concluded that actual age-associated changes in pain perception are subtle and probably not clinically significant.

On the other hand, elderly people often present with concurrent illness and sensory impairments that may mask pain complaints. Cognitive impairment, sensory neuropathies, and visual and hearing impairment, each may make communication of pain complaints more difficult and thus appear to be a perceptual problem. Elderly patients may be more stoic; they may expect pain with aging and fear diagnostic tests, other interventions, or the meaning of pain. These issues can make pain assessment and measurement much more difficult in older people.

## CLASSIFICATION OF PAIN

Pain is quite variable in description, character, and intensity among individuals. For the purpose of understanding, predicting, and treat-

ing pain, a variety of classification schemes have been used. For diagnostic purposes, it may be helpful to categorize pain as acute or persistent. The old term “chronic pain” is now considered obsolete, and the newer term “persistent” is used to reduce the common biases and negative stereotypes associated with the label “chronic pain patients” in the past. For treatment purposes, it may be more helpful to categorize pain as nociceptive versus neuropathic.

### Acute Versus Persistent Pain

Acute pain is defined by a distinct onset, obvious cause, and short duration. Trauma, burns, infarction, and inflammation are examples of pathological processes that result in acute pain. Acute pain is often associated with autonomic nervous system signs, including tachycardia, diaphoresis, or elevation in blood pressure. The presence of acute pain usually indicates an acute injury or acute disease, and the intensity of acute pain often indicates the severity of injury or disease. Thus, acute pain should trigger an urgent search for an underlying cause that might be life-threatening or require immediate intervention. The effective management of acute pain is important to facilitate diagnostic tests. Preoperative pain management of acute pain makes anesthesia easier and postoperative pain control better. In some cases, management of acute pain can help prevent development of chronic pain syndromes.

Chronic pain is usually defined by its persistence beyond an expected time frame for healing, usually longer than 3 months. Intensity of chronic pain is often out of proportion to the observed pathology and associated with prolonged functional impairment, both physical and psychological. Autonomic signs are often absent. Underlying causes of chronic pain are often associated with chronic disease and are less remedial.

Chronic pain is often more difficult to manage in older patients because the underlying cause is less curable and many treatment strategies are short lived, difficult to maintain, or associated with long-term side effects. Chronic pain usually requires a multidimensional approach to treatment, including use of both analgesic drug and nondrug strategies with attention to sensory, emotional, and behavioral components of the pain experience.

### Nociceptive Versus Neuropathic Pain

For treatment purposes, it may be helpful to identify the underlying mechanism of pain perception. Treatment aimed at specific pathophysiologic pain mechanisms may be more effective. Pain problems that result largely from stimulation of pain receptors are called nociceptive pain. Nociceptive pain may arise from tissue injury, inflammation, or mechanical deformation. Examples include trauma, burns, infection, arthritis, ischemia, and tissue distortion. Pain from nociception usually responds well to common analgesic medications.

Neuropathic pain results from pathophysiologic processes that arise in the peripheral or central nervous system. Examples include diabetic neuralgia, postherpetic neuralgia, and post-traumatic neuralgia (postamputation or “phantom limb” pain). In contrast to nociceptive pain, neuropathic pain syndromes are often persistent and difficult to treat. They may, however, respond to nonconventional analgesic medications such as tricyclic antidepressants and anticonvulsant drugs. For these syndromes, it is important to recognize them early and to begin treatment with adjuvant analgesic strategies before development of long-term complications of persistent pain including physical and psychological disability.

There are other physiological mechanisms of pain, including mixed nociceptive and neuropathic syndromes and pain syndromes of unknown mechanisms. Treatment for these is more problematic and often unpredictable. Examples include recurrent headaches and some vasculitic syndromes. Finally, psychologically based pain syndromes are those with psychological factors that play a major role in the pain experience. Examples include somatoform disorders and conversion reactions. These patients may benefit from specific psychiatric intervention, as traditional pain strategies are often ineffective.

## CLINICAL EVALUATION OF PAIN

Pain assessment is the most important part of pain management. Any pain complaint that has an impact on physical function or quality of life should be recognized as a significant problem. Unfortunately, there are no objective biological markers of pain. The most accurate and reliable evidence for the existence and intensity of pain is the patient's description.

### Pain History and Physical Examination

Assessment of pain should begin with a thorough history and physical examination to help establish a diagnosis of underlying disease and form a baseline description of pain experiences. The history should include questions to elicit: when the pain started, what events or illnesses coincided with the onset, where does it hurt (location), how does it feel (character), what are the aggravating and relieving influences, and what treatments have been tried. Past medical and surgical history is important to identify coexisting disease and previous experience with pain and analgesic use. The review of systems should probably focus on the musculoskeletal and nervous system because of the frequency of which these pain problems often occur in older persons. Any history of trauma should be thoroughly investigated because falls, occult fractures, and other injuries are common in this age group. Care must be taken to avoid attributing acute pain to preexisting conditions and recognize that chronic pain may fluctuate with time. Injuries from minor trauma and acute disease such as gout or calcium pyrophosphate crystal arthropathy can be easily overlooked. Finally, many older persons do not use the word "pain," but may refer to their problems as "hurting," "aching," or other descriptions. It is important to probe for and identify pain in the patient's own words so that references for subsequent follow-up evaluations are clearly established.

A physical examination should confirm any suspicions suggested by the history. Because of the frequency with which problems are often identified, the physical examination should probably concentrate on the musculoskeletal and nervous systems. Tender points of inflammation, muscle spasm, and trigger points should be palpated. Observation of abnormal posture, gait impairment, and limitations in range of motion may trigger a need for physical therapy and rehabilitation. Evidence of kyphosis, scoliosis, and abnormal joint alignments should be identified. A systematic neurological examination is also important to identify potential sources of neuropathic pain. Focal muscle weakness, atrophy, abnormal reflexes, or sensory impairments may indicate peripheral or central nervous system injury. Mottled skin in a denervated extremity, presence of a Charcot joint, orthostatic hypotension, impaired gastric emptying, or incontinence may indicate autonomic nervous system dysfunction that

can imply sympathetically maintained pain or a complex regional pain syndrome.

Assessment of functional status is essential to identify self-care deficits and formulate treatment plans that maximize independence and quality of life. Functional status can also represent an important outcome measure of overall pain management. Functional status can be evaluated from information taken from the history and physical examination, as well as the use of one or several functional status scales validated in elderly people.

A brief psychological and social evaluation is also important. Depression, anxiety, social isolation, and disengagement are all common in patients with persistent pain. There is clearly a significant association between persistent pain and depression, even when controlling for overall health and functional status. Therefore, assessment should, at least, include a screen for depression. Psychological evaluation should also include consideration of anxiety and coping skills. Anxiety is common among patients with acute and persistent pain, which requires extra time and frequent reassurance from health care providers. Persistent pain often requires effective coping skills for anxiety and other emotional feelings that can be learned. For those with significant psychiatric symptoms, referral for formal psychiatric evaluation and management may be required. In these patients, cognitive-behavioral therapy, specific counseling, supportive group therapy, biofeedback, or some psychoactive medications may be necessary for developing and maintaining effective coping strategies as well as management of major psychiatric complications. Social networks should also be explored for availability and involvement of family and other caregivers. Family and informal caregivers are often involved and can have a substantial impact on overall pain management. Evaluation of caregivers is necessary when complicated or high-tech pain management strategies are contemplated, such as continuous analgesic infusions. Some pain management strategies can place substantial demands on caregivers, resulting in substantial caregiver stress. Needs for frequent transportation, administration of pain treatments, and technical training may result in substantial stress for nonprofessional caregivers, which can result in work absence and emotional and physical illness.

### Pain Assessment Scales

A variety of pain scales are available to help categorize and quantify the magnitude of pain complaints. Results of these scales are helpful in documentation initially and periodically to maximize treatment outcomes. Results can be recorded in flow chart or graph, making it easy to identify stability or changes in pain over time. Since there are no "gold standards," the validity of pain scales relies largely on face value, correlation with other known scales (concurrent validity), correlation with pain-related constructs (convergence), and experience in many populations over several years.

Pain scales can be grouped into multi- and unidimensional scales. In general, multidimensional scales with multiple items often provide more stable measurement and evaluation of pain in several domains. [Table 30-2](#) summarizes some of the multidimensional scales available. For example, the Brief Pain Inventory has been shown to capture pain in terms of intensity, location, and interference with activities. At the same time, multidimensional scales such as the McGill Pain Questionnaire are often long and time consuming and can be difficult to score at the bedside, making them difficult to use in a busy clinical setting. [Table 30-1](#) provides a description of several available multidimensional scales for pain. For the last

**TABLE 30-2****Multidimensional Scales for Pain Measurement**

	<b>DESCRIPTION</b>	<b>TARGET</b>	<b>VALIDITY</b>	<b>RELIABILITY</b>	<b>ADVANTAGES</b>	<b>DISADVANTAGES</b>
McGill Pain Questionnaire	Subjects asked to identify words descriptive of individual pain from 78 words grouped in 20 categories; plus four other items (including a five-point word descriptive scale of pain intensity) at the moment [PPI] scored separately	All pain	Good	Good	Multidimensional, extensively studied over a long time; may discriminate between types of pain	Long, difficult to score
Short-form McGill Pain Questionnaire	15 words scored on Likert scale, plus a visual analog and PPI scales	All pain	Good	Good	Shorter than original McGill; not studied as deeply as original	May not discriminate between pain types
Wisconsin brief pain inventory	16-item scale; items scored separately	Cancer pain	Good	Good	Multidimensional	Studied largely in cancer pain
Memorial Sloan Kettering Pain Scale	Four-word descriptor scales	Cancer pain	Good	Good	Multidimensional	Studied largely in cancer pain
Geriatric pain measure	24-item questionnaire; 22 items scored dichotomously; two items scored 0–10	Ambulatory elderly	Good	Good	Multidimensional; tested in elderly	Limited experience; sensitivity to change unknown
Neuropathic Pain Scale	10 items each scored 1–10	Neuropathic pain			Specific for neuropathic pain	Individual item analysis may be more helpful than changes in total score
WOMAC	41 items in five domains: pain, stiffness, physical function, social function, and emotional function	Arthritis	Good	Good	Specific for arthritis	Difficult to use clinically
Roland and Morris Disability Questionnaire	24 items scored yes or no	Back Pain	Good	Good	Specific for back pain	May not be generalizable to other pain syndromes
Hurley Discomfort Scale	Designed to score discomfort behaviors in patients with severe Alzheimer's disease	Acute pain	Probably fair	Reasonable	Does not rely on self-report	Relies on behavioral observation
Osteoarthritis pain behavior observation system	Designed to score position, movement, and behavior among adults	Osteoarthritis of knee	Compared to 0–10 scale $r = 0.45$	Test–retest for more than 10 weeks $r = 0.53$	Does not rely on verbal ability	Limited to osteoarthritis of knee

Adapted from Ferrell BA. Pain. In: Osterweil D, Brummel-Smith, K, Beck JB, eds. *Comprehensive Geriatric Assessment*. New York, New York: McGraw-Hill, 2000:389.

10 years, data have been accumulating on some of these scales in older persons.

One example of a behavioral scale is the Hurley Discomfort Scale. This instrument was developed for the assessment of discomfort in patients with profound dementia. The scale consists of nine items

scored by a trained examiner after observation the behavior of a non-communicative patient. Behavioral observations such as breathing, vocalization, facial expression, body language, and restlessness are scored on Likert scales. Testing of the scale has demonstrated reasonable reliability and stability over time. The scale requires some

**TABLE 30-3****Unidimensional Scales for Pain Measurement**

	<b>DESCRIPTION</b>	<b>VALIDITY</b>	<b>RELIABILITY</b>	<b>ADVANTAGES</b>	<b>DISADVANTAGES</b>
Visual analog	100-mm line; vertical or horizontal	Good	Fair	Continuous scale	Requires pencil and paper
Present pain intensity	Six-point 0–5 scale with word descriptors (subscale of McGill Pain Questionnaire)	Good	Fair	Easy to understand, word anchors decrease clustering toward middle of scale	Usually requires visual cue
Graphic pictures	Happy faces; others	Fair	Fair	Amusing	Requires vision and attention
Sloan Kettering pain card	Seven words randomly distributed on a card	Good	Fair	Ease of administration	Requires visual cue
Verbal 0–10 scale	“On a scale of 0 to 10, if 0 means no pain and 10 means the worst pain you can imagine, how much is your pain now?”	Good	Fair	Probably easiest to use	Requires hearing

Adapted from Ferrell BA. Pain. In: Osterweil D, Brummel-Smith K, Beck JB, eds. *Comprehensive Geriatric Assessment*. New York, New York: McGraw-Hill, 2000:390.

skill and experience to administer, which may be problematic for some clinical settings.

Unidimensional scales consist of a single item that usually relates to pain intensity alone. These scales are usually easy to administer and require little time or training to produce reasonably valid and reliable results. They have found widespread use in many clinical settings to monitor treatment effects and for quality assurance indicators. [Table 30-3](#) describes some unidimensional scales that are commonly used, but a large number of variants that have similar characteristics and produce similar results are also available. Unidimensional pain scales often require framing the pain question appropriately for maximum reliability. Subjects should be asked about pain in the present tense (here and now). For example, the interviewer should frame the question: “How much pain are you having right now?” Alternatively, the interviewer can ask: “How much pain have you had over the last week?” or “On average, how much pain have you had in the last month?” The latter questions require accurate memory and integration of pain experiences over time, which may be more difficult for some older patients. Recent studies in those with cognitive impairment have shown that pain reports requiring recall are influenced by pain at the moment. Thus, it may be more useful to use unidimensional scales in this population to assess pain at the moment, much the way vital signs are used.

### Pain Assessment in Those with Cognitive Impairment

Cognitive impairment, delirium, dementia, Alzheimer’s disease, or stroke can present substantial challenges to pain assessment. Fortunately, it has been shown that pain reports from those with mild-to-moderate cognitive impairment are no less valid than other patients with normal cognitive function. Commonly available instruments, such as those in [Table 30-3](#), are feasible for use in most patients with cognitive impairment. Patients with severe cognitive impairment may represent substantial challenges, for which no generalizable methods for pain assessment have been identified. Although it has been assumed that those in deep coma do not experience pain, it is not clear that such brain damage necessarily results in complete anesthesia. Patients with “locked-in syndrome” (having intact perception and cognitive function but no purposeful motor function and no means of communication) may suffer severely. Unfortunately, no reliable methods exist to assess pain in these individuals. Health

care providers must be aware of these situations and provide analgesia empirically, especially during procedures or for conditions known to be uncomfortable or painful. More often, the majority with severe cognitive impairment can and do make their needs known in simple yes or no answers communicated in various ways. For example, those with profound aphasia can often provide accurate and reliable answers to yes and no questions when confronted by a sensitive and skilled interviewer. For these patients, it is important to be creative in establishing communication methods for the purpose of pain assessment.

Although pain is an individual experience, the use of family and caregivers in the assessment of pain can sometimes be helpful. Among patients with cognitive impairment, the history is often only obtainable from family or close caregivers. Family and caregivers are an excellent source of qualitative information about general behavior, medication usage, and actions that seem to aggravate or reduce pain. Family and caregivers are, however, limited in their interpretation of events and behaviors. In fact, evidence suggests that proxies are not always very accurate or reliable in estimating pain intensity. Studies of elderly patients having cancer suggest that caregivers may overestimate pain intensity and distress. It is often distressing to family and other caregivers who feel helpless in managing severe pain. Both physicians and nurses may underestimate pain as well as provide inadequate pain medication. In the final analysis, family and close caregivers can be valuable sources of qualitative information, but they probably should not be relied on entirely for quantitative assessment of pain intensity or distress, especially among those patients able to communicate their pain experiences.

## MANAGEMENT OF ACUTE AND PERIOPERATIVE PAIN

The treatment of acute pain relies largely on short-term use of analgesic medications and resolution of the underlying cause. A variety of nondrug strategies have also been shown to be helpful. The choice of analgesic medications and other strategies to be used may depend on the severity of pain, availability of technical equipment and expertise, expectations for resolution of underlying injury, and individual patient characteristics.

The most common approach to treating acute pain relies on the World Health Organization recommendations for choosing the potency of analgesic drugs based on the intensity of pain. Pain of mild intensity usually responds to nonopioid drugs, used alone or in combination with other physical and cognitive-behavioral interventions. Pain of moderate intensity often requires more intensive efforts such as weak opioids or low doses of more potent opioid drugs. Many of these drugs are compounded with nonsteroidal anti-inflammatory drugs (NSAIDs) or acetaminophen to achieve enhanced relief with only modest exposure to the risk and side effects of many potent opioids. Severe pain usually requires potent opioid analgesic medications given alone or in combination with other analgesic strategies. For severe trauma or postoperative pain, intermittent intravenous, continuous intravenous, or spinal anesthesia may provide faster and more continuous pain relief. Finally, when patients present with acute pain, even though establishing a diagnosis is a priority, symptomatic pain treatment should not be held while investigations are proceeding. It is rarely justified to defer analgesia until a diagnosis is made. In fact, a comfortable patient is better able to cooperate with diagnostic procedures.

Acute and postoperative pain is dynamic. Without treatment, sensory input from damaged tissue causes alterations in spinal cord neurons, which result in enhanced responses. Pain receptors also become more sensitive after injury. Studies have demonstrated long-lasting changes after brief painful stimuli. These observations may explain why long-standing pain is more difficult to suppress. Thus, patients should be encouraged to take pain medications continuously or to prevent pain before it becomes severe and requires higher doses of medication suppress. In general, it may be helpful to provide continuous analgesics initially, with intermittent or “prescribed-as-needed” doses reserved for breakthrough or intermittent pain as the injury resolves.

Aggressive pain prevention and control before, during, and after surgery can have both short- and long-term benefits. Good preoperative pain control has been shown to make postoperative pain easier to control. Postoperative patients who use analgesia via a continuous infusion pump with self-administered boluses for breakthrough pain report less pain and are more satisfied with their pain control. These patients use less medication, have fewer postoperative complications, and tend to be discharged earlier compared to similar patients who are given similar drugs on an intermittent or “as-needed” basis.

The importance of preoperative patient education cannot be overemphasized. Studies have shown that preoperative patient education and preparation dramatically enhance postoperative outcomes and improved pain management. Patients given complete information about specific procedures including detailed descriptions of expected discomfort postoperatively often have less pain, use less pain medication, and have earlier discharges.

## MANAGEMENT OF PERSISTENT PAIN

The management of persistent pain often requires a multimodal approach of drug and nondrug pain management strategies. Although analgesic medications are the most common strategy employed, the concurrent use of cognitive-behavior therapy and other nondrug strategies may be essential to reduce long-term reliance on medications alone, which have substantial side effects when used on a long-term basis. Persistent pain management is often a labor-intensive ef-

fort. Not unlike the effort required during warfarin anticoagulation, pain management requires frequent monitoring and often requires frequent adjustments. Indeed, elderly patients with chronic pain benefit particularly from physicians, nurses, and restorative personnel who are able to employ an interdisciplinary approach to complex problems.

In general, persistent pain is more difficult to relieve than acute pain. Patients should be given an expectation of pain relief, but it is unrealistic to suggest or sustain an expectation of complete relief for some patients with persistent pain. The goals and trade-offs of possible therapies need to be discussed openly. Sometimes a period of trial and error should be anticipated when new medications are initiated and titration occurs. Review of medications, doses, use patterns, efficacy, and adverse effects should be a regular process of care. Ineffective drugs should be tapered and discontinued.

Economic issues are also important in the management of persistent pain. It is appropriate to consider economic issues and make balanced decisions while basic principles of assessment and treatment are followed. Health care professionals should be aware of the costs and economic barriers patients and families may encounter with the strategies often prescribed. These issues include lack of Medicare reimbursement for some strategies, limited formularies, delays in referrals in some managed care environments, delays from mail-ordered pharmacies, and limited availability of strong opioid medications in some pharmacies.

## ANALGESIC MEDICATIONS

Any patient who has pain that impairs functional status or quality of life is a candidate for analgesic drug therapy. Analgesic medications are safe and effective in elderly people, but they carry a balance of benefits and burdens. For some classes of pain-relieving medications (opioids, for example), elderly patients have been shown to have increased analgesic sensitivity. However, elderly people are a heterogeneous population; thus, optimum dosage and known side effects are difficult to predict. Recommendations for age-adjusted dosing are not available for most analgesics. In reality, dosing for most patients requires beginning with low doses with careful upward titration, including frequent reassessment for dosage adjustments and optimum pain relief.

The least invasive route of drug administration should be used. Some drugs can be administered from a variety of routes such as subcutaneous, intravenous, transcutaneous, sublingual, and rectal. Most drugs are limited to only a few safe routes of administration, but new delivery systems are being created each year. The oral route is preferable because of its convenience and relatively steady blood levels produced. Significant drug effects are often seen in 30 minutes to 2 hours for most analgesics given orally, which may be a drawback in acute, rapidly fluctuating pain. Intravenous bolus provides the most rapid onset and shortest duration of action, which may require substantial labor, technical skill, and monitoring. Subcutaneous and intramuscular injection, although commonly used, has disadvantages of wider fluctuations in absorption and rapid falloff of action compared to oral routes. Transcutaneous, rectal, and sublingual routes are also more difficult to predict but may be essential for those with difficulty swallowing.

Timing of medications is also important. Fast-onset, short-acting analgesic drugs should be used for episodic pain. Medications for

intermittent or episodic pain can usually be prescribed as needed. For continuous pain, medications should be provided around the clock. In these situations, a steady-state analgesic blood level is more effective in maintaining comfort. Most patients with continuous pain also need fast-onset short-acting drugs for breakthrough pain. Breakthrough pain includes (1) end-of-dose failure as the result of decreased blood levels of analgesic with concomitant increase in pain prior to the next scheduled dose; (2) incident pain, usually caused by activity that can be anticipated and pretreated; and (3) spontaneous pain, common with neuropathic pain that is often fleeting and difficult to predict.

The use of placebos is unethical in clinical practice, and there is no place for their use in the management of acute or persistent pain. Placebos, in the form of inert oral medications, sham injections, or other fraudulent procedures, are only justified in certain research designs where patients have given informed consent and understand that they may be receiving a placebo as a part of the research design. In research, placebos help identify and measure random or uncontrollable events that may confound results of some research designs. In clinical settings placebo effects are common, but they are neither diagnostic of pain nor indicative of a therapeutic response. The effects of placebos are short lived, and most patients eventually learn the truth, resulting in loss of patient trust and more needless suffering.

### Acetaminophen

Acetaminophen is the drug of choice for elderly persons with mild-to-moderate pain, especially that of osteoarthritis and other musculoskeletal problems. As an analgesic and antipyretic, acetaminophen acts in the central nervous system to reduce pain perception. Although it may have some minor drug interactions (e.g., warfarin), given in a dose of 650 to 1000 mg four times a day, it remains the safest analgesic medication compared to traditional NSAIDs and other analgesic drugs for most patients. Unfortunately, acetaminophen overdose can result in irreversible hepatic necrosis. Therefore, the maximum daily dose should never exceed 4000 mg/day.

### Nonsteroidal Anti-inflammatory Drugs

NSAIDs have analgesic activity both peripherally and centrally. They are potent inhibitors of prostaglandin synthesis, which have effects on inflammation, pain receptors, and nerve conduction and may have central effects as well. There are two major NSAID-sensitive cyclooxygenase enzymes (COX-1 and COX-2) synthesized in a variety of organs. COX-1 is present in most organ systems and plays a role in normal organ function such as gastric mucosal blood flow and barrier function, renal blood flow, hepatic blood flow, and platelet aggregation. COX-2, normally present in lower concentrations, is an inducible enzyme in response to injury or inflammation. Selective inhibition of COX-2 gives rise to analgesic and anti-inflammatory activity with less organ toxicity compared to the nonselective inhibition of both enzymes. Clinical trials have found COX-2 inhibitors to be similarly effective to traditional NSAIDs in terms of peak pain relief and total pain relief and in reducing joint inflammation in patients with arthritis. Safety profiles of these agents have shown a 50% reduction of gastrointestinal injury when used alone, but little data are available to support additional gastrointestinal injury

with concomitant use of proton pump inhibitors or mesoprostyl. On the other hand, patients taking some COX-2-specific inhibitors (specifically rofecoxib) have been shown to increase the risk for cardiovascular events. Thus, patients at risk of cardiovascular events who are taking a COX-2-specific NSAID should also consider low-dose aspirin to offset this effect. Unfortunately, the COX-2 drugs remain expensive and the cost–benefit ratio remains controversial.

Nonspecific inhibitors of COX enzymes (most older NSAIDs) are still appropriate for short-term use in inflammatory arthritic conditions such as gout, calcium pyrophosphate arthropathy, acute flares of rheumatoid arthritis, and other inflammatory rheumatic conditions. They have also been reported to relieve the pain of headache, menstrual cramps, and other mild-to-moderate pain syndromes. These drugs can be used alone for mild-to-moderate pain or in combination with opioids for more severe pain. They have the advantage of being nonhabit forming. Individual drugs in this class vary widely with respect to anti-inflammatory activity, potency, analgesic properties, metabolism, excretion, and side-effect profiles. Moreover, failure of response to one NSAID may not predict the response to another. A disadvantage of NSAIDs (including COX-2-specific inhibitors) is that these all demonstrate a ceiling effect, that is, a level at which increase in dose results in no further increase in analgesia. A large number of NSAIDs are now available; however, there is no evidence to support a particular compound as the NSAID of choice. Several are available over the counter without a prescription. [Table 30-4](#) lists COX-2 and other selected NSAIDs for pain.

High-dose NSAIDs for long periods of time should be avoided in elderly patients. Of major concern is the high incidence of adverse reactions in elderly patients, including gastrointestinal bleeding, renal impairment, and bleeding diathesis from platelet dysfunction. The concomitant use of mesoprostyl, histamine-2 receptor antagonists, proton pump inhibitors, and antacids is only partially successful at reducing the risk of significant gastrointestinal bleeding associated with NSAID use. Also, the side-effect profiles of gastroprotective drugs in this population must be weighed against their limited benefits. These gastroprotective medications do nothing to prevent the renal impairment and other side effects. For those with multiple medical problems, NSAIDs are associated with increased risk of drug–drug and drug–disease interactions. NSAIDs may interact with antihypertensive therapy. Thus, the relative risks and benefits of NSAIDs must be weighed carefully against other available treatments for older patients with chronic pain problems. For some patients, long-term opioid therapy, low-dose or intermittent corticosteroid therapy, or many other nonopioid analgesic drug strategies may have fewer life-threatening risks compared to long-term, high-dose NSAID use.

### Opioid Analgesic Medications

Opioid analgesic medications act by blocking receptors in the central nervous system (brain and spinal cord), resulting in a decreased perception of pain. Many opioids also act similar to local anesthetics and have recently found widespread use in epidural anesthesia. Selected opioid analgesic medications are listed in [Table 30-5](#). Opioid drugs have no ceiling to their analgesic effects and have been shown to relieve all types of pain. Advanced age is associated with a prolonged half-life and prolonged pharmacokinetics of many

TABLE 30-4

## Selected Nonsteroidal Anti-inflammatory Drugs for Pain\*

DRUG	MAXIMUM DOSE	DESCRIPTION	COMMENTS
Celecoxib (Celebrex)	200 mg bid	Selective COX-2 inhibition; pain and anti-inflammatory activity similar to other NSAIDs	Less gastric toxicity; less platelet inhibition
Relafen (Nabumetone)	2000 mg/24 h (q 24 h dosing)	Partially COX-2 selective; gastric toxicity may be less; occasionally requires q 12 h dosing	Avoid maximum dose for prolonged periods
Aspirin	4000 mg/24 h (q 4–6 h dosing)	Prototype NSAID	Salicylate levels may be helpful in monitoring
Salsalate (Disalcid)	3000 mg/24 h (q 6–8 h dosing)	Hydrolyzed in small intestine to aspirin	Elderly may require dose adjustment downward to avoid salicylate toxicity; salicylate levels may be helpful in monitoring
Ibuprofen (Motrin by prescription; Advil, Nuprin, and others otc <sup>†</sup> )	2400 mg/24 h (q 6–8 h dosing)	Gastric, renal, and abnormal platelet function may be dose dependent; constipation, confusion, and headaches may be more common in older persons	Avoid high doses for prolonged periods of time
Diclofenac (Voldaren and Cataflam)	50 mg tid	Nonspecific COX inhibitor	As for ibuprofen
Diflunisal (Dolobid)	1000 mg/24 h maximum dose Loading = 1000 mg, then 500 q 12 h; or 750 mg, then 250 mg q 8 h in small patients or frail elderly	Relatively good analgesic properties but requires loading dose	Dose may need downward adjustment for small patients or elderly who are frail
Sulindac (Clinoril)	400 mg/24 h (q 12 h dosing)	Same as ibuprofen	Same as ibuprofen
Naproxen (Naprosyn by prescription; Aleve and others otc <sup>†</sup> )	1000 mg/24 h (q 8–12 h dosing)	Same as ibuprofen; may require a loading dose.	Same as ibuprofen
Choline magnesium trisalicylate (Trilisate)	5500 mg/24 h (q 12 h dosing)	Lower effect on platelet function	Salicylate levels may be helpful to avoid toxicity
Indomethacin (Indocin)	200 mg/24 h (q 8–12 h dosing)	Extremely high toxicity in frail elderly; should be reserved for acute inflammatory conditions (e.g., gout, etc.)	Keep dose to a minimum (25 mg q 8 h) and for short-term use only; avoid use for osteoarthritis or other noninflammatory problems
Ketorolac (Toradol)	IM <sup>‡</sup> —120 mg/24 h (30–60 mg loading dose; followed by half the loading dose, 15–30 mg q 6 h limited to not more than 5 days) PO <sup>§</sup> —60 mg/24 h (q 6 h dosing limited to not more than 14 days)	Substantial gastrointestinal toxicity as well as renal and platelet dysfunction; relatively high postoperative complications have been documented	Duration of treatment limited because of high toxicity; reduce dose in half for those <50 kg or >65 yrs of age

\*A limited number of examples are provided. For comprehensive lists of other available NSAIDs and a host of brand names, clinicians should consult other sources.

<sup>†</sup>otc indicates over-the-counter or available without prescription.

<sup>‡</sup>IM, by intramuscular injection.

<sup>§</sup>PO, per oral route or by mouth.

opioid drugs. Thus, elderly people may achieve pain relief from smaller doses of opiate drugs than younger people.

Opioid drugs have the potential to cause cognitive disturbances, respiratory depression, constipation, and habituation in older people. Drowsiness, cognitive impairment, and respiratory depression associated with opioids should be anticipated when opioids are initiated and doses are escalated rapidly. These effects occur in a dose-dependent fashion and can be used to judge dose escalations. If patients have unrelieved pain with little drowsiness or cognitive impairment, doses may be safely escalated. Tolerance usually develops in a few days to these side effects, at which time, patients usually return to a fully alert status and baseline cognitive function. Until tolerance develops, patients should be instructed not to drive and

to take precautions against falls or other accidents. But once tolerance to these effects has developed, patients can return to normal activities including driving and other demanding tasks, despite high doses of opioid drugs. In fact, cancer patients are often observed to improve physical function once pain is adequately relieved on opioid analgesics.

Constipation is a side effect of opioid drugs to which older patients do not develop tolerance. The management of constipation usually includes increasing fluid intake, maintaining mobility, and use of cathartic medications. Some patients find relief with remedies like prune juice or other natural laxatives. Other patients may require more potent osmotic laxatives such as milk of magnesia, lactulose, or sorbitol. But for many patients opioid-induced constipation may

**TABLE 30-5****Selected Opioid Analgesic Medications for Pain\***

DRUG	STARTING DOSE (ORAL)	DESCRIPTION	COMMENTS
Morphine (Roxanol, MSIR)	30 mg (q 4 h dosing)	Short-intermediate half-life; older people are more sensitive than younger people to side effects	Titrate to comfort; continuous use for continuous pain; intermittent use for episodic pain; anticipate and prevent side effects
Oxymorphone (Opana)	10–20 mg (q 4 h dosing)	Slightly more potent than morphine	Caution in opioid-naïve patients; ? advantage over morphine
Codeine (plain codeine, Tylenol #3, other combinations with acetaminophen or NSAIDs)	30–60 mg (q 4–6 h dosing)	10% of codeine is metabolized to morphine, which is responsible for most analgesia; subject to genetic enzyme polymorphisms	10%–30% of patients cannot metabolize to morphine
Hydrocodone (Vicoden, Lortab, others)	5–10 mg (q 3–4 h dosing)	Toxicity similar to morphine; acetaminophen or NSAID combinations limit maximum dose	Constipation, nausea, and drowsiness may limit effectiveness
Oxycodone (Roxicodone, Oxy IR; or in combinations with acetaminophen or NSAIDs such as Percocet, Tylox, Percodan, and others)	20–30 mg (q 3–4 h dosing)	Toxicity similar to morphine; acetaminophen or NSAID combinations limit maximum dose; oxycodone is available generically as a single agent	Same as above
Hydromorphone (Dilaudid)	4 mg (q 3–4 h dosing)	Half-life may be shorter than morphine; toxicity similar to morphine	Similar to morphine
Sustained release morphine (MS Contin, Oramorph, and Kadian)	MS Contin—30–60 mg (q 12 h dosing) Oramorph—30–60 mg (q 12 h dosing) Kadian—30–60 mg (q 24 h dosing)	Morphine sulfate in a wax matrix tablet or sprinkles; MS Contin and Oramorph should not be broken or crushed; Kadian capsules can be opened and sprinkled on food but should not be crushed	Titrate dose slowly because of drug accumulation; rarely requires more frequent dosing than recommended on package insert; immediate release opioid analgesic often necessary for breakthrough pain
Sustained release oxymorphone (Opana ER)	5 mg q 12 h in opioid-naïve patients	Titrate 5–10 mg q12 every 3–7 days	Do not crush or chew
Sustained release oxycodone (Oxycodone)	15–30 mg (q 12 h dosing)	Similar to sustained release morphine	Similar to sustained release morphine
Methadone (Dolophine)	2.5–5 mg (q 12 h)	Oxidized by CP450 system; may have NMDA receptor activity; no toxic metabolites; highly lipid soluble; analgesic half-life shorter than serum half life	High risk for drug accumulation in elderly persons; titrate slowly every 3–5 days
Transderm fentanyl (Durgesic)	25 µg patch (q 72 h dosing)	Reservoir for drug is in the skin, not in the patch; equivalent dose compared to other opioids is not very predictable (see package insert); effective activity may exceed 72 h in older patients	Drug reservoir is in skin, not patch. Titrate slowly using immediate release analgesics for breakthrough pain; peak effect of first dose may take 18–24 h; not recommended for opioid-naïve patients
Fentanyl lozenge on an applicator stick	Rub on bucal mucosa until analgesia occurs, then discard	Short half-life; useful for acute and breakthrough pain when oral route is not possible	Absorbed via bucal mucosa, not effective orally

\*A limited number of examples are provided. For comprehensive lists of other available opioids, clinicians should consult other sources.

require potent stimulant laxatives such as senna or bisacodyl. It should be remembered that stimulants should not be used until impactions have been removed and obstruction has been ruled out. Finally, some patients require regular enemas to ensure bowel evacuation during high-dose opioid administration for severe pain.

Nausea also occasionally complicates opioid therapy. Nausea from opioid medications may result from several mechanisms and may wane as tolerance develops. Traditionally, antiemetics such as prochlorperazine, chlorpromazine, and antihistamines have been the

mainstay of treatment for nausea in younger patients. Low-dose haloperidol has also been used, anecdotally noting lower side-effect profile compared to other neuroleptic drugs. All of these agents have high side-effect profiles in elderly patients, including movement disorders, delirium, and anticholinergic effects. Thus, clinicians should choose antiemetic medications with the lowest side effects and continue to monitor patients frequently.

Tolerance is a pharmacologic phenomenon that occurs with many drugs. Tolerance is defined by diminished effect of a drug associated

with constant exposure to the drug over time. For opioid drugs, tolerance is difficult to predict. In general, tolerance to drowsiness and respiratory depression occurs much faster than tolerance to analgesic properties of the drug. Previous reports that described tolerance among patients having cancer, resulting in the need for massive doses of morphine to achieve adequate analgesia, were probably misinterpreted because those patients also had rapidly advancing cancer. More recent studies of opioid managed arthritis pain have noted that tolerance was not often significant. In fact, some patients have been noted to remain on stable doses of opioids for many years without demonstrating significant tolerance to the analgesic effects.

Dependency is also a pharmacologic phenomenon associated with many drugs, including corticosteroids and beta-blockers. Dependency is present when patients experience uncomfortable side effects when the drug is withheld abruptly. Drug dependence requires constant exposure to the drug for some period of time, but it is difficult to predict. The minimum dose and time relationship between drug exposure and development of dependent withdrawal symptoms is not precisely known, but it appears to vary with individual opioid compounds. Symptoms associated with opioid withdrawal may include anorexia, nausea, diaphoresis, tachycardia, mild hypertension, and mild fever. Worsening symptoms may include skin mottling, gooseflesh, and frank autonomic crisis. Fortunately, these symptoms can be ameliorated easily by tapering opioids over a few days. In severe cases, clonidine given short term in titrated doses will usually control serious autonomic signs. It is important to remember that physiologic effects of opioid withdrawal are usually not life-threatening compared to serious withdrawal common with alcohol, benzodiazepine, or barbiturate withdrawal.

Addictive behavior is defined by compulsive drug use despite negative physical and social consequences and the craving for effects other than pain relief. Patients who are addicted often have erratic behavior that can be observed in a clinical setting in the form of selling, buying, and procuring drugs on the street, and the use of medication by bizarre means such as dissolving tablets for self intravenous administration. It is now clear that drug use alone is not the major factor in the development of addiction. Other medical, social, and economic factors play immense roles in addictive behavior. It is also important to not construe certain behaviors as necessarily addictive behaviors. Hoarding of medications, persistent or worsening pain complaints, frequent office visits, requests for dose escalations, and other behaviors associated with unrelieved pain has coined the term “pseudoaddiction.” Laws, regulations, and unintentional behavior by prescribing clinicians may require patients to hoard medication and seek other physicians for additional help. In fact, true addiction is rare among patients taking opioid analgesic medications for medical reasons. This is not meant to imply that opioid drugs can be used indiscriminately, only that fear of addiction and side effects do not justify failure to treat pain in elderly patients, especially those near the end of life.

### Other Nonopioid Medications for Pain

A variety of other medications not formally classified as analgesics have been found to be helpful in certain specific pain problems. The term “adjuvant analgesic drugs,” although frequently used, is a misnomer in that some of these nonopioid drugs may be the primary pain-relieving pharmacologic intervention in certain cases. [Table 30-6](#) provides some examples of nonopioid drugs that may help cer-

tain kinds of pain. The largest body of evidence available relates to the use of these drugs for neuropathic pain, such as diabetic neuropathies, postherpetic neuralgia, and trigeminal neuralgia. Tricyclic antidepressants, anticonvulsants, and local anesthetics are the most frequently used nonopioid analgesics for neuropathic conditions. In general, these drugs have had limited success in pain syndromes that are not associated with neuropathic mechanisms. Most reports have found that these agents are only partially successful. Typically, approximately 50% to 70% of patients have a measurable response, and of those most experience only partial relief. Thus, these drugs are often not panaceas and are rarely totally successful as single agents. One exception may be trigeminal neuralgia, where carbamazepine is probably the drug of choice. Usually these agents work better in combination with other traditional drug and nondrug strategies, in an effort to improve pain and keep other drug doses to a minimum. Failure of response to one particular class of drugs does not necessarily predict failure of another class of agents. In general, nonopioid medications for neuropathic pain should be chosen according to lowest side effects. Treatment should usually start with lower doses than recommended for younger patients, and doses should be escalated slowly based on known pharmacokinetics of individual drugs and appropriate knowledge of disease-specific treatment strategies. Unfortunately, most of the nonopioid medications for pain management have high side-effect profiles in elderly people. Thus, these medications often have to be monitored carefully.

Antidepressants have been the most widely studied class of nonopioid medications for pain. The mechanism of action for these drugs is not entirely known but probably has to do with interruption of norepinephrine and serotonin-mediated mechanisms in the brain. For neuropathic pain, the major effect of these drugs is not their mood-altering capacity, although this may also be helpful in those with concurrent major depression. More is probably known about tricyclic antidepressants than the other subclasses. A randomized placebo-controlled trial of amitriptyline, desimipramine, and fluoxetine indicated that desimipramine may be as effective as amitriptyline, but fluoxetine is no better than placebo for the treatment of diabetic neuropathy. Thus, desimipramine may be a better choice because it has a lower side-effect profile in elderly people than amitriptyline. Unfortunately, tricyclic antidepressants have been criticized for high anticholinergic side effects in elderly patients, which often limits their effectiveness.

The newer norepinephrine reuptake inhibitors (SNRIs) including venlafaxine and duloxetine have been shown to have modest effect on diabetic neuralgia, and duloxetine is FDA approved for use in diabetic neuropathy. Studies of these drugs have indicated small but statistically significant effect sizes.

Studies of the SSRIs, which may have lower side-effect profiles for elderly people, have not been shown effective for pain management. In fact, none have shown significant effect on pain despite being highly effective for depression.

It has been known for many years that some medications with antiepileptic activity may relieve the pain of trigeminal neuralgia (Tic Douloureux). Drugs such as dilantin, tegretol, and valproic acid may also help diabetic neuralgia and other neuropathic pains in some patients. In general, the usefulness of these drugs has been limited by their high side-effect profiles in elderly people and the fact that most patients respond only partially, making the overall risk/benefit ratio rather large in this population. Indeed, these drugs are not simple analgesics and should not be used for the relief of trivial aches and

TABLE 30-6

## Selected Nonopioid Medications for Pain\*

DRUG	DESCRIPTION	COMMENTS
Antidepressants: amitriptyline, desipramine, nortriptyline, and others	Older people are more sensitive to side effects, especially anticholinergic effects; desipramine, or nortriptyline are better choices than amitriptyline	Complete relief unusual; used best as adjunct to other strategies; start low and increase slowly every 3–5 days
Serotonin–norepinephrine uptake inhibitors (SNRIs): venlafaxine (Effexor) and duloxetine (Cymbalta)	Venlafaxine—25–37.5 bid or tid; titrate q 4 days Duloxetine—60 mg qd	Venlafaxine—taper gradually Duloxetine—do not crush or chew; taper gradually
Anticonvulsants: clonazepam and carbamazepine	Carbamazepine may cause leukopenia, thrombocytopenia, and rarely aplastic anemia; clonazepam side effects may be similar to other benzodiazepines in the elderly	Start low and increase slowly; check blood counts on carbamazepine
Gabapentin (also an anticonvulsant) Neurontin	Less serious side effects than other anticonvulsants	Start with 100 mg and titrate up slowly; tid dosing; monitor for idiosyncratic side effects such as ankle swelling, ataxia, etc.; effective dose reported 100–800 mg q 8 h
Pregabalin (Lyrica)	Similar to gabapentin. Start at 50 mg tid and gradually increase. Taper dose to discontinue	Side effects similar to gabapentin
Antiarrhythmics mexiletine (Mexitil)	Common side effects include tremor, dizziness, and paresthesias; may rarely cause blood dyscrasias and hepatic damage	Avoid use in patients with preexisting heart disease; start low and titrate slowly; monitor EKGs; q 6–8 h dosing
Local anesthetics: lidocaine (intravenous), lidocaine transdermal patch (Lidoderm), and capsiacin	IV lidocaine associated with delirium Transdermal patch has minimal systemic absorption Capsiacin depletes nerve endings of substance P	IV lidocaine may predict response to anticonvulsants and antiarrhythmics May apply up to three patches alternating 12 h intervals to improve pain, reduce denervation hypersensitivity, and decrease systemic absorption May take 2 weeks to peak effect
Tramadol (Ultram)	Partial opioid and serotonin agonist; more of a norepinephrine antagonist; may cause drowsiness, nausea, vomiting, and constipation	Has ceiling effect; dose >300 mg/24 h usually not tolerated because of nausea; q 4–6 h dosing
Muscle relaxants (baclofen, chlorzoxazone [Paraflex], and cyclobenzaprine [Flexaril])	Sedation; anticholinergic effects; abrupt withdrawal of baclofen may cause CNS irritability	Mechanism of action not precisely known; monitor for sedation and anticholinergic effects; taper baclofen on discontinuation
Substance P inhibitors (capsiacin) available otc; for topical use only	Burning pain during depletion of substance P may be intolerable by as many as 30% of patients; may take 14 days for maximum response; avoid eye contamination	Start with small doses; can be partially removed with vegetable oil
NMDA inhibitors: ketamine and dextromethorphan	<i>N</i> -Methyl-D-aspartate antagonists (NMDA) Ketamine: potent anesthetic Dextromethorphan: common cough suppressant	Ketamine only available IV Both may cause delirium
Drugs for osteoporosis: Calcitonin and bisphosphonates	Pain relief mechanisms unknown	Not effective on pain other than osteoporosis
Corticosteroids: Prednisone Dexamethazone	Decrease inflammation in many tissues	Classic corticosteroid side effects limit overall usefulness in chronic pain

\*A limited number of examples are provided. For comprehensive lists of other available medications for pain, clinicians should consult other sources.

pains. Of recent interest has been the effectiveness of gabapentin for treatment of diabetic and postherpetic neuralgias. Clinical observations suggest that this agent has a significant analgesic effect on neuropathic pain with a much lower side-effect profile compared to other antiepileptic drugs and most antidepressants as well.

Several local anesthetics have also been shown to relieve neuropathic pain when administered systemically, in addition to their known local anesthetic effects. Intravenous lidocaine has been found to sometimes predict the response to other anticonvulsant and systemically administered local anesthetics. Mexiletine, similar to lido-

caine but active orally, has also shown some activity against neuropathic pain of diabetic neuralgia. Although this drug also has a high risk/benefit ratio, some studies have reported response rates at lower doses than are often recommended for cardiac arrhythmias.

Finally, chronic pain associated with osteoporosis has often been shown to improve with calcitonin. Most investigators of the effects of calcitonin on osteoporosis have reported anecdotally that pain improves significantly. These studies have not been designed as pain studies, and more sophisticated assessment of pain in these studies would be welcome, but results thus far are encouraging.

## ANESTHETIC AND NEUROSURGICAL APPROACHES TO PAIN MANAGEMENT

A wide variety of anesthetic and neurosurgical approaches to pain are available, and some require highly specialized skills. Although it is beyond the scope of this chapter to review details of all of these techniques, a few deserve mention.

Trigger point injections have been used extensively for the treatment of myofascial pain syndromes. Myofascial pain with trigger points was first recognized more than 50 years ago. In a relatively high percentage of cases, trigger points may initiate a reflex mechanism that produces referred pain, tenderness, and muscle spasm. With local injection of the trigger point, followed by stretching and reconditioning of the muscles, the myofascial pain syndrome usually subsides. More recently, similar results have been obtained using ice massage or vapocoolant spray applied topically, followed by specific muscle stretching and physical therapy techniques. Nonetheless, for many myofascial pain syndromes, trigger point injection with dilute local anesthetics may be highly effective when combined with specific physical therapy.

Continuous drug infusions are highly effective for providing steady-state analgesic drug levels. Continuous infusions can be maintained by implantable pumps or external devices to deliver intravenous, subcutaneous, intrathecal, or epidural medications. Continuous infusions of opioid drugs have found widespread use in severe chronic cancer pain, especially among those near the end of life. Other uses have included continuous infusion of muscle relaxants for patients with severe muscle spasm from spinal injury, multiple sclerosis, or end-stage Parkinson's disease. The techniques are very expensive, but they are often reimbursed by third-party payers including Medicare. These issues have raised ethical concerns about the application of high-tech strategies for patients who might be equally well managed using oral medications that are not reimbursable. In general, these methods should be used only when oral medications become ineffective or the oral route of administration is no longer viable. More work needs to be done to justify these risky and expensive techniques that need to be carefully monitored in nursing homes, home care, and other low-tech long-term care settings.

## NONDRUG STRATEGIES FOR PAIN MANAGEMENT

Nondrug strategies, used alone or in combination with appropriate analgesic medications, should be an integral part of the care plan for most elderly patients with significant pain problems. Nondrug strategies for pain management encompass a broad range of treatments and physical modalities, many of which carry low risks for adverse effects. Used in combination with appropriate drug regimens, these interventions often enhance therapeutic effects, while allowing medication doses to be kept low to prevent adverse drug effects.

Among the nondrug interventions, the importance of patient education cannot be overstated. Studies have shown that patient education programs alone significantly improve overall pain management. Such programs often include content about the nature of pain, how to use pain diaries and pain assessment instruments, how to use medications appropriately, and how to use self-help nondrug

strategies. Whether conducted in groups or individually, education should be tailored for individual patient needs and level of understanding. Written materials and methods of reinforcement are important to the overall success of the program. Education on the use of heat and cold can be especially helpful for some patients.

Physical exercise is important for most patients with pain. A program of exercise can be tailored to most patients' needs and is extremely important for rehabilitation, and the maintenance of strength and endurance. Clinical trials of older patients with chronic musculoskeletal pain have shown that moderate levels of exercise (aerobic and resistance training) on a regular basis are effective in improving pain and functional status. Initial training for chronic pain patients usually requires 8 to 12 weeks, with supervision by a professional who can focus on the needs of older people with musculoskeletal disorders. There is no evidence that one form of exercise is better than another, so programs can be tailored for the individual's needs, lifestyle, and preference. Water aerobics may be especially helpful for older patients with arthritic pain. The intensity of exercise along with frequency and duration must be adjusted to avoid exacerbation of the underlying condition while gradually increasing and later maintaining overall conditioning. Stretching to relieve muscle spasm and prevent further muscle injury is another critical exercise intervention. It is important to remember that feeling better often gives rise to a false impression that the discipline of regular exercise is not necessary. Continued encouragement and reinforcement is often required. Unless complications arise, the program of exercise should be maintained indefinitely to prevent deconditioning and deterioration.

Psychological strategies have also been shown to be helpful for some with significant pain. Cognitive therapies are strategies aimed at altering belief systems and attitudes about pain and suffering. Cognitive therapies include various forms of distraction, relaxation, biofeedback, and hypnosis. Behavioral therapies are strategies aimed at enhancing healthy behaviors and discouraging abnormal behavior that is unpredictable and self-defeating. Cognitive therapy can be combined with behavioral approaches, and together they are known as cognitive-behavioral therapy. Cognitive-behavioral therapy, in its purest form, includes a structured approach to teaching coping skills, which might be used alone or in combination with analgesic medications and other nondrug strategies for pain control. Effective programs can be conducted by trained professionals with individual patients or in groups, and there is some evidence that the effect is enhanced with caregiver involvement. Although it may not be appropriate for those with significant cognitive impairment, there is evidence from randomized trials to support the use of cognitive-behavioral therapy for many patients with significant chronic pain.

Finally, a variety of alternative therapies are also used by many patients. Many patients seek alternative medicine approaches with and without the knowledge or recommendation of their physician or other primary-care provider. Alternative medicine approaches to chronic pain may include homeopathy, spiritual healing, or the growing market of vitamin, herbal, and natural remedies. Although there is little scientific evidence to support these strategies for pain control, it is important that health care providers not abandon patients or leave them with a sense of hopelessness.

# Palliative Care

*Audrey Chun* ■ *R. Sean Morrison*

Our society is facing one of the largest public health challenges in its history—the growth of the population of older adults. Improvements in public health, the discovery of antibiotics, and advances in modern medicine have resulted in unprecedented gains in human longevity. For most Americans, the years after the age of 65 are a time of good health, independence, and integration of one's life's work and experience. Eventually, however, most adults will develop one or more chronic illnesses with which they may live for many years before they die. More than three-quarters of deaths in the United States result from chronic diseases of the heart, lungs, brain, and other vital organs. Even cancer, which accounts for nearly a quarter of U.S. deaths, has become a chronic, multiyear illness for many. For a minority of patients with serious illness (e.g., metastatic colon cancer), the time following diagnosis is characterized by a stable period of relatively good functional and cognitive performance, followed by a predictable and short period of functional and clinical decline. However, for most patients with advanced illness (e.g., heart or lung disease, dementia, stroke, neuromuscular degenerative diseases, and many cancers), the time following diagnosis is characterized by months to years of physical and psychological symptom distress, progressive functional dependence and frailty, considerable family support needs, and high health care resource use. Indeed, as the population continues to age, most physicians will be caring for chronically ill individuals whose medical care is characterized by high degrees of complexity, lengthy duration of illness, and intermittent acute exacerbations interspersed with periods of relative stability. Abundant evidence suggests that the advanced stages of disease for most are characterized by inadequately treated physical distress; fragmented care systems; poor communication between physicians, patients, and families; and enormous strains on family caregiver and support systems.

## THE EXPERIENCE OF SERIOUS ILLNESS FOR PATIENTS AND THEIR FAMILIES

Whereas a century ago, most adults died suddenly as a result of an acute infection or accident, the leading causes of death today are chronic illness such as heart disease, cancer, stroke, and dementia. Accompanying this shift in the causes of death has been a corresponding change in the location of death. Whereas in the early part of the 20th century, most persons died at home, today, most Americans will die in an institution (57% in hospitals and 17% in nursing homes). The reasons for this shift in location of death are complex but appear to be related to health system and reimbursement structures that promote hospital-based care and provide relatively little support for needed home care and custodial care services. Whereas the majority of Americans will die in an institution, these statistics hide the fact that most of an older person's last months and years are still spent at home in the care of family members, with hospitalization and/or nursing home placement occurring only near the very end of life. National statistics also obscure the variability in the experience of dying. For example, need for institutionalization or paid formal caregiving in the last months of life is much higher among the poor and women. Similarly, persons suffering from cognitive impairment and dementia are much more likely to spend their last days in a nursing home compared to cognitively intact elderly persons dying from nondementing illnesses.

Multiple studies have demonstrated that the clinical care of older adults with serious and advanced illness is in need of improvement. Studies have suggested that the prevalence of significant pain in community-dwelling older adults may be as high as 56% and that almost one-fifth of older adults take analgesic medications on a regular

basis. Similarly, it has been suggested that 45% to 80% of nursing home residents have substantial pain and that many of these patients have multiple pain complaints and multiple potential sources of pain. Available data also point to a high prevalence of nonpain symptoms in older adults with serious and chronic illness. In retrospective interviews with family members of patients who died of noncancer illnesses in the United Kingdom, 67% of patients experienced moderate-to-severe pain, 49% had trouble breathing, 27% reported nausea, 36% reported depression, and 36% reported sleep disturbances. Similarly, SUPPORT (Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments), a study of 9 105 seriously ill hospitalized adults, found that after 1 week in the hospital, among patients who could be interviewed, about one in two patients reported pain, nearly one in six reported moderate-to-severe pain at least half of the time, and nearly one in six patients with pain were dissatisfied with its control. In subanalyses of patients with heart failure, end-stage liver disease, lung cancer, and chronic obstructive pulmonary disease (COPD), more than 20% of patients consistently experienced severe dyspnea during the 6 months prior to death. A companion study to SUPPORT reported almost identical pain findings for a cohort of hospitalized patients aged 80 years and older and also noted a high prevalence of anxiety and depression in the last 6 months of life.

The burdens of serious and chronic illness extend beyond patients to their families and friends. SUPPORT found that more than one-third of patients needed a large amount of family caregiving, which was not adequately provided for by the health care system. Similarly, another study of just less than 900 caregivers of persons with advance illness reported that more than one-third of these caregivers reported substantial stress. Furthermore, 86% of these respondents stated that they needed more help than what they were currently receiving or could afford including assistance. These needs included transportation (62%), homemaking (55%), nursing (28%), or personal care (26%). Caregiving has also been shown to be an independent risk factor for death, major depression, and associated comorbidities.

## PALLIATIVE CARE

Palliative care is interdisciplinary care focused on the relief of suffering and achieving the best possible quality of life for patients and their loved ones. It involves formal symptom assessment and treatment, aid with decision making and establishing goals of care, practical support for patients and their caregivers, mobilization of community support and resources to ensure secure and safe living environments, and collaborative and seamless models of care (hospital, home, nursing homes, and hospice). It is offered simultaneously with life-prolonging and curative therapies for persons living with serious, complex, and eventually terminal illness. Palliative care was recently approved as a subspecialty of internal medicine, family medicine, and seven other parent boards.

Perhaps because it is codified in the Medicare hospice benefit, palliative care, or more typically hospice, traditionally has been conceptualized as care that should be provided only at the end of life when treatments directed at the cure of disease and life prolongation are no longer effective. This artificial dichotomy (cure vs. comfort) ignores the fact that the overwhelming majority of older adults living with advanced chronic illness require both life-prolonging and palliative treatments and that the forced choice of cure versus comfort

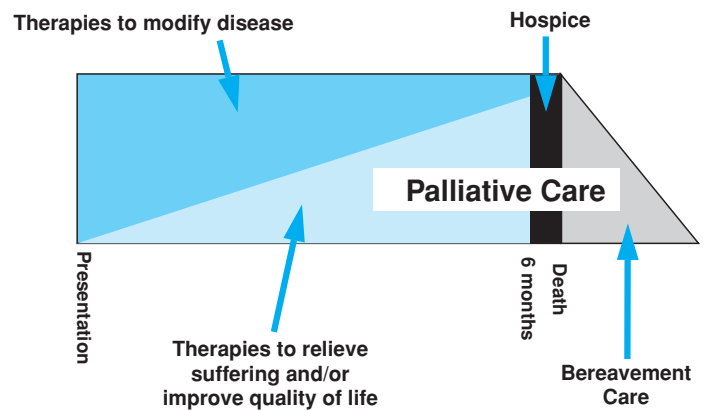

FIGURE 31-1. The integrated model of palliative care.

results not only in reflexive, burdensome, and costly life-prolonging treatments long after the time that these are beneficial to the patient, but also in preventable suffering during all stages of an advanced illness. For example, a frail 88-year-old woman with advanced heart failure, Parkinson's disease, diabetes, and deconditioning after hospitalization for pneumonia typically requires life-prolonging measures (medications for heart failure, oxygen, insulin, and antibiotics), preventive measures (influenza vaccinations), rehabilitation (home physical and occupational therapy to restore bed-chair mobility), and palliative care (setting goals of medical care; treatment of anxiety and depression; pharmacologic [psychostimulants] and nonpharmacologic [energy conservation therapies] management of fatigue; diuretics, oxygen, and opioids for breathlessness; and advance care planning and appointment of a health care proxy). Thus, the model of palliative care that patients and families require through the many-year course of illness, and the one promulgated in this chapter, is care focused on the simultaneous mix of beneficial (i.e., effective) life-prolonging treatments, palliation of symptoms, rehabilitation, and support for family caregivers, with the nature of these treatments varying in response to patient needs and preferences (Figure 31-1).

Palliative care for geriatric patients differs from what is usually appropriate in younger adults because of the nature and duration of chronic illness during old age. Specifically, the many-year duration of most geriatric chronic illnesses, the high prevalence of long-term functional and cognitive impairment, and the need for long-term caregivers are less common and rarely present in younger populations. Indeed, palliative care for younger adults is typically focused on the identification of symptoms associated with either a specific advanced terminal illness and its immediate manifestations or signs of poor prognosis/imminent death. Conversely, many of the characteristics of advanced old age (frailty, functional dependence, cognitive impairment, multiple comorbidities, and symptom distress) are multifactorial in etiology and are present for many years. In the frail elderly, disease-specific treatments may ameliorate or lessen the burdens of frailty, dependence, and symptom distress but are unlikely to eliminate them. Thus, palliative care for the elderly is most appropriately centered on the identification and amelioration of functional and cognitive impairment, development of frailty and dependence on caregivers, and the associated burden of symptom distress rather than, as is typical in advanced cancer and traditional hospice settings, identification of specific and advanced terminal illness and its immediate manifestations or signs of poor prognosis or imminent

death. In response to the unique needs of older adults, we believe that palliative care is as integral a part of geriatric medicine as is the focus on function.

## SYMPTOM ASSESSMENT AND TREATMENT

Successful approaches to the assessment and management of pain, many physical symptoms, and some psychological symptoms have been well established in controlled clinical trials. Effective symptom management requires the evaluation and treatment of underlying etiologies, when possible; therapies specifically targeted at symptoms; and frequent reassessment after therapies are initiated. [Table 31-1](#) details standard treatment approaches for pain and other symptoms.

### Pain

Despite major advances in the treatment of pain, studies continue to demonstrate undertreatment in the majority of patients and care settings. In addition to unnecessary suffering, studies suggest that untreated pain is associated with adverse outcomes, including delirium, atelectasis, and pneumonia; deconditioning; and impaired functional recovery.

Pain is the most common symptom experienced by those with advanced illness, and successful management requires three key components: routine and standardized assessment, appropriate analgesic prescribing and use of nonpharmacologic modalities; and expert management of opioid-related side effects. Although somewhat rudimentary, The World Health Organization's (WHO) analgesic ladder has traditionally been the framework most often cited for the management of malignant and nonmalignant persistent pain syndromes. Under the WHO analgesic ladder, patients rate their pain as mild (1–4 on a 10-point scale), moderate (5–6), or severe (7–10), and an analgesic is prescribed based on the patient's pain level: acetaminophen, a nonsteroidal anti-inflammatory agent, or a Cox-II inhibitor for mild pain; an opioid combination product (e.g., oxycodone/acetaminophen, hydrocodone/acetaminophen, and codeine/acetaminophen) for moderate pain; and a strong opioid (morphine, oxycodone, hydromorphone, and fentanyl) for severe pain.

Although the WHO ladder has been shown to be quite effective for the treatment of cancer pain in younger adults, recently, several expert panels and the American Geriatrics Society task force on persistent pain have recommended alterations to the WHO ladder. First, because of gastrointestinal and renal toxicities associated with nonsteroidal anti-inflammatory agents and the recent data on cardiovascular toxicity of Cox-II inhibitors, acetaminophen should be considered the medication of choice for older adults with mild pain. Nonsteroidal anti-inflammatory agents should be used with extreme caution and only in select patients with minimal risk factors (i.e., good renal function and no history of gastric ulcers or gastrointestinal bleeding). Patients with mild pain that persists despite maximal doses of acetaminophen should be started on a short-acting opioid and the opioid titrated until adequate pain relief is achieved. Once pain relief is achieved, consideration should be given to switching to a sustained-release opioid for ease of administration and to improve compliance. Second, combination products should be used with caution because of the danger of acetaminophen toxicity with dose escalation. Indeed, we recommend that combination prod-
