ucts be avoided altogether and that patients who do not respond to acetaminophen for mild pain or present with moderate or severe pain be started immediately on a pure opioid (morphine and oxycodone) and the opioid titrated upward until adequate pain relief is achieved. Acetaminophen can be prescribed separately for additive/opioid sparing analgesia.

The choice of which opioid to use is driven largely by price and route of administration. [Table 31-2](#) lists recommended starting doses for common opioids, equianalgesic doses, and the formulations of opioids currently available. For chronic or persistent pain, patients should be placed on a standing dose of a short-acting opioid, with the dosing interval being determined by the half-life of the drug (see [Table 31-2](#)). Patients should also receive “as-needed” opioids for breakthrough pain. This “breakthrough” or “prn” dose should be 10% of the total daily dose of the standing medication administered every hour as needed for an oral medication and every 15 to 30 minutes as needed for a parenteral medication. For uncontrolled pain, standing doses should be increased by 25% to 50% for moderate pain and by 50% to 100% for severe pain, with a corresponding increase in the breakthrough dose until adequate analgesia is achieved or intolerable side effects are present (see [Table 31-2](#)). Once a stable dose is reached and pain is well controlled, the patient can be switched to an extended-release oral or transdermal preparation. Given the difficulties with titrating sustained-release or transdermal preparations and the risk of opioid toxicity that can result if sustained release opioids are titrated too rapidly, we recommend that such preparations be used only after effective analgesia is achieved with a short-acting drug.

Neuropathic pain syndromes resulting from diabetes, spinal stenosis, side effects of chemotherapy or other medications, postherpetic neuralgia, or cancer are particularly resistant to treatment. Amitriptyline and other tricyclic antidepressants, although efficacious in some neuropathic pain syndromes and still considered first-line therapy by many, are poorly tolerated in older adults because of their anticholinergic properties and should only be used after other treatments have proven ineffective. Anticonvulsants such as gabapentin and local topical therapies such as transdermal lidocaine patches have both been shown to improve neuropathic pain in randomized controlled trials. Data with regards to selective serotonin reuptake inhibitors (SSRIs) and mixed norepinephrine/serotonin reuptake inhibitors (e.g., venlafaxine) on neuropathic pain are mixed with some studies showing modest benefit and others showing no improvement over placebo. Finally, several studies have shown that high-dose opioids are effective in neuropathic pain syndromes and should be considered in patients who do not respond to therapies detailed above or for patients who experience dose-limiting side effects with these medications (e.g., sedation with gabapentin or anorexia with SSRIs).

Successful management of pain requires not only appropriate analgesics dosing but also expert management of opioid-related side effects. [Table 31-3](#) lists common opioid side effects in older adults and approaches to their management. It is important to note that the majority of patients develop tolerance to almost all opioid-related side effects, with the exception of constipation. For example, tolerance to the respiratory depressive effects of opioids develops during 48 to 72 hours, tolerance to nausea typically occurs over a few days to a week, and tolerance to the cognitive side effects (sedation and mental cloudiness) occurs during 5 to 14 days. For patients who do not develop tolerance or for whom side effects are intolerable,

TABLE 31-1

## Common Symptoms in Seriously Ill Older Adults

SYMPTOM	ASSESSMENT	TREATMENT RECOMMENDATIONS
Anorexia/cachexia	Assess whether symptom is owing to disease process or secondary to other symptoms (nausea and constipation). Determine if the patient is troubled by symptoms—often families, more than patients, are bothered by anorexia.	Pharmacologic approaches that have been shown to improve appetite and quality of life include corticosteroids, megestrol acetate, and the cannabinoids. Dexamethasone is advantageous in that it allows once-a-day dosing, has minimal mineralocorticoid properties, and may improve mood and energy. Megestrol acetate has been shown to be the most effective appetite stimulant with fewest side effects in randomized controlled trials for younger, but not older, adults.
Anxiety	Is there excessive worry, restlessness, agitation, insomnia, hyperventilation, or tachycardia?	Supportive counseling and cautious use of benzodiazepines because of increased risk of delirium in older adults. Selective serotonin reuptake inhibitor (SSRIs) if life expectancy is greater than 2 months.
Constipation	Regular and routine assessment of constipation is critical, particularly for patients on opioids. Patients underreport constipation and life-threatening complications of fecal impaction, and perforation can develop quickly if regular bowel movements are not maintained.	With few exceptions, all patients on opioid therapy need an individualized bowel regimen. When an effective regimen is found, it must be continued for the duration of the opioid therapy. Most patients respond to a stool softener plus a stimulant. If dose escalation of the stimulant proves ineffective, addition of agents from alternate classes may be required. Agents available for the treatment of constipation are detailed below in order of suggested use. Additional recommendations are in Table 31-3. <i>Stool softeners</i> (ineffective alone and should be combined with other agents): docusate sodium and calcium docusate <i>Stimulant laxatives</i> : prune juice, senna, and bisacodyl <i>Osmotic laxative</i> : propylene glycol, milk of magnesia, and magnesium citrate Large-volume tap water enemas, high colonic enemas, or disimpaction may be needed in cases of severe constipation
Delirium	Are the symptoms acute with episodes of inattention? Is there disorganized thinking or an altered level of consciousness?	Identify underlying/reversible causes. Ensure an appropriately calm environment with caregivers/family at bedside. Prescribe haloperidol (0.5 mg every 4 h as needed, titrated to symptoms) or an atypical antipsychotic. Benzodiazepines should be avoided as they have been shown to worsen delirium.
Depression	Assess severity using validated instruments. The question “Are you depressed?” is a sensitive and specific question for patients with advanced illness. Reliable symptoms include feelings of helplessness, hopelessness, anhedonia, loss of self-esteem, worthlessness, persistent dysphoria, and suicidal ideation. Somatic symptoms are not reliable indicators of depression in this population of patients.	Supportive psychotherapy, cognitive approaches, behavioral techniques, and pharmacologic therapies have all been shown to be effective for treatment of depression in patients with advanced disease. Psychiatric consultation should be obtained in cases of severe depression. Patients should be asked specifically about suicidal ideation, and, if present, the reasons behind it should be carefully explored. Suicidal ideation often represents a measure of extreme distress in patients with advanced illness. Choice of pharmacologic therapy is often dictated by the patient’s estimated life expectancy. Psychostimulants (e.g., methylphenidate and dextroamphetamine) provide rapid treatment of symptoms (within days) with minimal side effects. Increased energy, decreased fatigue, and improved well-being have been reported with the use of psychostimulants. SSRIs are highly effective but may require 3–4 weeks to take effect. The side-effect profile of tricyclic antidepressants (sedation, dry mouth, constipation, and orthostasis) is a relative contraindication to their use in patients with advanced illness.
Dyspnea	Assess severity using validated instrument. Treat reversible causes if possible.	<i>Oxygen</i> : Oxygen provides relief of dyspnea in circumstances of hypoxia but has also been shown to provide symptomatic relief in situations where hypoxia is not present. A cool breeze across the face (either from oxygen or a fan) has been shown to decrease breathlessness through stimulation of the V2 branch of the trigeminal cranial nerve. <i>Opioids</i> : Opioids have been demonstrated to significantly reduce breathlessness in randomized controlled trials without measurable reductions in respiratory rate or oxygen saturation. Effective doses are often lower than those used to treat pain, and tolerance has not been demonstrated to be a clinical problem. <i>Anxiolytics</i> : Anxiety and breathlessness are tightly intertwined. Anxiety may worsen breathlessness, and breathlessness may heighten anxiety. Benzodiazepines, reassurance, relaxation, distraction, and massage therapy may decrease anxiety and improve breathlessness.
Fatigue	Assess severity and treat reversible causes if possible (e.g., anemia, electrolyte imbalances, infection, and hypoxia)	<i>Pharmacologic therapy</i> : Corticosteroids (e.g., dexamethasone) and psychostimulants (e.g., methylphenidate and dextroamphetamine) <i>Nonpharmacologic therapies</i> : energy conservation, frequent naps, occupational therapy, and physical therapy

(continued)

TABLE 31-1

## Common Symptoms in Seriously Ill Older Adults (Continued)

SYMPTOM	ASSESSMENT	TREATMENT RECOMMENDATIONS
Nausea	Assess severity and probable cause using validated instrument.	<p><i>Chemoreceptor trigger zone stimulation:</i> drugs (opioids, digoxin, estrogen, and chemotherapy agents), biochemical disorders (hypercalcemia and uremia), and toxins (tumor-produced peptides, infection, radiotherapy, and abnormal metabolites)</p> <p>Treatment: Butyrophenones/phenothiazines (e.g., haloperidol and prochlorperazine), prokinetic agents (e.g., metoclopramide), serotonergic antagonists (e.g., ondansetron), and atypical neuroleptics (olanzapine)</p> <p><i>Mechanical causes:</i> gastric irritation (drugs, alcohol, iron, mucolytics, expectorants, and blood), tumors (external compression, intestinal obstruction, constipation, liver capsule stretch, upper bowel, genitourinary, and biliary stasis, peritoneal inflammation, and cardiac pain), and gastric distension (opioid-induced stasis)</p> <p>Treatment: Antihistamines (e.g., diphenhydramine), serotonergic antagonists (e.g., ondansetron), prokinetic agents (e.g., metoclopramide), and cytoprotective agents (e.g., ranitidine and omeprazole)</p> <p>Treatment of delayed gastric emptying/squashed stomach: prokinetic agents (e.g., metoclopramide, and cisapride if not contraindicated)</p> <p>Treatment of nonsurgical bowel obstruction: Octreotide is effective both for nausea and for abdominal pain resulting from bowel obstruction</p> <p><i>Intracranial processes:</i> increased central nervous system pressure and anticipatory nausea.</p> <p>Treatment: corticosteroids and benzodiazepines</p> <p><i>Vestibular vertigo:</i> local tumors, opioids, and motion sickness</p> <p>Treatment: acetylcholine antagonists (transdermal scopolamine and meclizine)</p>
Pain	Assess severity, location, character, precipitating, and alleviating factors using a validated instrument.	<p>In general, pain medications should be administered on a standing or regular basis with "prn" or rescue doses available for breakthrough pain or pain not controlled by the standing regimen. Medications should be chosen based on patients' initial pain level, and, if pain remains uncontrolled, clinicians should advance to the next level.</p> <p><i>Mild pain (1–4/10):</i> Begin acetaminophen or a nonsteroidal anti-inflammatory agent in select patients (those with normal renal function and minimal risk of gastrointestinal toxicity). Do not exceed 3 or 2 g/d for those with hepatic dysfunction. If pain is not controlled by acetaminophen, initiate opioid therapy.</p> <p><i>Moderate pain (5–6/10):</i> Begin a short-acting standing opioid (morphine or oxycodone) and titrate every several days by 25%–50% of the current dose until pain relief is achieved. Once pain is well controlled, consider switching to a sustained release oral opioid or transdermal fentanyl (see Table 31-2 for recommended starting doses and conversion guidelines). Rescue doses employing immediate release opioids should be 10% of the 24-h total opioid dose and given every hour (oral) or every 30 min (parenteral) as needed. Because of their potency, hydromorphone and oxymorphone should be used with extreme caution in older adults with moderate pain and in most cases reserved for patients already on standing opioid therapy or those in severe pain. Acetaminophen can be employed for additive and opioid-sparing analgesia.</p> <p><i>Severe pain (8–10/10):</i> Begin a standing short-acting opioid (morphine sulfate, oxycodone, and hydromorphone) and titrate rapidly until pain relief is obtained or intolerable side effects develop. Strongly consider a parenteral opioid and titrate by 50%–100% of the dose every 30–60 min until pain is controlled. Long-acting opioids (sustained release morphine/oxycodone and transdermal fentanyl) should typically be started only after pain is well controlled and steady state is achieved. Rescue doses employing immediate release opioids should be 10% of the 24-h total opioid dose and given every hour (oral) or every 30 min (parenteral) as needed. Methadone should only be used by clinicians experienced in its use. All patients on opioids should be started on a bowel regimen.</p> <p>Adjuvant agents (corticosteroids, anticonvulsants, tricyclic antidepressants, and bisphosphonates) can be used depending on the pain syndrome and response to opioids.</p>

TABLE 31-2

## Opioid Analgesic Equivalences and Recommended Starting Dosed for Older Adults\*

OPIOID AGONIST	IV/SQ/IM <sup>†</sup>	PO/RECTAL	RATIO IV:PO	DURATION OF EFFECT (h)	STARTING DOSE (ORAL) <sup>‡</sup> (mg)	COMMENTS
Morphine	10	30	1:3	4	2.5–10	Oral liquid concentrated formulation recommended for breakthrough pain
SR morphine	NA	30	NA	8–12		Begin after stable dose obtained with short-acting opioid
Hydrocodone	NA	30	NA	4	2.5–10	
Oxycodone	NA	20	NA	4	2.5–7.5	Oral liquid concentrated formulation recommended for breakthrough pain
SR oxycodone	NA	20	NA	8–12		Begin after stable dose obtained with short-acting opioid
Oxymorphone	1	10	1:10	4	1–3	
SR oxymorphone	NA	10		12		
Hydromorphone	1.5	7.5	1:5	3–4	0.5–2	
Fentanyl <sup>§</sup>	0.2 (200 µg)	NA	NA	1–2		Transdermal fentanyl patch (µg/h) = IV fentanyl (µg/h). Duration of patch is 48–72 h and should be started only after initial dose determined by oral/parenteral opioids
Methadone <sup>¶</sup>				6–8		
Codeine <sup>**</sup>	130	200	1:1.5	4	30–60	

\*If converting between opioids when pain is well controlled, decrease the dose of the new opioid by 25% to 50% to account for incomplete cross-tolerance. Rapid titration to achieve effective analgesia may be required in the first 24 hours.

<sup>†</sup>Intramuscular administration is strongly discouraged because subcutaneous administration is as effective and less painful.

<sup>‡</sup>Starting doses are adapted from the American Geriatrics Society Panel on Persistent Pain in Older Adults. *J Am Geriatr Soc.* 2002;50(6 suppl):S214–S215.

<sup>§</sup>Breakthrough or “prn” doses of oral morphine for patients on the fentanyl patch are roughly one-third of the fentanyl patch dose (e.g., if a patient is prescribed a fentanyl patch 75 µg/h q 72 h, breakthrough dose of short-acting morphine is 25 mg q 1 h prn).

<sup>¶</sup>Methadone has a complex pharmacokinetic and pharmacodynamic profile that makes equianalgesic dosing particularly difficult. Consultation with an experienced clinician is recommended before initiating or adjusting the dose of methadone.

\*\*Codeine is highly emetogenic and its use is strongly discouraged.

Table 31-3 details strategies to manage the most common symptoms associated with opioids.

Finally, many physicians, patients, and families have concerns about physical and psychological (addiction) dependence. Almost all patients treated with opioids develop physical dependence, characterized by the presence of a withdrawal syndrome, if the medication is abruptly discontinued or the dose significantly reduced. For patients taking opioids, dependence can develop after only several days of therapy. For patients whose analgesic requirements are suddenly reduced (e.g., following a course of radiation therapy), tapering the opioid dose by 30% to 50% per day has been found to be a safe and effective strategy to avoid withdrawal symptoms.

Psychological dependence (addiction) is defined as the continued use of a medication despite harm to self or others. Studies to date suggest that the risk of addiction in patients treated with opioids for pain and without a history of substance abuse is extremely small (less than 1%). For patients with a life-threatening or terminal illness, concerns about psychological dependence should never inhibit appropriate analgesic prescribing. Persons with a history of substance abuse who require opioids for pain require specialized approaches to pain management. A description of these approaches is beyond the scope of this chapter.

## Dyspnea

Dyspnea is the subjective experience breathlessness and is one of the most common and distressing symptoms experienced by pa-

tients with advanced illness. For example, 70% of patients with advanced cancer and more than 56% of those with advanced COPD report moderate-to-severe dyspnea. Treatment of dyspnea begins with treating the underlying etiology whenever possible (i.e., inhaled  $\beta_2$  agonists and anticholinergics for COPD and diuretics, beta-blockers, and angiotensin-converting enzyme inhibitors in advanced heart failure). When disease-modifying therapies are not effective, a number of symptomatic treatments can significantly reduce breathlessness and improve patient comfort. These include oxygen, opioids, and anxiolytics (see Table 31-1).

Oxygen should clearly be utilized for breathlessness in the presence of hypoxia. However, even when hypoxia is not present, oxygen has been shown to be effective in reducing dyspnea by direct stimulation of the V2 branch of the trigeminal cranial nerve in the nares. When oxygen is not available, fans or positioning patients near an open window or door can be effective in reducing breathlessness.

Opioids remain the gold standard treatment for dyspnea. Opioids reduce breathlessness through several mechanisms. First, they diminish ventilatory response to hypoxia and hypercapnea, typically at doses lower than those required for pain control. Second, they act centrally to reduce the subjective sensation of breathlessness. Third, opioids reduce preload and can be particularly effective for patients with symptoms of volume overload associated with advanced heart or renal disease.

Finally, because dyspnea is often accompanied and exacerbated by anxiety, low-dose short-acting benzodiazepines such as lorazepam (0.5 mg every 6 hours) are often beneficial in reducing patient

TABLE 31-3

## Management of Opioid-Related Side Effects

Constipation	<p>Almost a universal complication of opioid therapy and prophylactic laxatives are always indicated unless there is a clear contraindication.</p> <p>Maintain a high index of suspicion for bowel obstruction or fecal impaction. Rule out impaction with digital rectal examination or abdominal X-ray if clinically suspicious. Rectal disimpaction must occur before treating with an oral laxative.</p> <p><i>Step 1:</i> Docusate 100 mg po tid plus senna 2 tabs qhs (can titrate up to 8 senna/d).</p> <p><i>Step 2:</i> Add polyethylene glycol (17 g mixed with 8 ounces water/d).</p> <p><i>Step 3:</i> If constipation persists for 3 or more days, add bisacodyl suppository (10 mg/24 h), docusate mini-enema qhs, fleet mineral oil retention enema, or sodium phosphate oral solution. If no results, consider a high colonic tap water enema.</p>
Nausea	<p>Opioid-induced nausea occurs in approximately 30% of patients. It is important to determine the etiology (gastric stasis/irritability, central irritation of the chemoreceptor trigger zone, or vestibular irritation) and choose a treatment based on the etiology. If nausea cannot be controlled, rotating to another opioid is often effective.</p> <p>See guidelines in <a href="#">Table 31-1</a> for treatment of nausea.</p>
Sedation	<p>Common at the start of therapy, but tolerance develops in the majority of patients. Psychostimulants can be useful at the beginning of treatment until tolerance develops. If sedation remains a problem, rotating to another opioid is often effective. See guidelines for psychostimulants in <a href="#">Table 31-1</a>.</p>
Myoclonus	<p>Opioid rotation to a more potent opioid is often useful as metabolite accumulation is often implicated.</p> <p>Benzodiazepines are also useful if opioid rotation fails to resolve the symptom.</p>
Pruritis	<p>Rarely a problem with chronic opioid therapy.</p> <p>Antihistamines are commonly used although highly sedating and rarely effective.</p> <p>Opioid rotation is likely to be the most effective treatment.</p> <p>Case series report that ondansetron may be effective.</p>
Respiratory depression	<p>Although highly feared, respiratory depression is a very rare complication for patients on chronic opioid therapy owing to the development of tolerance. If respiratory status is compromised (less than 8 breaths/min) opioid reversal with naloxone is indicated. One ampule of naloxone (0.4 mg/mL) should be diluted in 10 mL of saline and injected at a rate of 1 mL every 2–3 min with careful observation of respiratory rate and level of consciousness until the respiratory rate returns to a normal rate. As the half-life of naloxone is only 30 min, patients should be frequently reassessed and additional naloxone administered as above. Patients on methadone commonly require a naloxone infusion as a result of the extended half-life of methadone.</p>

suffering and breaking the cycle of anxiety–dyspnea–anxiety, which is commonly observed in patients with severe breathlessness.

## Gastrointestinal Symptoms

Gastrointestinal symptoms such as nausea, vomiting, anorexia, and constipation are common in patients with advanced illness and are particularly prevalent in patients receiving opioids. As with all symptoms, the cause of these symptoms should be investigated and treatable conditions addressed. Nausea is a subjective feeling that is caused by stimulation of the gastrointestinal lining, chemoreceptor trigger zone, vestibular apparatus, or cerebral cortex. [Table 31-1](#) details common etiologies of nausea and vomiting, details the primary neurotransmitters involved, and lists pharmacologic and nonpharmacologic approaches to treatment.

Anorexia, or loss of appetite, is usually more distressing for family members than for patients. Typically, anorexia is a reflection of the severity of underlying disease and usually cannot be permanently reversed. Approaches to the treatment of anorexia include educating patients and families as to the natural course of the disease process, providing favorite foods and nutritional supplements, encouraging small frequent meals, and determining if assistance with feeding is required. Patients should avoid gastric irritants like spicy food and milk and focus on foods that are enjoyed and easily digested. Although corticosteroids and progesterones (e.g., megestrol acetate) have been associated with increased appetite and sense of well-being in cancer and AIDS patients, there are few corresponding studies in

older adults. One study of megestrol acetate (400 mg/day) in nursing home residents was found to improve appetite but did not result in meaningful weight gain. Potential benefits of both classes of agents should be weighed against their known adverse effects. Corticosteroids can cause mood swings, sleep disturbances, hyperglycemia, edema, delirium, and myopathy. Progesterones have been associated with delirium, venous thromboembolism, and edema. [Table 31-1](#) summarizes approaches to the treatment of anorexia.

Constipation presents both as a primary symptom and, often, as a consequence of other treatments (e.g., opioids, calcium-channel blockers, etc.). Before initiating any laxative treatment, patients should be assessed for the presence of fecal impaction and, if present, disimpacted with tap water or fleets enemas, manually, or with high colonic enemas if the former two approaches prove ineffective. All patients started on opioids should receive prophylactic stool softeners in combination with a stimulant laxative (e.g., senna and bisacodyl), unless contraindicated. Although most patients respond to this combination, persistent constipation (opioid-induced or primary) can be addressed by a trial of additional laxatives with a different mechanism of action such as an osmotic agent (e.g., polyethylene glycol) or regular enemas. Lactulose, although commonly prescribed, is relatively expensive and large volumes are needed to effectively treat constipation. Additionally, lactulose causes flatulence and abdominal cramping in about 20% of patients. Bulk agents (e.g., bran) should be avoided because they may precipitate obstruction in debilitated patient by forming a viscous mass in the setting of inadequate fluid intake.

## Depression, Delirium, and Anxiety

Delirium in advanced disease is a marker of worsening illness and often associated with the last stages of life. Characterized by an acute change in cognition with variable degrees of inattention as well as disorganized thinking or an altered level of consciousness, delirium increases the need for higher levels of care and limits the opportunities to communicate and direct one's own care. For delirium near the end of life, haloperidol is recommended as first-line treatment owing to its multiple forms of administration and wide therapeutic window. Extrapyramidal effects are of less concern when used in the setting of limited life expectancy, and there is little evidence that the atypical antipsychotics are more effective than traditional antipsychotics in the treatment of terminal delirium. If symptoms of delirium are especially distressing, particularly in the final hours to days of life, sedating major tranquilizers such as chlorpromazine is highly effective and should be considered.

Patients with advanced illness should always be assessed for depression and anxiety. Asking "Are you depressed?" is a relatively sensitive and specific screen for depression in patients with advanced illness. For patients with a life expectancy greater than 2 months, SSRIs are the treatment of choice for both depression and anxiety because of their more favorable side-effect profile. For patients with more limited time, psychostimulants for depression and low-dose benzodiazepines for anxiety should be considered. Methylphenidate is probably the best choice for older adults, given its relatively short half-life. Therapy should be initiated at 2.5 to 5 mg twice a day (upon awakening and between noon and 2 PM) and titrated upward as tolerated. Although benzodiazepines have the potential for precipitating delirium and falls and can result in somnolence and cognitive impairment in some patients, these risks should be weighed carefully against the marked benefit that these medications can provide in reducing the distress of anxiety. [Table 31-1](#) provides additional details about dosing and contraindications to these medications.

## Fatigue

Fatigue is usually multifactorial in patients with advanced disease. Patients and families should be encouraged to promote energy conservation, and, indeed, explicit permission by the physician to rest and to nap is often required. Consultation with a physical therapist with palliative care experience—local hospice programs are often an excellent referral source—can be extremely useful in teaching patients and families techniques for energy conservation. Physicians and nurses should carefully evaluate and review patients' medications and discontinue those that might be contributing to fatigue (calcium channel-blockers, beta-blockers, anticholinergics, and antihistamines). Optimizing fluid and electrolyte intake should also be undertaken to minimize the effects of dehydration. As in the case of anorexia, communication and education about the role of underlying diseases are important in establishing realistic expectations for patients and their caregivers.

Pharmacologic management of fatigue involves primarily corticosteroids and psychostimulants. Corticosteroids may increase feelings of well-being and energy levels, but the effect typically wanes after 4 to 6 weeks. Psychostimulants such as methylphenidate can be used in debilitated patients, but side effects of tremulousness, anorexia, tachycardia, and insomnia can limit their use in some patients.

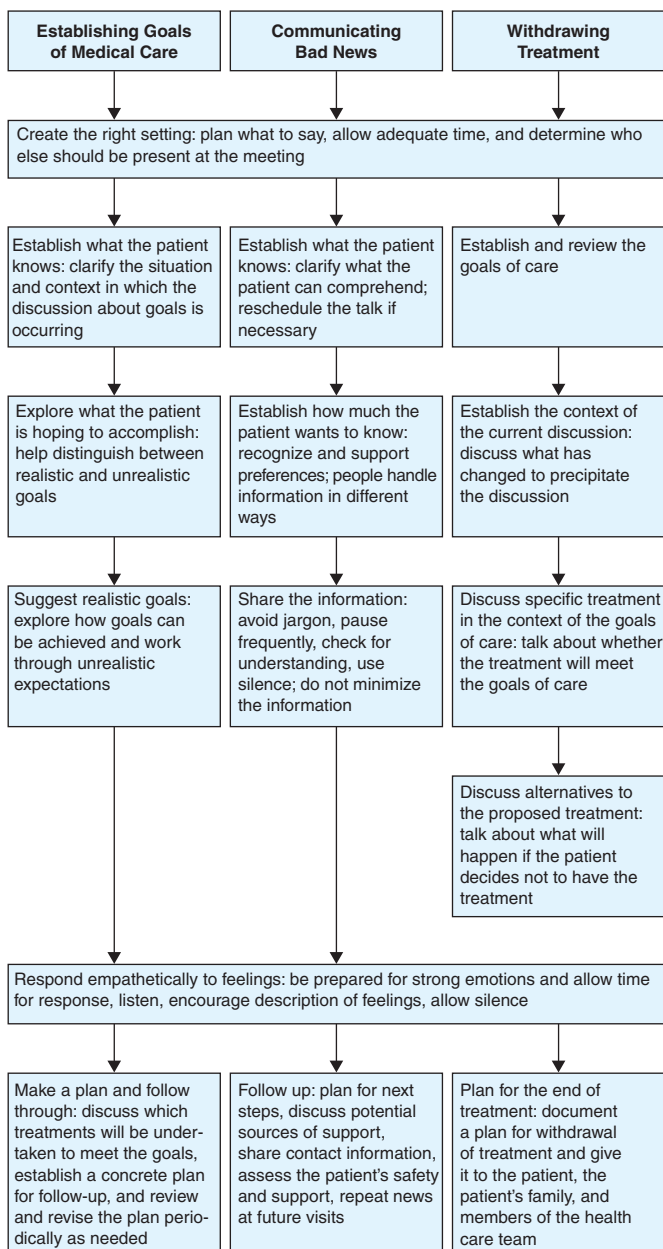

## Last Hours of Life

The last hours of life often are marked by a constellation of symptoms that can be especially distressing for family members. Family education about expected symptoms such as delirium, excessive secretions, edema, and coma can help prepare families for the impending death, alleviate anxiety if these symptoms develop, and improve families' abilities to care for their loved ones in the last hours of life ([Table 31-1](#)). Aside from terminal delirium (discussed above) the presence of the "death rattle"—a gurgling sound caused by air moving through uncleared secretions in the trachea and vocal cords of a comatose patient—is perhaps the most distressing symptom experienced by families of dying patients. Education of family members as to the cause of the noise is critical. It is crucial to emphasize that the noise does not represent gasping or suffocation, and the patient is not experiencing suffering or breathlessness. Despite understanding its etiology, some families and caregivers still find this symptom distressing, and, in these situations, medications such as hyoscyamine, transdermal scopolamine, or atropine drops; positioning patients to the side; and reducing fluid intake can be employed to reduce or eliminate the "death rattle." If edema is present, therapies that can exacerbate edema, such as IV fluids, should be discontinued when at all possible. Skin care should continue with a focus on prevention of skin breakdown using lubricants and emollients rather than turning or repositioning, which can cause increased discomfort and pain. If pressure ulcers are present, efforts should be focused on pain management and minimizing discharge and odors rather than turning, repositioning, or active wound care directed at ulcer healing.

## COMMUNICATION

Communication skills are essential to the relief of suffering and the practice of palliative medicine. Surveys of patients suggest that health care workers typically elicit fewer than half of patients' concerns and consistently fail to discuss patients' values, goals of care, and treatment decisions. Conversely, improved physician–patient communication, including advance care planning, is associated with decreased anxiety, improved patient well-being, higher satisfaction with providers and health care, and improved outcomes.

Essential components of communication in the setting of advanced illness have been identified. A qualitative focus group study of 137 providers, family members, and patients identified six themes of central importance in communicating with patients with advanced illness: talking honestly and in a straightforward way, being willing to talk about dying, giving bad news in a sensitive way, listening, encouraging questions, and being sensitive to patients when they want to talk about difficult issues such as death and dying. Specific interviewing techniques that include establishing eye contact, eliciting and clarifying disclosures, probing for emotional and psychological concerns, displaying empathy, and responding to distress have been shown to improve the detection of anxiety, depression, and other patient concerns in general medical and oncology practices. Protocols ([Figure 31-2](#)), based largely on expert opinion, qualitative data drawn from patient interviews, and data from studies detailed above, are available to guide discussions focused on establishing goals of medical care, communicating bad news including balancing hope with realistic expectations, and withholding and withdrawing medical treatments (including cardiopulmonary resuscitation and feeding).

**FIGURE 31-2.** Communication protocols for delivering bad news, communicating goals of care, and withholding or withdrawing medical treatments. (Reproduced with permission from Morrison RS, Meier DE. *Palliative care*. *N Engl J Med*. 2004;350:2582–2590.)

Recently published data from cancer patients suggest that these protocols are effective in communicating information to both patients and caregivers in a sensitive manner and can be taught to trainees.

## SYSTEMS OF CARE FOR THE SERIOUSLY ILL

The current reimbursement system fails to address many of the needs of seriously ill patients and their families. Medicare coverage is targeted to acute, episodic illness and is not equipped to respond to the long-term needs of the chronically ill. Patients with serious chronic illness typically make multiple transitions between care settings and require long-term care at home or in skilled nursing facilities, care

coordination as they traverse a fragmented system, prescription drug coverage, personal and custodial care needs, home infusion therapies, and transportation to physicians' offices and other health care settings. Medicare does not cover most of these aspects of care coordination. Although the Medicare hospice benefit covers comprehensive services; only patients who are certified by their physicians as within 6 months of the end of life and who are willing to forego coverage for certain life-prolonging treatments are eligible for this benefit. Thus, in reality, it is the minority of persons with life-threatening illness—those with predictable prognoses who are willing to give up life-prolonging efforts—who can benefit from this system.

For patients unable or unwilling to access the hospice benefit, Medicaid, a means-tested reimbursement system designed as a safety net for the poor, remains the only payment system that covers comprehensive care services. Since Medicaid eligibility is means tested, coverage is not an available option for most patients in most states. As a result, almost 26 million Americans provide an average of 18 or more hours of uncompensated personal care per week to a seriously ill homebound relative, which, using a conservative estimate of \$8/hour, amounts to an annual figure of \$194 billion dollars. SUPPORT found that 31% of families caring for patients with serious and chronic illness lose the majority of their family savings and 29% lose the major source of their family income. Families with significant care needs are more likely to take out a loan or mortgage, spend their savings, or obtain an additional job.

Fortunately, programs that coordinate care for complex patients are becoming increasingly available in many communities. Hospital palliative care programs providing comprehensive interdisciplinary palliative care are now present in greater than 30% of U.S. hospitals and greater than 70% of hospitals with more than 250 beds. These programs have been shown to improve clinical care, improve family satisfaction, and facilitate transitions from the acute care hospital to more appropriate care settings. Increasingly, nonhospice palliative care programs for ambulatory or homebound patients who are not eligible for or unwilling to access the Medicare hospice benefit are being established by hospitals, hospices (open access or bridge programs), or traditional home care agencies. Additionally, comprehensive multidisciplinary home care programs targeting frail older adults are available under both the Medicare and the Veteran's Administration programs. The Program of All Inclusive Care for the Elderly (PACE) is a capitated Medicare and Medicaid benefit for frail older adults featuring comprehensive medical and social services provided at adult day health centers, home, and/or inpatient facilities. Studies of PACE have demonstrated increases in advance directive completion rates and decreases in nursing home admissions, hospitalization rates, and hospital death. Similar programs of team-coordinated, home-based care exist within Virginia. Finally, geriatric home care programs that provide visiting physician and nursing services to homebound elders are available in select cities and communities throughout the United States.

## CARE TRANSITIONS

Patients with chronic and serious illness undergo transitions across multiple care sites ranging from the home to ambulatory practices, acute hospital stays, rehabilitation admissions, nursing homes, and more. Both qualitative and quantitative studies suggest that transitions from one care site to another are associated with inadequate

transfer information and follow-up, conflicting advice about disease management, and adverse drug events. Several recent studies suggest that transitions can be made safer for seriously ill older adults. One patient-centered care transition intervention, which included assistance with medication self-management, a patient-centered record owned and maintained by the patient, timely follow-up with primary or specialty care, and a list of “red flags” indicative of a worsening condition and instructions on how to respond to these, reduced recurrent hospital admissions. Other interventions, including hospital discharge checklists and pharmacy medication reconciliation, have been shown to improve patient safety during care transitions. Because transitions are such a vulnerable time for any patient, all providers should take responsibility for ensuring adequate information exchange and follow-up. Assistance for clinicians in managing transitions can be found at [www.caretransitions.org](http://www.caretransitions.org).

## SPECIAL ISSUES

### Dementia

Identification of distressing symptoms in dementia patients can be especially challenging, given that the gold standard for pain and symptom assessment is patient self-report. Work by Ferrell and colleagues has shown that even patients with mild-to-moderate dementia can self-report symptoms and that such symptoms are as valid as those obtained from cognitively intact adults. In patients unable to self-report, behavioral signs such as agitation, withdrawal, tachypnea, vocalizations, grimacing, tense body posturing, and excessive sedation or changes in sleep–wake cycle patterns resulting from sleep deprivation can indicate untreated pain or other symptoms. Several behavioral scales have been developed for use in long-term care populations to aid clinicians in identifying pain and discomfort in dementia patients (Hurley Discomfort Scale, Feldt Checklist of Nonverbal Pain Indicators).

Pain should always be in the differential diagnosis for an unexplained behavior change in a dementia patient, and a time-limited trial of an analgesic medication should be considered if the source of the behavior is not clearly identified. Common and often undiagnosed sources of pain include osteoarthritis, contractures, pressure ulcers, fecal impaction, and neuropathy resulting from diabetes or spinal stenosis.

### Artificial Hydration and Nutrition

In serious illness, anorexia and weight loss are common symptoms. As a result of the social, religious, and ethical values surrounding nutrition, the decision regarding initiation of artificial hydration and nutrition through tube feeds and/or IV therapy can be especially difficult for patients and their families. For patients who are actively dying, it is important to point out to both patients and families that artificial nutrition has not been shown to prolong survival and, indeed, may cause nausea, diarrhea, and electrolyte abnormalities. Artificial hydration, particularly when used in frail, hypoalbuminemic, and debilitated dying patients, can worsen discomfort by causing increased ascites, peripheral edema and anasarca, pulmonary edema, and excess secretions. Data from cognitively intact cancer patients who have voluntarily stopped eating and drinking suggest that that

the only symptoms experienced are dry mouth and thirst, and, importantly, such patients do not experience either hunger or gastric distress. Approaches to treating dry mouth and thirst include the use of artificial saliva, lip emollients, and sips of water, ice chips, or popsicles when desired.

Decisions about long-term tube feeding often arise for patients with advanced dementia. As dementia progresses, patients may exhibit behaviors such as pocketing food without swallowing, turning the head when food is offered, keeping the mouth shut when food is offered, or spitting food out. When considering the benefits of providing artificial nutrition and hydration, a focus on the goals of medical care is critical. Specifically, one must consider the evidence that artificial nutrition prolongs survival, improves comfort, reduces aspiration and malnutrition, and improves quality of life. Prospective and retrospective cohort studies using matched designs have found no evidence that tube feeding improves survival, results in meaningful weight gain or healing of pressure ulcers, or prevents the lean body and muscle mass loss. Furthermore, no studies to date have reported meaningful reductions in aspiration or infections including pneumonia. Conversely, some studies have shown that tube feeding can increase discomfort for dementia patients by producing uncomfortable gastrointestinal sensations and distention including nausea, gastroesophageal reflux, and diarrhea. Less common but not rare, complications include aspiration pneumonia, tube occlusion, local infection, and leaking. Finally, it is also important not to discount the discomfort and distress of placing a permanent external tube into a patient who can neither understand why such a device is in place nor understand or consent to the hospitalizations required if replacement or repair is necessary.

Despite the facts cited above, many caregivers and clinicians equate the withholding of artificial nutrition with starvation and worry that withholding nutrition from dementia will result in discomforting hunger pangs and thirst. Evidence to date contradicts these beliefs. Observational studies of dementia patients who have stopped eating or drinking and who have not received tube feeding have not revealed behaviors associated with pain or discomfort, and, indeed, such patients appear quite comfortable. Families and caregivers should also be aware that there are effective alternatives to tube feeding. A well-designed study by Volicer and colleagues demonstrated that feeding difficulties in advanced dementia patients can be successfully managed by an aggressive spoon feeding program, which includes verbal reminders, frequent small meals, specialized pureed diets, and appropriate feeding postures, and that survival in patients enrolled in this feeding protocol was equal to patients who received gastrostomy tube feeding.

In summary, although data from randomized controlled trials are not available, prospective cohort studies suggest that tube feeding in end-stage dementia is associated with neither increased survival nor comfort and that alternate measures of providing nutrition (e.g., careful and time-intensive spoon feeding) are effective interventions in the majority of patients.

### Grief and Bereavement

Grief and bereavement is a normal response to the death of a loved one, and it is important to recognize that normal grief can persist for up to 6 months. Contrary to the traditional five-stage theory of grief developed by Kubler-Ross (denial–dissociation–isolation, anger, bargaining, depression, and acceptance), emerging evidence

suggests that disbelief, yearning, anger, depression, and acceptance more accurately describe the experience of bereaved individuals. Whereas most of these feelings dissipate within 6 months of the death of a loved one, 10% to 20% of bereaved individuals may continue to experience such feelings beyond 6 months. Prolonged grief disorder (previously termed complicated grief) has been linked to poor physical and mental health outcomes as well as impairments within social, familial, and occupational domains and increased risk of suicide. Spouses are at particular risk of morbidity and mortality during this period. Short screening tools to identify prolonged grief disorder in bereaved individuals are now available (Inventory of Complicated Grief), as are effective therapies for individuals diagnosed with this disorder.

## CONCLUSION

In summary, palliative care is an interdisciplinary care that is focused on relieving suffering and improving quality of life for patients and families living with chronic serious illness. It is neither end-of-life care nor hospice, and it is offered simultaneously with all other appropriate medical treatments. As the population continues to age and more and more persons are living with chronic illness, multiple comorbidities, and frailty, the need to incorporate palliative care into geriatrics will become even more pressing. Whereas the need for palliative care is perhaps greatest in older adults, the current evidence base to provide such care is relatively weak and based largely on expert opinion and studies from young adults. Considerable knowledge gaps exist with respect to the prevalence of pain and other symptoms in older adults; the association of pain and other symptoms on outcomes of function, independence, and quality of life; interventions directed at the assessment and treatment of pain and other symptoms and their effect on outcomes; and research instruments, designs, and analytic techniques to conduct the necessary research. Investment in research directed at helping older adults with serious and advanced illness live in comfort and with dignity over the course of the rest of their lives is critically needed.

# Legal Issues

*Marshall B. Kapp*

The law regulates human relationships, both prospectively and retrospectively, in a wide variety of ways. To a large extent, the legal implications of medical practice are generic, in the sense that these apply to patients of all ages. Rules developed to deal with the care of younger adults apply with full force to older persons, whose rights do not diminish just because of advanced chronological age. However, a patient's advanced years may sometimes raise issues demanding particular attention by the involved participants in the professional/patient relationship. This chapter concentrates on several selected aspects in which the law influences the delivery of geriatric services through its impact on the recognition and enforcement of the respective rights and responsibilities of the parties, within the specific dynamics of an older patient/health care provider relationship.

## OVERVIEW OF HEALTH CARE REGULATION

The U.S. Constitution establishes a federal system of government, under which health care delivery and other matters are regulated at the national (federal), state, and local levels. Under separation of powers principles, such regulation takes the form of constitutional (federal, state, and local) provisions, statutes enacted by elected legislatures, rules or regulations promulgated by executive branch administrative agencies like health or social service departments on the basis of authority conferred on the agency by the legislature via a statute, and common law doctrines created by the courts as a matter of public policy and prior case precedent. These various forms of regulation may impose specific or general duties on parties, may authorize but not require parties to act in specific ways, or may prohibit parties from engaging in particular conduct. Health care regulation may be directed at individual health professionals or at health care facilities, agencies, institutions, and other organizations.

### Regulation of Health Professionals

One primary mechanism for regulating individual health professionals to assure adequate qualifications and acceptable conduct is

licensure, which entails the requirement that an individual satisfy—on both an initial and a continuing basis—certain enumerated standards to be permitted to practice a particular profession. Professional licensure ordinarily occurs at the state level through statutes (such as state Medical Practice Acts or Nursing Practice Acts) and regulations promulgated by a state's licensing body (such as the Medical Board or Nursing Board) to implement the Practice Act. Licensure statutes and regulations limit certain activities to licensed professionals; engaging in those activities without prior state approval (in other words, practicing medicine or nursing without a valid license) subjects the wrongdoer to potential civil fines and even criminal sanctions.

Many statutory and regulatory requirements or prohibitions imposed on health professionals occur as conditions attached to payment for professional services under government insurance programs, especially Medicare and Medicaid. Professionals who treat patients covered by these government programs must satisfy the positive (e.g., "Thou shalt" maintain adequate patient records) or negative (e.g., "Thou shalt not" engage in self-referral) "strings" placed on the payment of public dollars to receive compensation for services rendered.

Another significant manner of health professional regulation under the civil law is tort liability in private lawsuits claiming malpractice; this form of regulation is discussed below. Particularly egregious behavior (such as patient abuse or billing fraud) may subject a health professional to criminal law punishments.

### Regulation of Health Care Facilities and Agencies

Besides regulating individual health professionals, government additionally regulates provider facilities and agencies through licensure requirements, conditions attached to the receipt of compensation under public insurance programs including Medicare and Medicaid, criminal prohibitions on specific behaviors such as the filing of false claims, and civil liability for malpractice claims brought by

or on behalf of individual patients. For example, Congress enacted the Nursing Home Quality Reform Act, codified at Title 42 U.S. Code §1395i-3(a)-(h), as part of the Omnibus Budget Reconciliation Act (OBRA) of 1987, Public Law No. 100-203. This act, which has been amended several times subsequently, contains many of the recommendations proposed in a 1986 Institute of Medicine report that Congress had directed the Department of Health and Human Services to commission. OBRA 1987 amended the Social Security Act, Titles 18 (Medicare) and 19 (Medicaid), to require substantial upgrading in nursing home quality and enforcement. To implement this legislation, Department of Health and Human Services published a series of regulations, which have been codified at Title 42 Code of Federal Regulations Part 483. Violation of these regulations subjects nursing homes to a range of sanctions, up to decertification from participation in the Medicare and Medicaid programs.

## STANDARDS OF CARE AND PROFESSIONAL LIABILITY IN GERIATRICS

### Overview of Malpractice Liability

In a private civil lawsuit predicated on a theory of professional negligence, the plaintiff is required to establish four distinct elements by a preponderance of the evidence (Table 32-1). First, the patient/plaintiff has the burden of proving that the professional/provider defendant owed the patient an obligation defined by the appropriate standard of care. The existence of this duty ordinarily is established by showing that there existed, within the relevant time frame, a professional relationship between the patient and provider; that is, that the plaintiff was a patient of the provider for diagnostic and/or therapeutic purposes.

Second, the plaintiff must present sufficient evidence that the professional/provider breached or violated the appropriate standard of care within the professional relationship. The professional/provider does not guarantee particular results, let alone perfection. By the same token, however, it is not enough for professionals/providers to “do their best” if their conduct does not rise to the applicable level of care, even when the errors or omissions were unintentional (i.e., negligent). How the law determines the applicable level of professional care is discussed in the following section.

The third element that a medical malpractice plaintiff is required to prove is the occurrence of some financially compensable injury or damage. Besides special or economic damages that include such quantifiable items as lost income and past and future health care–related costs, plaintiffs may be awarded general or noneconomic damages for such things as pain and suffering, mental anguish, grief, and other emotional complaints. In recent years, juries have become

much more willing to award substantial noneconomic damages to older patients claiming medical negligence. In very rare circumstances, punitive or exemplary damages may be awarded over and above compensatory damages, where the defendant’s conduct has been not merely negligent, but actually reckless or malicious. For example, a jury might award punitive damages when it finds that a patient has developed serious pressure ulcers because of a hospital’s or nursing home’s demonstrated ongoing pattern of neglect.

The final component of proof in a professional malpractice lawsuit is the element of causation. To succeed, a plaintiff must persuade the jury, to a reasonable (not absolute) degree of medical certainty, that his or her injuries were the result of the defendant’s negligence. A plaintiff must prove not only that the defendant’s negligence was a “substantial factor” in bringing about the injury or that “but for” (*sine qua non*) the defendant’s negligence the injury would not have happened, but further that there were no intervening, superceding (i.e., not reasonably foreseeable) forces that acted to break the chain of proximate or direct causation between the defendant’s negligence and the patient’s injury. For example, a physician might negligently fail to diagnose cancer in an older patient in a timely manner and the patient, on learning that cancer is at such stage that it cannot be treated effectively, commits suicide. Assuming the availability of effective treatment if the cancer had been properly diagnosed in a timely manner, representatives of the deceased patient may argue that “but for” the physician’s negligence the death would not have taken place; however, the physician would respond that the patient’s act of committing suicide was an intervening, superceding (i.e., not reasonably foreseeable) factor that disrupted the chain of proximate causation between the physician’s negligence and the patient’s injury.

### Developing and Disseminating Standards of Care

Legal standards of care have been established mainly by the courts as a matter of common law on an incremental, case-by-case basis. State statutes, such as those containing professional licensure requirements, also help to define the required standards of care.

Under the traditional formulation, a professional who is accused of negligent acts or omissions in a medical malpractice claim is usually held to a standard requiring the professional to have and exercise that level of knowledge and skill ordinarily possessed and exercised by competent, reasonable professional peers (determined on a national rather than a local basis) in similar circumstances. Put differently, under long-standing tort principles of negligence, professionals have been judged legally according to the prevalent practice or custom of peer professionals in clinical circumstances like the situation that confronted the particular defendant in the case immediately before the court.

However, there is a significant current trend in many states to deviate from the traditional customary professional standard of care in favor of imposing more objective, external standards of “reasonableness” against which the professional’s behavior is to be evaluated by the jury. An objective, evidence-based standard of reasonableness may exceed (i.e., require more knowledge and sophistication than) the prevailing customary practice within the professional community at the time in handling a specific clinical challenge presented by a patient. Thus, the state of the art in a particular area of care, required under a reasonableness standard, frequently may not be synonymous with and reflected in the current customary practice within the practitioner community. Courts adopting a reasonableness

**TABLE 32-1**

#### Elements of a Professional Negligence Claim

1. Duty owed by professional/provider to the patient
2. Breach or violation of duty
3. Damage or injury to the patient
4. Causal (both general and proximate) link between the professional/provider breach of duty and the injury suffered by the patient

**TABLE 32-2****Proof of the Standard of Reasonable Care Under the Circumstances**

1. Expert testimony about appropriate care
2. Professional codes of ethics
3. Medical journal literature
4. Textbooks (learned treatises)
5. *Physician's Desk Reference* (PDR) and pharmaceutical package inserts (PPIs)
6. Relevant statutes or regulations
7. Voluntary accreditation standards
8. Clinical practice guidelines or parameters

standard often recite the famous maxim of Judge Learned Hand: "Courts must in the end say what is required; there are precautions so imperative that even their universal disregard will not excuse their omission."

When a reasonableness standard is imposed on malpractice defendants, expert witnesses may be allowed to testify, and thereby educate the lay jurors, regarding the appropriate professional conduct under the circumstances. To establish what conduct would have been reasonable, the parties may also introduce other kinds of evidences to supplement the testimony provided by the expert witnesses (Table 32-2). Additional forms of evidence introduced for this purpose may include professional codes of ethics, medical journal literature, textbooks (learned treatises), the *Physician's Desk Reference* (PDR) and pharmaceutical package inserts (PPIs) pertaining to the correct use and dosage of prescription drugs, pertinent statutes or regulations, voluntary accreditation standards such as those of the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO), and, of increasing importance, pertinent clinical practice guidelines or parameters.

Leaders in health care delivery and financing acknowledge (although frequently not in public) that a good deal of routine medical practice has long been predicated more on habit and inertia than on solid empirical evidence establishing clinical efficacy. Out of a concern about both the wasteful resource usage and the quality of patient care, in the last couple of decades professional organizations and specialty societies including the American Geriatrics Society and the American Medical Directors Association, governmental agencies led by the federal Agency for Healthcare Research and Quality (AHRQ), and individual institutions and agencies in the United States and elsewhere have engaged in a concerted movement to develop, collect, and disseminate to practicing clinicians a variety of evidence-based clinical practice guidelines or parameters to educate practitioners about whether a particular diagnostic or therapeutic intervention actually has been demonstrated to produce desired health benefits for patients. The Institute of Medicine has defined clinical practice guidelines as "systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances."

The legal ramifications of clinical practice guidelines or parameters continue to evolve. Nevertheless, there is a growing tendency for the courts to admit into evidence, on behalf of either side to a malpractice dispute (that is, for either inculpatory or exculpatory purposes), properly validated, scientifically supported contemporary practice parameters on the issue of the standard of care to be applied under any particular set of circumstances. This develop-

ment already has consequences, in that surveys show that plaintiffs' attorneys consider health professionals' compliance with or deviation from relevant practice parameters in making decisions about whether to initiate malpractice litigation at all and how to conduct settlement negotiations for claims that are pursued.

## INFORMED CONSENT

### Basics of Informed Consent

The informed consent doctrine originates with the ethical principle of autonomy or self-determination, especially regarding the physical integrity and dignity of one's own body. A health professional/provider may be held civilly liable, usually under a negligence theory but in rare cases under a battery or intentional tort theory, for subjecting a person to any diagnostic, therapeutic, or research-related intervention without that person's effective consent to the intervention. In their legal formulation, the substantive parts of the informed consent rule have evolved over time as a function of state common (judge-made) law. Moreover, the majority of states have, by now, enacted statutes and regulations spelling out a jurisdiction's specific details regarding informed consent, for clinical care generally and/or within particular settings such as nursing homes or public mental institutions.

For a patient's decision about whether to accept or reject a suggested medical intervention to be considered legally valid, three separate but interrelated elements must be present (Table 32-3).

First, the patient's participation in the decision-making process and the final decision(s) regarding intervention must be voluntary, as opposed to being unduly dictated by force, fraud, duress, or any other actual or perceived ulterior form of constraint or coercion. Second, the patient's agreement or disagreement with recommended interventions must be properly informed. The professional is obligated to disclose sufficient information about the proposed intervention to empower the patient to make a knowledgeable, intelligent consent or refusal. The third essential element of legally effective medical decision making is adequate capacity on the part of the patient to cognitively and emotionally understand and manipulate pertinent information about personal care.

In terms of the informed component of the informed consent doctrine, there are two competing standards for determining how much information about a proposed medical intervention must be

**TABLE 32-3****Elements of Legally Valid Medical Decision Making**

1. Voluntary
2. Informed
  - a. Diagnosis or nature of the problem
  - b. Expected benefits
  - c. Risks
  - d. Alternatives, including complementary and alternative interventions
  - e. Risks and benefits of refusal
  - f. Cost implications
  - g. Level of uncertainty
3. Competent/capable decision maker

shared with the patient in advance. The medical custom or reasonable professional standard requires the disclosure of such information that an objective reasonable, prudent professional would disclose under similar circumstances. By comparison, the materiality or patient orientation standard compels the sharing of information that might make a difference (that is, might be material) in the decision-making process of a reasonable, average patient in similar circumstances. The different states are approximately evenly split between these two competing standards of information disclosure.

Under either the materiality or the reasonable professional standard, the basic components of information disclosure implicated by the professional's fiduciary or trust obligations to the patient include the following items: diagnosis or nature of the patient's medical problem; nature and purposes (the expected benefits) of the proposed interventions; reasonably foreseeable risks associated with the intervention, specifically, the likelihood of a risk materializing and the severity or gravity if it does occur; reasonable alternative interventions and their anticipated risks and benefits; and the reasonably foreseeable risks and benefits of not undergoing the proposed intervention. Other informational items that a health professional should seriously consider disclosing to the patient are: complementary and alternative medicine alternatives, which are increasingly popular with older individuals; cost ramifications to the patient of proposed alternatives; professional-specific information pertinent to the particular intervention (for instance, the professional's own track record with the particular intervention or any financial incentives the professional has regarding the patient's course of care); and the level of uncertainty within the medical community concerning the particular intervention.

Informed consent to a medical intervention may be implied or expressed. There are many situations in which a patient's permission to proceed with a medical intervention does not need to be put into words but, instead, may be implied from the context. This happens when, through demonstrative actions, the patient indicates a wish (or at least willingness) to undergo a specific intervention by voluntarily submitting to it in a manner that the health professional can reasonably rely on to conclude that the intervention has been authorized. Implied consent is appropriate for most routine, non-invasive, nonrisky kinds of medical interventions such as taking a patient's blood pressure or listening to the heart. Implied consent is not an exception to the general informed consent requirement, but just a different (created by behavior instead of words) form of permission.

Express consent (put into spoken or written words), by contrast, is more appropriate when the proposed medical intervention is intrusive and/or significantly more risky than ordinary, everyday life. With a small number of exceptions created by particular state statutes for designated kinds of interventions (such as testing for the HIV virus), express consent in the form of spoken rather than written patient words is quite legally adequate, as long as the consent is voluntarily and competently given on the basis of sufficient information being disclosed. However, for particularly intrusive or risky interventions, the professional/provider should consider documenting the patient's decision to consent or refuse by asking the patient to sign a separate written form, in addition to the professional making a progress note in the patient's medical record. Also, voluntary accreditation standards with which the provider complies, such as those of the JCAHO, may require the use of separate written consent forms for particular sorts of medical interventions.

**TABLE 32-4**

### Components of Functional Assessment of Decisional Capacity

1. Ability to communicate decisions
2. Ability to give reasons for decisions
3. Reasons given are logical and factually accurate
4. Appreciation of ramifications
5. Comprehension of ramifications

## Decisional Capacity Issues

Sometimes, a patient is not mentally and/or emotionally capable of assimilating pertinent information and engaging in a rational, voluntary decision-making process about the proposed and alternative medical interventions. Some older persons with dementia, depression, or other age-related mental disorders are so impaired that they fall into this category. When the patient personally lacks adequate decisional capacity, the health professional is not at all relieved of the duty to obtain informed consent but, instead, must work with someone else who is willing to act as a surrogate on the patient's behalf.

Assessing decisional capacity in older persons entails a functional inquiry. Among the basic questions to be posed are the following (Table 32-4): (1) Can the person make and communicate in an understandable form any decisions at all? (2) Is the person able to offer reasons for the choices made, indicating some degree of reflection and consideration? (3) Are the reasons given based on logical reasoning proceeding from factually accurate suppositions? (4) Can the patient appreciate the ramifications (that is, the likely risks and benefits) of the options outlined and the choices expressed, and the reality that these ramifications apply to that patient? (5) Does the individual, in fact, comprehend the practical implications of his or her choices?

A patient's present cognitive and emotional capacity should be evaluated on a decision-specific, rather than a global or all-or-nothing, basis. A patient may be capable of making some kinds of decisions, but not others; partial or limited capacity is quite possible even when total capacity is not. Moreover, capacity may fluctuate within a specific patient according to variables such as time of day, day of the week, physical location, acute and transient physical problems, other persons available to support or coerce the patient's choice, and medication reactions. Older individuals may be especially vulnerable to fluctuations in capacity induced by these factors. Some of these factors may be susceptible to manipulation by caregivers (for example, through changes in the timing of drug administration) so that discussions with the patient (rather than or in addition to the surrogate) about the care plan can take place under the most lucid circumstances possible.

## Advance Health Care Planning as Prospective Decision Making

There are several legal mechanisms available to maximize a patient's medical autonomy. An older person (although these planning tools are available to any decisionally capable adult) may, while still competent, execute certain legal instruments to take steps to anticipate and prepare for eventual incapacity by voluntarily delegating or directing

the exercise of future medical decision-making power. Although oral advance medical directives, theoretically, are completely legally valid, patients should be encouraged to execute written versions to maximize the likelihood that the directive will be ultimately respected by family members and health professionals. Organizational providers are required by the federal Patient Self-Determination Act to initiate discussions with competent patients about the availability of advance medical directive opportunities.

The durable power of attorney (DPOA) consists of a written document in which an individual (the principal) appoints an agent, or attorney-in-fact, to make various kinds of decisions for the principal. Each state has enacted one or more statutes that explicitly authorize the use of a DPOA for health care to empower an agent (including a nonfamily member) to make medical choices on a patient's behalf, should the patient later lose decision-making capacity. A DPOA may be immediate in nature, meaning that it comes into effect as soon as the agent is named. In a springing DPOA, on the other hand, the legal authority transfers (springs) from the patient to the agent only on the occurrence of some specified future event, like a declaration of the principal's incapacity by a designated number of examining physicians. The patient should be informed by attending health professionals when they have decided to act as though decision-making authority has sprung to the designated agent, so that the patient can utter a protest, if desired, to the agent's exercise of power.

The DPOA is a proxy directive, and hence distinguishable from a living will, which is an instruction-type directive. In an instruction directive, a presently competent patient documents his or her wishes regarding future medical treatment (e.g., "no extraordinary measures" or "keep me alive forever no matter what pain or expense") rather than naming an agent to make future treatment decisions in the case of eventual incapacity. The two kinds of legal devices are not mutually exclusive; indeed, patients may be encouraged to execute them in tandem because the living will can help an agent named under a DPOA to exercise the patient's substituted judgment (defined below) more accurately.

When a patient is decisionally incapable but has not previously executed an instruction or proxy directive, in a majority of states health professionals may rely on legislation empowering family members and enumerated other persons to make medical decisions for incapacitated persons. In states with such family consent statutes, the approved procedure usually consists of documenting unanimous agreement among the attending physician, specified relatives or others (listed in a stated order of preference), and sometimes consultant physicians as well.

When there is no valid proxy or instruction directive, family consent statute, or judicial precedent in one's jurisdiction authorizing the family to act as patient surrogate, or in those relatively uncommon situations in which family members strongly and irreconcilably disagree about the best course of care for their decisionally incapacitated loved one, judicial creation of a guardianship or conservatorship (nomenclature varies by jurisdiction) may be advisable to transfer decision-making power formally and definitively from an incapacitated patient to a single, specific surrogate. However, the official legal process (ordinarily entailing significant financial, time consumption, and emotional costs) should not be initiated unless and until less formal approaches, such as mediation or consultation with an Institutional Ethics Committee (IEC) or ethics consultation service, have been exhausted in an effort to reach a sufficient level of agreement among all the interested stakeholders. In a guardianship/

conservatorship case, professionals who have evaluated and/or treated the alleged incompetent person usually are called on to provide evidence to the court in the form of a written affidavit and/or live sworn testimony. Many jurisdictions have public or volunteer guardianship programs that operate to provide surrogate decision makers for individuals with substantially impaired cognitive and/or emotional capacity who have no suitable family members or other private parties to be appointed guardians for them.

In the past, a surrogate has been expected to make decisions consistent with the guardian's view, as a trust agent, of the patient's best interests. The more modern trend, however, is toward enforcement of a substituted judgment standard of proxy decision making, whenever it is realistically feasible. Under this latter approach, the surrogate is obligated to make those decisions that the patient would make, according to the patient's own preferences and values to the extent these can be accurately ascertained, if the patient were presently able to make and express his or her own competent decisions.

## CONFIDENTIALITY

In the course of providing care, health professionals routinely are exposed to very private information about patients and their families. Professionals owe patients a fiduciary responsibility to hold in confidence all sensitive patient information entrusted to them as a consequence of the professional/patient relationship. This ethical obligation, predicated on the patient's important interest in protecting personal privacy and avoiding the social stigma and potential discrimination that breach of one's medical privacy might entail, is enforceable legally under both state and federal law.

### State Law

Every state, both within its various state professional practice acts and in separate statutes pertaining to particular health care delivery settings, has legislatively enacted provisions pertaining to the confidentiality duties of health care professionals, institutions, and agencies. Often, state agencies have published accompanying regulations to implement these statutes. Moreover, a strong common law health care confidentiality doctrine has been forged by state court decisions rendered over time. Violation of state common law or the relevant statutory or regulatory requirements regarding the confidentiality of patient information may subject erring health professionals/providers to civil damage suits, brought by or on behalf of the patient whose privacy was improperly infringed; additionally, violation of state Practice Act provisions may subject the violator to administrative sanctions by the state, including license suspension or even revocation.

However, numerous exceptions to the general confidentiality rule have been recognized, either by the courts as part of the common law or embedded in state legislation or regulation (Table 32-5). The most prominent exception occurs when a patient, expressly or impliedly, voluntarily and knowingly waives, or gives up, the right to assert the confidentiality of particular information. These waivers take place daily to make information available to third-party payers (for instance, Medicare claims processors and private health insurers), quality of care auditors (such as JCAHO surveyors), and other public and private entities like health care surrogates authorized to make medical decisions on behalf of a decisionally incapacitated

**TABLE 32-5****Exceptions to the Duty of Confidentiality**

1. Patient permission (waiver)
2. Danger to others
3. Mandatory or permissive reporting statutes
4. Legal process (court order)
5. "Treatment, payment, and health care operations" (HIPAA)

patient. Also, because the modern delivery of health care most often is a team endeavor, each patient implicitly gives permission for the sharing of certain otherwise private pieces of information among the members of the treatment team. Internal information sharing of this nature is essential to optimal care, especially for accomplishing coordination and continuity of long-term care for older patients with disabilities. Indeed, failures in communication among the multiple providers involved in the care of a patient needing such coordination and continuity may form the basis for negligence liability claims when harm results.

Second, the usual confidentiality duty may be outweighed in situations of jeopardy to innocent, at-risk third parties, such as happens when a patient with serious sensory or cognitive impairments insists on continuing to drive an automobile or maintaining loaded firearms in the home for protection against intruders. Particular details regarding methods for the health professional to discharge the responsibility to report a credible threat of harm to public health or law enforcement authorities vary on the basis of state statutory and case law.

Third, the patient's reasonable expectation of privacy must give way when the health professional is mandated by state statute to report to enumerated public health or law enforcement authorities (e.g., Adult Protective Services [APS]) the professional's reasonable suspicion that certain conditions or activities have occurred or are occurring. Such reportable conditions or activities may include elder mistreatment or neglect (in many states including cases of self-neglect within that definition), domestic violence, infectious diseases, births, and deaths. Some states that have declined to mandate the reporting of particular situations to public authorities nonetheless encourage voluntary reporting; a few states have pursued this approach regarding cases of suspected elder abuse or neglect. Those states supply an incentive for voluntary reporting by expressly providing legal immunity against any form of civil or administrative liability for covered persons making good faith reports to public authorities. Mandatory and voluntary reporting statutes embody the state's exercise of either its inherent police power to protect and promote the general health, safety, welfare, and morals of the community or its *parens patriae* power to step up and safeguard individuals (such as persons with serious cognitive or emotional disabilities) who are not capable of protecting themselves. Further, a health professional may be compelled to reveal otherwise confidential information about particular patients by the force of legal process, namely, by a judge's issuance of a court order requiring such release. This is a possibility in any civil or criminal lawsuit involving a factual dispute about a patient's physical or mental condition. A court order (as opposed to a subpoena or subpoena *duces tecum*, which is issued simply as an administrative, nondiscretionary matter by the court clerk rather than by a judge) requiring one to produce personally identifiable patient information may overrule the state's provider/patient testi-

monial privilege statute that ordinarily would prohibit the provider from testifying in a legal proceeding regarding private patient information. Every state testimonial privilege statute provides for judicially compelled testimony on the part of the health professional when, for example, the patient has placed his or her own health condition and medical treatment in issue in a lawsuit. This could occur when, for instance, the individual challenges the allegations propounded by others about one's mental impairments made in a guardianship/conservatorship petition.

## Federal Law

### Particular Health Care Settings

There are a variety of federal statutes and regulations imposing on health professionals/providers' particular confidentiality obligations when care is provided within specific types of health care settings, including federal penal institutions, veterans affairs facilities, military institutions, federal community health centers, and facilities specializing in the treatment of persons having drug and alcohol addiction. Violation of these laws may result in substantial civil fines. Statutes and regulations setting the conditions for receipt of Medicare and Medicaid payments contain confidentiality provisions, set within general patients' rights standards, applicable specifically to nursing homes and home health agencies. Noncompliance with those provisions could trigger a range of regulatory sanctions, at the extreme including decertification of the facility or agency from participation in federal health care financing programs.

### Health Insurance Portability and Accountability Act

Federal regulations, codified at Title 45, U.S. Code Parts 160 and 164, became effective in 2003 to implement the Health Insurance Portability and Accountability Act (HIPAA) of 1996 (Public Law No. 104-191, title XI, Part C). These regulations, published in the form of a Privacy Rule and a Security Rule, impose on covered health care entities (defined as any health providers who transmit any patient-related information electronically) an extensive set of requirements regarding the handling of personally identifiable medical information contained in patient records. These regulations impose severe criminal and civil sanctions for unauthorized disclosures of personal health information, although as of the beginning of 2007 the Department of Health and Human Services Office of Civil Rights had brought no enforcement action against any covered health entity for an HIPAA violation, despite the receipt of more than 23,000 complaints.

Substantively, HIPAA and its implementing regulations, in essence, codify preexisting state statutory and common law protections for patients, with the addition of provisions making it clear that patients now have the right to access the information contained in their own medical records. (Previously, state law had varied or was unclear regarding the issue of patient access to records.) HIPAA contains provisions authorizing covered entities to transmit personal health information to certain others for purposes of "treatment, payment, and health care operations" such as quality assurance or marketing. These and other exceptions explicitly contained in HIPAA basically track the preexisting state statutory and common law exceptions discussed in the previous section.

## SUMMARY

Individual health care professionals and organizational providers serving older patients inevitably and continuously interact with laws and the legal system. This chapter has outlined a handful of the arenas in which this interaction is likely to occur. For advice in particular circumstances, especially pertaining to relevant state law, specialized legal consultation should be sought from knowledgeable attorneys in private practice, counsel and/or risk managers employed or retained by the health provider, the professional's or provider's liability insurance carrier, or an Institutional Ethics Committee.

# Spirituality

*Timothy P. Daaleman*

New information about linkages between religious and spiritual factors and health-related outcomes continues to be reported by both the popular media and the scientific community. From a cover story in *Newsweek*, to a case conference in *JAMA*, to a clinical trial of intercessory prayer published in *Lancet*, there is ongoing interest in the intersection of religion and spirituality with health and health care in the United States. Such a trend reflects America's overall fascination with spirituality—much of which lies outside of organized religion—so much so that some forecasters have projected a future view of health that places spiritual factors alongside physical, psychological, and social determinants.

This chapter provides an overview and framework for understanding the current phenomenon of spirituality and health, particularly as it relates to the care of older adults. The first section orients how religion and spirituality are defined and understood by several academic disciplines. The core part of the chapter outlines and illustrates a categorical approach to the study of spirituality that has been proposed by Bernard McGinn. The next segment briefly reviews the organization of spiritual care before the final section closes with a perspective that introduces some ideas about a spirituality of practice within a spirituality of place.

## WAYS OF UNDERSTANDING RELIGION AND SPIRITUALITY

Religion and religiosity are generally understood in several ways: the totality of belief systems, an inner piety or disposition, an abstract system of ideas, and ritual practices. For communities of faith, religious doctrine and faith traditions provide a foundation for understanding the wide range of human experience in areas such as suffering, death, and relationships with God and others. The term spirituality, on the other hand, has multiple connotations and interpretations that are less easily defined; academic disciplines such as sociology, psychology, and theology have approached and con-

ceptualized spirituality in various ways. The social work literature, for example, operationalizes spirituality as a process of making sense of self and the world. Here spirituality is proposed as a condition of asking and answering major philosophical questions: who am I, why do I exist, what is my purpose, and how do I fit in the world? Several sociological perspectives resonate with this decidedly existential orientation. Spirituality is represented as that which promotes human agency, or the power that comes from within, in addition to an ongoing search to know our deepest selves and what is held to be sacred.

A psychological perspective is often used when considering spirituality's relationship with health or well-being, since theoretical or conceptual frameworks, which postulate a causal, mediating, or moderating relationship between variables of interest, can be employed. In this way of thinking, the characteristics of spirituality are presented as a web of plausible relationships, predominantly within the domain of well-being. The growing interest in positive psychology, for example, casts an individual's subjective experience in an optimistic light and often depicts spirituality as providing a foundation for adjustment, growth, and reaching one's human potential. A related approach, one that is especially relevant to older adults, considers spirituality within the framework of religiously based coping mechanisms.

The social and psychological sciences have contributed greatly to contemporary perspectives of spirituality; however, the roots of this concept lie within theological sources. Historians trace the etymology of spirituality to the spirit of God (*ruah*) in the Old Testament, which subsequently provided emphasis for the term "spirit" (*pneuma*) found in the New Testament. Despite the central place of this idiom in such foundational texts, the abstract word *spiritualitas* (spirituality) did not arise until the fifth century, here having a biblical meaning of a spiritual person, or one whose life is ordered or influenced by God. By the 12th century, spirituality was associated mainly with what pertained to the inner life of the soul. However, this usage of spirituality went into eclipse by the 18th and 19th

centuries, largely because of Voltaire and other contemporary thinkers who wrote about spirituality in disparaging ways. The genesis of contemporary understandings regarding spirituality is linked with French Catholic writers who used the term in a devotional sense in the early part of the 20th century. As time progressed, spirituality gradually migrated into more academic and technical circles, predominantly within the Catholic tradition.

Current, generally more inclusive theological contexts consider spirituality in light of beliefs in God or a divine being, as well as the sociological, philosophical, and psychological manifestations of those beliefs. One representative viewpoint locates spirituality within the stories, practices, and beliefs that are developed within religious traditions and communities but that are ultimately carried into and worked out in ordinary and everyday life events. A more applied perspective—a white paper on professional chaplaincy—depicts spirituality as “an awareness of relationships with all creation, an appreciation of presence and purpose that includes a sense of meaning.” Such representations shed light on how most Americans can consider themselves to be religious and/or spiritual, grasping these concepts as independent, although perhaps related, qualities of what it is to be human.

## A CATEGORICAL APPROACH TO SPIRITUALITY

McGinn provides a categorical approach to spirituality, one that is useful to clinicians and other providers seeking to understand the multiple ways in which spirituality is manifested in care settings, as well as to investigators interested in developing better ways to study it. The three approaches—historical/contextual, anthropological/social scientific, theological/normative—are collectively holistic in scope, since these seek to capture the range of human experience. As a result, these are not mutually exclusive; more than one may be operational or applicable at a given time.

### Historical/Contextual

A historical/contextual approach looks at the place of spirituality within the context of a shared lived history by a defined group, community, or population. Such an approach can lend insight into the current, accelerated interest and recognition of spirituality in health care circles by examining two parallel, patient-centered movements: end-of-life care and complementary and alternative medicine. Both movements may be viewed as an impetus to rehumanize a health care system in the United States, which has become increasingly impersonal, spiritually barren, and grounded in technology. The ongoing momentum to improve end-of-life care is understandably inclusive of spiritual factors, despite the lack of consistency in how spirituality is addressed in clinical settings.

Complementary and alternative medicine has also promoted rapprochement between spirituality and health care, yet also holds a conflicted perspective on the place of spirituality within its armamentarium. Studies that have examined the prevalence and patterns of complementary and alternative medicine usage vary in their assignment of alternative spiritual interventions—such as faith healing and prayer—as either a therapeutic modality or a conventional religious or spiritual ritual that is exclusive of complementary and alternative medicine. In 1993, a widely publicized survey on unconventional therapies found that 25% of respondents acknowledged

using prayer as a medical modality. A 5-year follow-up study by the same investigators documented an increase in the use of self-prayer and a prevalence of spiritual healing as a common therapy for anxiety, depression, and lung problems. In a subsequent analysis of this data set, one-third of U.S. adults surveyed were found to use prayer for health concerns, both for wellness and for illnesses characterized by painful or aggravating symptoms, nonspecific diagnoses, and limited treatment options such as depression, headaches, and back and/or neck pain. Respondents in this study who used prayer for their health concerns also reported high levels of perceived helpfulness, or efficacy.

For clinicians and other care providers, a historical/contextual approach can enhance a richer, more complete understanding of how patients view the relationship between their own spirituality, however defined, and their health and health care. Here it is important to appreciate and distinguish the various organizational and social contexts in which care is provided; care within a clinical setting is very different than care offered within a faith-based setting, or within the supportive environment of a religious or spiritual community. A historical/contextual perspective can facilitate spiritual assessments—the process of discerning an individual’s spiritual needs and determining what resources are available to meet those needs—which have recently been recommended by the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO) for all hospitalized patients.

Well-developed clinical skills are the soil for fruitful spiritual assessments: empathic and active listening; open-ended questioning; validating, restating, or clarifying information that the patient provides; and determining whether a directed physical or mental status examination is necessary. The 7 × 7 Model, developed by George Fitchett, is a useful tool that incorporates a multidimensional approach to a spiritual assessment, since it includes medical, psychological, and spiritual domains. The model encourages care providers to consider seven different areas: belief and meaning, vocation and obligations, experience and emotions, courage and growth, ritual and practice, community, and authority and guidance. Equally important, it provides a way for providers to effectively communicate with other spiritual caregivers, such as community clergy, hospital chaplains, family members, or other sources of spiritual support.

### Anthropological/Social Scientific

An anthropological or a social scientific approach, according to McGinn, views spirituality as a basic element in human nature and experience. Such a viewpoint allows the spiritual to be distinguished ontologically from the social and psychological and provides for the study of spirituality by the human sciences. More than a century ago, Emile Durkheim’s seminal work on the association between suicide rates and religious denominations in Europe ushered in the scientific study of the relationship between religion, spirituality, and health, which continues to this day. The pace of this research has accelerated in the last 20 years, and more than 1600 studies have been published in this area. For example, a series of articles in the late 1980s suggested that morbidity and mortality rates varied by religious denomination and that high levels of involvement with religious activities were associated with better overall health status.

Religion, and now spirituality, occupies a central place in the lives of older Americans. Popular polls report that religion is very

important in the elderly; 67% of those aged 50 to 64 years, 79% of those aged 65 to 74 years, and 72% of those 75 years and older note that religion is very important. Longitudinal studies suggest that the relationship between age and the importance of religion is nonlinear; importance initially declines between early and middle adult life but increases as people enter old age. African-Americans and women report more strongly held religious and spiritual beliefs than whites and men, even after adjusting for age, level of education, marital status, family income, and region. Finally, attendance at religious and spiritual services is common among older adults, with 52% of those aged 65 to 74 years and 43% of those 75 years and older reporting participation within the last 7 days.

A field analysis of the literature on religion, spirituality, and health highlights several methodological and conceptual shortcomings in this area, but it also concludes that many studies investigating the relationship between church/service attendance and mortality are persuasive. Lynda Powell and colleagues provide a thorough review of this empirical evidence by examining 11 independent, longitudinal studies of the relationship between church/service attendance and mortality incidence. In representative, population-based studies, the strength of the relationship was a 30% reduction in mortality after adjustment for demographic, socioeconomic, and health-associated confounders, and a 25% reduction in mortality after adjustment for established risk factors. In their summary, the reviewers proposed several hypotheses for the protective impact that service attendance may have on mortality: (1) healthy lifestyle behaviors; (2) religious social support; (3) positive emotional experience; (4) modeling of positive and caring behaviors, attitudes, and beliefs; and (5) access to material, emotional, and social resources.

In light of empiric evidence, which is largely mixed, most Americans continue to hold positive attitudes and beliefs about the efficacy of spiritually related interventions (e.g., prayer) in healing, although many remain skeptical about the place of spirituality in clinical encounters. A *USA Weekend* poll reported that 79% of respondents believed that spiritual faith can help people recover from disease, but only 56% said that their faith had actually helped in their recovery. Eighty percent of people sampled in a *CBS News* poll believed that prayer helps healing, but only 34% agreed that prayer should be a standard part of medical care. One multisite survey study found that a small proportion of primary-care outpatients preferred that physicians address spiritually related matters during routine office visits. However, the study also reported that the context of the visit was important, since patients desired greater physician involvement with their spiritual and religious concerns when the severity of their illness increased (i.e., when hospitalized or near death).

Exploratory studies provide some illumination to the inconsistencies in these survey findings. When asked to describe spirituality in the context of well-being, patients in focus group interviews depicted positive thinking and self-efficacy beliefs, and agency beliefs or their use of power or influence. Agency beliefs are empowering beliefs, viewing individuals as active participants constructing their own life course through the actions that they take. Patients also outlined an ongoing process of finding meaning in the face of illness and of placing their illness experience within a larger life context. These qualitative data substantiate one conceptualization of spirituality as the capability to construct an empowering interpretative framework—an explanatory model so to speak—through which health, illness, and life events are viewed: a lattice of meaning and self-identity.

Yet if spirituality is somehow tied to individual systems of empowered meaning, what is the link between the lived experience of the patient and the larger culture that shapes the illness experience? Anthony Giddens provides a useful theoretical orientation for integrating the individual perspectives and social currents found in these surveys and narratives. Giddens posits that maintaining self-identity is an ongoing process of selecting and editing individual narratives amid a diversity of options and possibilities. Self-identity provides a sense of control or mastery in day-to-day activities, but, when there are threats to self-identity and personal meaning, individual biographies are reconfigured and reconstructed.

Consider the chronically ill older adult. The diagnosis and treatment confront this person, with the specter of a life-limiting illness, a functional limitation, or a compromised quality of life, all threats to self-identity. Here, spirituality may be understood in how such individuals begin to integrate their illness experience within their larger life course and how well meaning making empowers them to live their life. Yet this patient, and each one of us, arrives at such a point with a lifetime accumulated with beliefs, stories, and practices: our *background spiritualities*, according to John Shea. Many of these spiritualities will be linked with an identified religious or faith tradition, some will not. But all background spiritualities can be responsive to threats to self by offering beliefs, stories, and practices that provide a template for the ongoing creation of a personally meaningful world, a constructed empowered “reality” in the face of current illness. This constructed world is manifested by the recreated beliefs, stories, and practices that have been transformed by ongoing experiences: our *foreground spiritualities*, in Shea’s way of thinking. More importantly, such a constructed world is contingent upon the social actions and interactions maintained in a larger social world, with family and friends and care providers.

### Theological/Normative

If spiritualities—those beliefs, practices, and stories that respond to a shared human need for meaning—are generated from social actions and interactions, theological, ethical, and normative issues are never far off from the beliefs and values that guide human action and behavior. A theological or normative approach seeks to develop and establish criteria—either by philosophical consistency and cogency or by theological orthodoxy—for determining what may be considered to be “healthy” or “legitimate” spirituality. A Nazi or Satanic spirituality viscerally illustrates “unhealthy” spirituality; it is normatively discomfiting despite how well such a belief system may be integrated, or how effectively it empowers its adherents.

The lived worlds of patients and providers intersect during care encounters, and both arrive with a lived history that is located in specific social and cultural frameworks. Larger cultural and social influences within and outside of the encounter are embedded within this activity. Factors such as race/ethnicity, social support, education, gender, and religion are parts of the scaffolding in the construction of a meaningful world as illness, disability, or death is faced. Faith traditions, for example, provide an important ethical foundation for decision making in related areas such as end-of-life care.

Moral imperatives are part of the fabric of care encounters, specifying what ought to be done to maintain health, avoid illness, and promote healing. Approaching spirituality from an ethical or normative perspective would consider how the intersecting spiritualities of patient and provider are negotiated. At the outset, any proposed

model must be congruent with ethical principles that guide aspects of clinical practice, such as those found in medicine. However, the concept of power is at the forefront of ethically considering spirituality in care encounters. Howard Brody identifies several useful guidelines for power's ethical use. First, the provider and patient should use all of their power to affect a good patient outcome, which is determined by the patient's definition of the presenting problem and by the provider's contextual understanding of the patient's life course. Providers should also be supportive of the patient's own sense of power, as long as it is consistent with a good outcome and the patient's goals and interests. When a conflict arises between the patient's use of power and those ends, it should be handled with negotiation and persuasion and with concern for the patient's vulnerability.

Brody recommends that providers should share their power with patients by informing them about the nature and treatment of the disease, or the presenting problem. This interaction can be extended to include contextual interpretations that are generated, such as cultural scripts and illness trajectories that are conveyed to patients through clinical impressions, and by the recommendation of selected therapeutic interventions. For example, an encounter in which a patient discloses to have cancer and is hopeless, an assessment of a major depressive episode and consultation with a psychiatrist frames hopelessness in a traditional medical model. However, if hopelessness results in the patient declining treatment, another provider may view this as the beginning of a more active dying process and possibly recommend hospice care.

Implicitly or explicitly, providers wield power through their respective frameworks and in the selection of cultural scripts and illness trajectories that are presented to patients. The power wielded by such an interpretative and framing process can be minimized by offering more than one template. In each care encounter, patients may choose to either incorporate or discard proffered scripts as they construct or reconstruct their self-identity. The resultant clinical narratives are stories of a therapeutic activity facilitated and cocreated by the spiritualities of both patient and provider.

Ongoing clinical narratives that are cocreated by both patient and provider spiritualities can be therapeutic for providers as well. Older adults, especially those with chronic illness, can confront and perhaps threaten a provider's sense of self through their disability, serious illness, or death. Yet the spiritualities found in patient narratives can contribute to the ongoing construction of a provider's own self-identity, by presenting and affirming the human condition in its entirety. For some providers, spiritualities may be inclusive of practices that are common to patients, such as prayer, reflection, and self-awareness. For others, spiritualities may arise as philosophical or religious belief systems: beliefs that may be held or shared with their patients and beliefs that provide a foundation of purpose. However, for all providers, spiritualities that are brought forth by patient stories, and are woven into ongoing narratives, are responsive to a basic human desire of finding meaning in an integrated way.

## THE ORGANIZATION OF HEALTH-RELATED SPIRITUAL CARE

The Institute of Medicine, the National Hospice and Palliative Care Organization, and the JCAHO advocate attention to the spiritual care of patients, despite ambiguity in how spirituality is understood

in health care settings. In clinical arenas, physicians, nurses, and other health care workers are being called upon to assume greater responsibility for addressing and meeting the spiritual needs of their patients, tasks that have been traditionally assigned to pastoral care providers and clergy.

Investigations into the structure, process, and outcomes spiritual care have been limited to qualitative research and small survey studies, largely of nursing staff in long-term care. For example, one exploratory study of nurses described the spiritual care of dying nursing home residents using five themes: honoring the person's dignity, struggling with end-of-life treatment decisions, wishing to do more, personal knowledge of self as a caregiver, and intimate knowledge of the resident. Other survey studies of oncology nurses suggest that spiritual care involves several tasks: referring to pastoral care providers and clergy, acknowledging and supporting patients' spiritual or religious concerns, and being attentive to both patients and family members.

A recent multistate study of spiritual care at the end of life adds greater understanding to the organizational aspects of spiritual care. This report of 284 decedent residents, from a sample of 100 residential care/assisted living facilities and nursing homes, found that most residents (87%) nearing the end of life received assistance with their spiritual needs. Residents who received spiritual care were perceived to have had better overall end-of-life care by their family members, and the provision or facilitation of individual devotional activities was found to be an essential component of spiritual care. Other qualitative studies of family members and nurses caring for dying residents provide a richer understanding of what may constitute the practice of spiritual care. For example, one study reported that an intimate knowledge of the resident and the provision of spiritual comfort—largely through life review and shared devotional activities—were important to end-of-life care in nursing homes. Another report described a variety of caring behaviors by nursing staff, such as listening and answering questions and allowing family members to grieve, as integral parts of spiritual care.

The aforementioned multistate study also found that spiritual care delivered by facility staff, rather than clergy or chaplains, was a key care component; decedents who received care from staff had better overall perceived care. Care and support from the staff was more common in religiously affiliated facilities, which may have been owing to a self-selection among staff who chose to work in such an organizational setting. However, the influence of an organizational ethos, or a commonly held value and mission, which promoted spiritual care in religious facilities, may be more at play.

## FUTURE DIRECTIONS: A SPIRITUALITY OF PRACTICE WITHIN A SPIRITUALITY OF PLACE

In *After Heaven*, Robert Wuthnow suggests that contemporary spirituality in the United States can be understood for the last 50 years as a movement from a spirituality of dwelling to a spirituality of seeking, and he introduces the idea of a practice-oriented spirituality. For older adults and their care providers, who dwell within and are major constituents of multiple organizations and communities—congregations of faith, acute care hospitals, senior centers, and long-term care facilities—a future challenge will be how to integrate a spirituality of practice within a spirituality of place.

One envisioned spirituality of place would be predicated on Peter Senge's work regarding the learning disciplines, as interpreted through Alasdair MacIntyre's idea of communities of virtue. Each of the learning disciplines described by Senge—systems thinking, personal mastery, mental models, building shared vision, and team learning—may be considered on three levels: practices, principles, and essences. Practices are the tasks and work involved in an organization, a primary focus of both individuals and groups. Senge's perspective theoretically represents a point of reference for organizational members, by helping individuals make sense of, and through which they are continually refining, their practices.

Essences are states of being or self-perceptions that come to be experienced spontaneously and naturally by individuals or groups with high levels of mastery in the disciplines. MacIntyre contributes to a complementary understanding of communities, which are formed in identified virtues, including the virtue of "just generosity." This way of thinking may contribute to the health of organizations, communities, and their members. Faith communities and health care organizations, for example, are particular and distinctive types of communities formed over time, with the virtue of "just generosity" as a commonly held virtue, embedded in the guiding principles and practices of learning organizations of virtue. As such, community members have the capacity to become formed in the practices of relatedness and caring and come to embody essences that contribute to the health of both members and the larger community.

A spirituality of practice would be grounded in the practice of narrative, where both patients and providers readily welcome spiritualities—the stories, beliefs, and practices—that reside outside of care encounters but are central to shared experiences of illness and health. A narratively based spirituality of practice can be the foundation to enlarge and sustain the inner life of both patient and provider by forming and nurturing essences: a self that arise spontaneously, authentically, and creatively. This is a normative and moral activity of spirituality, an activity that has the potential for laying the foundation for a greater and sustained therapeutic activity. And

it is here where the purpose and goals—the principles—of care can be fashioned and refashioned.

A spirituality of practice embedded within a spirituality of place would be holy common ground, a place filled with a creative, transformative tension, generated by lives that are linked to a present moment but that are uncertain how the story will continue to unfold, and eventually end. In this way of believing, thinking, and relating, spirituality is embodied as caring within a much larger enterprise: authentic human interactions in which ongoing meaningful life stories—moments of incandescence, both human and divine—are cocreated, nurtured, and shared.

# Ethical Issues

*Jason H. T. Karlawish* ■ *Bryan D. James*

## INTRODUCTION

The competent practice of geriatric medicine requires physicians and other clinicians to master both a body of knowledge about how to diagnose and treat geriatric health conditions and an ethic to apply this knowledge to the care of their patients. In general, the ethics of patient care focus on using the principles of respect for autonomy and beneficence. Perhaps, one of the most important mechanisms to apply these principles is informed consent: the voluntary choice of a competent patient. In these respects, geriatrics is just like fields such as cardiology and endocrinology, which have carved out a particular focus of research, education, and practice and share a common ethic to guide the care of patients.

However, geriatrics differs from other fields of medicine in a number of distinct and ethically substantive ways. Most fields are largely organized around an organ system, such as the gastrointestinal system, or around pathology, such as cancer. But geriatrics is organized around a group of persons defined by a label: the elderly. Being elderly does not simply equate to an organ system or pathology. Instead, it describes a stage in a life course, with an indeterminate beginning and features constructed out of a matrix of biological, social, political, and cultural conditions. For example, geriatric patients are often defined as persons aged 65 years and older. This age cutoff, while precise, is constructed out of the legislation that defines eligibility for state or federal retirement and health care benefits.

Of course, all medical practice is, in some manner, bound to social, political, and cultural conditions. For example, concepts of mental illness are influenced by concepts of what is “normal behavior.” Geriatricians face the challenge of negotiating the fungible borders between illness and normal aging, and between living and dying. This means that mastery of the common ethic of medicine is necessary, but it is not sufficient. This chapter addresses the ethics of medicine focused on the care of elderly patients. The focus is an ethic that addresses the relationship between the patient and the clinician—informed consent—and particular issues in informed

consent that are important for the competent practice of geriatric medicine: diagnostic disclosure, advance care planning, quality of life, refusal of treatment, withdrawal and withholding of treatment, and surrogate decision making. We will also discuss the conditions that underlie decisions: voluntariness and the system of care.

## DECIDING WITH PATIENTS

The ethical foundation of making decisions with patients is informed consent: the voluntary choice of a competent patient following adequate disclosure of the relevant facts. Competency is an essential guiding principle to assure that clinicians strike a proper balance between protecting patient autonomy and promoting patient welfare. In other words, competency provides a tool to balance the two ethical principles of respect for autonomy and beneficence. A competent patient should be allowed to choose even if the choice is harmful or “goes against medical advice.” In contrast, an incompetent patient is not allowed to choose. This denial of choice is not because the clinician objects to the patient’s choice but because the patient cannot make a choice. Chapter 13 defines and discusses how to assess competency and decision-making capacity. The point of this section is to address three challenges in the practice of informed consent.

Informed consent originated largely from surgical cases whose essential theme is as follows. A patient suffers a harm after an intervention such as lower extremity paralysis after an aortic angiogram. The patient argues that when the intervention was agreed on the clinician did not inform about the chance of hemiplegia and had the clinician told about it, the patient would not have agreed to the intervention. From these surgical cases grew an ethical model of informed consent, applicable not only to surgical procedure but to all of medical practice.

The model is that a clinician provides the patient facts about the decision, verifies that the patient has adequate decision-making abilities to use these facts in making a decision, and then practices

care based on the patient's choice. This model describes patients who desire information and control over the decision and want their care guided by their values. It is seen as a remedy to a clinician making unilateral decisions for patients based on the clinician's preferences and values, that is, paternalism.

Informed consent is a vital ethic to guide medical care. In certain kinds of decisions, informed consent is useful to facilitate decision making. These include a choice between interventions with very different kinds of risks and benefits (such as surgery vs. medical therapy vs. watchful waiting for prostate cancer), decisions that are highly personal and value laden (such as advance care planning, which is discussed in more detail below), and decisions that are not part of the formal physician–patient relationship (such as enrollment in research). As useful as informed consent is, there are at least three challenges to its practice.

First, informed consent may not be the ethic that a patient wants to follow. Specifically, many patients describe an asymmetry between their desire for information and their desire to make their medical decisions. In particular, elderly patients often indicate that they want their physician to give them information but they want the physician to make the decision. This asymmetry is often greatest in the case of decisions about the management of serious and life-threatening situations. In these cases, patients will describe decision making built on trust and identification with their physician.

The second challenge to the practice of informed consent is effectively communicating medical information. Much of medical information is probabilistic. This means that the occurrence of an event, such as a fall, is bounded by a chance. Such information can be expressed numerically using figures such as an odds ratio or percentage, or qualitatively using expressions such as “rare” or “likely.” Each of these presents challenges to the practice of informed consent. People—both patients and clinicians—have difficulty with quantitative expressions. This numerical illiteracy means that people may misunderstand information. Related to this is the ambiguity of qualitative expressions such as “rare,” which can mean 1% to one person and 0.001% to another. Finally, biases often influence people's decisions as well as clinicians' communication of information and, thus, should be addressed in the communication of information.

Related to the challenge of communicating medical information is a third challenge: Many patients have impairments in their cognition as a result of geriatric conditions such as dementia and delirium. These impairments can limit a patient's decision-making abilities, specifically the ability to understand, appreciate, and reason through information. Consequently, their capacity to make a decision is impaired to the degree that they are incompetent to make the decision. In these situations, the traditional model of informed consent simply cannot hold. The clinician has to talk to another person, commonly called a proxy or surrogate.

Table 34-1 summarizes these challenges to the practice of informed consent and for each challenge suggests strategies to address them. A general strategy is to reject a “consumer model” of informed consent wherein the patient is the “informed customer” and the clinician a kind of “service provider.” A more useful strategy is one grounded in the relationship between physician and patient. In this relationship, doctor means “teacher” (from the Latin *doctore*) and consent means “to feel together” (from the Latin *con plus sentire*). Taken together, these concepts mean that the geriatrician's practice should recognize that patients, like students, have different kinds of learning needs and skills.

Some patients are quick studies who take charge of the task, while others need careful tutoring and even prompting. Some simply cannot be taught or do not want to be. In each of these cases, the goal is to create a shared understanding of the relevant facts and the patient's values. These skills are essential for all of medical decision making. The issue is not that some patients are more or less intelligent than others, but that some patients, even very intelligent ones, choose not to control decision making. Below, we discuss additional skills needed to address common challenges to making decisions with older patients: diagnostic disclosure; advance care planning; quality of life; refusing, withdrawing, and withholding treatment; and decisions at the end of life.

## Disclosing a Diagnosis of Alzheimer's Disease

In the care of persons with Alzheimer's disease, diagnostic disclosure is an ethically and clinically challenging issue. On the side for disclosure is the argument that patients deserve the truth and to deny this information to them is to deny an adult's right to the truth. The argument against disclosure is that not all truth is good to tell, especially to a person who may be harmed by it. In ethical terms, these competing arguments square off as a dilemma between respecting the principles of autonomy versus beneficence and non-maleficence. In short, is it better to be honest but risk cruelty or kind but risk paternalism? Two issues resolve this question: a person's capacity and desire to know the diagnosis and the moral challenge that Alzheimer's disease presents to the family of a person diagnosed with it.

One critical step in living with an illness is to understand and appreciate it. Understanding is about knowing the facts. In the case of a person with a chronic illness, it means knowing what the illness is, what stage the patient is at, what to expect in the future, and what can be done to maximize quality of life. In contrast, appreciation describes how well a person recognizes how facts apply to him- or herself. This ability is distinct from understanding because it refers to integrating knowledge into one's sense of self.

In the case of persons with Alzheimer's disease, several studies have shown that many persons with mild-stage Alzheimer's disease can understand information. Although they may not remember it, when taught, they are often able to provide a relatively accurate restatement of the facts when asked to summarize what they have learned. This information ranges from descriptions of clinical trials for Alzheimer's disease and treatments for Alzheimer's disease to issues such as voting.

Appreciation is a complex issue in persons with Alzheimer's disease. It is often mixed. A patient may appreciate one feature of the disease, but not another. In the case of appreciating Alzheimer's disease, there are at least three features: the diagnosis, the severity, and the prognosis. Studies examining appreciation show that patients may appreciate one of these features but not the other. That is, patients may be aware of their diagnosis, but not the severity and prognosis. Or, patients could be aware of the severity and prognosis of their cognitive problems, but not the diagnosis.

These findings suggest that to argue either for or against diagnostic disclosure as the standard of care for the class of persons with very mild-to-moderate Alzheimer's disease oversimplifies the issue. It treats the class of persons indiscriminately when, in fact, patients differ in ethically relevant ways: some know there is something wrong, see that it has gotten worse, and have even figured out or remembered

TABLE 34-1

## Common Challenges to the Practice of Informed Consent in Geriatrics and Strategies to Address the Challenge

**Challenge #1.** A patient wants information but does not want to make own medical decisions

*Address information needs*

Find out what the patient does know: "Can you tell me in your own words what you see as the options for your [fill-in name of medical problem]?"

Find out what kinds of information the patient wants to know: "What else is important for you to know about?"

Verify that the patients have fulfilled their information needs: "What else [and then pause for a 15 second count]?"

*Identify decision-making preferences*

Ascertain the patient's decision-making preference. "Patients are all unique. I want to make sure I do what is right for you. Is this the kind of decision you want to make on your own, with me, or leave it up to me?"

*Other strategies*

Address issues that can impact on the legitimacy of the patient's trust. For example, identify and address conflicts of commitment and interest such as serving as a researcher and clinician, ownership of a facility the patient is referred to, and receiving speaking fees from a manufacturer of an intervention the patient is considering.

**Challenge #2.** Quantitative information is difficult to understand

*Numerical illiteracy*

Many people do not understand quantitative expressions very well.

*Numerical indeterminacy*

People attach variable meanings to qualitative expressions of probability such as "rarely" and "likely."

*Biases*

Biases are unintended prejudices or distortions in the way people perceive reality that may introduce error into a decision. They affect both physicians and patients. Biases are best addressed by "debiasing" techniques. Once aware of the potential for the bias, the effective teacher explicitly shows the bias to the patient.

*Availability bias*—the most recent or salient event determines a person's estimate of the chance of the event.

*Framing bias*—the description of event in positive (e.g., chance of cure is 95%) versus negative terms (e.g., chance of no cure is 5%) influences willingness to have the intervention.

*Representativeness Bias*—the chance of an event is evaluated based on how much that event resembles a similar thing without attention to the chance of the event

In the rare instances when quantitative information is available, present it using teaching aids such as graphics. For particularly complex decisions or decisions in which patient values significantly can influence the importance of probabilities, use decision aids. Examples of such decisions include the care of low-grade prostate cancer.

Identify the availability bias by asking "Do you know anyone else who faced this decision?"

The framing bias is best addressed by presenting both sides of probabilistic information. For example, of 100 persons, five will experience the event and 95 will not experience the event.

The representativeness bias occurs when hoofbeats are taken to be the sounds of a zebra instead of a horse (except in Africa). People need to pay attention to the prior probability of an event.

**Challenge #3.** Patients may have cognitive impairments

The presence of a diagnosis such as dementia does not mean that a patient is not competent. It does increase the likelihood compared to patients who are not demented of being not competent.

Assess the patient's decision-making abilities (see Chapter 13). This skill should be applied to all patients, but in the care of cognitively impaired patients it requires careful practice.

that they were told that they have Alzheimer's disease, while others do not.

Diagnostic disclosure depends on the capacity of the persons to understand and appreciate the diagnosis, their expressed desire to know what is wrong, and the emotional and moral impacts that this knowledge may have. Decisions concerning disclosure should also account for the role of the caregivers and the power they hold over the patients. Table 34-2 describes a four-step approach a clinician can use to assess whether and how to disclose a diagnosis of Alzheimer's disease.

## Advance Care Planning

Elderly patients often have chronic and ultimately fatal illnesses. The care of patients in the severe-to-terminal stages of these illnesses typically involves decisions that require tradeoffs between different kinds of symptoms, or quality versus quantity of life. The patients are often unable to make decisions. One strategy to make these difficult decisions is to make them in advance when the patient is competent. Advance care planning describes competent patients dis-

cussing and then documenting their preferences for future medical care. This preserves patients' self-determination even after they have lost decision-making capacity. The classic mechanism to do this is an advance directive.

An advance directive is a set of instructions indicating a competent person's preferences for future medical care should the person become incompetent or unable to communicate. Advance directives typically focus on the conditions of being terminal, comatose, or in a state of irreversible suffering. However, there is no reason why an advance directive cannot address periods of incapacity as a result of other conditions, such as the years spent in the moderate-to-terminal stages of dementia or a period of delirium that might follow a planned surgery. There is no reason as well why an advance directive cannot address decisions that are not necessarily tied to a terminal condition. For example, persons whose religious beliefs proscribe the receipt of blood products can have an advance directive that instructs health care providers not to give them a blood transfusion.

There are two types of advance directives: a living will and a durable power of attorney. These are described briefly in Table 34-3, and more in depth in Chapter 32 on legal issues. The Patient

**TABLE 34-2****Steps to Disclose a Diagnosis of Alzheimer's Disease\***

Step 1. Assess patients' awareness of their cognitive problems:

*Are you having problems with your memory or thinking?*

*What about even a little problem?*

*Are you noticing problems with remembering a list of items? Remembering the date?*

Among patients who have little or no awareness of cognitive problems, diagnostic disclosure is problematic and may need to be skipped.

Step 2. Assess the degree to which patients are bothered by these problems:

*Do these problems bother you?*

*How do you cope with them?*

The degree of patient distress over their symptoms helps to guide how they might cope with the diagnosis of Alzheimer's disease, and it also gauges their desire to know the cause of their cognitive problems.

Step 3. Assess patients' desire to know the cause of their memory problems:

*Do you want to know what is causing these problems?*

This question gives patients the opportunity to express their values about knowing the cause of their cognitive problems. The prior questions lead up to this question in a manner that makes this question relevant.

Step 4. Assess patients' understanding of Alzheimer's disease and their desire to know if they have that disease:

*One common cause of memory problems is a disease called Alzheimer's disease. Have you ever heard of that disease? What do you know about it?*

*Would you want to know if you had that?*

As with step 3, these questions give patients the opportunity to express their values about knowing the cause of their cognitive problems. Together with the prior questions, these give the patients several opportunities to not learn their diagnosis and these inform the physician about how well prepared the patients are to learn the diagnosis.

\*At the end of these steps the clinician has patient specific data to guide whether to disclose the diagnosis of Alzheimer's disease.

Self-Determination Act (PSDA) is a federal law requiring health care facilities that receive Medicaid and Medicare funds (such as hospitals and nursing homes) to inform patients of their rights to execute advance directives. Many states have template forms based on the specifics of advance directive laws. An advance directive that does not strictly follow such a template is valid in most states. Persons may revoke or change their advance directive at any time. A physician who morally objects to a patient's advance directive may

**TABLE 34-3****Advance Directives***Living will*

A document describing a patient's preferences for the initiation, continuation, or discontinuation of particular forms of treatment.

*Durable power of attorney (DPA), a.k.a., health care proxy*

A document that designates a surrogate (also called an "agent," "proxy," or "attorney-in-fact") to make medical decisions on a person's behalf should that person become unable to make a decision.

*Recognized in some states: oral statements*

Oral statements that arise in conversations with family, friends, and physicians are recognized ethically, and in some states legally, as advance directives, if properly charted in medical records.

choose not to comply but must facilitate the patient's transfer to another physician.

At their debut, advance directives were hailed as the solution for unnecessary suffering at the end of life, potentially circumventing the inherent dilemma among conflicting views of the right way to care for frail, seriously ill, or dying patients. It was predicted that dilemmas between "the right to die" versus "the right to life" would be avoided because clinicians and patients would plan ahead. But evidence suggests that advance directives have not achieved this goal. Despite efforts to make advance directives more accessible to patients, overwhelming endorsement by major medical and law associations, and patient interest in the discussion of advanced care planning with their physicians, few patients have them. Even when patients do complete advance directives, evidence suggests that these actually may not assure that the patients' wishes are followed. A number of studies show that advance directives have little effect on resuscitation decisions or the use of medical treatments.

There are three major reasons why advance directives have not accomplished their intended goals. First, they have conceptual limitations. Living wills may seem to assure the strictest adherence to a patient's self-determination (e.g., "*I do not want a blood transfusion.*"). However, they often apply only to specific scenarios such as "terminal illness" or a "persistent vegetative state." This limited scope means that they can often be the source of uncertainty in other scenarios or if there is disagreement about the patient's current state or prognosis. Living wills may not be specific enough to deal with certain clinical questions that arise. In contrast, a durable power of attorney allows for much greater flexibility, as the surrogate can make decisions should any unforeseen circumstance arise. However, surrogates' preferences may be at odds with the patient's preferences. This suggests that a durable power of attorney may not preserve a patient's true autonomous choice.

A second reason for the limited success is that advance directives fail to follow the patients when they are transferred from institution to institution (such as nursing home to hospital), and most clinicians do not know when their patients have completed advance directives.

A third reason is that patients may not see advance directives as an instrument to assure that their will is carried out. Only one-third of patients who have advance directives indicate that they expect them to be strictly followed. Instead, many patients regard their advance directive as a guide for their care and that decisions should also address what is in their best interests.

Advance directives are only effective in promoting patient control over treatment decisions if the patient, surrogates such as family, and health care professionals all have the same understanding of what the document says and how the patient wants it interpreted. Advance care planning is not intended simply to produce a document. Rather, it should be viewed as a process of discussion and feedback in which the clinician is able to elicit the values and preferences that are important to the patient, and the patient is able to understand, appreciate, and reason through the prognoses and treatment options. Furthermore, approaching advance care planning with a checklist of consent for specific treatments does not meet a patient's needs. Such discussions are valuable only as part of a broader discussion of the patient's values and experiences of the illness. [Table 34-4](#) describes the steps in a discussion about end-of-life care and questions to achieve them. [Table 34-5](#) lists useful questions to guide a discussion about advance care planning.

**TABLE 34-4****Steps to Follow in a Discussion About End-of-Life Care and Questions to Achieve Them**

<p><i>Step 1. Identify the patient's present concerns with attention to both the patient and the family.</i></p> <p>What concerns you most about your illness?          How is treatment going for you? What about for your family?          What has been most difficult about this illness for you? What about for your family?</p>
<p><i>Step 2. Learn the patient's understanding about potential outcomes. Correct any misunderstandings of pertinent facts.</i></p> <p>When you think about your illness, what is the best that could happen?          When you think about your illness, what is the worst that could happen?</p>
<p><i>Step 3. Identify patient's concerns about the future.</i></p> <p>What are your hopes for the future?          What are your fears for the future?          As you think about the future, what matters most to you?</p>
<p><i>Step 4. Identify how the patient conceives quality of life.</i></p> <p>If you were dying where would you want to receive medical care? At home?          In a hospital? In a hospice?          What makes life worth living?</p>
<p><i>Step 5. Clarify vague terms.</i></p> <p>What do you mean by "being a vegetable?"</p>
<p><i>Step 6. Identify a proxy decision maker.</i></p> <p>If you were to become ill and could not speak for yourself like you are talking with me now, who would you want to speak on your behalf? Who do you trust?</p>

## Quality of Life

An overarching theme in discussions about the care of patients with chronic illness is quality of life. The term is often invoked as the best means to assess the outcomes of care or balance of the risks and benefits of treatment options. Quality of life is the substance of what is in the patient's best interests. There are many ways to measure it. These include utility measures such as time tradeoffs, functional measures such as the ability to perform basic activities of daily living, disease-specific measures, symptom severity, or a global measure.

**TABLE 34-5****Guidelines for Successful Communication About Advance Care Planning**

<p>Treat advance care planning as an ongoing process, not a discrete event.</p>
<p>Shift focus away from completion of documents toward a discussion of values and preferences.</p>
<p>Do not just focus on specific treatments or likely scenarios. This can lead to a false specificity to the directive. Be sure to elicit patients' deeper values and goals and address the more common uncertainty of end-of-life decisions.</p>
<p>Elicit patients' emotions. Patients' emotions and concerns are very important when exploring their goals.</p>
<p>Do not dominate the conversation. Spend at least as much time listening to patients as talking.</p>
<p>Ensure that patients understand the implications of their stated preferences and that you understand their values.</p>
<p>Establish trust that everything possible will be done to meet the patients' goals and to respect how the patients want their autonomy respected.</p>

Scales to measure quality of life are especially useful to guide decisions about how to treat groups of patients. For example, measures of function or global quality of life can inform the clinical significance of clinical trial results or to track the quality of care in a long-term care facility. Measures of quality of life can be useful in clinical practice as well. In clinical practice, these scales can help to assess the overall effect of care on a patient. In this setting, simplicity of measurement is essential. For example, a global rating—"How would you rate your overall quality of life? Would you say poor, fair, good, very good, or excellent?"—followed by an open-ended question to explain the choice is a useful way to determine how a patient is doing and what matters to the patient.

## Refusing, Withdrawing, and Withholding Treatment

In the United States, patients have an ethical and legal right to refuse life-sustaining treatments including artificial nutrition and hydration. Surrogates have a similar right, but, in some states, they must achieve a standard of evidence to support that the decision reflects what the patient would have wanted. Specifically, in some states, strict evidentiary standards govern the decision about artificial nutrition. In other words, a surrogate cannot refuse or withdraw artificial nutrition based on what is in the patient's best interests but only on the basis of a well-documented substituted judgment. Geriatricians who practice in these states have a clear warrant to discuss these issues with patients and family members.

Some clinicians are comfortable accepting a patient's or surrogate's refusal of treatment before it is initiated, yet find themselves ethically opposed to withdrawing the treatment after it is initiated. The distinction between withholding and withdrawing treatment is understandable psychologically, but it lacks both ethical and legal justification. The concept of this distinction relies heavily on the feeling that withholding is an act of omission, not performing an action, while withdrawing is an instance of commission, performing an action. Withholding a procedure is often seen as wisely abstaining from subjecting the patient to an overly invasive intervention. Conversely, withdrawing a treatment already initiated can give the clinician a sense of responsibility for action bringing about the patient's death and can be regarded as an act of abandonment or breach of expectations or promises.

However, both starting and stopping treatment can be justified depending on the circumstances. Both can *cause* the death of a patient and both can *allow* the patient to die. In the cases of both withholding and withdrawing treatment according to a patient's wishes or best interests, it is the underlying illness that is the cause of death, not the clinician's actions. Moreover, the distinction's reliance on the difference between omission and commission is ambiguous. Withdrawing can happen through an omission such as not putting the infusion into a feeding tube, and withholding the next stage of treatment can be viewed as stopping treatment (i.e., withdrawing). Crimes and moral wrongs can be committed through omission as well as commission. The more important concern is whether a patient or proxy has granted an informed consent.

## Euthanasia, Physician-Assisted Suicide, and Terminal Sedation

The physician's role at the end of life is no longer to cure or control the patient's illness but to provide adequate relief of pain and suffering.

Comprehensive palliative care is the standard of care for the dying. This includes adequate pain and symptom management, support for the patient and family, and the opportunity to achieve meaningful closure to life. Unfortunately, situations may arise in which standard management efforts fail to control pain and suffering. Sometimes patients may ask to die to relieve their suffering. At this point, the clinician's dual obligations of beneficence and nonmaleficence come into conflict. There are a number of options available to the geriatrician at this point, some of which are not accepted as the standard of care and are illegal in some states.

Euthanasia is the act of a physician ending the life of a patient having terminal illness or an incurable disease. The physician acts directly in bringing about the patient's death, such as injecting a lethal dose of drugs. This practice raises strong objections. When it is done to a noncompetent patient, it can be called "murder." When it is done to a competent patient, it remains controversial because many argue it violates core physician duties. Euthanasia is currently illegal throughout the United States. Physician-assisted suicide is the act of providing a lethal dose of medication to a patient to self-administer. Thus, the physician is a necessary instrument but does not actively take part in the ending of the patient's life. This practice is currently legal in only a handful of countries; in the United States, it is illegal in all states except for Oregon. Terminal sedation is the act of administering high-dose medication to relieve extremes of pain and suffering. As the name implies, the patient is sedated to unconsciousness (sedation), and this practice may hasten the death of the patient (terminal) by the impairment of respiratory function. Terminal sedation properly done is distinct from both assisted suicide and euthanasia. Medication doses are increased until sedation occurs (along with the possible risk of the hastening of death) only if nonsedating doses do not achieve pain relief. Also, the dose of medication is maintained but not increased once sedation occurs, and no further intervention, such as a muscle-paralyzing agent, is given to hasten the onset of death. The purpose of terminal sedation is *not* the death of the patient, but the relief of overwhelming physical suffering. The desired and expected benefit of pain relief is significant enough to warrant the risk of hastening death. Terminal sedation is legal throughout the United States.

## DECIDING WITH OTHERS: SURROGATE DECISION MAKING

A common scenario in the practice of geriatric medicine is the following: The patient is not competent but either does not have an advance directive or has one but the directive is not a useful guide. This may be the case because the patient's condition does not meet the terms described in the directive (for example, the patient is not terminal) or the patient indicated that his or her best interests should be part of the decision. In these situations, who decides and how that person should decide invoke issues of surrogate decision making.

The immediate response of most clinicians is to talk to the patient's family. In some states, the law endorses this and describes an ordered list of the kinds of persons who can make decisions, such as the spouse, then adult children, then adult siblings, and so on. In some states, the family is proscribed from making certain kinds of decisions. For example, in New York, the family cannot withdraw or refuse artificial nutrition or hydration for a patient who lacks an advance directive that permits that. Finally, in the majority of states,

the law is simply silent as to who can make decisions for a non-competent patient. This is the case in the vast majority of medical decisions, for example, the choice of treatments, or whether a patient can benefit from rehabilitation. In clinical situations in which the law does not direct medical practice (which is, fortunately, most of medicine), a physician should practice usual and customary medical practice. In the case of medical decision making for noncompetent patients, this means talking to the family.

In general, surrogates should be treated in much the same way as patients. However, there are unique conditions that guide surrogate decision making. Surrogate decision makers should use the patient's preferences to the extent that these are known. Using a patient's previously disclosed preferences to make medical decisions for that patient is called a substituted judgment. Substituted judgments are intended to preserve the patient's autonomy after the patient is not competent to make a choice. However, in many cases, the patient's preferences are unknown, or, because of significant changes in the patient's health and well-being, these are not relevant to the decision at hand. In these circumstances, the guide for surrogate decision makers becomes the patient's dignity and quality of life. This standard of decision making is called the best-interests standard, as the surrogate must assess the risks and benefits of various treatments and alternatives to treatment and choose the one that best maximizes the patient's quality of life.

Western bioethics argues that the best-interests standard should only be used when the patient's preferences are unknown or irrelevant to a particular decision. However, substituted judgments may not be legitimate expressions of patients' autonomous choices. Multiple studies have shown surrogate decision makers to be only slightly better than random chance at predicting patient preferences. This evidence has been used as evidence against the moral authority of surrogate decision makers. But this criticism, based on a strict focus on substituted judgments, misses the strengths of surrogate decision making. For many patients, their relationships with their loved ones are more important than specific decisions, and placing the process of end-of-life decision making within these relationships can offer a great sense of control. Many patients realize that they cannot anticipate every circumstance of dying, but they can assure that the people who love them and care for them will be there to make these difficult decisions when the patients no longer can. Patients generally want their surrogate decision makers to use their judgment rather than be bound by the specifics of living wills.

Surrogate decision making is among the most fulfilling challenges of geriatric medicine. Consider the case of Mrs. A with profound-stage Alzheimer's disease. Her husband and her daughter are faced with a tough choice about the management of recurrent aspiration pneumonia. One key strategy to effective decision making is to make sure that everyone shares a common story about the patient's diagnosis and prognosis. Open-ended questions are a useful way to determine how each person understands or misunderstands the progression and prognosis of the patient's illness. In addition, the clinician should screen for depression and related emotional disorders. These are common among caregivers of chronically ill people and can influence how they assess the patient's quality of life. The clinician should explain to a depressed caregiver how this can impact on how the caregiver perceives the patient's situation. One of the most common consequences of depression is that people fail to see options (in the extreme, this leads to suicidal ideation). Sharing the insight about the impact of depression on decisions may help the

TABLE 34-6

## Guide to Facilitating Surrogate Decision Making

GUIDING PRINCIPLES	ETHICAL BASIS
Substituted judgment	Deciding based on patient's previously stated preferences. Ethical basis: autonomy.
Best interests	Deciding based on patient's dignity and quality of life. Ethical basis: beneficence. Usually used when patient preferences are unknown.
Combination	Patients often want loved ones to use their judgment rather than be bound by specifics of living will.
STRATEGIES	REPRESENTATIVE QUOTES/OPEN-ENDED QUESTIONS
Allow surrogate to narrate how the patient has come to this stage of illness and elicit his or her understanding of diagnosis and prognosis.	"I know you've been through a lot with [ <i>name of patient</i> ] Mrs. A., what's your understanding of how [ <i>he/she</i> ] got to this point and what is wrong now?"
Teach the decision makers about the expected clinical course of the patient's disease.	The following is an example of how to communicate the judgment that a patient is dying: "[ <i>Name of patient</i> ] has an incurable, progressive, and ultimately fatal disease. I can't say for certain when [ <i>she/he</i> ] will die of [ <i>his/her</i> ] Alzheimer's disease, but given its severity, we shouldn't be surprised when it does."
Screen for depression and related emotional disorders. Explain how these can impact decision making.	"Many people caring for a person like your relative feel sad and worry that this affects how they think about what to do for their relative. Is this something you've felt?"
Decisions should be based on (1) the patient's preferences and (2) a balance of the burdens and benefits of each option in terms of relieving suffering and maximizing dignity and quality of life.	"As you think about the options for your relative., a useful guide in making a choice is to focus on what [ <i>he/she</i> ] would have wanted, and to make sure that we maximize [ <i>his/her</i> ] dignity and quality of life."
Provide guidance on basis of existing data and clinical experience.	The following is an example of communication about enteral feeding in persons with neurogenic dysphagia: "For patients like your relative, feeding with a tube does not significantly reduce the risk for pneumonia. On the basis of my experience, a speech therapist can give us some useful hints on ways to feed her that will allow her to continue to eat by mouth."

family member to see the other side. Once there is a common understanding about the patient, it is useful to give the surrogates guidance on how to make the decision. A useful guide is to invoke simultaneously both the principles of substituted judgment and best-interests to assure that Mrs. A's preferences as well as quality of life are respected. These strategies and representative quotes and open-ended questions to guide surrogate decision making are listed in Table 34-6.

## DECIDING TOGETHER: LIVING AND WORKING IN HEALTH CARE SYSTEMS

The issues discussed in this chapter largely address the ethics of interacting with patients and their proxies. Informed consent, instruments such as advance directives, and ethical and legal consensus on matters of refusing treatments (including nutrition and hydration) all have an implicit message: maximizing patient choice will maximize the quality of their care. However, attempts to maximize patient choice may do little to actually affect patient care. For example, the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments, a 2-year trial, which randomly assigned 4804 seriously ill patients to either "usual care" or an intervention arm to promote communication between patients and clinicians, found no difference between the treatment and control groups in any of the following outcome measures: incidence and timing of do-not-resuscitate orders; patient-physician agreement on preferences for cardiopulmonary resuscitation; days in ICU, in coma, or in ventilated state before death; pain; and hospital resource use.

These results suggest that facilitating communication and disseminating information about options for care may not be sufficient to improve patient choice. Instead, we must be cognizant of the conditions that either enable or constrain a patient's ability to choose or for those choices to influence care. A host of institutional factors influence a patient's choices and the provision of care in adherence to these choices. In particular, the voluntariness of a choice can be limited. This is especially true in the care of patients with chronic illness because they develop a long-term interdependence with health care. Nursing homes are, perhaps, the best example of this. Here, the borders between where older persons live and receive health care are indistinct. In this kind of total institution, freedom of choice can be elusive. Instead, resources such as unoccupied nursing home beds, the number of area hospitals, and the institution's tacit culture and attitudes establish the boundaries of permissible choices.

The individual geriatrician who cares for patients may feel powerless in the face of institutional factors. Institutions are slow to change. When they do change, it is largely a political as opposed to a scientific process. And even when science is the chosen instrument of change, medicine's fascination with the randomized controlled trial as the "gold standard" to establish whether an intervention works leaves geriatricians in a bind. Much of geriatrics involves caring for complex patients. It is difficult to control for all factors and still measure clinically significant changes on meaningful end points. In addition, randomized trials are difficult to apply to interventions at the level of an institution. These difficulties include blinding/masking subjects and researchers and selecting what to randomize (the subjects, different wards, or the institution).

**TABLE 34-7****Options for Improving Medical Care**1. *Implementing changes without measurement*

Least desirable for obvious reasons: changed based on theory alone; no measurement of outcomes or definitive proof that change is an improvement.

*Example:* Asking nursing home staff to get patients to make decision-specific living wills.

2. *Formal studies with experimental designs, i.e., randomized controlled trials (RCTs)*

These forms of scientific investigation can lead to large-scale changes in medical care. However, these are often not useful for change at the local level. These require a large investment in resources—time, money, large sample sizes, and disruption of daily patient care—and these may not be feasible.

*Example:* A randomized controlled trial of “usual care” versus an intervention with a trained nurse facilitator to improve communication, decision making, and treatment patterns (e.g., the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments study).

3. *Quality improvement through plan–do–study–act (PDSA) cycles*

Short, small-scale tests of change of procedure. Very useful for improving local systems with their own special conditions. Allows for small cycles of change based on measurement and reflection that can cumulatively lead to large-scale improvement. Quality improvement is particularly useful when the intervention has been shown to work, using techniques such as a randomized and controlled trial.

*Example:* Staff at a long-term care facility jointly identify barriers to advance care planning; they then design interventions to address these barriers, and, after a cycle of intervention, they reassess rates of advance directive completion and discussions.

But there is a way to affect change in an institution that respects political realities as well as scientific rigor: quality improvement. In this model, a community such as a nursing home or an inpatient geriatrics unit sets clear goals, plans an intervention to achieve them, assesses the response, and reevaluates the intervention. This model of plan, do, study, and act can galvanize a system to change. [Table 34-7](#) discusses how plan, do, study, and act cycles can be useful in the quality improvement of medical care systems.

**CONCLUSION**

The central focus of much of western Bioethics is a concern with equalizing the power between physician and patient. In this model, “paternalism” is a wrong, and ethical dilemmas are largely framed as a tension between autonomy and beneficence. Informed consent directs clinicians to “empower” their patients to be “informed consumers of health care.” It is no accident that this ethic gained popularity in the free-market models of fee for service and man-

aged health care. It is a useful way to conduct cosmetic medicine. But it is simply bizarre to consider an 83-year-old frail woman with mild dementia who resides in a nursing home as someone we should assume wants to be treated like a customer who makes medical decisions according to a hyperrational utility maximizing process of decision making. And yet, we cannot imagine that the values of a young clinician who sees her once a month and the culture of a busy and highly regulated long-term care facility should determine this woman’s care. For these kinds of patients, the clinician and the system’s duty is to promote the patient’s independence guided by her abilities and values.

# Perioperative Evaluation and Management

*Preeti N. Malani* ■ *Peter V. Vaitkevicius* ■ *Mark B. Orringer*

## THE OLDER SURGICAL PATIENT

The progressive aging of the American population is challenging the surgical and medical communities with an expanding group of patients who will require surgical interventions much later in life. In coming years, our health care system will continue to be stressed by the need to provide surgical care that not only prolongs life but also promotes the greatest level of functional independence for older patients, without an excessive risk of complications. Among the most frequently performed surgical procedures in this age group are hip repairs, cataract extractions, coronary artery bypass grafting, cholecystectomies, and hernia repairs.

When factors influencing postoperative complications are examined, chronologic age remains an independent risk for adverse surgical outcomes. Advancing age is a marker for significant medical comorbidities that can complicate surgical procedures. The age-associated reduction in the capacity to adapt to stress, a progression in functional frailty, and the number of comorbid illnesses are better predictors than age alone for doing poorly with the rigors of surgery. In addition to increasing operative risk, these factors also prolong recovery times, promote postoperative functional declines, and increase the need for rehabilitation, nursing, and home care support after surgery. Therefore, a comprehensive review of each patient's medical, social, cognitive, and functional status is paramount. Whenever possible, the preoperative clinical assessment should include a discussion with the primary-care physician. The primary-care physician typically has the greatest experience with the patient and is often able to provide useful insights, such as history of developing delirium during hospitalizations, which prove useful in guiding the older patient through surgery. The availability of high-quality geriatric medical care is also essential. A lack of communication between the surgical and the medical providers is a frequent reason why important clinical issues are overlooked, concerns that may have an adverse impact on the older patient's perioperative care. Formal "co-management" approaches have emerged, which involve both medi-

cal and surgical specialists in the perioperative period and appear to improve overall quality of care, including decreased length of stay. The critical nature of the transition between in- and outpatient and subacute care has been recognized as an important area for quality improvement at many institutions.

Because the medical and surgical managements of older patients often overlap, a comprehensive review of the medical and surgical goals and any ethical implications should be routinely completed. The primary goal of surgery is to maximize the life span of these patients in a manner that ensures dignity, self-esteem, and independent function; limits suffering and pain; and occasionally palliates adverse clinical symptoms. To accomplish these goals, an ongoing dialogue between medical and surgical providers is essential.

## HOW AGE INCREASES SURGICAL RISK

The effect of age on risk of surgery is reviewed in Chapter 37. An effort to identify reversible factors associated with perioperative morbidity in geriatric surgical patients is critical to improving surgical outcomes (Table 35-1). In patients older than 80 years, the most prevalent operative risk factors are a history of hypertension, coronary artery disease (CAD), impaired pulmonary function, and prior neurologic events. In one study of older patients, the only intraoperative event predicting a postoperative complication was the use of vasoactive agents. Twenty-five percent of these patients developed neurologic, cardiovascular, or pulmonary complications. Intraoperative events were less important than preoperative comorbidities in predicting adverse postoperative outcomes.

One example of how age increases operative risk is the age-associated changes in cardiac physiology. Primarily as a result of a loss of vascular compliance, the left ventricle demonstrates an increase in stiffness, impaired diastolic relaxation, and an increase in filling pressures. These changes make the ventricle less tolerant of shifts in intravascular volume. An acute increase in volume (e.g.,

**TABLE 35-1**

from intravenous fluids administered during surgery) leads to a further increase in left ventricular filling pressures and could result in pulmonary congestion as a consequence of the age-related increase in diastolic stiffness. Conversely, an acute loss of intravascular volume, such as the third spacing of fluid or intraoperative blood loss, reduces preload to the stiffened ventricle and could produce a marked reduction in systolic blood pressure. CAD, a common comorbidity, increases the risk associated with these adverse age effects. Adding the intraoperative burden of myocardial ischemia to the already impaired diastolic relaxation leads to a further worsening of ventricular filling pressures and increases the risk of pulmonary edema.

Altered renal and hepatic drug metabolisms place the older patient at a greater risk of perioperative drug toxicities. A previously unrecognized disorder of cognitive function may cause an older person to decline substantially with the stress of surgery. Such a decline may present atypically, such as the development of an acute confusional episode or frank delirium. Adverse changes in cognitive function will often prolong a hospital stay and worsen clinical outcomes. Significant age- and disease-related reductions in skeletal muscle mass (sarcopenia) decrease the capacity of the older patient to make a functional recovery, possibly resulting in a discharge to a subacute or long-term care facility.

The older patient may be unable to adequately communicate concerns or clinical history to a health care provider. Therefore, to ensure the best possible surgical outcome for the older patient, it may be necessary to maximize the communication and exchange of data between the surgical team and the medical providers. Clinical programs that have fostered a closer relationship between the sur-

geon and the consulting internist or geriatrician have demonstrated a trend for better surgical outcomes and greater functional recoveries. Several groups within the academic community are promoting comprehensive programs to increase geriatric expertise in the surgical and medical specialties by direct education of the surgical and consulting teams in the principles of geriatric medical care. These efforts are likely to further improve operative outcomes for older patients.

In summary, because normal aging does not account for the bulk of operative risk, the clinician's task is to identify underlying illnesses in older surgical patients and assess their impact on perioperative risk. Teamwork and communication between the various services are critical to promoting the best possible understanding of the patient's clinical situation, helping to mitigate surgical risk.

## SPECIFIC CONSIDERATIONS

### Cardiac Complications

CAD is highly prevalent in older populations and remains the primary cause of death for the elderly patient. An estimated 25% to 30% of all perioperative deaths are attributed to cardiac causes. Because older adults are more likely to have significant CAD, these patients should be carefully screened for signs and symptoms of occult or overt disease. As previously noted, the age-associated increases in vascular and left ventricular stiffness result in a greater sensitivity to volume shifts. Age-related declines in the electrical conduction

system place the elderly patient at a greater risk of drug-induced bradycardia or high-grade atrioventricular blocks. A history of prior myocardial infarction or a low ejection fraction is associated with a greater risk of ventricular tachycardia.

### Pulmonary Complications

With advancing age, the respiratory system demonstrates several changes in function, which may include a loss of pulmonary elastic recoil, decreased diffusion capacity, and reduced cough and gag reflexes, as a consequence of either neurological injury or respiratory muscle weakness. Postoperatively, it is common for older patients to experience atelectasis or frank aspiration. An estimated 14% of older patients will have a major pulmonary perioperative complication (pneumonia, pulmonary edema, or a pulmonary embolus), particularly after an abdominal or a cardiothoracic procedure. Postoperative pneumonia in older patients is associated with a 15% to 20% mortality rate and must be treated with aggressive respiratory therapy and appropriate antimicrobials. A detailed pulmonary and occupational exposure history prior to surgery can help predict impaired respiratory function. Because neurological events that may impair airway protection are occasionally subtle, obtaining a history of swallowing difficulties or prior aspiration may prompt an early start to postoperative interventions aimed at reducing aspiration risk.

### Renal Complications

Renal function is reduced as a result of glomerular and tubular senescence. The progressive sclerosis of glomeruli that occurs with increasing age is typically hastened by comorbid conditions like hypertension, diabetes mellitus, and CAD. In the older patient, the serum creatinine often does not fully reflect the reduction in renal function. The age-associated reduction in skeletal muscle reduces creatinine production, so a reduced creatinine clearance is not always as apparent, even in the setting of diminished filtration. There is greater risk for volume and pH disturbances in the perioperative period because of baseline renal insufficiency. Medications and use of contrast dye can also contribute to renal toxicity.

### Infectious Complications

Postoperative infectious complications represent a major source of morbidity and mortality for older adults. In addition, the development of a surgical site infection or other health care-acquired infection can substantially increase length of stay and associated health care costs. The extended use of indwelling devices, prolonged ventilation, and length of stay are important risk factors for postoperative infections. Infections associated with devices and prosthetic material can present unique treatment challenges. The treatment of significant infections often requires extended courses of parenteral and/or oral antimicrobial therapy, which can raise issues related to safety and tolerability of antimicrobial agents, including nephrotoxicity. Prolonged need for antimicrobials can also contribute to the development of *Clostridium difficile*-associated disease, which is frequently severe in older adults.

### Functional Capacity

Functional impairment is an index of the severity of many chronic diseases, and its severity predicts operative risk to some degree.

For example, poor performance on a bicycle ergometer is a better predictor than the Goldman criteria of surgical outcomes and postoperative pulmonary complications. The metabolic demand of surgery and the physical immobility associated with recovery may promote further declines in strength and function. Not infrequently, a previously independent older adult can become so frail postoperatively that rehabilitative care is needed. Promoting clinical services that increase physical activity and rehabilitation during the surgical recovery process may improve the level of functional independence, shorten recovery times, and prevent readmissions. Postoperatively, the “transitional” care plan must be seamless. Some patients also benefit from referral to a formal cardiac rehabilitation program.

### Emergency Surgeries

While emergency surgeries are associated with a higher overall death rate in all age groups, this finding is most apparent in older patients who have the highest rates as a consequence of a greater number of complications. The causes for the increased risk are multifactorial. The identical surgical disease in the elderly patient may present later in its course, and diagnosis can be delayed because of an atypical presentation. Also, the elderly patient may be treated later by surgeons wishing to correct the associated comorbidities prior to surgery. In the older patient, a delay in a needed nonemergent surgery may have a greater risk if there is a chance that the delay could result in an emergent procedure. Therefore, clinicians should be aware that if the time needed to optimize the patient for surgery is extended, an anticipated elective procedure could become a higher mortality emergent procedure.

### Other Concerns

A neurologic event, such as a stroke, may increase the risk of aspiration by making it difficult to swallow, to move food through the esophagus, and to control respiratory secretions. Advancing age is also associated with a decrease in esophageal peristaltic wave amplitude, reduced tone of the lower esophageal sphincter, a greater incidence of hiatal hernias, delayed gastric emptying, and increased gastroesophageal reflux. All are factors that may increase the perioperative aspiration risk. Age-associated changes in the immune system are subtle but may contribute to a greater risk for infection from organisms that colonize the pulmonary and urinary tracts. Impaired glucose regulation and risk for stress hyperglycemia are common in this age group and may increase infection risks. Thus, careful monitoring to control blood sugars perioperatively may have important benefits. Pressure ulcers are another important postoperative complication (see Chapter 58). Age-related changes in mobility and sensation can contribute to breakdown of skin integrity. Aggressive preventative measures including frequent assessment and pressure unloading are essential aspects of postoperative management.

Taking the time to discuss the surgery with the older patients and their families promotes a clearer understanding of risk and benefits and will help to reduce the chance of false expectations with surgery. Incorporating the common geriatric care format of patient and family conferences in the surgical environment can be very helpful. In such discussions, it is often apparent that an older patient has a different outlook and acceptance of a specific level of care. Shorter-term

goals, such as the quality, not quantity, of life may be most important. Additionally, the tolerance of surgery may be different than that of a younger person. The understanding that a longer time to recover may be necessary is often best communicated in this forum. It is also important to inform the patient and family that an intermediate-care program may be needed, such as a subacute care center, a rehabilitation unit, or the extended use of home care services.

### Period of Risk

Anesthesia is generally considered a safe procedure in elderly patients, with a progressive decline in complication rates being observed in recent years (see Chapter 36). Preoperative risk factors are a better predictor of 7-day mortality than is the duration of anesthesia or the experience of the anesthesiologist. The type of anesthesia (e.g., spinal vs. inhalational) fails to predict outcomes once the preoperative risk factors are controlled. The greatest period of risk for complications remains the time after surgery, with half of adverse events occurring within 3 weeks of surgery.

## PREOPERATIVE MANAGEMENT

### History and Physical

The accurate assessment of risk begins with a detailed review of the clinical history and physical examination. This comprehensive review guides the patient along the various algorithms and directs the selection of preoperative testing. Underlying decline in cognitive function is an essential aspect of the risk assessment of the older patient and may reduce the validity of reported signs and symptoms. A discussion with family members should be sought if clinical data are unclear, cognitive impairment is profound, or the responses are misleading.

The assessment should include a review of physical function, cognitive ability, competency, availability of social support, and symptoms of depression. Cognitive impairment places the patient at an increased risk of perioperative delirium and a longer hospital course. Elderly patients should be screened for impairments using the minimal state examination or similar standardized screening instrument. An elderly patient with little family or social support who undergoes surgery is likely to have a protracted recovery period. Therefore, a preoperative evaluation by a social worker with experience in geriatric medicine is helpful in structuring a supportive network of resources that will reduce complications during the recovery process. Subacute nursing care facilities may play a particularly helpful role in advancing the frail older patient through the recovery process and back to independence. Many institutions have active geriatrics consult services, which can provide detailed guidance on discharge planning issues.

The physical examination can be altered by age and disease. For example, a systolic ejection murmur suggesting aortic stenosis may represent aortic valve sclerosis rather than a hemodynamically significant valvular stenosis. Additionally, markers of severe aortic stenosis, a diminished S<sub>2</sub>, or a delay in the carotid up-stroke may be less apparent in older patients. When the examination is uncertain, echocardiography and Doppler studies are warranted to establish an

accurate cardiac diagnosis, particularly if the murmur is late peaking or radiating to the carotids.

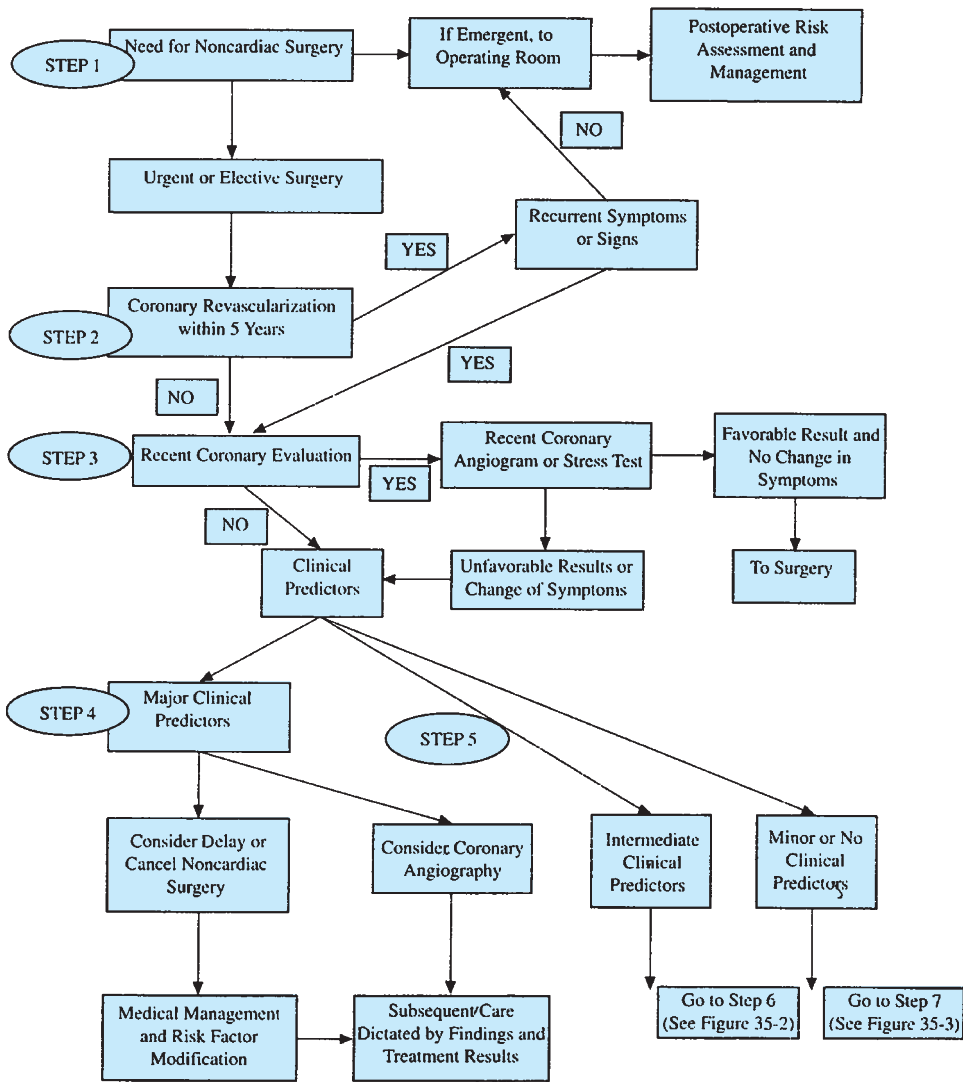

### Medications

The preoperative examination is an ideal time to review medication lists and to determine the overall benefit of these drugs for the patient. Aspirin, clopidogrel, nonsteroidals, and other antiplatelet drugs increase the risk of perioperative bleeding and, if not essential, should be held for a recommended 7 to 10 days. Drugs with anticholinergic properties, such as diphenhydramine or meclizine, are likely to increase the risk of perioperative delirium and should be held. Chronic benzodiazepine use is common and often under-recognized. These drugs should be tapered to reduce the risk of withdrawal symptoms when the patient is made NPO (nothing by mouth). Holding diuretics for 24 to 48 hours prior to surgery should be considered if these are not needed to treat excessive volume or symptoms of pulmonary congestion in patients with congestive heart failure.

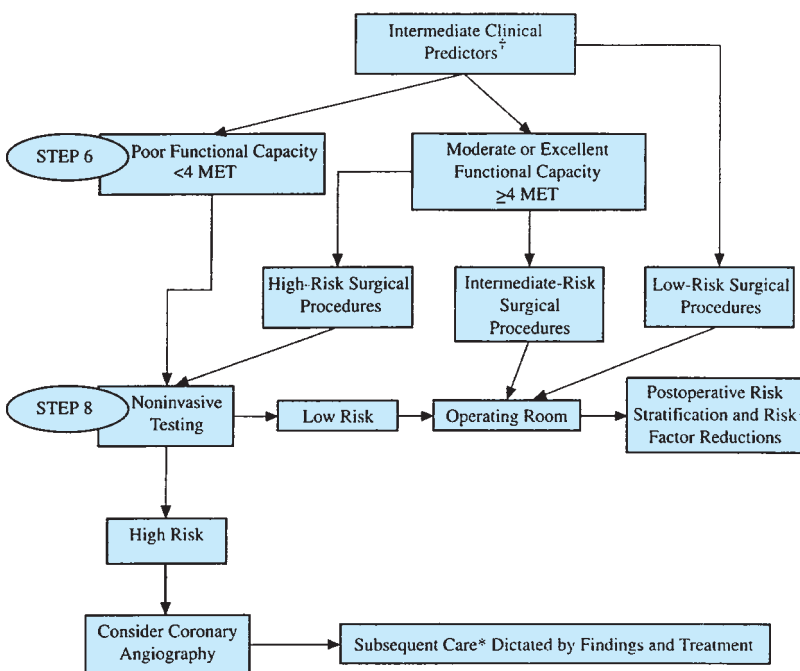

Patients on antiepileptic, cardiovascular, and antihypertensive medications typically should take their medications on the morning of surgery with limited amounts of water. Abrupt discontinuation of beta-blockers and clonidine is associated with significant cardiovascular complications. Patients using these medications can be effectively managed with intravenous propranolol, metoprolol, or transcutaneous clonidine patches. Oral hypoglycemics are generally held the night prior to surgery, to reduce the risk of perioperative hypoglycemia. Insulin-treated diabetic patients typically receive half of their usual dose of intermediate-acting insulin on the morning of surgery and are typically given appropriate amounts of a 5% dextrose solution intravenously, based on blood glucose monitoring. Postoperative glucose above 250 mg/dL is safely managed with subcutaneous insulin or short-acting intravenous infusions of insulin, if hemodynamic instability is present (a cause of variable absorption of subcutaneous insulin). Recent data suggest that tight glucose control in the perioperative period may help decrease risk of surgical site infection, especially related to cardiac procedures. If tight glucose control is chosen, comanagement with a diabetes care team is recommended. Adrenal suppression resulting from chronic steroid use should be treated with stress doses of a steroid, typically 100 mg of hydrocortisone every 6 hours beginning the night prior to surgery and tapering to the maintenance dose in 3 to 5 days, as is permitted by their postoperative course.

### Preoperative Assessment for Noncardiac Surgery

As 25% to 30% of perioperative deaths are attributed to cardiac causes, much of the risk assessment is focused on predicting these cardiac complications. The poor surgical performance of the older patient reflects the high prevalence of CAD, which is often subtle or even silent until the stress of surgery. The current American College of Cardiology and American Heart Association (ACC/AHA) guidelines are a rapidly applied algorithm, which is helpful in assessing risk and directing appropriate preoperative testing and management (Figures 35-1 to 35-3). The Coronary Artery Revascularization Prophylaxis trial used a randomized design to compare preoperative revascularization (either percutaneous coronary intervention or coronary artery bypass grafting) versus medical therapy in patients with stable coronary disease undergoing major vascular surgery. The results suggest that preoperative revascularization does not

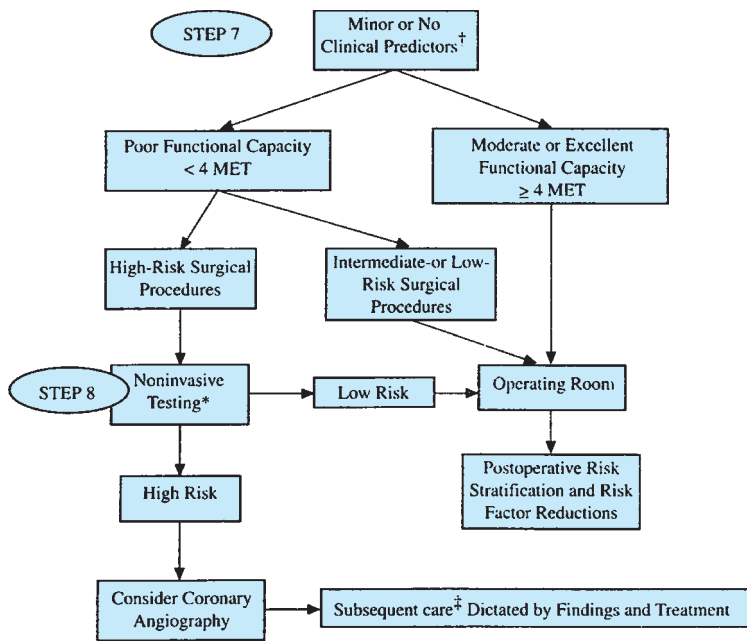

**FIGURE 35-1.** Stepwise approach to preoperative cardiac risk assessment.

**FIGURE 35-2.** Stepwise approach to preoperative cardiac risk assessment. MET, metabolic equivalents of task. \*Subsequent care may include cancellation or delay of surgery, coronary revascularization followed by noncardiac surgery, or intensified care. †See Table 35-2.

**FIGURE 35-3.** Stepwise approach to preoperative cardiac risk assessment. significantly alter long-term outcomes in terms of mortality as well as cardiac events. Based on these findings, a strategy of revascularization before elective vascular surgery in patients with stable cardiac symptoms is generally not recommended.

An in-depth review of the preoperative assessment prior to noncardiac surgery is beyond the scope of this chapter. However, the reader is encouraged to review the published guidelines for a comprehensive understanding of their appropriate use. The aggressiveness of the evaluation is determined by the patient's clinical symptoms. If a surgical emergency exists, appropriate testing and treatment are provided until the time of surgery. On occasion, medical concerns may require the cancellation of surgery.

The initial history, physical examination, and electrocardiogram are helpful in identifying potentially serious cardiac disease such as a prior myocardial infarction, angina, congestive heart failure, conduction abnormalities, or arrhythmias. It is essential to define the severity of the disease, its stability, and any prior treatments before surgery. Clinical factors that are significant tools in assessing risk are functional capacity, age, comorbidities, and the type of surgery. Vascular procedures or prolonged thoracic, abdominal, and head and neck surgeries are considered higher risk.

The benefit of the ACC/AHA guidelines is the stepwise strategy that uses clinical characteristics to define surgical risk in algorithmic tables (see Figures 35-1 to 35-3). Eight key questions help to direct the decision process down the flow chart and are briefly reviewed.

- **Step 1. Urgency of surgery:** If a patient has an immediate need for surgery, with a poor likelihood of survival without it, then it is best to provide medical management as needed and permit the surgery without delay (see Figure 35-1).
- **Step 2. Revascularization:** Have the patients had coronary revascularization in the past 5 years? If yes, have they remained stable or are they currently symptomatic? Further testing is generally not necessary if they have stable symptoms.
- **Step 3. Recent evaluation:** Has there been an evaluation of ischemic symptoms in the past 2 years? If yes, have the symptoms been

adequately assessed and the CAD appropriately treated? If it has been appropriately addressed, it is typically not necessary to repeat the workup, unless new symptoms are noted.

- **Step 4. Disease instability:** Does the patient have major clinical predictors (Table 35-2); unstable signs or symptoms that are concerning such as unstable angina, decompensated heart failure,

**TABLE 35-2**

**Clinical Predictors of an Increased Risk for Perioperative Cardiovascular Events**

**Major clinical predictor of risk (Step 4)**

- Unstable coronary signs and symptoms
  - Recent myocardial infarction\* with ischemic risk by symptoms or testing
  - Unstable or severe angina† (class III to IV)‡
- Decompensated heart failure
- Significant arrhythmias
  - High-grade atrioventricular block
  - Symptomatic ventricular arrhythmias with underlying heart disease
  - Supraventricular arrhythmias with uncontrolled ventricular response
- Severe valvular heart disease

**Intermediate predictors of risk (Step 6)**

- Mild angina (class I to II)
- Prior myocardial infarction by history or pathologic
  - Q waves
- Compensated or prior congestive heart failure
- Diabetes mellitus

**Minor predictors of risk (Step 7)**

- Advanced, age
- LVH, LBBB, ST-T abnormalities on electrocardiogram
- Rhythm other than normal sinus
- Low functional capacity
- History of stroke
- Uncontrolled systemic hypertension

LBBB, left bundle-branch block; LVH, left ventricular hypertrophy.

\* Recent myocardial infarction is  $\geq 7$  days but  $< 30$  days.

† May include stable angina in those who are very sedentary (e.g., nursing home patients).

MET, metabolic equivalent of task.

symptomatic arrhythmias, and severe valvular heart disease; or a recent myocardial infarction? A yes answer to one of these concerns indicates a significant risk factor that may lead to a delay in surgery until symptoms are addressed and potential interventions are thoroughly considered.

- *Step 5. Intermediate risk:* Does the patient have intermediate clinical predictors of risk (see Table 35-2)?
- *Step 6. Functional capacity:* Patients lacking major risk factors but having intermediate predictors of risk and who have a moderate-to-excellent functional capacity can routinely undergo intermediate risk surgeries with a small probability of perioperative death or myocardial infarction (see Figure 35-2). Functional capacity is best assessed in metabolic equivalents of task (MET) and is helpful in predicting risk (Table 35-3). Noninvasive testing is considered for patients with a poor or moderate functional capacity when higher-risk surgery is planned, especially if two or more intermediate predictors are present. Perioperative and long-term cardiac risks are higher in patients unable to meet a four-MET level of exertion during most daily activities.
- *Step 7. Minor or no clinical predictors:* Noncardiac surgery is generally safe for patients lacking both major and intermediate predictors of risk and who have a moderate or excellent functional capacity ( $\geq 4$  MET) (see Figure 35-3). Further testing is considered on an individual basis for patients without clinical markers but with a poor functional capacity who are facing higher-risk operations, especially those individuals with several minor clinical predictors who will undergo a vascular surgery. Table 35-4 lists examples of a given surgery's specific risks.
- *Step 8. Noninvasive testing:* The result of noninvasive testing can be used to determine further preoperative management, which may include further medication or revascularization.

These steps facilitate selecting the appropriate direction on the algorithms. Clinical situations not addressed by these protocols should be reviewed with a consultant cardiologist.

## Other Cardiovascular Concerns

### Hypertension

Severe hypertension should be controlled before surgery, as permitted by the clinical circumstances. Continuation of preoperative

antihypertensive treatments throughout the perioperative period is critical, particularly if that agent is a beta-blocker or clonidine.

### Valvular Disease

Indications for the evaluation and treatment of valvular heart disease are similar to those in the nonoperative setting. Symptomatic mitral or aortic stenosis is associated with significant perioperative risk, severe congestive heart failure, or shock. Patients could be considered for percutaneous valvotomy or valve surgery preoperatively. Symptomatic aortic or mitral regurgitant disease is typically of less risk during surgery, when managed with intensive medical therapy and monitoring. The patient with both severe valvular regurgitation and reduced left ventricular function is best managed with the assistance of a consultant cardiologist.

### Perioperative Beta-Blockers

Beta-blocker therapy is recommended perioperatively for all patients at high risk of coronary events who are scheduled for noncardiac surgery, provided contraindications do not exist. When atenolol was

TABLE 35-4

†Further perioperative cardiac testing is generally not required.

given intravenously or orally, beginning 2 days before surgery and continuing for 7 days after, the event-free survival at 6 months was higher in the atenolol group. Ideally, beta-blocker therapy should be initiated several days to weeks prior to surgery. The dose is adjusted to achieve a resting heart rate of no more than 60 beats per minute. The use of a shorter-acting agent may be preferable in the elderly patient because it permits greater flexibility in dose titration and allows the opportunity to stop the drug quickly, with less risk of sustained side effects such as symptomatic bradycardia. Beta-blocker therapy should be continued throughout the perioperative period.

### Other Preventive Measures

The waiting period before an elective procedure can be used to promote activities that may enhance the recovery from surgery. Patients who receive exercise training twice a week, education, nurse-initiated telephone calls, and an offer to participate in postoperative cardiac rehabilitation have fewer days in the hospital, less time in the intensive care unit, and greater improvements in measures of quality of life. Many surgeons recommend preoperative physical conditioning by encouraging the patient to walk daily for 2 to 3 weeks prior to an elective surgery. This is often coupled with postoperative care plans that encourage early ambulation.

Patients with severe lung disease or who are debilitated should have an introduction to the proper use of incentive spirometry prior to surgery, to reduce the risk of pulmonary atelectasis and its associated complications. This is, perhaps, the most important element in reducing postoperative pulmonary complications, particularly when there is an aggressive education program that encourages the use of these devices in the weeks prior to an elective surgery. Aggressive efforts to promote smoking cessation prior to surgery should be encouraged. Reactive airway disease should be maximally treated with bronchodilators and possibly steroids prior to surgery.

Intravascular volume status is critical and should be optimized preoperatively. Volume contraction should be avoided because of the older patient's greater dependence on left ventricular preload to maintain cardiac output. Routine hemodynamic monitoring using invasive techniques may prevent a few complications, but its routine use remains highly controversial. The use of an intraoperative pulmonary artery catheter to optimize preload, afterload, and isotropic support is of benefit only in selected patients.

Deep venous thrombosis (DVT) is a vexing concern in the postoperative patient. Pulmonary emboli are still thought to be one of the leading causes of in-hospital death and may account for one-third of the postoperative deaths of elderly patients. Procedures commonly performed in the older person, such as hip or knee replacement and urologic or gynecologic procedures, place the older patient at a high risk for this complication. For low-to-moderate-risk procedures, low-dose heparin subcutaneously or external pneumatic compression devices started immediately after surgery is recommended and should be continued until the time of discharge. For higher-risk surgeries, low-molecular-weight (LMW) heparin or warfarin should be considered as a means to prevent postoperative DVT.

Endocarditis remains a risk because of the higher prevalence of valvular disease in older patients. Oral, bowel, urinary tract, biliary, and pulmonary procedures may result in bacteremia and an increased risk for infection if significant valve disease exists. Use of central venous catheters is another important source of bacteremia.

The use of such devices should be minimized whenever possible. The AHA/ACC recommendations for endocarditis prophylaxis, as well as the preoperative assessment guidelines, can be reviewed at the following websites: [www.americanheart.org](http://www.americanheart.org) and [www.acc.org](http://www.acc.org).

### Do Not Resuscitate Orders

The need for surgery in patients with do-not-resuscitate (DNR) orders or concerns of medical futility may be an issue in some elderly patients. Unfortunately, many elderly patients still do not have discussions with their health care providers prior to a hospitalization concerning DNR status, even though this is often mandated. The Patient Self-Determination Act requires that hospitals and other health care facilities inform patients of their right to appoint a proxy or surrogate decision maker to act on their wishes regarding life-sustaining care should they become incompetent. Focused efforts by nurses, clinicians, and consultants to enhance communication can increase the use of advance directives. Debate exists about honoring these orders in the operating suite when a patient requests a DNR status and still must undergo surgery (e.g., percutaneous feeding tube). Surgery may hasten a death as the result of an unanticipated complication. Most of the immediate operative causes for a cardiac arrest are more treatable than the causes of an arrest in other clinical settings, such as the nursing home, because these may include correctable conditions such as oversedation, an arrhythmia, hypotension, pulmonary edema, or bleeding. It is a common practice to suspend a DNR order during the procedure and for 24 to 48 hours afterward. If a complication occurs, the patient is treated and the family or those with decision-making responsibilities are consulted. An evaluation of survivability is made and a decision to suspend or continue the interventions is discussed. This process is less clear when there is a concern that the surgical procedure is potentially medically futile (i.e., when a procedure would have only marginal benefit).

## POSTOPERATIVE MANAGEMENT

Postoperative management includes the appropriate use of medications for pain, increasing mobilization, proper use of urinary catheters, the treatment and prevention of delirium, and anticoagulation use.

### Pain Control

The American Geriatrics Society has published a comprehensive review of pain management in the elderly patient. This report notes that pain is undertreated in older patients because of the concern of using potent analgesics in older patients and a misconception that pain sensations are diminished in such patients. Postoperative patients should be regularly asked about the severity of their discomfort using analog scales, and analgesics should be given according to anticipated needs rather than "as needed." Simply scheduling pain medications is another useful approach. Comments on the management of persistent pain, medication dosing, and metabolism, as well as associated toxicities, are well summarized by the American Geriatrics Society's review of this topic.

## Early Mobilization

Prolonged bed rest can adversely affect the elderly patient. Changes noted with prolonged immobility include a decrease in cardiac output and aerobic capacity, baroreceptor desensitization and orthostatic hypotension, skeletal muscle deconditioning, bone loss, hypercalcemia, joint contractures, constipation, incontinence, pressure sores, sensory deprivation, an increased risk for DVT, atelectasis, hypoxemia, and pneumonia. The earliest possible mobilization from bed is vital, helping to reduce the risk for complications. If the recovery process prevents full mobilization, then a physical therapy referral for range of motion exercises and the maintenance of an upright posture (chair) may reduce the frequency and severity of these complications.

## Catheters

Postoperative urinary drainage is typically managed by an indwelling catheter but that predisposes to urinary tract infection and associated complications. Catheter use should be short, with a goal of prompt removal by the morning after surgery. If there is a concern for urinary retention or bladder distension, then intermittent catheterization should be considered. The use of a urinary catheter beyond 48 hours should be avoided, except when retention cannot be managed by other means. Patients requiring longer-term use of a urinary catheter should not be given prophylactic antimicrobials.

## Postoperative Delirium (see Chapter 53)

An acute confusional state occurs in 10% to 15% of older patients undergoing general surgery, 30% of cardiac surgery patients, and, in one study, up to 50% of hip fracture repairs. Making the correct diagnosis of delirium is important. Although the causes are numerous, it is often the result of a postoperative complication that may not be apparent. Delirium is also a marker for worse functional recovery, and older patients with in-hospital delirium are at risk of significant long-term reduction in cognitive function.

Delirium is often subtle and can easily be missed. Clinical factors key to the diagnosis are a rapid onset, a disturbed level of consciousness, decreased attention and environmental awareness, memory deficits, disorientation, perceptual disturbances, and evidence of a condition that contributes to its development. A history of dementia as well as prior delirium, advanced age, and a prior decline in cognitive function are risk factors for perioperative delirium. As a rule, delirium fluctuates and may not be evident during all visits. Nursing staff and family members are often the most reliable source for the serial assessments of an at-risk patient.

Delirium often compromises postoperative care and extends length of stay. Behaviors can often be controlled with environmental measures, such as a bedside sitter, increased visitations by family, orientation stimuli, minimizing abrupt relocations, and permitting patients to return to a more normal day–night cycle. If medically appropriate, the use of a sleep protocol is often helpful. Symptomatic control of agitation to prevent harm is occasionally needed. Unfortunately, no single drug has an accomplished record. High-potency antipsychotics such as risperidone, haloperidol, olanzapine, and quetiapine should be cautiously titrated to improve symptoms. Lower-potency drugs such as chlorpromazine and thioridazine should be avoided because of their anticholinergic and arrhythmogenic effects.

If delirium is secondary to alcohol withdrawal, short-acting benzodiazepines can be used with close monitoring for excessive sedation. Formal delirium prevention protocols can be helpful, especially in the intensive care unit setting.

## Other Complications

Postoperative surveillance for myocardial ischemia, infarction, arrhythmias, and DVT should ideally lead to a reduction in mortality. Postoperative myocardial ischemia is the strongest predictor of cardiac morbidity. Anginal pain may be masked by narcotics or may be difficult to verbalize during recovery. Postoperative ST-segment changes are indicative of myocardial ischemia and are an independent predictor of events. Such changes are associated with a worse long-term survival. The optimal surveillance strategy for the diagnosis of postoperative ischemia or infarction has not been defined. Currently, no evidence supports the routine use of pulmonary artery catheter monitoring of ventricular performance. In patients without documented CAD, surveillance should be restricted to patients who develop signs or symptoms of cardiovascular dysfunction. In patients with high- or intermediate-risk surgical procedures, an electrocardiogram at baseline, immediately after surgery, and daily for the first 2 days appears to be the most cost-effective strategy. Cardiac troponin measurements should be part of the diagnostic plan for myocardial infarction detection, but additional research is needed to correlate outcomes to the magnitude of an isolated cardiac troponin elevation. As a rule, postoperative myocardial infarctions have a similar pathology to infarction occurring in a nonsurgical patient, the spontaneous thrombosis of the coronary artery. Therefore, when this complication occurs, an aggressive attempt at opening the infarct-related artery should be considered in the appropriate postoperative patient.

Postoperative arrhythmias are often caused by correctable non-cardiac problems such as infection, hypotension, metabolic abnormalities (hypokalemia and hypomagnesemia), and hypoxia. Ventricular arrhythmias (frequent ventricular ectopic beats or nonsustained ventricular tachycardia) may occur in more than one-third of high-risk patients. Prophylactic use of antiarrhythmics other than beta-blockers is currently not justified. Sustained ventricular tachycardia with or without hemodynamic complications requires consultation with a cardiologist. Atrial fibrillation is common. Approximately 25% of elderly patients develop this rhythm. Age and the type of surgery are strong predictors for the development of atrial fibrillation. The prophylactic use of a beta-blocker and amiodarone has shown some benefit by reducing the frequency of this rhythm.

Hemoglobin levels often fall after major surgery. Many elderly patients will tolerate a hemoglobin level below 10 g/dL. Transfusions should be reserved for patients with symptoms and those with levels below 7 g/dL. Controlled trials of oral iron in hip fracture patients demonstrate a lack of benefit, and its routine use is not beneficial. If iron is given, once-daily dosing should be considered.

Cognitive decline has been noted following a variety of surgeries. The International Study of Postoperative Cognitive Dysfunction found that 26% of patients older than 60 years who had either intra-abdominal or orthopedic procedures had a significant decline in cognitive function 1 week after surgery. Risk factors included older age, greater use of anesthetics, and postoperative respiratory and infectious complications. In coronary artery bypass surgery, where the aorta is often cross-clamped and a bypass pump is used, embolization

of both gas and particulates occurs. Central nervous system ischemic damage is often noted after these procedures. Postoperative infarcts are the likely cause of cognitive decline noted with cardiac surgery. Off-pump coronary artery bypass surgery seems to have a lower rate of short-term decline in cognitive function (21% vs. 29%), but similar decline is noted at 6 months (31% vs. 38%). The risk of further decline in cognitive function should be incorporated into the decision process for patients with underlying dementia who are not undergoing emergent or life-saving surgery. Finally, postoperative critical pathways involving regimens, including low-dose opiates, early extubation, and an emphasis on accelerated functional recovery, can be safely applied to older patients.

The management of anticoagulants prior to surgery is briefly summarized. For patients on chronic warfarin with an Int'l normalized ratio (INR) goal of 2.0 to 3.0, four scheduled doses should be withheld to allow the INR to normalize to less than 1.5 before surgery. If the INR is typically kept above 3.0, then longer periods without a warfarin dose may be required. The INR should be measured a day before surgery to ensure that it has reached an acceptable range. If the INR is excessive (>1.8), a small dose of vitamin K, 1 mg SQ, may be given. When the INR is <2.0 other prophylactic antithrombotic interventions should be considered.

Elective surgery is best avoided for a month following a DVT. If this is not possible, then LMW heparin should be given before and after the procedure while the INR is <2.0. LMW heparin should be stopped 6 hours before surgery; restarting it can be considered as soon as 12 hours after surgery, depending on the type of surgery and its result. Patients with a DVT on warfarin for 2 to 3 months need not be on heparin prior to surgery unless there are additional risks. LMW heparin should be given postoperatively until the INR returns to >2.0. Patients with a DVT on warfarin for more than 3 months may not need preoperative heparin. These patients should receive postoperative prophylaxis with LMW heparin until the INR returns to >2.0. These recommendations should be combined with mechanical prophylaxis (gradient compression stockings intermittent pneumatic compression). Elective surgery should be avoided in the first month after an arterial embolism.

## SUMMARY

As our society ages, the need for surgical procedures of all types will continue to increase among older adults. Age alone is not a very

good predictor of operative risk and should not be the sole criteria for deciding who should and who should not have surgery. However, age is associated with a higher prevalence of chronic diseases, which, in turn, are strong predictors of risk and are determinants of who might benefit from surgery and preoperative testing. The AHA and ACC have published revised algorithms, which are helpful in preoperative risk assessment. Perioperative care requires a careful medical evaluation and comprehensive postoperative observation that anticipates potential complications. Newer techniques related to minimally invasive surgery appear promising. Besides decreasing recovery time and postoperative pain, there is some suggestion that overall operative risk may be decreased. Future studies examining clinical outcomes of interest in older adults will be an essential component of evaluating the relative risks and benefits of new interventions.

# Anesthesia

Jeffrey H. Silverstein ■ G. Alec Rooke

Perioperative management of the older adult is complex. Anesthetic care itself is challenging, and both preoperative preparation and postoperative care for older adults assume greater importance than for young, healthy adults. Ideally, care is based on a comprehensive plan that integrates the roles of the anesthesiologist, surgeon, geriatrician, primary caregivers, and medical specialists. This chapter provides an overview of the role of the anesthesiologist and anesthesia techniques in pre-, peri-, and postoperative care of the older adult, in order to improve communication with other professionals who provide care to this vulnerable population.

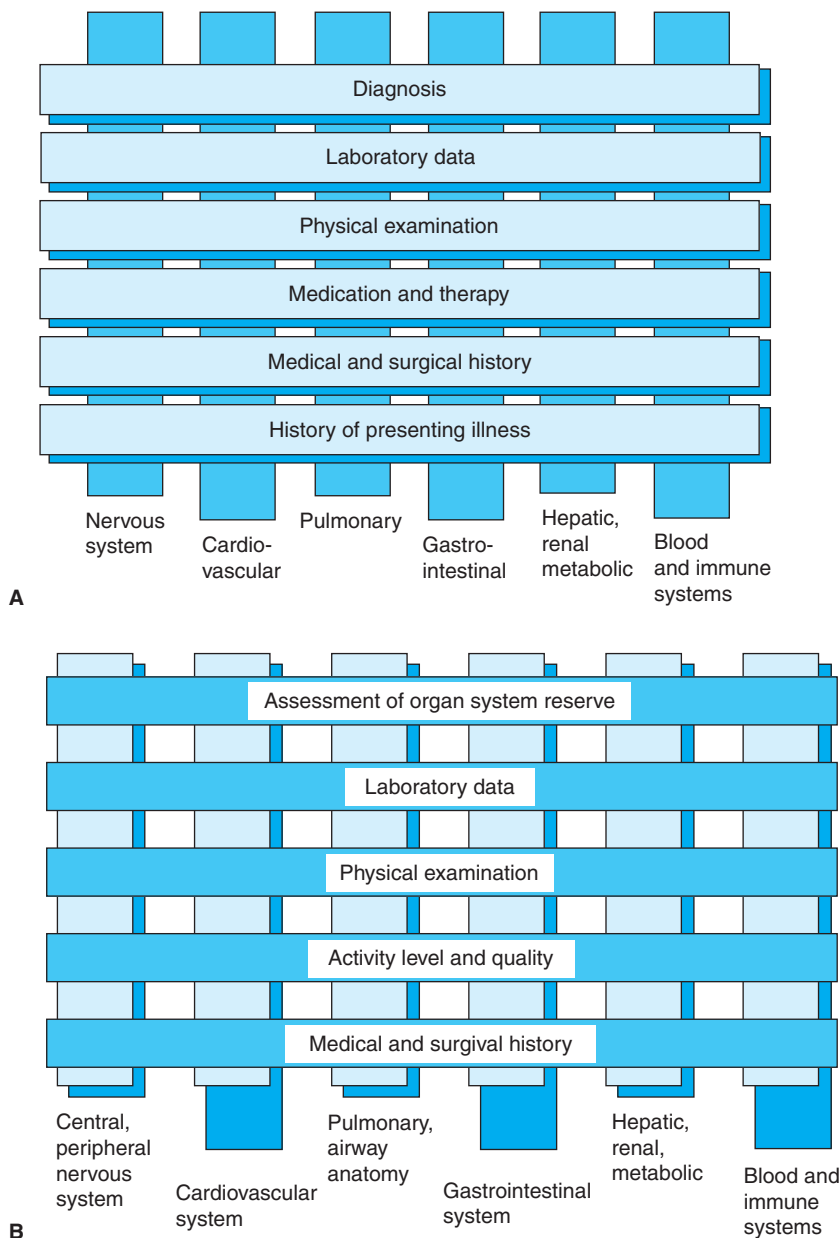

## ANESTHESIA AND THE ANESTHESIOLOGIST

Anesthesia is the art and science of controlling physiologic processes in order to permit interventions on the body that would be intolerable owing to normal compensatory mechanisms. Surgery, which involves a direct assault on body tissues, is the standard paradigm for understanding anesthesia. Anesthesiologists perform other valuable services, including sedation for less invasive procedures, management of pain syndromes, and the provision of critical care. European anesthesiologists are also actively involved in emergency care. Anesthesia is based on an understanding of homeostatic mechanisms and their manipulation. *Homeostenosis*, the restricted range and capacity of homeostatic mechanisms associated with aging, provides a challenge to the anesthesiologist. In order to tailor appropriate anesthesia care for an older adult, the anesthesia team must be familiar with the effects of aging on multiple organ systems, particularly the heart, lungs, and brain, and must be familiar with physiologic changes of age, such as increase in body fat, decreased glomerular filtration, and reduced hepatic blood flow, which affect anesthetic drug action and duration.

## PREOPERATIVE CARE OF THE OLDER SURGICAL PATIENT

Preoperative care can take place in multiple settings and can occur briefly or over a period of time. The most important goal of preoperative assessment is not the risk assessment, but the improvement of the patient's medical status prior to surgery and planning for the recovery process. The anesthesiologist provides care in a different time frame and uses a different approach than is typical for other specialties. The chief complaint usually takes the form of a request for anesthesia services for a specific operation. The anesthesiologist uses a vertical or systems-based approach, most clearly articulated by Stanley Muravchick (Figure 36-1). As part of this approach, the anesthesiologist assigns an American Society of Anesthesiologists physical status classification (Table 36-1). The American Society of Anesthesiologists score is a clinician's tool, not a predictor of perioperative risk, because, while the American Society of Anesthesiologists score correlates broadly with outcomes, it does not incorporate age or type of operation, both significant influences on outcomes.

In terms of ability to tolerate anesthesia and surgery, physiologic status is more important than chronological age. Aging is a highly variable process; young adults are more similar to each other physiologically than are older adults. While chronological age is insufficient to explain surgical outcomes, it has repeatedly been found to be associated with an increased risk of morbidity, mortality, and poor surgical outcomes. Age appears to be an important modifier of disease load, and the number of diseases (disease burden) appears to be the primary determinant of outcomes. Older adults with limited or low disease load have relatively lower risk of postoperative complications (Figure 36-2A), and the combination of high disease load and age is associated with extremely high rates of morbidity and

**FIGURE 36-1.** A. The traditional medical approach to diagnosis can be represented schematically as a series of horizontal techniques of inquiry (open bars) applied across the various organ systems (shaded bars) to consolidate data describing the status of different organs into a unified diagnostic group. B. An organ-system-based "vertical" approach to preoperative assessment of the elderly patient by anesthesiologists differs from the traditional diagnostic approach because it applies the various technique of inquiry (shaded bars) sequentially in each major organ system (open bars) in order to assess organ function and functional reserve. The primary objective of preoperative assessment should be evaluation of physical status, rather than the identification of specific underlying disorders. (Used with permission from Muravchick S: *Geroanesthesia. Principles for Management of the Elderly Patient*. St. Louis, Mosby, 1997, page 17–18.)

mortality (Figure 36-2B). In addition, aging is not uniform across organ systems, and some organ systems may have aged or have been affected by disease more than others. Since aging is so heterogeneous, a careful preoperative evaluation is extremely important in preparing the older adult for surgery.

**TABLE 36-1**

**American Society of Anesthesiologists Physical Status Categories**

P1	A normal healthy patient
P2	A patient with mild systemic disease
P3	A patient with severe systemic disease
P4	A patient with severe systemic disease that is a constant threat to life
P5	A moribund patient who is not expected to survive without the operation
P6	A declared brain-dead patient whose organs are being removed for donor purposes

How and when the preoperative evaluation occurs is highly variable. Many modern surgical practices admit patients for major surgery on the day of the operation. In this scenario, the anesthesiologist must perform the preoperative evaluation and discuss the perioperative experience and anesthetic options with the patient in a tight time frame. Alternative approaches include preoperative clinics and telephone calls, which can provide important opportunities to develop an understanding of the patient's physical condition prior to the day of surgery.

The preoperative evaluation is an essential process in developing an anesthetic plan. Just as importantly, it provides an opportunity to answer questions for the patient and family. The most constructive of preoperative evaluations provide plans for minimizing risk in the perioperative period (i.e., before, during, and after surgery). As part of the evaluation, a general internist maybe consulted. Institutional policy and practices vary as to whether such input is required or even routine. A generalist's statement that the patient has been "cleared for surgery" is of limited value. Much more useful to the

**FIGURE 36-2.** (A) Major anesthetic complications per 1000 related to age. (B) Major anesthesia complications per 1000 as a function of age and associated disease. Legend indicates the number of diseases identified (0 = no disease, 3 = 3 or more diseases). Note that the disease burden significantly increases the likelihood of major complications as patients age.

anesthesiologist and surgeon is a complete overview of the patient's medical condition, recent evaluations, and medications. The more the preoperative evaluator knows and understands, the less often the need for additional consultation. The best plan is based on good communication between the generalist and specialist physicians, the surgeon, the anesthesiologist, and the patient.

Preoperative management of significant medical problems should be determined. Medication regimens (such as anticoagulants, antidiabetic agents, and antiparkinsonian medications) require modifications and advance planning prior to surgery. Several members of the medical team can lead this effort, but the individual responsible should have a good understanding of the issues that need to be addressed and how they should be handled. Medication management protocols that have been jointly set by surgeons, anesthesiologists, and internists are often useful. When additional consultation is sought, the request should clearly define the issues that need to be addressed and the expected role of the consultant. The example shown in Figure 36-3 illustrates a reasonable delineation of the problem to be addressed. Anecdotally, an organized preoperative clinic can improve patient satisfaction and decrease the number of perioperative consults.

Risk assessment is a part of the preoperative process. Most of the time the objective of risk assessment is to decide how aggressive one should be in preparing the patient for surgery, rather than deciding that the surgical risk is too high. Risk assessment is most formalized in the form of the AHA/ACC guidelines for the evaluation of cardiac disease. The guidelines attempt to integrate severity of comorbid disease, exercise tolerance, and surgical severity into a rational plan, in order to determine who needs to enter an advanced evaluation process or to avoid diagnostic procedures with a risk greater than the proposed surgery itself. In fact, the AHA/ACC guidelines were originally developed specifically to limit the frequency of noninvasive cardiac testing, which has the potential to be used unnecessarily. It is important to remember that the AHA/ACC guidelines have never been formally tested, nor are they meant to supplant clinical judgment. Many medical problems in the older adult cannot be addressed using established guidelines so that decisions are based

on clinical judgment. The impact on postoperative outcomes of optimizing medical conditions prior to surgery is usually unknown. Typical conditions that might be optimized preoperatively, even if not seriously unstable, include high blood pressure, diabetes, reactive airway disease, and coronary artery disease. One of the best examples of medical optimization leading to improved outcome is the use of beta-blockade for patients with known or suspected coronary heart disease.

Sometimes internists and anesthesiologists disagree on preoperative management, often about whether or not planned diagnostic tests can be delayed until after the surgery. The consult shown in Figure 36-3 provides an example. In this case, atrial flutter is not a contraindication to surgery. Why should its evaluation delay surgery? Some would argue that if the tests provide useful information or lead to an intervention that improves the patient's status, then the patient will be better off having the tests done prior to elective surgery.

To: General Medicine Consult Service  
From: General Surgery

Mr. DD is a 71 y/o man scheduled for resection of a recurrent dermatofibrosarcoma of the right clavicle. He has diet-controlled adult onset diabetes. He also has a history of a "racing heart" previously evaluated with a Holter 8 months ago revealing brief runs of asymptomatic atrial tachycardia. Today's EKG shows atrial flutter with variable block, and a ventricular rate of approximately 90. Please evaluate his arrhythmia and clear for surgery so anesthesia doesn't cancel him.

To: General Surgery  
From: General Medicine Consult Service

The patient reports no new symptoms over the past several months. He describes some shortness of breath on exertion, but denies past or present angina, MI or symptoms of CHF. According to ACC guidelines, he has intermediate clinical predictors (diabetes) and is undergoing a low-risk surgical procedure.

Recommend:

1. Beta-blockade to limit the heart rate response to surgical stress.
2. Proceed with surgery.
3. Subsequent outpatient evaluation/treatment for his atrial fibrillation (Echocardiogram, TSH level, anticoagulation and a trial of cardioversion).

Thank you for this interesting consult.

**FIGURE 36-3.** An example of a consult request from a surgical service to a medical service.

In the example in [Figure 36-3](#), an echocardiogram provides useful information, even if normal. If a test should be performed, it is reasonable to do it before surgery, unless surgical urgency dictates otherwise. Furthermore, if elective cardioversion is being considered, it should be done before surgery because heart rate control in the intra- and postoperative periods is more easily achieved when the patient is in sinus rhythm. As stated above, there is frequently little evidence upon which to base such judgment but coherent preoperative planning in an older adult can avoid confusion, surgical delay, and requests for emergent consultations that are rarely as complete as elective evaluations.

Geriatrician involvement improves perioperative care but is undervalued in most usual care settings. Comprehensive geriatric assessment (discussed in detail elsewhere) has a place in perioperative care because it is the best way to prevent geriatric-specific postoperative issues like delirium and pressure ulcers.

A unique part of the preoperative assessment of the older adult arises when a patient has a “do not resuscitate” order or other advanced care directives. Many patients have, in consultation with their primary-care physicians, elected to forgo resuscitative measures, because of fears that resuscitation will lead to poor outcome, or because they feel that resuscitation measures will be futile. These fears are supported by numerous studies that demonstrate that cardiac arrest in most settings carries a very poor prognosis, because arrests are usually unwitnessed and may be caused by advanced disease states. However, the operating room is a special setting in this regard. In contrast with other in-hospital cardiac arrests, cardiac arrests in the operating room carry a very favorable prognosis, because arrests are often because of reversible causes such as hemorrhage or drug effects, and because they are witnessed events where resuscitation is instituted within seconds. This means that, in the setting of surgery, a patient’s DNR order must be reconsidered in light of the different prognostic implications of cardiac arrest during surgery. Some organizations have standing policies that DNR orders are rescinded in the operating room. The DNR may be reinstated either upon a physician’s order or automatically upon return to the ward. Regardless of the management plan, DNR orders require review and discussion with the patient. While the anesthesiologist should have such discussions with the patient, input from the patient’s other physicians can be invaluable.

Sometimes a primary-care physician or consultant offers advice on anesthetic management as a part of the anesthesia preoperative referral. These recommendations are usually not helpful. Requests to avoid hypotension and hypoxemia are so obvious as to be unnecessary. Surgical clearance limited to local or regional anesthesia can create problems. These restrictions may not be based on clear evidence. Regional techniques have limitations (see section on “regional anesthesia”). Regional anesthetic techniques occasionally fail in the operating room, requiring an immediate alternative. In some cases, local anesthesia may be feasible, but not preferable, as a result of patient characteristics such as apprehension or positioning issues, or because adequate anesthesia would be difficult to achieve with local approaches alone.

## ANESTHETIC METHODS AND THE OLDER ADULT

Anesthesiologists have developed two major approaches to the provision of anesthesia. The first is general anesthesia, based on the

systemic administration of medications whose principal effects occur in the central nervous system. The provision of various levels of sedation can be thought of as a subtype of general anesthesia. The second major approach is regional anesthesia, based on the use of one of a family of local anesthetics to block nerves. Spinal or epidural anesthesia applies these agents either in or around the spinal canal. Peripheral nerve blocks provide them around nerves subserving specific areas of the body. Local anesthetic agents injected into areas of skin to block the surrounding nerve endings can be thought of as a form of regional anesthesia. The two main forms of anesthesia are not mutually exclusive. A patient undergoing general anesthesia may have a peripheral nerve block to control postoperative pain, and a patient undergoing a procedure with spinal anesthesia is likely to receive hypnotic medications in concentrations that produce sedation. General anesthesia and regional anesthesia work via different mechanisms, so their effects in the older adults are discussed separately below.

### General Anesthesia

This section will review the goals of general anesthesia, principles of intraoperative care, types of anesthetic agents, and age-related special management issues. While unconsciousness is the most apparent distinguishing feature of general anesthesia, it has many other important effects. The cardinal features of general anesthesia are (1) lack of consciousness, including amnesia for events that occur under anesthesia, (2) analgesia or absence of pain, (3) lack of movement in response to painful stimuli, and (4) control of the reflex responses to painful stimuli. In the early years of anesthesiology, ether was found to provide all of these properties, although it did cause prolific vomiting following emergence and had a tendency to cause explosions in the operating theater. The observation that ether, a relatively simple molecule, produced an adequate anesthetic state, along with compelling physicochemical evidence suggesting that potency was linked to the length of the carbon chain of the anesthetic, led anesthesiologists to search for a single mechanism or receptor that was responsible for anesthesia. In subsequent years, it has become clear that anesthesia does not result from alterations of a single receptor, but that all available drugs with anesthetic properties have specific targets. General anesthesia results from alterations at multiple receptors and multiple drugs are almost always used to produce general anesthesia.

### Intraoperative Anesthesia Care

Standard procedure for anesthetic care is to monitor the electrocardiogram, blood pressure, and oxygen saturation. When general anesthesia is undertaken, end-tidal carbon dioxide monitoring is required and temperature should be monitored for most procedures. Intravenous access with large-bore (18 gauge or larger for major surgery) catheters inserted into peripheral veins is almost universally required as part of anesthetic care. The induction of anesthesia is generally accomplished with intravenously administered hypnotic agents. The appropriate dosages of these agents are all decreased with aging. Maintenance of a patent airway and adequate ventilation are primary goals, usually attained via an endotracheal tube and positive pressure ventilation. In recent years, anesthesiologists have developed a variety of new airway devices, such as the laryngeal mask airway, as alternatives to endotracheal intubation. The choice of device and backup procedures varies with procedure and practitioner.

Spontaneous breathing is also a feasible and potentially desirable alternative to positive pressure ventilation.

Adjustment of the depth of anesthesia consumes a good deal of the anesthetic manipulations during surgery. How “deep” or “light” the patient is at any moment depends on the balance of drug effects and the surgical stimulus. Titration of the depth of anesthesia is typically a matter of balancing the tendency of the surgical stimulus to activate the brain and stimulate the sympathetic nervous system against the anesthetic’s ability to depress brain activity and limit the stimulation of the sympathetic nervous system. Thus, a patient might be fully anesthetized one moment and then be inadequately anesthetized a moment later if the surgical (painful) stimulus suddenly increases. The effective depth of anesthesia can be monitored through a variety of methods. The primary approach for years has been to monitor blood pressure and heart rate. Hemodynamic signs of light anesthesia generally appear long before a patient has any chance of “waking up” or of having postoperative recall. A rise in blood pressure and/or heart rate is typically the first sign of light anesthesia and triggers an increase in the concentration of volatile gas (currently isoflurane, sevoflurane, or desflurane) concentration or administration of a small bolus of a fast-acting opioid such as fentanyl. A safe strategy is to keep blood pressure at or slightly lower than the patient’s usual baseline, although this can be quite difficult to accomplish in older patients. The risk of awareness/recall is relatively remote under such circumstances.

Since depth of anesthesia is such a critical issue in perioperative care, and because it can change moment to moment, anesthesiologists have attempted for years to use electroencephalograms to define a brain-based measure of depth of anesthesia. Recently, devices have been developed that use advanced signal processing and computer miniaturization to provide a single number between 0 and 100 that indicates depth of anesthesia. When these devices have been applied to older adults, the findings suggest that the amount of anesthetic typically used to control blood pressure and heart rate frequently results in extremely deep anesthesia for the brain. Excessive depth of anesthesia has been proposed to contribute to poor outcomes. This important area requires further study and might be valuable in the clinical arena in the future.

Patient movement in response to a surgical stimulus, even if very slight, suggests an inadequate depth of anesthesia. Too light anesthesia can result in patient awareness and failure of amnesia. The amount of movement is usually subtle. Most slight movement does not imply such a light level of anesthesia as to result in awareness or recall. Movement cannot be used as an indicator of depth of anesthesia if a patient is paralyzed by neuromuscular blocking agents and common adjuvants for abdominal surgical cases or in cases where even minimal movement is surgically unacceptable. Unintentional excessively light anesthesia is most likely to occur when neuromuscular blocking agents produce muscle relaxation in the presence of lighter general anesthetic agents, such as nitrous oxide and opioids, with little or no potent gases. The electroencephalogram monitors described above have an unclear role in preventing awareness during surgery.

### Anesthetic Agents

The pharmacokinetics and pharmacodynamics of the intravenous and volatile anesthetic agents are altered in the older adult, so that administration must be adjusted. A general rule of the thumb is

that all drugs will have more dramatic and longer-lasting effects in older patients, although this is not universally true. The mechanisms vary with the drug but include changes in protein binding, decreases in initial volume of distribution, alterations in receptor sensitivity, and slowed renal or hepatic metabolism. The therapeutic effect of many intravenous anesthetic agents is not dissipated by metabolism, but by redistribution of the drug from the brain to the fat. These drugs are highly lipid soluble and cross membranes rapidly. On initial injection, the blood levels are very high but will fall as the drug is taken up into fat. The high initial blood levels will promote rapid transfer of the drug into highly perfused organs such as the brain. Even though fat serves as an almost limitless sink for lipid-soluble drugs, blood flow to fat is low and transfer of drug into fat takes time. Transfer time largely dictates the duration of a drug’s clinical effect. As blood levels decrease, drug returns to the blood from the more vascular organs and is then transferred to the fat, dissipating the therapeutic effect. Substantial and/or prolonged administration of many drugs results in drug levels in fat that become high enough to sustain a (residual) blood level that has a therapeutic effect. From an anesthetic management viewpoint, the pharmacokinetic and pharmacodynamic changes of aging rarely present a major problem. Patient response to drugs is variable at any age, so, with the exception of induction, drugs are given in small doses and titrated to effect. The trend today in anesthesia practice is to use drugs that are short acting. These drugs either have shorter metabolic half-lives or redistribute to yield very low blood levels with minimal residual effects, or do both. For example, propofol and thiopental are equally effective induction agents and both are “short-acting” because these redistribute rapidly into fat. The residual blood levels of propofol, however, produce less residual sedation than occurs with thiopental, and propofol also has a shorter metabolic half-life. These principles of drug pharmacokinetics apply to patients of all ages, but the ability to use drugs with rapid fat uptake, but minimal residual effects, is particularly helpful in older patients.

### Hemodynamic Stability During Anesthesia

Hemodynamic stability is a core goal of anesthesia and one of the more challenging aspects of anesthetic care of the older adult. Many characteristics of aging contribute to the increased vulnerability of older adults to hemodynamic instability (Table 36-2). General anesthesia lowers the blood pressure in everyone. This effect is owing to decreased sympathetic tone, which, in turn, may lower heart rate, decrease systemic vascular resistance, and cause peripheral pooling of blood, which will lower cardiac preload. There is also some direct myocardial depression. These effects are exaggerated in older adults. Sympathetic nervous system activity commonly increases with age and so may be more reactive to stimuli than in young people. Chronic hypertension, common in older patients, further exaggerates the vascular response to changes in sympathetic nervous system activity. In particular, the aorta stiffens with age and typically results in left ventricular hypertrophy. Hypertrophy leads to a reduction in the rate of diastolic relaxation, which, in turn, diminishes early diastolic filling. Adequate ventricular preload becomes dependent on passive filling related to left atrial pressure and active filling related to atrial contraction. Both mechanisms must overcome the increased ventricular stiffness and both require a full atrium. Yet atrial blood volume is difficult to keep constant. Veins also stiffen with age. Venous stiffness reduces the capacity to buffer changes in blood volume, making

TABLE 36-2

## Cardiovascular Aging and Anesthetic Implications

AGING-INDUCED CARDIOVASCULAR CHANGE	PHYSIOLOGICAL CONSEQUENCE	ANESTHETIC AND PERIOPERATIVE IMPLICATION
Loss of sinoatrial node cells and conduction system fibrosis	First-degree block and occasional sick sinus syndrome	Severe bradycardia when coupled with potent opioids
Stiff arteries	Systolic hypertension Impedance mismatching at end ejection, leading to myocardial hypertrophy and impaired diastolic relaxation	Labile blood pressure Diastolic dysfunction and sensitivity to volume status
Myocardial hypertrophy and connective tissue stiffening	Increased ventricular stiffness Ventricular filling dependent on a well-maintained atrial pressure	Failure to maintain filling causes an exaggerated decline in cardiac performance; excessive volume more easily increases filling pressures to congestive failure levels
Decreased beta-receptor responsiveness	Limited increases in heart rate and contractility in response to endogenous and exogenous catecholamines Impaired baroreflex control of blood pressure	Increased dependency on Frank–Starling mechanism to maintain cardiac performance. Labile blood pressure
Stiff veins	Decreased buffering of changes in body blood volume impairs ability to maintain constant atrial pressure	Changes in blood volume or body distribution of blood cause exaggerated changes in cardiac filling Hypovolemia more easily impairs cardiac performance, whereas hypervolemia more easily leads to symptoms of congestive failure
Increased sympathetic nervous system activity at rest and in response to stimuli	Basal vascular resistance more dependent on basal sympathetic nervous system	Hypotension from anesthetic blunting of sympathetic tone Increased blood pressure lability from changes in sympathetic tone in response to the surgical stimulus

atrial filling more sensitive to overall volume status as well as to the effects of the sympathetic nervous system on blood distribution. In consequence, older patients are more prone than young patients to both hypotension and hypertension during surgery.

Management of the inevitable swings in blood pressure can be a challenge. Alterations of blood pressure are particularly common during induction of anesthesia and the laryngoscopy/intubation sequence. Hypertension is usually managed by increasing the depth of anesthesia with more opioid and/or increasing the anesthetic gas concentration. Unfortunately, the surgical stimulus can increase or decrease faster than the depth of the anesthetic can be manipulated. One approach is to complement the anesthetic with beta-blockade to minimize the hemodynamic response to the surgical stimulus. Another approach is to use relatively high doses of opioid and relatively less volatile anesthetic. Opioids produce less intrinsic depression of blood pressure than do volatile anesthetics while preventing significant rise in blood pressure during surgery. If high-dose opioids are used to prevent the hemodynamic response to the surgical stimulus, the primary role of the volatile anesthetic is to produce unconsciousness, requiring approximately half the concentration of gas needed without opioids. An ultra-short-acting opioid, remifentanyl, can be employed primarily for short cases that are accompanied by profound stimulation in sensitive areas. High doses of moderate-duration opioids (e.g., fentanyl or morphine) are limited by residual respiratory depression, which can unacceptably depress ventilatory drive at the end of the surgery. Continuous use of ultrashort agents is not currently encouraged because of cost. Another approach is to use a limited amount of opioids compatible with the surgical procedure and then maintain the volatile anesthetic concentration high enough to block the hemodynamic response to the highest level of surgical stimulus. Such a strategy will minimize hypertension but will also make the patient more prone to hypotension at other, less stimulat-

ing, times of the surgery. Sometimes even the minimum level of anesthesia causes an unacceptable depression of blood pressure. In these circumstances, blood pressure must be actively supported. Volume administration can support blood pressure but is of limited utility in older patients. Volume may restore stroke volume but will not compensate for hypotension caused by severe bradycardia or a low vascular resistance. Bradycardia generally responds to glycopyrrolate, an anticholinergic drug that crosses the blood–brain barrier poorly and is presumably less likely to promote postoperative delirium than atropine. Ephedrine stimulates both alpha and beta-receptors and effectively raises pressure, but tachyphylaxis eventually develops and so it is not used for extended time periods. Phenylephrine, a pure alpha agonist, can be conveniently given as either a bolus or a low-dose infusion and effectively maintains blood pressure. On occasion, inotropic infusions (e.g., dopamine) are used, especially if bradycardia does not respond to anticholinergics or there is concern over baseline ventricular function. All pressors have potential adverse effects, of course, but serious problems from their use are infrequent.

Intravascular fluid therapy in older adults is a controversial topic. Much has been written, little has been proven, and clinical practice tends to be based more on habit than on science. Much of the science underlying the most standard anesthetic and surgical approach to volume replacement is based on studies undertaken in the 1960s and 1970s. As noted above, cardiovascular aging makes volume administration more difficult. The stiffness of the venous system exaggerates the response to a given volume excess or deficit. Well-anesthetized patients may appear hypovolemic during surgery as a result of the suppression of sympathetic nervous system activity. A common concern of the geriatric anesthesiologist is that large amounts of crystalloid used for blood pressure control may achieve what appears to be normovolemia during surgery, but, when surgery is over and postoperative pain restores sympathetic activity, that volume may

shift back to the central circulation and create a volume overload. Recently, the basis for fluid administration has been questioned, and an alternative strategy that uses less fluid has been proposed. To date, this approach to fluid management has not been extensively tested or adopted in the United States. The recent literature on reduced fluid volume has not attended to the special issues of cardiovascular aging. Strategies that limit fluid administration frequently are attended by increased use of vasopressors (phenylephrine, norepinephrine, and vasopressin). Since traditional anesthesia care reserves vasopressor use for when fluid administration has failed to maintain perfusion, vasopressor use can be considered an ominous clinical sign that is frequently cited as an adverse consequence of limited fluid administration. In many cases, volume administration is unavoidable and there are no extant guidelines for managing fluid, particularly in older adults. There is also an extensive literature about the proper content of fluids; particularly comparing crystalloid to colloid solutions. There are no clear-cut guidelines for use in older adults.

### Anesthesia and the Pulmonary System

Aging and general anesthesia have important effects on the respiratory system (Table 36-3). Closing capacity increases with age because of diminished airway tethering by connective tissue. General anesthesia enhances expiratory muscle tone and diminishes inspiratory muscle tone, thereby decreasing functional residual capacity. Sighs are suppressed. Atelectasis develops more easily because of the increased closing capacity, decreased functional residual capacity, and the loss of sighs. Atelectasis occurs in the great majority of patients undergoing general anesthesia. Mechanical ventilation disturbs the normal pattern of diaphragmatic breathing in the supine patient, altering normal ventilation/perfusion matching. Volatile anesthetics reduce the effectiveness of hypoxic pulmonary vasoconstriction. Both volatile anesthetics and the placement of an endotracheal tube diminish ciliary action of the respiratory tract, an effect that extends into the postoperative period. Opioids diminish the carbon dioxide ventilatory drive. Volatile anesthetics suppress the hypoxic ventilatory drive, even at the low concentrations present postoperatively. Particularly very frail patients are at increased risk of ventilatory failure postoperatively. The increase in body oxygen consumption

during recovery from surgery may exceed the ventilatory reserve that is compromised by increased chest wall stiffness and decreased skeletal muscle mass. Finally, silent regurgitation and aspiration is more common in older patients. At-risk patients will be challenged postoperatively by drugs that may further depress the airway protective reflexes and impair gastric emptying. Aspiration is much more likely to occur postoperatively than intraoperatively. It is important to understand, however, that patients who suffer aspiration to a degree that causes clinical signs or symptoms will present with some evidence of dysfunction (e.g., hypoxia) within a few hours of the aspiration. It is unlikely that a patient will aspirate, have no consequences for many hours, and then develop a clinical problem that could be attributed to much earlier aspiration.

Intraoperative respiratory management of older patients is straightforward. Bronchospasm is probably the most common intraoperative untoward event. Bronchospasm usually resolves promptly with easily administered treatments. Volatile anesthetic gases themselves produce bronchodilation, and inhaled bronchodilator medications can be administered through the endotracheal tube. Atelectasis prevention strategies during the intraoperative period have been variously successful. Supplemental oxygen is freely used in the operating room, and all patients are monitored by pulse oximetry and frequently with expired gas analysis. This has allowed the anesthesiologist to ensure that all patients are well oxygenated and has markedly decreased the incidence of clinically significant hypoxemia in all age groups.

Most pulmonary problems do not manifest until after surgery. Some degree of hypercarbia is common for at least the immediate postoperative period, especially after considerable opioid administration. This finding usually means nothing more than the presence of good analgesia, so long as supplemental oxygen is administered and the patient can be watched carefully. Supplemental oxygen will likely be necessary for a longer period of time after surgery in older patients. Patients with tenuous respiratory function may need ventilatory support until they are past the acute recovery period. Pneumonia remains an important complication and the ability to prevent its development is limited. Deep breathing and vigorous coughing by the patient are thought to help prevent pneumonia, but postoperative pain may impair these maneuvers. Improved pain control may

**TABLE 36-3**

#### Pulmonary Aging and Anesthetic Implications

AGING-INDUCED PULMONARY CHANGE	PHYSIOLOGICAL CONSEQUENCE	ANESTHETIC AND PERIOPERATIVE IMPLICATION
Decrease in bony thorax elasticity	Stiff chest that is hard to move, increasing the work of breathing and making it more difficult to increase minute ventilation Increased residual volume	Increased risk of respiratory failure
Loss of muscle mass	Reduced strength to meet the increased minute ventilation requirements secondary to the metabolic demands after surgery	Increased risk of respiratory failure
Decreased lung parenchymal stiffness	Increased lung compliance Decreased "tethering" of small airways, leading to increased closing volume Impaired ventilation-perfusion matching	Increased risk of atelectasis, hypoxia, and pneumonia
Impaired airway-protective reflexes	More frequent aspiration	Increased risk of pneumonia and Adult Respiratory Distress Syndrome
Decreased central nervous system responsiveness	Decreased hypercapnic and hypoxic drives	Increased risk of hypoxia Greater sensitivity to anesthetic agents

be one mechanism by which epidural analgesia improves perioperative outcome (see section on “postoperative analgesia”). The role of silent aspiration in the development of postoperative pneumonia is unclear and warrants closer examination.

## Regional Anesthesia

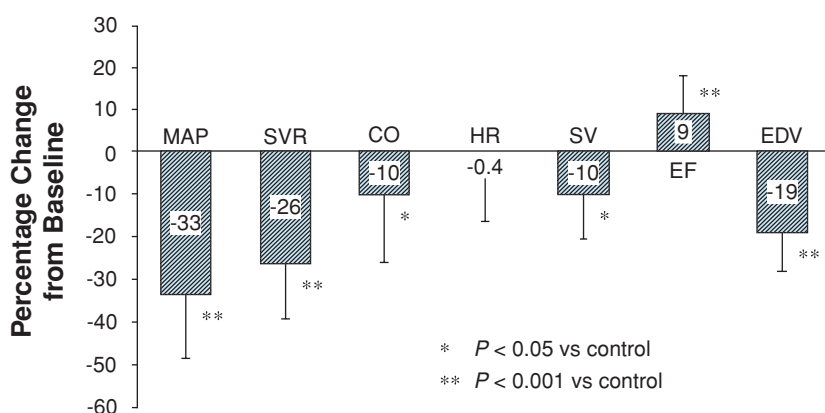

Regional anesthesia uses a family of pharmacologic agents with unique properties and a range of techniques designed to meet the needs of the surgical plan. This section will review agents first and then techniques. Local anesthetic agents reversibly inhibit the propagation of signals along nerves. When applied to a specific nerve or pathway in sufficient concentration, these agents produce anesthesia (loss of sensation) and paralysis (loss of muscle power). The currently used local anesthetics belong to one of two classes: aminoamide and aminoester local anesthetics. All of these medications are structurally related to cocaine but do not stimulate the sympathoadrenal system and, thus, do not produce hypertension or local vasoconstriction, nor do they have any abuse potential. Local anesthetics vary in their pharmacological properties. Field and nerve blocks are frequently performed using long-acting drugs such as bupivacaine. This often provides exceptional postoperative analgesia for up to 24 hours. The local anesthetic lidocaine is also used as a Class Ib antiarrhythmic drug. At higher doses, lidocaine and all local anesthetics are arrhythmogenic. All agents have limited therapeutic windows, and over-dosage can result in cardiac arrest and death. There are large variations in how aging alters the pharmacokinetics of local anesthetics, and aging per se accounts for less than 20% of variability. There is little suggestion that sensitivity to local anesthetics is altered by aging. Some forms of regional anesthesia can be combined with a light general anesthetic.

Regional anesthesia techniques include topical anesthesia (surface), infiltration, plexus block, epidural (extradural) block, and spinal anesthesia. As a rule, field and nerve blocks have minimal systemic effects unless there is an untoward event during placement, such as intravascular injection of the local anesthetic, or there is an allergic reaction to the drug. Many procedures, such as cataract surgery, can be accomplished with local anesthetic drops and no additional sedation. Blocks of specific nerves or nerve plexi are associated with anatomically specific side effects and complications. An interscalene block of the cervical plexus provides good anesthesia for operations on the shoulder. It may also result in anesthesia of the ipsilateral phrenic nerve, resulting in hemidiaphragmatic paralysis. An ipsilateral Horner syndrome may also be observed. Field blocks

are often placed by the surgeon at the operative site prior to or at the conclusion of surgery.

Neuraxial blocks, including spinal and epidural anesthesia, are considered complete anesthetics; no other supplemental treatment is necessary, although sedation is often provided at the request of the patient or the surgeon. These blocks produce the greatest physiological effects and are presented here in more detail than other forms of regional anesthesia because their use in older adults is common. Spinal anesthesia differs from epidural anesthesia in the location of anesthetic administration, in the consequences of location of administration on type of nerve affected, and on the resulting clinical manifestations of treatment. With spinal anesthesia, the local anesthetic is injected into the cerebrospinal fluid, inside the dura and arachnoid, where it quickly diffuses into the spinal nerves. Inside the dura and arachnoid, spinal nerves have minimal connective tissue surrounding them so that the local anesthetic effectively blocks all nerve fibers, including motor, touch, and sympathetic nerves. The patient is, thus, provided not only anesthesia but also paralysis and sympathetic blockade. In contrast, an epidural anesthetic is typically administered through a catheter placed just outside the dura. In the epidural space, spinal nerves are covered with a thick connective tissue sheath, which slows the onset of anesthetic effect. By varying the concentration of the injected local anesthetic, nerve types can be differentially blocked. Differential blockade is important for postoperative analgesia, where partial blockade of pain fibers are desired, but touch and motor nerves are to be spared. Unfortunately, it is not possible to fully anesthetize pain fibers without also affecting the sympathetic nerves. When high concentrations of the local anesthetic will be used to achieve full anesthesia, all nerve types will be blocked.

The hemodynamic effects of neuraxial anesthesia stem from the blockade of sympathetic nerves. The hemodynamic response depends on many factors, including how many thoracic dermatomes of sympathetic fibers are affected and how much of a reflex response can be mounted via the vagus and any unblocked sympathetic fibers. In the case of spinal anesthesia, the sympathetic fibers may be at least partially blocked for many dermatomes above the level of sensory blockade, as defined by sharp–dull discrimination. It is not uncommon, therefore, to have a near-total sympathectomy with spinal anesthesia. The hemodynamic consequences can be dramatic. If one accepts the hypothesis that vascular resistance is increased with age because of increased sympathetic tone, then removal of that tone often results in a large decrease in vascular resistance (Figure 36-4). Pharmacologic sympathectomy in young adults results in a much

**FIGURE 36-4.** The hemodynamic response to high spinal anesthesia is shown in 15 elderly men with cardiac disease. The large decrease in mean arterial blood pressure (MAP) was primarily because of decreases in systemic vascular resistance (SVR) and not decreases in cardiac output (CO). Overall, heart rate (HR) did not change; therefore, the decrease in cardiac output was because of a decrease in stroke volume (SV). The decrease in left ventricular end-diastolic volume (EDV) did not cause a comparable decrease in stroke volume because the ejection fraction (EF) increased. (Adapted with permission from Rooke GA, Freund PR, Jacobson AF. Hemodynamic response and change in organ blood volume during spinal anesthesia in elderly men with cardiac disease. *Anesth Analg.* 1997;85:99–105.)

smaller decrease in vascular resistance but a similar decrease in cardiac output. In [Figure 36-4](#), the sympathectomy also decreased left ventricular filling as blood volume shifted to the legs and mesentery. However, the increase in ejection fraction ameliorated much of what the decrease in preload would have otherwise been expected to do to stroke volume and cardiac output.

Many patients request sedation during surgery performed under a regional anesthetic, usually because they are not interested in being aware of the activities in the operating room. Small quantities of midazolam and fentanyl often suffice, but if higher levels of sedation are desired, typically a propofol infusion will be used. Interestingly, older patients commonly fall asleep during spinal anesthesia, even in the absence of any sedative medications. The mechanism behind this phenomenon is unknown but may involve the loss of sensory input to the brainstem. If sedative and analgesic drugs are used, the risk of airway obstruction increases. The combination of sedation plus spinal anesthesia, for example, produces more postoperative hypoxia than sedation or spinal anesthesia alone. With careful monitoring and skill in airway management, the risk of airway obstruction should be minimal. In unskilled hands, however, airway obstruction can rapidly lead to hypoxia and patient injury. This risk to the patient forms the basis for the recent JCAHO requirement that trained personnel must be present at procedures performed anywhere in the hospital whenever the patient is likely to be sedated to the point of drowsiness that requires verbal stimuli or worse to arouse. The requirements include assigning a person to the sole task of monitoring the patient.

Regional anesthetic techniques can be combined with general anesthesia. Combined general/regional anesthesia involves the provision of primarily a high thoracic epidural anesthetic with subsequent induction of general anesthesia with endotracheal intubation. This approach has been most extensively studied in Denmark in association with a fast-track approach to colonic surgery, which also includes rapid ambulation and food consumption (day of surgery) and early discharge (postoperative day 2). The advantages of the technique combine the ability to use considerably less general anesthetic with resulting rapid emergence, with the complete absence of pain, because the epidural is still active and will be used to manage postoperative pain. The main limitation of the technique is the added difficulty in maintaining blood pressure in the operating room. In addition, it is common to place an epidural catheter exclusively for postoperative pain control, which will only be activated at the end of surgery, i.e., it is not used as part of the anesthetic technique.

### Regional Versus General Anesthesia

Many anesthesiologists prefer regional anesthesia over general anesthesia. There is something attractive to providing an anesthetic that just blocks nerves but spares direct effects to the brain and other vital organs. Markers of stress such as cortisol, catecholamines, and cytokines become elevated during and after surgery with a general anesthetic, while spinal and epidural anesthesia markedly attenuate these changes during surgery, and much of the attenuation will continue after surgery if epidural analgesia is continued postoperatively. The presumption has been that the reduction in stress would translate into a reduction in morbidity and mortality, but it has been surprisingly difficult to prove this hypothesis. Early studies centered around the benefits of postoperative analgesia via an epidural catheter typically infused with a dilute local anesthetic plus opi-

oid. These studies employed random group assignment but enrolled small numbers of patients (40–60 each). Perhaps because a high-risk population was recruited, several of the studies demonstrated lower mortality and morbidity with respect to cardiac and pulmonary complications. Other studies have demonstrated additional benefits of regional anesthesia, including less blood loss during hip replacement surgery, a decreased incidence of deep vein thrombosis and pulmonary emboli, and a reduction in early graft thrombosis in peripheral vascular surgery. Not all studies demonstrate consistent benefits, however.

In order to circumvent the problem of small patient enrollment, a meta-analysis has been performed on 141 studies that had employed randomized assignment to general anesthesia versus spinal or epidural anesthesia. In approximately half of the studies, the regional anesthetic was accompanied by a general anesthetic. When an epidural catheter was employed (75% of the neuraxial blocks), postoperative epidural analgesia was frequently employed. Thus, group comparison was somewhat muddled. Nevertheless, the results were strongly in favor of the regional technique with deaths from all causes reduced by 30%. Decreases in rates of myocardial infarction, pneumonia, and pulmonary embolism (but not stroke) were also demonstrated.

These encouraging results must be tempered by two prospective studies, each involving roughly 1000 patients randomly assigned to general anesthesia alone with parenteral opioids for postoperative analgesia versus combined general plus epidural anesthesia with postoperative epidural analgesia. In one study, the general plus epidural group demonstrated a decreased incidence of respiratory failure. The other study only found a lower incidence of adverse events in the subset of patients within the epidural group who were undergoing repair of an abdominal aortic aneurysm. Therefore, neither study found overwhelming evidence of improved outcome from the addition of epidural anesthesia/analgesia.

It is apparent, then, that the current evidence of the benefit of postoperative epidural analgesia is weak, as is the evidence of the superiority of neuraxial anesthesia over general anesthesia as the primary anesthetic technique. Nevertheless, better pain relief is usually achieved by regional techniques, and it is still possible that some medical benefits exist. Therefore, these techniques continue to be used, at least in selected circumstances. Given the difficulty in proving a difference in outcome between regional and general anesthesia, it would be surprising if any study could demonstrate a difference in mortality or major morbidity when comparing, for example, different types of general anesthesia. In the absence of compelling outcome data, whether to perform a regional or a general anesthetic depends on many factors. Carotid endarterectomies, for example, may be performed under either a local block with an awake patient or a general anesthesia. Experienced teams of surgeons and anesthesiologists can perform either of these techniques with excellent and equivalent results. Usually, a center chooses one or the other technique. Both the surgeon and the anesthesiologist must be comfortable working with the chosen technique. Patient physical limitations, including uncomfortable patient positioning for the surgery, may prevent the use of a pure regional technique. For example, total hip replacement surgery requires the patient to lie in a fixed position on their side for the entire procedure. Even with careful positioning and padding, the position can be uncomfortable if only the lower half of the body is anesthetized. Sometimes sedation is adequate to make the procedure tolerable, whereas other patients require sedation bordering on

general anesthesia that requires a secured airway. The presence of coagulopathies or the use of preoperative anticoagulation may preclude the use of regional techniques, as a result of the risk of bleeding and, in the case of spinal or epidural anesthesia, the risk of epidural hematoma (see the section below on “postoperative analgesia”). Also, the patient must be willing to undergo the regional technique, which will invariably involve placing a needle somewhere into the body. Some patients will not accept needles under any circumstance unless they are totally asleep, but, for safety reasons, most blocks will not be performed under such conditions. Other patients may refuse regional techniques owing to prior bad experiences. There is also a common fear of paralysis following spinal anesthesia, which is, for the most part unfounded, representing an extremely unusual complication with multiple potential causes. On the other hand, many patients welcome the opportunity to avoid a general anesthetic and the attendant postoperative sedation and risk of nausea. There is little evidence to suggest that the choice of anesthesia has a significant impact on either cognitive abilities or the incidence of postoperative delirium. All anesthetics should be preceded by a thorough discussion with the patient about anesthetic options, including their benefits, disadvantages, and associated risks. This discussion is best carried out by an anesthesiologist, who is best able to recognize the characteristics of the patient and procedure that will determine which anesthetic options are appropriate, and to explain to the patient the important risks and benefits of each option. In many cases, the choice of anesthetic technique can include patient preference; therefore, it is important to provide patients with comprehensive information and involve them in the decision-making process.

## POSTOPERATIVE ANALGESIA

The options for postoperative analgesia have expanded considerably in the past 15 years. Highlighted here are patient-controlled analgesia and peripheral nerve blocks.

### Patient-Controlled Analgesia

Patient-controlled analgesia devices are programmable infusion pumps that can provide either basal infusion or controlled access on request (usually pushing a button) to an opioid preparation, which is maintained in a locked compartment. The device offers the patient the opportunity to obtain pain medication without having to wait for a busy nurse. The device also provides more smooth analgesia compared to intermittent administration, which produces a cycle of heavy sedation with the initial peak effect, followed by a period of alertness and reasonable analgesia, and ending with increasing pain and anxiety until the next dose comes due. Patient-controlled analgesia allows the patient to finely titrate the analgesia against the opioid side effects, including nausea, sedation, dysphoria, and itching. In recent years, patient-controlled analgesia has become a standard part of postoperative pain management, in which orders follow specific templates. Since there is a tremendous variability in pain tolerance and response among individuals in general, and older adults in particular, effective postoperative pain management programs require a knowledgeable individual to observe the patient on a regular basis, in order to adjust the device properly. While elderly patients are sensitive to the respiratory depressant effects of nar-

cotic agents, it is impossible to prescribe an age-specific approach to the use of postoperative opioids. Each patient is highly individual, and the therapeutic window for many analgesics is narrowed in the elderly.

### Peripheral Nerve Blocks

Peripheral nerve blocks performed with long-acting local anesthetics provide up to 24 hours of postoperative analgesia. These blocks provide both significant advantages and risks. These are typically performed in a sedated, but awake and cooperative, patient prior to surgery. The most elaborate technique for postoperative analgesia is provided through indwelling catheters. Given the time involvement for catheter placement and management and the uncertainty of enhanced outcome, this technique is used selectively. Initially, epidural analgesia was nothing more than boluses of morphine through a lumbar catheter. Now the typical formula is low concentrations of both a local anesthetic and an opioid, which are infused continuously through a catheter placed at the dermatome most central to the incision, be it thoracic or lumbar in location. The quality of analgesia afforded by a well-managed epidural catheter is excellent and associated with high levels of satisfaction.

There are significant risks to epidural catheter use. The most common problem is failed placement. The next most common problem is inadvertent dural puncture. As epidural catheters are placed with large-bore needles, the risk of a spinal headache is relatively high. Fortunately, the risk of postdural puncture headache decreases with age. If a thoracic catheter is placed, dural puncture could also lead to direct spinal cord trauma. This complication is rare. The most feared complication is the development of an epidural hematoma. The epidural space has many veins that are occasionally punctured. Generally, any bleeding stops spontaneously and quickly, but if it does not, epidural hematoma may cause cord compression. Permanent paraplegia becomes likely, since the success of emergency laminectomy is poor once symptoms appear. Retrospective analysis of spinal and epidural anesthetics suggests that the intrinsic risk of paralysis is less than 1:150 000. Patients who have abnormal coagulation, however, are thought to be at greater risk. Most reports of epidural hematoma have been in patients who were anticoagulated when the block was performed or when heparin therapy was instituted less than an hour after the needle placement. The relative risk owing to anticoagulation is unknown, as all reports are anecdotal and do not include a denominator. In the case of epidural catheters, epidural hematomas develop almost as often on catheter removal as on insertion, so the catheter removal must be considered an at-risk event as well. There are case series reports on spinal or epidural block performed in anticoagulated patients, but the largest series involved 1000 patients and is too small to be meaningful despite a zero incidence of hematoma. Even subcutaneous heparin can provide enough anticoagulation to increase risk at its peak effect at around 2 hours after administration. Particularly distressing has been the high number of epidural hematomas reported in patients receiving low-molecular-weight heparin. Many of the hematomas developed after catheter removal. In response to these reports of epidural hematoma, it is recommended that any patient with an epidural catheter be given frequent neurologic checks if they receive anticoagulants (warfarin, heparin, and low-molecular-weight heparin). Guidelines for catheter placement and removal are given in [Table 36-4](#).

**TABLE 36-4****Guidelines for Epidural Catheters in Anticoagulated Patients\***

MEDICATION	RECOMMENDATIONS
Warfarin	Do not place needle or remove catheter if prothrombin levels are therapeutic. Discontinuation of warfarin must be of sufficient duration to restore all prothrombin factors, not just factor VII. If warfarin is initiated prior to needle placement or catheter removal, check the prothrombin time even if only one dose of warfarin has been given.
Intravenous heparin	Do not place needle or remove catheter if partial thromboplastin time is elevated. Heparin therapy should not be initiated until at least 1 h after needle placement or catheter removal. Catheter removal should be preceded by heparin discontinuation for 2–4 h and evaluation of the coagulation status.
Subcutaneous (mini-dose) heparin	Needle placement and catheter removal is not contraindicated, but it may be wise to avoid doing so at the peak heparin effect at around 2 h after injection.
Low-molecular-weight heparin (LMWH)	Needle placement and catheter removal should occur at least 2 h before, and at least 10 h after, once-a-day LMWH therapy. Twice-a-day LMWH dictates holding one dose, and waiting 20–24 h after the last dose.
Nonsteroidal anti-inflammatory drugs	No evidence of increased risk.
Combination therapy	Little data, but risk may be increased, especially if low-molecular-weight heparin is one of the therapies.

## PERIOPERATIVE COMPLICATIONS

The most common surgical indicator of complications is morbidity and mortality within a defined period following a procedure, frequently 30 days. Hamel reported on 26 648 patients aged  $\geq 80$  years (median age 82 years) and 568 263 patients  $< 80$  years (median age 62 years) from the Veterans Administrations National Surgical Quality Improvement Program (NSQIP) database. Mortality is low ( $< 2\%$ ) for many common procedures (transurethral prostatectomy, hernia repair, knee replacement, carotid endarterectomy, vertebral disc surgery, laryngectomy, and radical prostatectomy). The incidence of complications increases and the impact of complications on mortality and functional recovery increases with age. The presence of a complication increased mortality from 4% to 26%. Respiratory and urinary tract complications were most common.

Anesthetic risk is difficult to quantify separately from the risk of surgery, because few people receive an anesthetic in the absence of a surgical procedure. For healthy patients, the risk of death purely caused by the anesthetic has been estimated to be as low as 1 in 250 000. Such a figure is trivial in comparison to the 1 in 500 risk of death associated with surgery and anesthesia overall. Mortality is dependent on patient age and strongly influenced by the type of

surgery. Even in patients older than 90 years of age, minor surgeries carry a near-zero 30-day mortality, but major abdominal, thoracic, and vascular surgeries are associated with a 20% to 30% mortality. Clearly, comorbid disease, the effects of surgical trauma, and presumably the anesthetic must interact in some way to increase risk. The mechanisms underlying increased risk are poorly understood but are presumed to be influenced by the interaction of age and comorbid disease on reduced physiological reserve. This reduced reserve is presumed to make the body less able to withstand the various stresses associated with surgery such as pain, a hypermetabolic state, and altered neuroendocrine hormones.

## Course of Recovery and Common Perioperative Complications in Older Patients

The influence of age on the course of recovery after surgery has not been a focus of research but a recent study by Lawrence et al. provides valuable insights. Among geriatric patients who had undergone abdominal surgery, recovery of independence in basic activities of daily living took almost 3 months on average. Some measures, such as hand grip strength, had, on average, not returned to baseline even at 6 months. Since recovery from surgery involves patient effort, it is important for the patients to understand their own role in the recovery process and to have a realistic idea of how long it will be before they will feel like themselves again.

An exhaustive discussion of complications that may occur in association with anesthesia and surgery is beyond the scope of this chapter. Nevertheless, it is worth commenting on a few complications. The most feared complication from anesthesia is the loss of the ability to ventilate a patient with subsequent hypoxic injury. This type of complication has become rare, and there is nothing to suggest that these events are more common in elderly patients.

Pulmonary complications are most common in elderly surgical patients, with postoperative pneumonia carrying a 20% mortality rate. Gag reflexes are decreased in the elderly and easily impaired by sedative and analgesic medications. Unless an older adult is specifically assessed as needing prolonged mechanical ventilation following surgery, there is nothing to suggest an advantage delaying extubation based on age. The current practice is to return to spontaneous ventilation and avoid prolonged intubation. Programs to prevent the development of pneumonia have had mixed results to date.

Cardiac events have received intensive focus in the perioperative arena. The nature of perioperative risk has changed during the years, with full Q-wave infarctions becoming less common. The risk of myocardial infarction increases with the prevalence of coronary disease in the patient population examined. In a relatively high-risk group such as patients undergoing peripheral vascular surgery, the incidence of myocardial infarction is approximately 4% and congestive heart failure around 9%. Among patients with a prior history of myocardial infarction, a perioperative myocardial infarction is still associated with approximately 30% mortality. The most common time when myocardial infarctions and congestive heart failure are detected is 2 days after surgery. The use of perioperative beta-blockers for patients at risk of myocardial infarction is rapidly becoming a standard of care, and there is no reason to avoid beta-blockers solely on the basis of age.

Stroke is a less frequent, but feared, complication of surgery. Perioperative stroke occurs much more frequently than would be expected for the same population in the absence of surgery. The most

common cause of stroke in medical patients is thromboembolism, and there is no indication that it is any different perioperatively. In all likelihood, the same changes that increase the risk of myocardial infarction are responsible for the increased risk of stroke. While perhaps widely assumed to be a contributor to surgical stroke risk, hypotension is not a likely cause of stroke in the setting of surgery and anesthesia. There are two main sequences of evidence for this assertion. The first rests on the timing of onset of stroke in the perioperative period, and the second rests on the lack of relationship between duration of hypotension and stroke. The vast majority of strokes occur after the patient recovers from anesthesia and has demonstrated an immediate postoperative unchanged neurologic examination. Intraoperative hypotension is certainly not uncommon in older patients, although it rarely is allowed to persist for long periods of time. It is unlikely that brief periods of intraoperative hypotension are associated with stroke. If brief periods of hypotension caused strokes, then extended periods should, too. Yet no study involving deliberate hypotension for control of blood loss has reported an associated stroke. The best such study, involving 235 patients with an average age of 72 years who were randomly assigned to have mean arterial pressure maintained between 45 and 55 mm Hg or 55 and 70 mm Hg during surgery, demonstrated no strokes. Of much greater concern than hypotension as a mechanism for stroke is atrial fibrillation and cardiac emboli, perhaps accentuated by hypercoagulability. The degree to which atrial fibrillation is a risk factor is not well understood, but it raises the issue of how to manage patients who take warfarin chronically for atrial fibrillation or artificial valves. Based on the low risk of stroke in the immediate few days surrounding surgery in the absence of anticoagulation, it seems statistically safe to stop warfarin 4 days before surgery. A heparin infusion does not need to be used unless the patient has a history of arterial embolus or deep vein thrombosis within the previous 3 months. Warfarin therapy should be reinstated postoperatively as soon as feasible.

There are two neurocognitive syndromes, delirium and postoperative cognitive dysfunction (POCD), that emerge in the postoperative period most commonly in older adults. Postoperative delirium is a change in mental status that consists of the inability to focus, sustain, and shift attention that is accompanied by other cognitive symptoms (e.g., disorientation and episodic memory dysfunction), and/or perceptual disturbances (misinterpretations, illusions, or hallucinations). Delirium as an entity is discussed elsewhere in this text. There are two forms of delirium after anesthesia. Emergence delirium occurs early, during emergence from general anesthesia. Postoperative delirium on the other hand develops later, usually 24 to 48 hours after an otherwise uneventful recovery from surgery. The risk of postoperative delirium is higher in older adults. For any major general surgery, the incidence is approximately 9% but may be as high as 60% in select surgical populations (major orthopedic and cardiac procedures). In contrast to medical patients, surgical patients rarely have delirium on hospital admission. Approximately a third to a half of the cases of delirium in medical patients are present at admission to the hospital, while only 7% of patients with delirium associated with hip fracture were delirious on admission. The etiology of delirium in general, and in postoperative delirium in particular, remains unknown. Drugs such as meperidine and anticholinergics are potential contributors and should be avoided in the elderly, but the risk from opioids is not clear, especially when failure to use such drugs could lead to increased pain and decreased sleep.

One might expect general anesthesia to be a major risk factor for delirium, but multiple studies have all failed to demonstrate any differences in rates of delirium between general and regional anesthesia, even when careful monitoring of attention and cognitive function is performed. Delirium, if present at any time in the hospitalization, is associated with increased rates of complications, significantly prolonged hospital stay, and a decrease in function (e.g., ADLs) on hospital discharge. Aggressive management of geriatric patients can result in significant decreases in the incidence of postoperative delirium, as shown primarily by Edward Marcantonio in hip fracture patients (see section below on “integrated care”). Both the regular confusion assessment method (CAM) and the CAM-ICU can be used in the perioperative period to detect delirium. As with medical patients, some patients are hyperactive and aggressive, but many delirium patients are hypoactive and quiet, so monitoring programs are required to reliably detect postoperative delirium. Management resembles delirium prevention and care in other settings (see Chapter 53). POCD is defined as a measurable decline in performance on a battery of neurocognitive tests. POCD appears to be distinct from delirium but may prove to be related. For years, there have been anecdotal reports of cognitive decline following surgery and anesthesia. In 1998, a prospective study tested surgical patients before and at 1 week and 3 months after surgery. A matched set of control subjects not having surgery was selected and tested as well. At 3 months, 10% of the surgical patients had demonstrable cognitive decline, in comparison to only 3% of the control subjects. Subsequent follow-up of this cohort suggested that approximately 1% had a persistent deficit after 2 years. As neurocognitive testing is not routinely done prior to surgery, POCD is primarily a research finding. It appears to be primarily a problem of the elderly, in that incidence is minimal below 60 years of age. POCD is uncommon following minor surgery. POCD following cardiac surgery occurs at a higher rate, approaching 50% at discharge from the hospital. POCD following cardiac surgery had traditionally been attributed to the influence of cardiopulmonary bypass; however, a recent study showed similar levels of cognitive decline among patients undergoing coronary artery bypass with and without cardiopulmonary bypass. Thus, the cause of POCD for both cardiac and noncardiac surgery remains unknown. There are neither strategies to prevent POCD nor treatments once cognitive decline occurs.

## MODELS OF COLLABORATIVE CARE FOR THE SURGICAL PATIENT

The most mature literature regarding the role of geriatricians in the care of surgical patients has been focused on patients with fractures of the upper femur. Heyburn and colleagues described four models that have been applied to hip fracture patients: the traditional model in which care is directed by the orthopedic surgeon and medical queries are directed to a consultant, the second is a variation in which multidisciplinary rounds with geriatricians and surgeons increase awareness of cross specialty issues, the third involves early postoperative transfer to a geriatric rehabilitation unit, and the fourth is combined orthogeriatric care in which the patient is admitted to a specialized ward where care is coordinated by geriatricians and orthopedic surgeons. There are clear advantages to patients from these models, the key factor being the implementation of the geriatric parts of the care plan. Marcantonio demonstrated the potential for a

marked improvement in outcome in a randomized trial of proactive geriatric consultation based on a structured protocol for patients with hip fractures. The intervention reduced delirium by more than one-third. Some perioperative comprehensive geriatric assessment programs have cut down on length of stay. More complex programs such as the Hospital Elder Life Program are being evaluated for their impact on surgical patients.

## CONCLUSION

Since there are more and more older adults, and since surgical procedures are increasingly feasible in complex older adults owing to technical and medical advances, the demand for anesthetic care of older patients is increasing. This care is intricate and carries real risks. Better preoperative preparation and postoperative care are likely to have a greater impact on outcomes than further advances in intraoperative anesthetic management, at least in the near future. The role of postoperative analgesia in improving outcomes and reducing the costs of medical care is still in its infancy. Optimal care of the older adult in the perioperative setting depends on the combined expertise of many specialties and an integrated, comprehensive approach.

# Surgical Outcomes

Emily Finlayson ■ John D. Birkmeyer

As the population ages, an increasing number of elderly patients become candidates for major surgery. According to the National Center for Health Statistics, the rate of hospital discharges for hip replacement in elderly people rose from 2.5 per 10 000 in 1970 to 72.5 per 10 000 in 2004 (<http://www.cdc.gov/nchs/agingact.htm>). Based on current rates of surgery and census projections, the number of elderly patients undergoing oncologic procedures is expected to increase by up to 51% by the year 2020.

Surgical risks in general are declining over time, and many assume that surgery for elderly patients is getting safer. Case series suggest that surgery can be performed with low morbidity and mortality in elderly people. For lung, esophageal, and pancreatic resection, single-center studies report operative mortality rates between 3% and 4% in very elderly patients. Case series are advocating bariatric surgery in obese patients older than 65 years, touting low morbidity and mortality rates.

Results from clinical series, however, may lead to unrealistic expectations about the safety of surgery in the elderly population, as many published studies have selection bias. Reports of operative mortality tend to represent experiences of high-volume, tertiary academic centers. It is well documented that for high-risk cancer surgery, high-volume surgeons and hospitals have superior outcomes. In addition, results from case series are more likely to be submitted and published if the observed mortality is low, resulting in a publication bias toward lower operative mortality. As a result, existing data generally yield unrealistic risk estimates.

This chapter examines operative risk in very elderly patients using “real-world” results from large databases. In addition, evidence will be reviewed about predictors of surgical outcomes in elderly patients—fatal surgical outcomes as well as functional status and independence after major surgery.

## PREDICTORS OF OPERATIVE MORBIDITY AND MORTALITY

### Age

In general, increasing age is associated with increased rates of morbidity, functional dependence, and mortality after surgery. Countless studies for several decades have documented that age predicts adverse outcomes after surgery. In a comprehensive analysis of more than 50 000 patients undergoing noncardiac surgery in the Veterans Affairs National Surgical Quality Improvement Project (NSQIP) database, Hamel et al. found that age was an independent predictor of operative mortality, after adjusting for comorbidities. For all operations in aggregate, 30-day mortality was 2.8% for patients younger than 80 years compared with 8.2% in older patients. For colectomy, mortality was 6.4% in younger patients versus 11.9% in older patients. Similarly, younger patients undergoing elective hip replacement had much lower operative risk (1.3%) when compared to older patients (6.8%). In a single-center study, patients aged 80 years and older had a fourfold increase in risk of both operative mortality and discharge to nursing home after cardiac surgery. This finding persisted after adjustment for patient characteristics. Age is also a known independent predictor of deterioration in cognitive function after coronary artery bypass graft (CABG) surgery.

To assess the impact of age on mortality for a wide range of procedures frequently performed in the elderly, national mortality rates were examined using the Nationwide Inpatient Sample. The Nationwide Inpatient Sample is a large national database containing hospital discharge data for all payers. It is a sample of all U.S. nonfederal hospitals and contains data from approximately

**FIGURE 37-1.** Operative mortality, by age. (Unpublished data from the Nationwide Inpatient Sample (NIS), 2003. The NIS contains hospital discharge data for all payers from approximately 1000 hospitals in 22 states.)

1000 hospitals in 22 states. Selected hospitals represent five strata of hospital characteristics: ownership control, bed size, teaching status, rural–urban location, and geographic region. Based on analysis of all discharges for CABG, mitral and aortic valve surgery, hip replacement, colectomy, and cystectomy in 2003 using ICD-9 procedure codes, operative mortality increased substantially with age for all six procedures (Figure 37-1). Operative mortality was highest for mitral valve replacement, ranging from 7% for patients younger than 65 years to 21% among patients aged 85 to 99 years. For CABG, aortic valve replacement, colon resection, and cystectomy, operative mortality rates among patients older than 85 years ranged from 7% to 11%. Operative mortality was low after hip replacement (0.2%–3%).

### Comorbidity

The presence of medical comorbidities increases operative risk in all age groups. In general, with age, patients accumulate medical conditions. It is unclear whether age—as a risk factor for adverse outcomes after surgery—is primarily a proxy for increased comorbidity burden. The relative importance of age and medical comorbidities has been examined carefully in vascular surgery. While age is an independent predictor of mortality in vascular surgery, in multivariate analysis, cardiac, pulmonary, and renal dysfunction have a greater impact on mortality than age for abdominal aortic aneurysm repair,

lower extremity bypass, and amputation. In an analysis of noncardiac procedures, Hamel found that risks associated with selected comorbidities were the same in patients younger or older than 80 years. While it is well known that both age and comorbidity impact operative risk, the interaction between age and comorbidity in surgical outcomes has not been fully elucidated.

### Functional Status and Cognitive Function

There is limited evidence that functional status is an important independent predictor of morbidity and mortality after surgery. In a comprehensive analysis of surgical outcomes after abdominal surgery in 24 patients older than 80 years, including physiologic, biochemical, and functional characteristics as well as surgical process measures, age, and activities of daily living score were two of three independent predictors of operative mortality. For gastrectomy, patients with partially dependent functional status are at higher risk of operative mortality than fully independent patients. Poor preoperative functional status has also been shown to predict neurologic and cardiac complications after major surgery in elderly patients.

Although cognitive impairment is common in older adults, the influence of cognitive function on clinical and functional outcomes of surgery in this population is largely unexplored. In one study, surgical patients with cognitive impairment were at higher risk of mortality than other general surgery patients (9.6% vs. 6.3%).

## Frailty

Frailty is a common clinical syndrome in elderly patients characterized by decreased physiological reserve and vulnerability to stressors (see Chapter 52). The phenotype includes unintentional weight loss, self-reported exhaustion, grip weakness, slow walking speed, and low physical energy. Frailty appears to be an independent predictor of surgical complications in elderly patients. In one study, frailty was highly associated with postsurgical complications, while ASA score and Lee's Revised Cardiac Index score were not.

## FUNCTIONAL OUTCOMES

### Functional Status Outcomes

For frail older adults undergoing surgery, functional status is an essential outcome measure. Small changes in functional status after surgery are likely to have an important impact on the ability of such patients to care for themselves and live independently. In a study of 672 elderly patients admitted to the intensive care unit after general, vascular, or trauma surgery, activities of daily living scores decreased significantly at late follow-up, and 13% of patients lost their ability to live independently. For cardiac surgery, functional declines are even more dramatic. In a study of 191 patients aged 80 years and older, undergoing elective cardiac surgery, only 64% of late survivors were fully autonomous. Only the occurrence of a postoperative complication was a significant predictor of impaired postoperative autonomy.

Postoperative functional impairment is common and often protracted in elderly patients. In one study, elderly patients undergoing major open abdominal surgery had comprehensive postoperative functional assessments at 1, 2, and 6 weeks and 3 and 6 months. Mean functional recovery time ranged from 3 weeks for Folstein mini-mental state examination to 6 months for instrumental activities of daily living (Table 37-1). A substantial proportion of elderly patients did not return to baseline function after 6 months for instrumental activities of daily living, Medical Outcomes Study Short Form-36 Physical Component Scale, timed walk, and functional reach. In this study, preoperative physical conditioning and depression were important predictors of functional recovery after surgery.

**TABLE 37-1**

#### Mean Functional Recovery Time After Surgery

FUNCTIONAL OUTCOME	MEAN RECOVERY TIME
Mini-mental state examination	3 weeks
Activities of daily living	3 months
Instrumental activities of daily living	6 months
SF-36 Physical Component Scale	3 months
Functional reach	3 months
Timed walk	6 weeks

## Cognitive Outcomes

Acute confusional state is common in older surgical patients in the postoperative period. The incidence of delirium ranges from 5% to 45% in elderly patients undergoing major surgery. Advanced age, hearing and visual impairment, dehydration, sleep deprivation, immobility, severe illness, preoperative narcotic use, and baseline mental status are independently associated with the development of postoperative delirium. Targeted interventions such as frequent re-orientation, nonpharmacological sleep protocols, early mobilization, early use of visual and hearing aids, and volume repletion protocols can reduce the incidence of delirium in elderly hospitalized patients.

Long-term declines in cognitive function after cardiac surgery have been well studied. A meta-analysis of both cohort and randomized trials estimated neurocognitive dysfunction after CABG surgery to be 22% at 2 months after surgery, with a range from 14% to 47%. The mean age in most of these studies ranged from 54 to 64 years. Cognitive outcomes of elderly patients are likely to be substantially worse. Although there is some improvement in cognitive function after hospital discharge in CABG patients, one study with long-term follow-up suggested that cognitive function remains poor in this population, with a pattern of early cognitive improvement followed later by decline. Among 261 patients studied by Newman et al., the incidence of cognitive decline was 53% at discharge, 36% at 6 weeks, 24% at 6 months, and 42% at 5 years. Significant predictors of late cognitive decline were older age, fewer years of formal education, and the presence of cognitive decline at discharge.

Less is known about late cognitive outcomes after noncardiac surgery. In one study, noncardiac surgery was associated with long-term postoperative cognitive decline in elderly people, and the risk increased with age. Cognitive dysfunction occurred in 26% of elderly surgical patients at 1 week and in 10% at 3 months, compared to 3% in a control population. Similar to the findings in cardiac surgery, older age and less formal education were independent predictors of poor cognitive outcome.

### Discharge Disposition and Independent Living

Discharge disposition after surgery can be considered a proxy for functional and cognitive outcomes. Functional limitations in the perioperative period often prevent older patients from being discharged to home after surgery. The very elderly are much more likely to require admission to a skilled care facility after surgery than their younger counterparts. In Michigan, 20% of elderly patients are discharged to a skilled care facility after cardiac surgery. Of those discharged to home, more than 30% are readmitted to the hospital or a skilled care facility. In the 2003 Nationwide Inpatient Sample database, age was associated with discharge to an extended care facility (i.e., rehab, nursing home, or another hospital) after CABG, valve replacement, hip replacement, colon resection, and cystectomy (Figure 37-2). Patients undergoing hip replacement in all age groups had a high rate of discharge to an extended care facility, but the likelihood of discharge to a facility increased dramatically with age, from 28% for patients younger than 65 years to 87% for patients older than 85 years. Over half of patients aged 85 years and older undergoing cardiac procedures were not discharged to home after surgery. Rates of discharge to a facility were nearly as high after colectomy and cystectomy in the oldest patients. This information is important for several reasons. First, elderly patients and their families need to

**FIGURE 37-2.** Rates of discharge to a facility, by age. (Unpublished data from the Nationwide Inpatient Sample (NIS), 2003. The NIS contains hospital discharge data for all payers from approximately 1000 hospitals in 22 states.)

have realistic expectations about recovery after major surgery when deciding whether to undergo an elective operation. Second, once the decision for surgery has been made, patients and caregivers need to anticipate the longitudinal needs of elderly patients in the recovery period.

### LATE SURVIVAL AFTER CANCER SURGERY

There has been considerable debate about the appropriateness of major surgical resection in very elderly patients with cancer. As surgery is perceived as safer, there is more enthusiasm about offering high-risk cancer operations to elderly patients. Frail elderly patients, however, should be carefully evaluated preoperatively to assess their perioperative risks (see Chapter 35). Some of these patients have competing risks of mortality. These risks may make the risk–benefit tradeoff of a major surgical resection for cancer with a poor prognosis (e.g., pancreatic cancer) tip in favor of foregoing surgery. For many cancers, the use of surgery for “resectable” cancer declines with age. Analysis of the Surveillance, Epidemiology, and End Results database has shown that rates of surgical resection for breast, colon, and rectal cancer are high in all age groups. However, the likelihood of undergoing surgery for localized lung, liver, esophageal, or pancreatic cancer—higher-risk operations with a lower chance for cure—declines sharply with age. Whether decreased use of cancer-directed surgery in the elderly population is appropriate is unknown.

In addition to higher operative mortality rates, elderly cancer patients have substantially lower 5-year survival when compared to younger patients. A retrospective cohort study of octogenarians undergoing major resections for lung, esophageal, and pancreas cancer used the Surveillance and End Results–Medicare-linked database

(1992–2003) to measure late survival. Five-year survival in octogenarians was low for all three cancers: 11% after pancreatectomy, 18% after esophagectomy, and 31% after lung cancer resection. Survival among octogenarians with two or more comorbidities was substantially worse than those with fewer comorbid diagnoses—10% versus 14% for pancreatectomy (Figure 37-3), 15% versus 23% for esophagectomy (Figure 37-4), and 27% versus 37% for lung (Figure 37-5). These population-based outcomes after high-risk cancer surgery in octogenarians were considerably worse than typically reported in case series and in frequently cited survival statistics. Realistic information about long-term survival should be available to elderly patients and their caregivers to better inform clinical decision making—particularly in multimorbid patients.

### SUMMARY

Surgical procedures are being performed with increasing frequency in elderly patients. Rates of surgery in this population are likely to skyrocket as the population ages. While advances in surgical technique and perioperative care are making surgery safer, morbidity and mortality rates in elderly patients remain substantially higher than in younger patients. In addition to common medical complications, elderly patients are at increased risk of sustained cognitive dysfunction and loss of independence after surgery. For elderly patients with cancer, survival benefits gained from surgical resection are not equivalent to those seen in younger patients.

Comprehensive risk assessment and realistic expectations about outcomes after a major surgery in elderly patients are essential for several reasons. In this age group, functional status and frailty need to be taken into consideration when estimating the risk of surgery.

**FIGURE 37-3.** Five-year survival after pancreatic resection, by age and comorbidity count. (From Finlayson E, Fan Z, Birkmeyer JD. Outcomes in octogenarians undergoing high risk cancer surgery. *J Am Coll Surg.* 2007;205(6):726-734.)

**FIGURE 37-4.** Five-year survival after lung surgery, by age and comorbidity count. (From Finlayson E, Fan Z, Birkmeyer JD. Outcomes in octogenarians undergoing high risk cancer surgery. *J Am Coll Surg.* 2007;205(6):726-734.)

**FIGURE 37-5.** Five-year survival after esophagectomy, by age and comorbidity count. (From Finlayson E, Fan Z, Birkmeyer JD. Outcomes in octogenarians undergoing high risk cancer surgery. *J Am Coll Surg.* 2007;205(6):726–734.)

Toward this aim, more research is needed to improve risk stratification for this complex and diverse population. Although age strongly predicts morbidity and mortality after major surgery, it is only one of many risk factors. Complex interactions of age, functional status, cognitive status, and frailty likely explain what clinicians generally characterize as a “young” 85-year-old patient versus an “old” 85-year-old patient. Understanding the risk implications of these patient characteristics on surgical outcomes will inform preoperative counseling and decision-making. Elderly patients and their families should also be aware that, in addition to increased risk of mortality after surgery, many elderly patients may experience substantial functional decline and loss of independence after surgery—either temporary or permanent. It is important for elderly patients, caregivers, and physicians to be aware of the likelihood of protracted functional recovery in order to inform operative consent as well as plan for extended postoperative support.

A better understanding of operative risk factors unique to elderly people will also inform risk reduction strategies. In the general population, the identification and dissemination of processes of care shown to reduce morbidity and mortality after surgery (e.g., perioperative beta-blockade in patients with coronary artery disease) have resulted in improved outcomes. In addition to cardiac and pulmonary assessment, the preoperative evaluation of elderly patients should include screening for functional status and frailty. Future work is needed to identify, develop, and test targeted interventions to improve medical and functional outcomes in this vulnerable population of elderly patients. Once these interventions are identified, protocols can be developed by multidisciplinary teams of surgeons and geriatricians to standardize evidence-based preoperative evalua-

tion and perioperative care for elderly patients undergoing surgery. Through collaboration and dissemination of “best practices” in this vulnerable population, outcomes after surgery are likely to improve substantially.

# Nutrition and Aging

*Dennis H. Sullivan* ■ *Larry E. Johnson*

## INTRODUCTION

Throughout life, nutrition is an important determinant of health, physical and cognitive function, vitality, overall quality of life, and longevity. The quantity and variety of available foods, as well as the meaningfulness of the social interactions provided by meals, are important to psychological well-being. The composition of the diet and the amount that is consumed are strongly linked to physiological function. When a well-balanced diet is not maintained, malnutrition may develop with consequent detrimental effects on health and well-being.

Malnutrition can have many manifestations. As outlined in Chapter 40, a diet that is deficient in one or more required nutrients (e.g., calories, protein, minerals, fiber, or vitamins) can lead to a state of nutritional deficiency. The greater the magnitude and duration of the nutritional deprivation and the more fragile the individual, the more likely nutritional deficits will produce noticeable body compositional changes, functional impairments, or overt disease. Even borderline dietary deficiencies can have important health consequences such as producing subtle organ system impairments, diminished vitality, or increasing the individual's susceptibility to disease. Protein and protein-energy undernutrition are two of the most common, frequently unrecognized, and potentially serious forms of nutritional deficiency. The prevalence of these conditions is particularly high among chronically ill older individuals and those in hospitals, nursing homes, and other institutional settings. Although there is a complex interrelationship between nutrition, disease, and clinical outcomes, protein and protein-energy undernutrition appear to be significant contributors to disease-related morbidity and mortality in these populations. At the other end of the spectrum, the persistent consumption of excess quantities of one or more nutrients can have similar untoward consequences. Forms of malnutrition that result from excess consumption include hypercholesterolemia, hypervitaminosis, and obesity. Studies indicate that obesity is the most common nutritional disorder of advanced age in western societies

with a high prevalence among the noninstitutionalized free-living elderly. Many obese older individuals have other nutritional disorders. Among chronically ill or functionally debilitated obese older individuals, protein undernutrition is a common, serious, and frequently unrecognized problem that can develop for many reasons including an imbalanced diet, disease, and inactivity.

Recognizing and maintaining an optimally balanced diet is an important challenge, particularly as individuals age. The challenge is particularly great for older people who already are malnourished, especially if they have nutritional disorders that developed earlier in life, such as obesity, osteoporosis, or protein undernutrition. Even healthy individuals often fail to maintain an optimal diet owing to lack of knowledge, resources, or willpower. The process of aging can introduce other factors including acute and chronic disease, physical disabilities, social isolation, use of multiple medications, depression, impaired cognitive ability, and dysregulation of appetite control that may contribute further to poor eating habits and the development or exacerbation of nutritional disorders. In turn, inappropriate dietary intake and poor nutritional status can impact the progression of many acute and chronic diseases such as coronary heart disease, cancer, stroke, diabetes, and osteoporosis, which are among the 10 leading causes of death in the United States. The 1988 Surgeon General's Report on Nutrition and Health noted that two-thirds of all deaths within the United States are because of diseases associated with poor diets and dietary habits.

Assessing the quality of the diet of elderly persons is critical to addressing issues relevant to their health and nutritional status. Such an assessment must be based on knowledge of what constitutes a balanced diet for a given individual. The goal of this chapter is to identify an approach to nutrition evaluation and management that takes into account the unique needs, limitations, and desires of each elderly individual. The chapter starts out by examining the interrelationship among nutrition, activity, disease burden, and health outcomes and then focuses on age-related changes in body composition, lifestyle, and appetite regulation that affect nutritional status and nutrient requirements. Also included is a discussion

of specific dietary considerations related to optimal health requirements.

## THE INTERRELATIONSHIP BETWEEN NUTRITION, ACTIVITY, AND DISEASE

Although nutrition is a vital component of good health, it cannot be evaluated in isolation. The relationship between nutrient intake and health is influenced by other factors, most notably activity level, disease burden, and advancing age. A basic understanding of these interrelationships is essential in order to assess the potential benefits and limitations of nutritional interventions.

### Nutrition–Activity Interrelationship

Nutrition and physical activity are closely linked, each having vitally important and interacting effects on body composition, functional ability, and well-being. The balance between nutrient intake and physical activity is particularly important in determining muscle mass and strength, body fat content and distribution, and bone density and resilience. In recognition of the importance of the interrelationship between nutrition and activity on health, the U.S. Department of Agriculture (USDA) has released the MyPyramid food and activity guidance system. The MyPyramid symbol (Figure 38-1), which replaces the prior food pyramid, is designed to emphasize this interrelationship. The symbol is also designed to convey the message that variety, proportionality, moderation, gradual improvement, and personalization are all important in both diet and exercise prescriptions. Consumers can go to the MyPyramid Web site ([www.mypyramid.gov](http://www.mypyramid.gov)) to learn more about this system and to obtain a detailed assessment and analysis of their current eating and physical activity habits.

To preserve existing muscle mass and strength, it is necessary to maintain both an adequate level of physical activity and a balanced diet that includes sufficient protein, energy, vitamins, and minerals to meet metabolic demands and prevent negative nitrogen balance (as discussed in detail below). It is not known precisely what level of physical activity is needed to prevent loss of existing muscle mass and strength in older adults. However, studies indicate that even a week or two of bed rest or similar degrees of activity restriction can result in noticeable loss of muscle mass, strength, and function even when the diet is adequate and the individual is otherwise healthy. In one study of 12 healthy, moderately active older adults, 10 days of voluntary total bed rest resulted in a 16% loss of strength and a 6% loss of skeletal muscle mass from the lower extremities. Muscle biopsies indicated that muscle protein synthesis declined by 30%. Despite the provision of a diet containing the recommended dietary allowance for protein, the participants remained in negative nitrogen balance throughout the study. In contrast, fat mass did not change. The combination of inadequate diet and inactivity can result in an even more rapid loss of muscle. In contrast, overfeeding does not prevent muscle atrophy associated with inactivity and may exacerbate the functional consequences since the excess nutrients are converted to fat.

To increase muscle strength, size, or endurance, the average daily level of exertion has to increase significantly. Aerobic exercises are most effective in improving the oxidative capacity of muscles and are the mainstay of endurance training. High-intensity, progressive resis-

tance training, such as weight lifting, is needed to build strength and mass. Nutrition alone has never been demonstrated to be an effective method of repleting muscle mass, improving strength, or increasing endurance in frail older individuals who have experienced a recent loss of weight. Efforts at repletion should focus on both increasing nutrient intake and exercise. Based on studies of healthy elderly men, the combination of progressive resistance muscle strength training and a high protein diet (containing up to 1.6 g of protein/kg body weight/d) may be the most effective method of improving muscle mass.

Exercise can have an important effect on body fat content and distribution. In obese older individuals, exercise can play a synergistic role with caloric restriction in promoting weight loss and preventing further weight gain. With weight loss, visceral fat is mobilized at a rate two to five times that of other fat stores. Even when total body weight does not change, exercise can induce a significant decrease in intra-abdominal fat in both obese and nonobese individuals. The preferential mobilization of fat stores has important metabolic implications for the prevention or treatment of the insulin resistance syndrome, since it is predominantly excess visceral fat that is associated with the derangements of dyslipidemia, elevated fibrinogen, hyperinsulinemia, and hypertension.

Exercise and nutrition also play a critical role in maintenance of optimal bone density and strength. As discussed in Chapter 117, the nutrient needs of bone include the correct balance of protein and energy and adequate intake of vitamins and minerals, especially vitamin D and calcium. The amount of exercise that is needed for optimal bone health is not defined. However, it is known that people who exercise regularly have higher bone density than more sedentary age-, race-, and gender-matched controls. Randomized controlled trials involving postmenopausal women demonstrate that those assigned to progressive resistance muscle strength training or weight-loading aerobic exercise programs attain a 1% to 1.6% greater bone mineral density in both the lumbar spine and femoral neck region per year compared to the controls. It is also known that bed rest and weightlessness are associated with a rapid decline in bone mineral density. Consequently, osteopenia can develop despite an optimal diet if exercise or other weight bearing activities are not adequate. Because of its apparent beneficial effects on bone mineral density, exercise should be combined with an appropriate diet for both prevention and treatment of osteoporosis and fracture-related disability.

Having both direct and indirect effects on numerous metabolic processes within muscle, bone, and adipose tissues, exercise has a major impact on how nutrients are utilized by the body during health and illness. By inducing an increase in the mass and metabolic capacity of muscle, exercise affects energy expenditure, glucose metabolism, and size of protein reserves in a manner that counteracts some of the effects of aging and thus has important nutritional implications for individuals as they grow older. Total energy expenditure (TEE) represents the sum of basal energy expenditure, postprandial thermogenesis, and the energy expenditure of activity. Muscle represents not only the primary source of energy expenditure during physical activity, it is also the primary contributor to basal energy expenditure, which may represent 50% to 80% of TEE. With advancing age, there is a parallel decline in muscle mass and both basal and total daily energy expenditure that may be partially or fully accounted for by the fact that people tend to become more sedentary as they grow older. A study of master athletes demonstrates that men who maintain a vigorous weekly routine of weight training throughout

GRAINS Make half your grains whole	VEGETABLES Vary your veggies	FRUITS Focus on fruits	MILK Your calcium-rich foods	MEATS & BEANS Go lean with protein
<p>Eat at least 3 oz of whole-grain cereals, breads, crackers, rice, or pasta every day</p> <p>1 oz is about 1 slice of bread, about 1 cup of breakfast cereal, or 1/2 cup of cooked rice, cereal, or pasta</p>	<p>Eat more dark-green veggies like broccoli, spinach, and other dark leafy greens</p> <p>Eat more orange vegetables like carrots and sweetpotatoes</p> <p>Eat more dry beans and peas like pinto beans, kidney beans, and lentils</p>	<p>Eat a variety of fruit</p> <p>Choose fresh, frozen, canned, or dried fruit</p> <p>Go easy on fruit juices</p>	<p>Go low-fat or fat-free when you choose milk, yogurt, and other milk products</p> <p>if you don't or can't consume milk, choose lactose-free products or other calcium sources such as fortified foods and beverages</p>	<p>Choose low-fat or lean meats and poultry</p> <p>Bake it, broil it, or grill it</p> <p>Vary your protein routine—choose more fish, beans, peas, nuts, and seeds</p>

For a 2000-calorie diet, you need the amounts below from each food group. To find the amounts that are right for you, go to MyPyramid.gov.

Eat 6 oz every day	Eat 2 1/2 cups every day	Eat 2 cups every day	Get 3 cups every day; for kids aged 2 to 8, it's 2	Eat 5 1/2 oz every day
--------------------	--------------------------	----------------------	--	------------------------

**Find your balance between food and physical activity**

- Be sure to stay within your daily calorie needs.
- Be physically active for at least 30 minutes most days of the week.
- About 60 minutes a day of physical activity may be needed to prevent weight gain.
- For sustaining weight loss, at least 60 to 90 minutes a day of physical activity may be required.
- Children and teenagers should be physically active for 60 minutes every day, or most days.

**Know the limits on fats, sugars, and salt (sodium)**

- Make most of your fat sources from fish, nuts, and vegetable oils.
- Limits solid fats like butter, stick margarine, shortening, and lard, as well as foods that contain these.
- Check the Nutrition Facts label to keep saturated fats, trans fats, and sodium low.
- Choose food and beverages low in added sugars. Added sugars contribute calories with few, if any, nutrients.

U.S. Department of Agriculture  
Centre of Nutrition Policy and Promotion

CNPP-15

USDA is an equal opportunity provider and employer.

**FIGURE 38-1.** MyPyramid.gov, U.S. Department of Agriculture, Center for Nutrition Policy and Promotion, April 2005, CNPP-15, <http://www.mypyramid.gov>

their lives have the muscle mass and energy capacity comparable to that of healthy 30-year-old males. Nonexercising older men have significantly less muscle mass than their younger counterparts.

Exercise-induced increases in muscle size or protein content result in greater body protein reserves, which can be critical to survival during episodes of nutritional deprivation that usually accompany profound physiologic stress such as that caused by trauma, sepsis, or other acute disease. Such acute physiologic insults trigger an acute inflammatory response that causes ketogenesis to be suppressed, leaving glucose as the primary energy source available to the body. The problem is invariably compounded by reduced nutrient intake that results as a consequence of the anorexia and gastrointestinal tract dysfunction induced by the inflammatory response. With nutrient intake suppressed, gluconeogenesis becomes the predominant source of glucose. Since the substrate for gluconeogenesis is provided by catabolism of skeletal muscle, lean body mass becomes an important determinant of survival. Once lean body mass falls below a critical level, the chance of surviving a serious acute illness diminishes dramatically. Studies conducted within the Warsaw Ghetto, hospital intensive care units, and other settings suggest that a loss of >40% of baseline lean mass is incompatible with life. Other studies indicate that very few healthy people have a lean body mass that is <70% of the mean for that of adults aged 20 to 30 years.

In addition to inducing muscle hypertrophy, exercise also affects insulin sensitivity, glucose disposal, and HDL levels directly and plays a synergistic role with diet in maintaining a healthy weight and a sense of well-being. These effects of exercise can be important adjuncts to good nutrition in the prevention and treatment of hypertension, diabetes, dyslipidemia, and osteoporosis.

### Nutrition–Disease Interrelationship

There is a complex interrelationship between nutrition, health status, and clinical outcomes. Although a full discussion of this topic is beyond the scope of this chapter, it is important to emphasize several key points. First, nutrient requirements and the ability to metabolize select nutrients are influenced by many disease states. In addition, many diseases compromise the older individual's ability to consume adequate amounts of all nutrients. This can occur through a number of mechanisms including disease-induced suppression of appetite, alteration of the normal swallowing mechanism, maldigestion or malabsorption, and a loss of self-feeding ability.

The detrimental effects of disease on nutrient metabolism often become more pronounced with advancing age. This is particularly true of the many acute and chronic diseases that induce an inflammatory response, including acute and chronic infections, congestive heart failure, chronic pulmonary disease, cancer, end-stage renal disease, and rheumatoid arthritis. With advancing age, the inflammatory response often becomes dysregulated as indicated by persistently elevated serum concentrations of proinflammatory cytokines and other inflammatory mediators (Chapter 4). The proinflammatory cytokines include interleukin(IL)-6, IL-1(beta), tumor necrosis factor(TNF)-alpha, and possibly IL-8 and others. These cytokines function both as intermediaries and directly to induce many of the signs and symptoms associated with inflammation including weight loss. The proinflammatory cytokines have been implicated in the pathogenesis of many of the detrimental consequences of chronic inflammation including anemia, hypoalbuminemia, and cachexia. IL-1, IL-6, and TNF-alpha all contribute to the loss of skeletal muscle,

fat tissue, and bone mass that characterizes inflammation-associated cachexia. Although anorexia is almost always a contributing factor, the inflammation-induced loss of fat and lean mass is often refractory to nutrition support. Proinflammatory cytokines create a state of muscle catabolism by suppressing muscle protein synthesis and/or accelerating muscle protein breakdown independent of dietary factors. Additionally, the proinflammatory cytokines induce lipolysis while suppressing fat and liver lipoprotein lipase activity resulting in hypertriglyceridemia and a decrease in the availability of fat to be used as an energy source. As energy production from fat diminishes, the importance of glucose as an energy source increases. The amino acids derived from the muscle proteolysis are either converted to glucose or are consumed in hepatic synthesis of acute phase proteins. Additionally, cytokines stimulate the release of cortisol resulting in a further acceleration of the muscle catabolism. Since these potentially deleterious effects of disease can be difficult to predict, older individuals with one or more acute or chronic health problems should have frequent reassessments of their nutritional status and their nutritional care plan revised as necessary. Although nutrient intake may not be adequate to completely reverse inflammation-induced catabolism, a low nutrient intake will accelerate the development of cachexia. Optimally, good nutritional care should be part of the overall plan of medical intervention aimed at treating the underlying pathology as well as addressing protein and energy deficits. Although a number of specific nutrients are being studied to determine their value in counteracting inflammation-induced loss of lean body mass, there is not yet adequate evidence that any given dietary supplement is more effective than current standard dietary or nutrition support practices.

## AGE-RELATED CHANGES THAT AFFECT NUTRITION

### Changes in Body Composition

With advancing age, there are significant changes in body composition that affect the nutritional needs of an individual. Based primarily on cross-sectional studies, weight increases steadily in most people from age 30 to 60 years. An increase in total body fat accounts for a majority of this weight gain. After age 60, weight usually stabilizes, and then begins to decline. Improved survival of nonobese individuals during middle age and cohort effects may account for some of the decline in weight with age that is reported in the cross-sectional studies. However, weight maintenance becomes increasingly difficult in the advanced years of life. The incidence as well as the potential causes of weight loss increases with age, particularly beyond age 75.

Regardless of whether or not weight changes, advancing age is characterized by a progressive loss in lean body mass, a relative increase in fat mass, and a redistribution of fat from peripheral to central locations within the body. Based primarily on cross-sectional studies, it appears that all of these changes begin in the third decade and increase at an accelerated rate after age 65. This late accelerated phase may be a threshold effect brought about by the loss of lean body mass and the increased prevalence of chronic disease in old age. The loss of lean body mass consists predominantly of skeletal muscle, particularly type II or fast twitch fibers. Central lean body mass, such as the liver and other splanchnic organs, is relatively preserved. Some studies indicate that muscle mass may decline by up to 45%

**FIGURE 38-2.** Declining muscle mass with increasing age. (Reproduced with permission from Frontera WR, Hughes VA, et al. A cross-sectional study of muscle strength and mass in 45- to 78-yr-old men and women. *J Appl Physiol.* 1991;71:644.)

between the third and eighth decade of life (Figures 38-2 and 38-3). The few longitudinal studies that have been reported indicate that the loss of muscle mass with age may be greater in men than women. However, this remains controversial.

The loss of muscle mass with age appears to be the result of multiple interrelated factors including age-related changes in metabolism, function, or structure of organ tissues, disease, medical therapeutics, heritability, and behavior and lifestyle choices of the individual. Notable age-related changes that appear to contribute to loss of muscle include a progressive loss of alpha motor units in the spinal column, a diminution in the intrinsic muscle protein synthesis capacity, and a decline in the production of multiple hormones including testos-

**FIGURE 38-3.** Cross-sectional computed tomography images of the mid-thighs of a younger and an older woman demonstrating the decline in muscle mass and relative increase in fat mass with age.

terone, estrogen, and the insulin-like growth factors. The decline in the intrinsic muscle protein synthesis capacity parallels and may be causally related to a loss of mitochondrial ATP production with advancing age. Other age-related changes detrimental to muscle include the increased production and delayed inactivation of catabolic mediators and a change in liver protein metabolism that may decrease the availability of amino acids to axial muscles. The decline in nutrient consumption and activity level that often accompanies advanced age are possibly modifiable contributors to the loss of muscle mass. Many diseases accelerate the age-related decline, particularly degenerative diseases of the central nervous system and those affecting any part of the motor pathway. An accelerated loss of muscle mass can occur when a serious illness requires treatment with steroids or other antianabolic drugs or is accompanied by low nutrient intake and the need for prolonged bed rest. In all individuals, the loss of muscle mass with age is closely linked with a reduction in muscle strength and exercise capacity, a decline in one causing further loss of the others. When exercise capacity falls below that required to comfortably perform basic activities of daily living, physical activity often becomes very limited, which causes a rapid acceleration of the downward spiral. The loss of muscle mass and exercise capacity is also linked to the development of coronary artery disease, diabetes mellitus, and other diseases that contribute further to the decline.

In parallel with the loss of lean body mass, there is an increase in the relative amount and the distribution of body fat with advancing age. Between the second and ninth decades of life, the percentage of body weight that is fat increases by 35% to 50% in females and to an even greater extent in males. In one cross-sectional study of 500 healthy individuals between the ages of 18 and 85 years, fat mass as a percentage of body weight increased across the age range of the sample from 33% to 44% in females and 18% to 36% in males. Whether or not total body weight changes, intra-abdominal (visceral) fat increases quantitatively and proportionally more than peripheral fat mass. In females, the accumulation of intra-abdominal fat accelerates at menopause and represents primarily a shift from peripheral sites. In males, the increase in intra-abdominal fat with age represents primarily an increase in total body fat mass. For a given waist circumference, older adults have greater visceral fat than young adults and men have greater visceral and less subcutaneous fat than women.

Numerous factors have been cited as potential contributors to the changes in adipose tissues with advancing age. Some studies suggest that much of this change can be accounted for by the reduction in both the quantity and oxidative capacity of skeletal muscle that also occurs during the same time interval. With advancing age, fat oxidation is reduced at rest, following a meal, and during exercise. This reduced rate of fat metabolism with age promotes accumulation of fat at both peripheral and central locations. The decline in total skeletal muscle mass that occurs with age correlates with, and may be responsible for, the decreased rate of metabolism of fat at rest. Likewise, the decline in maximal oxidative capacity of muscle may cause the reduction in fat metabolism with exercise. The decline in physical activity resulting from the loss of muscle with age contributes to the increase in intra-abdominal fat. Other factors that may also contribute to the increased intra-abdominal fat with age include declining testosterone in men, estrogen withdrawal or increased testosterone in females, the decline in growth hormone, increased resistance to leptin, and increased secretion of cortisol.

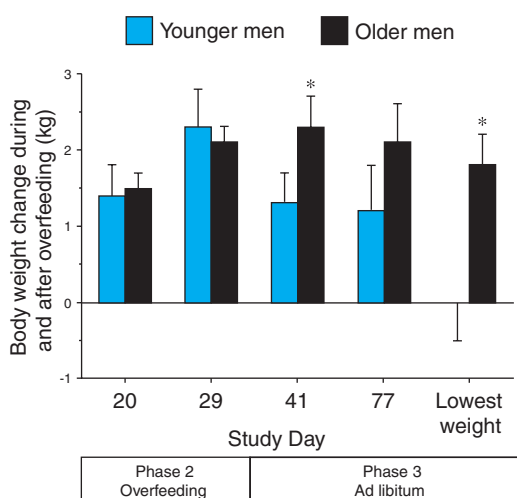

Weight cycling can also contribute to the relative increase in fat mass in some older adults. When older adults lose weight, particularly when this weight loss occurs in association with an acute illness, they usually experience a greater decline in lean compared to fat mass. Those individuals who later regain some or all of the lost weight usually gain predominantly fat mass. It is not known whether exercise, specialized diets, or anabolic agents would be effective in helping to restore lean body mass in these older adults. Given the high prevalence of illness-induced weight loss among older adults, this is an important area for further research.

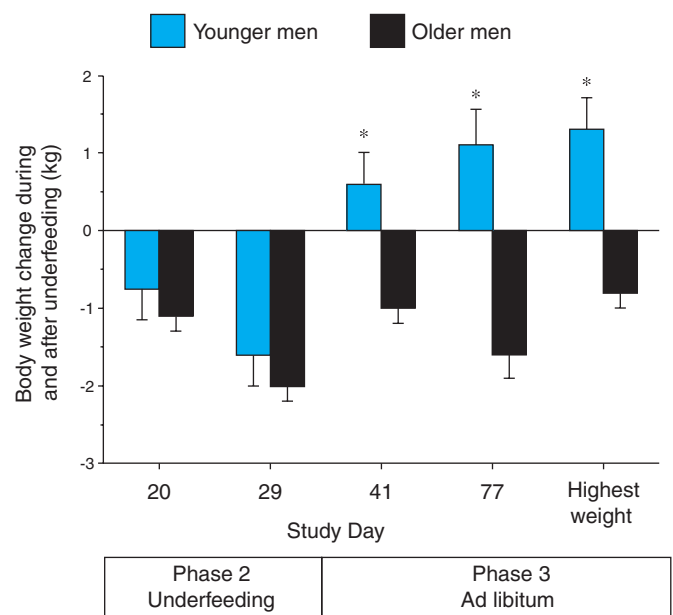

### Changes in Appetite and Energy Intake Regulation

Maintenance of a stable weight requires a steady balance between nutrient intake and energy expenditure. With advancing age, the metabolic, neural, and humoral pathways that normally maintain this delicate balance by regulating appetite and hunger begin to lose their compensatory responsiveness to changes in energy demands. Psychological, socioeconomic, and cultural influences and numerous disease processes further contribute to the dysregulation. From the third to seventh decade of life, these factors integrate to create an imbalance usually favoring a tendency toward weight gain and increased fat deposition, at least in societies where food is plentiful and the physical demands of life are light. However, after age 70, the risk of losing weight increases steadily with each year of survival. This correlates with the findings from numerous studies that indicate that low dietary energy intake is common among both healthy and frail elderly people.

Impaired regulation of food intake has been observed in sedentary elderly men. As shown in Figure 38-4, young and older subjects gained similar amounts of weight during overfeeding. When allowed to resume a normal ad libitum diet, the young subjects decreased their energy intake and lost weight. In contrast, the elderly subjects failed to readjust their nutrient intake and at the end of the study remained above their starting weight. As shown in Figure 38-5, there were similar age group differences in the response to underfeeding.

**FIGURE 38-4.** Body weight change during 21 days of overfeeding by 1000 kcal/d (phase 2) and a subsequent 46-d period of ad libitum diet (phase 3). Values are means (+SEM) for younger ( $n = 7$ ) and older ( $n = 9$ ) men. The asterisks indicate significance at  $P < 0.05$  relative to the younger men. (Reproduced with permission from Roberts SB, Fuss P, et al. Control of food intake in older men. *JAMA*. 1994;272:1601.)

**FIGURE 38-5.** Body weight change during 21 days of underfeeding by 792 kcal/d (phase 2) and a subsequent 46-day period of ad libitum diet. Values are means (+SEM) for younger and older men. The asterisks indicate significance at  $P < 0.001$  relative to the younger men. (Reproduced with permission from Roberts SB, Fuss P, et al. Control of food intake in older men. *JAMA*. 1994;272:1601.)

The young and old subjects experienced similar amounts of weight loss during the intervention phase. However, the young men increased their nutrient intake and regained weight after returning to an ad libitum diet, whereas the elderly subjects did not. These findings suggest that a reduced ability to regulate food intake may contribute to the progressive loss of weight that many older individuals experience when their lives are disrupted by illness, psychological stress, or economic hardship.

### Loss of Taste, Smell, and Appetite with Advancing Age

Numerous pathologic and age-related physiologic changes contribute to the difficulty older people have maintaining a balance between metabolic needs and nutrient intake. The look, smell, taste, and texture of food all contribute to the desirability of a meal and can serve to stimulate or inhibit further consumption. Normal sensory systems are therefore necessary for the full enjoyment of food and are important regulators of nutrient intake. The abilities to smell and taste food are particularly important. The aroma of food can serve as a powerful appetite stimulant. After food enters the mouth, aromatic substances released from the food circulate up through the nasopharynx to the olfactory cleft where they enhance taste. The sensations of smell and taste add to the pleasure of eating while serving as chemosensory signals for food digestion by triggering salivary, gastric, pancreatic, and intestinal secretions. The texture, temperature, and quantity of food in the mouth also contribute to the hedonic qualities of a meal and serve to promote further consumption.

A significant deterioration in sight, olfactory function, taste sensation, or ability to feel the temperature and texture of food in the mouth can have a deleterious effect on eating habits and the likelihood of maintaining an adequate diet. This becomes an important concern with advanced age. Even healthy older individuals

**TABLE 38-1****Conditions That Can Suppress Appetite and Alter Olfactory Function**

experience a modest deterioration in their ability to detect odors and to differentiate one odor from another. There is a similar pattern to the loss of taste. Compared to young people, older individuals who suffer from no diseases and take no medications have a moderately reduced ability (i.e., require greater concentrations) to both detect and to identify sweet, sour, salty, and bitter substances and amino acids such as glutamate salts. Elderly persons also have reduced ability to discriminate intensity differences and to recognize taste mixtures.

Much greater losses in taste and smell occur in association with medication usage and other health-related concerns. [Tables 38-1 and 38-2](#) contain a representative listing of local, central nervous system, and systemic diseases; nutritional deficiencies; medications; surgical interventions; and environmental exposures (including smoking) that can cause appetite suppression and a loss of olfactory function

**TABLE 38-2****Classes of Medications That Can Suppress Appetite and Alter Olfactory Function\***

Anticonvulsants
Vasodilators

\*Numerous drugs in each category can alter appetite and olfactory function.

and taste sensation. Poor oral health and many diseases that decrease mastication, salivary flow, or ability to swallow can also lead to deterioration in taste and smell and adversely affect appetite. The grinding and mixing of food with saliva play important roles in the release of volatiles and in bringing substances in contact with taste receptors, while swallowing movements are essential to pump the released volatiles up to the olfactory cleft where they are perceived.

### Gastrointestinal Tract and Postabsorptive Effects on Appetite

In addition to the special senses, there are various neural and humoral pathways within the gut that change with advanced age. Although controversial, some of these changes may contribute to the inability of many older individuals to adequately regulate food intake. Normally, stretch reflexes within the wall of the stomach play a key role in signaling the brain when adequate amounts of food have been ingested. Some investigators theorize that these reflexes become overly responsive in advanced age leading to early satiety and reduced food intake. Other investigations have revealed that gastric emptying is delayed with advanced age and that this may lead to slower absorption of carbohydrates, a reduction in insulin secretion, and a relative suppression of the hunger response. However, other studies have found postprandial insulin levels to be elevated in the elderly suggesting that it is the age-related change in the meal-induced pattern of insulin secretion that may be the more important determinant of food intake. There is also evidence that certain gastrointestinal hormones, such as cholecystokinin, contribute to the appetite dysregulation with advancing age. Both the amount of cholecystokinin released in response to a meal and its potency in producing early satiety are greater in old compared to younger individuals. A number of other hormones have also been linked to appetite control. These include ghrelin, a gastric peptide that has apparent orexigenic properties, and leptin, a hormone produced by adipose tissue that induces satiation at high serum concentrations. Whether age- or disease-related changes in the secretion of these and other hormones are causally related to the decline in nutrient intake and loss of weight seen in many frail older adults remains controversial.

### Psychological, Socioeconomic, and Cultural Influences on Appetite

After the seventh decade of life, the importance of psychological, socioeconomic, and cultural factors to maintaining an adequate diet increases. Depression is a common, frequently unrecognized, and potentially treatable cause of a poor appetite and must always be considered when evaluating an older patient who is losing weight. A correct diagnosis is often difficult to make in the elderly, particularly when the individual suffers from other medical problems or dementia. Similarly, bereavement is associated with a lack of appetite. Poverty, lack of education, limited mobility, feeding dependency, and social isolation are also important risks. Some, though not all, studies of healthy adults have found that eating alone is associated with a lower energy intake than when eating with others and that the presence of family and close friends leads to greater nutrient intake than eating with less familiar individuals. Within institutional settings, particularly nursing homes, physical environment and ambience within the dining areas are known to affect appetite. Interventions to a meliorate the dining experience within nursing homes have been shown to improve nutrient intakes and promote weight gain.

Therapeutic diets (e.g., low salt or low cholesterol) are frequently prescribed in nursing homes, often to residents who are losing weight, even though they may add little or nothing to disease management. For these reasons, the American Dietetic Association has published a position statement suggesting that use of therapeutic diets in the nursing homes be restricted.

## NUTRIENT REQUIREMENTS TO MAINTAIN HEALTH

### Energy

Daily energy requirements per kilogram of body weight generally decline with age, dropping as much as 33% between the third and ninth decade of life. Male gender and chronic disease are associated with a greater rate of decline. However, a decrease in energy requirements with age occurs even among those who remain healthy. The primary reason for this decline is the loss of muscle mass that is nearly universal with advanced age. Muscle is much more metabolically active than adipose tissue. As muscle mass is lost, the ratio of fat to lean mass increases leading to a greater drop in basal metabolic rate (BMR) than predicted by the decrease in total body mass. With advanced age, there is also a slight decline in metabolic rate per kilogram of fat-free mass. This may relate to the age-related change in the ratio of high (e.g., muscle) to low (e.g., bone) metabolic rate tissues within the fat-free mass compartment. Because the BMR generally accounts for 60% to 75% of TEE, the end result of the muscle loss is a significant decline in TEE and thus in energy requirements. It is estimated that every 10-kg loss of skeletal tissue mass results in an approximate 150 kcal/d decline in basal energy expenditure.

A second mechanism accounting for the decline in energy requirements with age is a decrease in physical activity. Energy expenditure of physical activity (EEA) generally declines with age to the same extent as BMR, accounting for approximately 15% to 35% of TEE in the majority of elderly adults. However, EEA can range from 5% of TEE in those who are bedridden to 50% in highly active, physically fit older adults. Studies of free-living older adults demonstrate that the strongest independent predictors of EEA are maximum oxygen consumption, fat-free mass, and body mass. After adjustment for body composition, there are no significant differences in TEE, BMR, or EEA between males and females. Other studies indicate that lifestyle plays a big role in determining EEA of older people, just as it does in those who are younger. Although the increased prevalence of chronic disabling disease accounts for some of the decline in physical activity with advancing age, even healthy older adults tend to be more sedentary than younger individuals.

Many chronic diseases, including congestive heart failure, Parkinson disease, and Alzheimer dementia, are associated with an increase in BMR. However, these conditions have been found to be associated with a decreased TEE because of decreased energy of physical activity. Some chronic conditions may result in an increased TEE, although this remains controversial. Individuals with Alzheimer's disease who constantly pace would fall into this category, as would individuals with a constant tremor. Even when individuals appear to be rather sedentary, their TEE from physical activity may be greater than expected, particularly if they have certain disabilities such as neurologic disorders and amputations. These conditions sometimes result in a loss of neuromuscular energy efficiency and thus excep-

tional levels of energy expenditure are required to complete even basic activities of daily living.

Several different clinical methods of estimating the energy requirements of older adults have been validated with sophisticated energy expenditure measurement techniques, such as doubly labeled water studies. These estimates are reviewed in Chapter 40 and summarized in Table 40-2.

The decline in energy requirements with advancing age means that older persons need to consume less food in order to maintain their weight and customary activity level. This places the older individual at risk of developing protein and micronutrient deficiencies, since requirements for other nutrients do not decrease as much as energy. Consequently, it is important that older individuals increase their activity level and change their diet to protein and micronutrient rich foods in order to maintain their muscle mass and avoid obesity.

### Protein

Because of the paucity of high-quality nutrition studies with adequate representation from older age groups, current recommendations for protein intake do not differentiate individuals older than 65 from those who are younger. Various panels have recommended protein requirements for healthy adults of 0.6 to 0.8 g per kg of body weight per day. However, the question of whether protein requirements change appreciably with advancing age continues to be debated. Based on their interpretation of available data, some recommend that protein intake for elderly adults should be 1.0 to 1.25 g/kg/d. Until better measurement techniques become available, it may not be possible to determine the protein requirements of older adults with any higher level of certainty.

Several metabolic methods have been used to estimate the protein requirement of older adults. However, because of the many concerns about the accuracy of these metabolic study techniques, some believe that epidemiologic methods should play a larger role in setting recommendations for protein intake. The amount of protein consumed by healthy adults who have a stable body composition could be included as a basis of the recommendation. In most studies of community-dwelling older adults, median protein intakes tend to exceed the RDA. However, the population variance is significant. One study found that healthy older community-residing individuals eating a self-selected diet in the United Kingdom were in equilibrium with daily intakes equivalent to 0.97 g/kg body weight. Another study found that homebound elderly people consuming their habitual dietary protein intake of 0.67 g/kg/d were in negative nitrogen balance.

### Factors That Influence Protein Requirements

The protein requirements of an individual can change with time, being influenced by age, nonprotein content of the diet, activity level, medications, and health status. The energy content of the diet is particularly important. The protein intake required to maintain nitrogen balance increases with decreasing energy intake. Carefully conducted metabolic studies of healthy young males indicate that nitrogen balance can not be attained at any protein intake when total energy intake is less than 126 kJ/kg (30 kcal/kg). Although comparable data are not available for individuals older than 65, the importance of energy intake in older individuals is well recognized.

A negative energy balance usually precipitates a negative nitrogen balance, especially in individuals who are ill or who have a low level of activity. Whether progressive resistance muscle strength training, alone or in combination with a high protein diet, can prevent loss of lean body mass in older individuals during periods of voluntary caloric restriction and weight loss is being investigated. As a general rule, protein requirements increase with high levels of activity such as sustained high-intensity exercise.

Many disease states and medications can induce a catabolic state for protein by altering the normal balance between protein synthesis and degradation. Older individuals who are both confined to bed and have an injury, infection, or another acute inflammatory condition are at particularly high risk of developing a profoundly negative nitrogen balance that can lead to a rapid loss of lean body mass, particularly skeletal muscle mass. High doses of corticosteroids can have a similar effect. The amount of protein that needs to be consumed in order to minimize loss of lean body mass and optimize recovery from such disease states is often difficult to determine. In general, older hospitalized patients who are acutely ill or recovering from major surgery or trauma warrant a protein intake of 1.5 g/kg of body weight/d unless they have a condition that necessitates protein restriction such as renal or hepatic insufficiency. Chronically ill and bedridden older residents of long-term care institutions are also likely to have similarly high protein requirements.

The source of the dietary protein may be another important factor influencing protein requirements following illness. Although far more needs to be learned about this subject, current evidence suggests that a number of factors including the ratio of the various amino acids within a dietary protein may influence how effectively the protein can be utilized by the body. Several animal and laboratory-based human studies suggest that protein or amino acid supplements containing high concentrations of branched-chain amino acids such as leucine may be more effective than other dietary proteins in stimulating muscle protein synthesis, particularly in sedentary or chronically ill older adults.

## Fat and Cholesterol

Fat serves as a key source of energy and essential fatty acids as well as a vehicle for transporting fat-soluble vitamins. Even when obesity and elevated cholesterol or triglycerides are a concern, fat intake should not fall below 10% of total energy requirements in order to allow for adequate absorption of fat-soluble vitamins (A, D, E, K) and to ensure that the requirements for the essential fatty acids are met. There are two main types of essential fatty acids, the omega-6 series, derived from linoleic acid (e.g., arachidonic acid and gamma-linolenic acid), and the omega-3 series, which could be derived from alpha-linolenic acid (from plant sources) or contained in certain cold water fish (e.g., eicosapentaenoic acid [EPA] and docosahexaenoic acid [DHA]). The essential fatty acids are required for the synthesis of cell membrane phospholipids and eicosanoids, which include prostaglandins, leukotriene, and hydroxy acids. Cell membrane phospholipids influence the biomechanical properties of the membranes and their membrane-bound receptors. The eicosanoids, derived predominantly from arachidonic acid and EPA, serve many functions including modulation of inflammation and host defenses. It is currently recommended that intake of the omega-6 linoleic acids be at least 1% of total food energy. Clinical deficiency of these essential fatty acids is rarely seen in adults since western diets generally

provide 8 to 15 g/d and adipose tissue provides a reserve of 0.5 to 1~kg. When a deficiency does develop, it is usually a result of profound cachexia or extensive small bowel disease or necrosis and the inadequate provision of nutrition support. Although current recommendations call for the omega-3 derivatives of alpha-linolenic acid to be at least 0.2% of total food energy, many nutritionists suggest higher intakes owing to their beneficial effects on lipid metabolism. Oils from a variety of cold water fish species including halibut, mackerel, herring, and salmon are high in the omega-3 fatty acids. Mediterranean fish, namely sardine, anchovy, and picarel, contain moderate amounts of omega-3 fatty acids. Several omega-3 fatty acid supplements are readily available in many stores, but these provide varying amounts of marine-based EPA and DHA. Alpha-linolenic acid, which serves as a precursor of EPA, is also a polyunsaturated omega-3 fatty acid and is found primarily in plant products such as soybeans, canola oil, flaxseed oil, and walnut oil. However, it is controversial as to how effectively humans can convert alpha-linolenic acid to EPA; some studies suggest that only 10% of alpha-linolenic acid is converted. Omega-6 fatty acids are abundant in many of the foods common to the average American diet including most vegetable oils, nuts, cereals, seeds, and legumes.

The optimal fat intake for older adults needs to be determined on an individual basis. Although coronary heart disease (CHD) remains the number one killer of older Americans, the importance of dietary fat after the age of 65 remains controversial. Recent studies indicate that total cholesterol (TC) may be as strong a risk factor for CHD in nondisabled men and women older than 71 years as it is in middle-aged individuals. Since many healthy older adults in this age range have reasonably long life expectancies, they may benefit from dietary interventions designed to prevent coronary artery disease or its consequences (see Chapter 110). However, fat and cholesterol restricted diets probably do not have any beneficial effects in reducing CHD mortality and may have detrimental consequences in frail older individuals, especially those who are having problems maintaining their weight. Therefore, it seems prudent to adjust fat intake only in healthy older individuals who otherwise would not be adversely affected by such dietary restrictions.

Serum TC and low-density lipoprotein cholesterol are influenced by the ratio of unsaturated to saturated fats and the total amount of energy, fat, and cholesterol in the diet. The National Cholesterol Education Program (NCEP) recommends that all adults limit their total fat intake to 30% or less of total dietary energy, with saturated fatty acids providing 8% to 10%, polyunsaturated fatty acids up to 10%, and monounsaturated fatty acids up to 15% of total energy intake. Cholesterol intake should not exceed 300 mg/day. If elevated serum lipids remain a concern despite adherence to this diet for 3 months, further reductions in dietary fats (especially saturated and trans-fatty acids) are recommended. This is a reasonable recommendation for healthy older adults. However, few are willing to adhere to a diet that contains less than 25% to 30% fat. Even at this level of dietary restriction, the average TC reduction is in the range of 3% to 5% after 1 year. If greater reductions are indicated, other types of dietary modifications or drug therapy may be needed.

Some studies indicate that increasing the ratio of monounsaturated and polyunsaturated fat to saturated fat, without changing total fat intake may be beneficial. For this reason, some experts support the use of the Mediterranean-style diet, which promotes the use of flaxseed and olive oil and the avoidance of saturated fats. More recently, concern has been raised about the use of partially

hydrogenated fats rich in trans-fatty acids, as these products have also been demonstrated to have an adverse effect on lipid metabolism. Although more study is needed before any special diet can be recommended, it is probably prudent to emphasize the use of natural fats derived from vegetable oils (both poly- and monounsaturated), nuts, and fish, while avoiding those from animal products and partially hydrogenated oils.

These guidelines may not be applicable to frail older individuals, especially those who are losing weight involuntarily, have a body mass index less than 20, or have disease conditions limiting their nutrient intake. Since fats have twice the energy content per gram as carbohydrates and protein, a diet high in fat may be necessary for such frail older individuals in order to meet their maintenance energy requirements or to replete deficits.

## Carbohydrates

Recommendations for carbohydrate content of the diet are generally based on two considerations, the source of the carbohydrates and the energy requirements of the individual. Ideally, food sources should be rich in fiber (see section on “fiber content of diet below”) and provide primarily complex carbohydrates rather than simple sugars. The amount of carbohydrates that should be included in the diet is usually determined by default. The energy, protein, and fat requirements of an individual are determined first. Carbohydrate requirements are then determined by subtracting the amount of energy supplied by protein and fat from the total energy requirements. Since protein requirements represent approximately 15% of the total energy content of the diet and fat ideally should be less than 30%, carbohydrates usually represent 55% to 70% of the total. When carbohydrates are excluded from the diet, energy requirements of the body are met by the incomplete oxidation of fatty acids, which leads to ketosis and often causes lethargy and depression. To prevent ketosis, at least 50 to 100 g of carbohydrates should be consumed each day.

## Water

Although fluid requirements do not change appreciably with age in adults, people older than 65 years have a reduced ability to regulate their fluid intake and are much more likely than young adults to become dehydrated when their health status or environment changes. Aging is associated with a decline in the intensity of the thirst response to fluid deprivation, a delay in correcting the resulting increase in serum osmolarity, and a reduced ability of the kidneys to concentrate the urine despite an increase in serum vasopressin concentration. Chronic disease and injuries that cause a deterioration of cognitive or physical function increase the risk of dehydration further by altering the perception of thirst, reducing the ability to express the desire for water, or diminishing the capability to access and drink adequate amounts of fluids. When an acute febrile illness occurs in an older individual who is already physically or cognitively impaired, life-threatening dehydration can develop rapidly. This scenario occurs with alarming frequency in nursing homes. The failure of many health care providers, family members, and personal aid assistants to recognize the risk factors and early warning signs of dehydration contributes to the danger that a frail older individual will become severely dehydrated. Many older adults themselves do not recognize their risks and may inappropriately restrict their fluid intake, sometimes as a method of controlling incontinence. Prolonged exposure to elevated environmental temperatures, such as may occur during heat waves, may also precipitate profound dehydration.

Care must be taken to prevent dehydration by recognizing those at highest risk, especially older individuals with cognitive and physical deficits, swallowing problems, ongoing weight loss, diarrhea, fever, or poorly controlled diabetes, or receiving enteral feeding, diuretics, or laxatives. Maintenance water requirements range from 1500 to 2500 mL/d or approximately 30 mL/kg body weight/d. With a normal diet, this would equate to approximately 1 mL/kcal of food intake/d. Requirements increase with fever, activity, or prolonged exposure to elevated environmental temperatures. Those at high risk for developing dehydration should be given set prescriptions for fluid intake and have their fluid intake monitored closely. Whenever hydration status is in doubt, the subject should be weighed, orthostatic blood pressure reading recorded, and serum electrolytes, urea nitrogen, and creatinine checked. In some settings, it may also be appropriate to monitor urine output. Skin turgor is not a reliable indicator of hydration status and should not be used as such in the care of older subjects. Patients, family, and all health care staff, especially in nursing homes, need to be trained to recognize the importance of maintaining an adequate fluid intake at all times, and to carefully monitor intake if there is a change in mental status, activity level, or health status, or if fluid requirements increase, as occurs during heat waves.

## Fiber

Dietary fiber is derived from structural components of plant cell walls and consists of plant polysaccharides and lignin, which are resistant to digestion by intestinal enzymes. Many professional health organizations recommend a diet containing 20 to 35 g of fiber a day or 10 to 13 g dietary fiber per 1000 kcal consumed. Dietary fiber may be associated with health benefits including a decreased rate of certain forms of cancer, diabetes, heart disease, and obesity. However, the average American diet is very low in fiber with consumption usually in the range of only 10 to 15 g daily.

There are two general categories of dietary fiber: water-insoluble fibers (cellulose, hemicellulose, and lignin) and water-soluble fibers (gum and pectin). Each category of fiber has a somewhat different spectrum of beneficial effects. Both types lower the energy density of the diet. The added bulk also has a short-term satiety effect, which helps control appetite and prevent overconsumption. Water-insoluble fiber has the further effect of holding water within the intestinal contents, which results in an increased fecal bulk, a decreased gut transit time, and a lower intraluminal pressure within the colon. These properties of water-insoluble fiber make it an important dietary component, since it reduces constipation and may help to prevent the formation of colonic diverticula. There is considerable controversy as to whether a high-fiber diet reduces the risk of colon cancer. Population-based studies demonstrate that intake of fiber-rich foods, which contain primarily insoluble fiber, is inversely related to the risks of developing both colon and rectal cancer. However, several short-term (less than 4 years) clinical intervention trials failed to find any benefit of a high fiber diet in reducing the incidence of recurrent adenomatous colon polyps or cancer. Until more definitive studies are available, the importance of fiber intake in preventing colon cancer will remain uncertain. Sources of insoluble fiber include fruits, vegetables, dried beans, wheat bran, seeds, popcorn, brown rice, and whole grain products such as breads, cereals, and pasta. Approximately two-thirds to three-fourths of the dietary fiber in typical mixed-food diets is water insoluble. There are many excellent Web sites that provide tables listing the soluble and insoluble fiber content of foods (e.g., <http://www.wehealny.org/>

healthinfo/dietaryfiber/fibercontentchart.html, <http://www.md-phc.com/fiber/food.htm>, <http://www.mayoclinic.com/health/fiber/NU00033>).

Water-soluble fiber increases the viscosity of intestinal contents, prolongs gut transit time, and decreases the rate of small intestinal absorption of carbohydrates and bile acids. These effects have important physiologic implications that can be used to advantage clinically. By slowing the rate of carbohydrate absorption, a high soluble-fiber diet appears to be effective in lowering the postprandial surge in the serum glucose, which may be beneficial in the treatment and prevention of diabetes. Through its effects on bile acid absorption, soluble fibers can lower TC and LDL cholesterol by 3% to 10%. The greatest decreases are attainable when initial blood cholesterol concentrations are elevated. Some studies demonstrate an inverse association between the total dietary fiber intake and the rate of fatal and nonfatal myocardial infarctions suggesting the possible importance of fiber in cardiovascular disease prevention. Most of these effects of soluble fibers were demonstrated using fiber concentrates. Comparable amounts of fiber can be obtained from food sources if the diet is carefully formulated. Fruits such as apples, oranges, pears, peaches, and grapes, vegetables, seeds, oat and rice bran, dried beans, oatmeal, barley, and rye are good sources of dietary soluble fiber. Diets that are high in fiber from food sources also provide essential micronutrients and nonnutritive compounds such as xenobiotics, antioxidants, and phytoestrogens that may have important health promoting consequences.

As a general rule, a diet rich in fresh fruits, vegetables, legumes, and whole-grain products is recommended. As portrayed in the USDA MyPyramid, this should include 2 to 3 servings of fruit, 3 to 4 servings of vegetables, and 6 or more servings of grains each day (Figure 38-1). Since most fruits and vegetables contain less than 2 g/serving total fiber and most refined grain products contain less than 1 g/serving, legumes, whole grains, and cereal brans should be substituted for other foods whenever possible in order to increase the amount of both kinds of fiber. Supplementing the diet with any of the commercially available concentrated fiber sources may be necessary, especially in the frail elderly. Concentrated sources of dietary fiber may also be helpful in the treatment of chronic constipation when a limited variety of food is available or the amount of food consumed is inadequate. A large increase in fiber intake over a short period of time may result in bloating, diarrhea, gas, and general discomfort. It is important to add fiber gradually over a period of several weeks to avoid abdominal problems. Fiber should always be taken with adequate fluid in order to avoid worsening constipation.

## Vitamins and Minerals

### Recommended Intakes

The Food and Nutrition Board of the US National Research Council, between 1997 and 2001, developed the Dietary Reference Intakes (DRIs), which updated and expanded the 1989 Recommended Dietary Allowances (RDAs) for vitamins and minerals. The new DRIs include separate intake recommendations for adults aged 51 through 70 years, and for adults older than 70 years. There are not enough scientific data to calculate requirements for all micronutrients, some of the recommendations already appear outdated, and any person with a medical disorder may need more or less than the RDA for some nutrients. Table 38-3 lists the recommended intakes for various vitamins, as well as the recommended Tolerable Upper Intake levels

**TABLE 38-3**

### Adult Recommended Dietary Allowances and Tolerable Upper Limits for Selected Vitamins and Minerals

VITAMIN OR MINERAL	RECOMMENDED DAILY ALLOWANCE*	TOLERABLE UPPER LIMIT
Vitamin A (retinol)	900 $\mu$ g (males) 700 $\mu$ g (females)	3000 $\mu$ g
Vitamin D	200 IU (age <50) 400 IU (age 51–70) 600 IU (age >70)	2000 IU
Vitamin E	15 mg 22 IU (natural vitamin E) 33 IU (synthetic vitamin E)	1000 mg
Vitamin K	120 $\mu$ g (males) 90 $\mu$ g (females)	†
Vitamin B-1 (thiamin)	1.2 mg (males) 1.1 mg (females)	†
Vitamin B-2 (riboflavin)	1.3 mg (males) 1.1 mg (females)	†
Niacin (nicotinamide)	16 mg (males) 14 mg (females)	35 mg
Vitamin B-6 (pyridoxine)	1.7 mg (males) 1.5 mg (females)	100 mg
Vitamin B-12 (cobalamin)	2.4 $\mu$ g	†
Folic acid (folate)	400 $\mu$ g	1000 $\mu$ g
Vitamin C (ascorbic acid)	90 mg (males)‡ 75 mg (females)‡	2000 mg
Calcium	1200 mg	2500 mg
Selenium	55 $\mu$ g	400 $\mu$ g

\*The recommended daily allowance is the recommended average daily intake that will fulfill the nutritional needs of most healthy adults. The tolerable upper limit (UL) is the highest level of daily nutrient intake that is likely to pose no adverse health risk in most people. As intake above the UL occurs, there is an increasing risk of adverse effects.

†Tolerable upper limit not yet determined.

‡Increase by 35 mg for smokers.

(ULs). Intakes of micronutrients that are lower than the UL usually pose little risk for toxic side effects in healthy people. The UL allows patients and health care workers to understand possible risks if large amounts of vitamins and minerals are consumed. Understanding and consuming the RDA for vitamins and minerals have reduced the risk for classic deficiency disorders (like scurvy and pellagra and beriberi, etc.), but the ideal intake of vitamins and minerals needed for optimum health, which may be higher than the RDAs or ULs, remains controversial. For example, new information regarding vitamin D suggests that much higher intakes than the current RDAs are necessary to reduce risk for osteopenia with aging. Any changes to the DRIs are controversial and have major medicolegal and financial implications for fortified foods and the supplement/health food industry.

### Vitamin and Mineral Supplementation

Many older adults, including those who are healthy and living independently as well as those who are frail, ill, or institutionalized, are at risk for micronutrient deficiencies. Several population-based nutritional surveys demonstrate that community-dwelling older adults commonly consume as little as 50% of the RDAs for many vitamins. These findings reflect the fact that even healthy adults do not consistently consume recommended amounts of fortified dairy

products and fruits and vegetables (see MyPyramid, Figure 38-1). Risk factors for poor intake, adverse drug–nutrient interactions, and nutrition-related diseases all increase as a function of age, and clinical (and subclinical) deficiencies of vitamins and minerals become more likely, particularly once frailty and the need for institutionalization occurs. The micronutrients most commonly deficient include vitamins C, D, E, B-12, thiamine (B-1), and folic acid, and the minerals calcium, magnesium, and zinc. Because of this, many nutritionists recommend that older adults add a general vitamin and mineral supplement to their diets, although the evidence for benefit remains weak. The least controversial recommendation is for one daily iron-free multivitamin–mineral tablet supplying the RDA for most micronutrients, since the cost is low and associated with no significant side effects. On the other hand, it remains unclear whether intakes of individual micronutrients above the RDA in selected populations are associated with significant health benefits or toxicity. High intakes of some micronutrients (such as vitamins A, D, and pyridoxine) are well known to cause toxicity, which may be so subtle and nonspecific that the harmful effects may not be easily diagnosed. High supplemental intakes of other vitamins or provitamins (like vitamin E and beta carotene), which had been thought to be risk free, have now been associated with adverse health consequences. Older adults should be counseled not to exceed the ULs (Table 38-3) for vitamin intake (see discussion of vitamin D, below as a possible exception), and to disclose all vitamin and mineral supplement use whenever medications are reviewed by any health professional. Any vitamin and mineral supplementation should always be part of an overall program of healthy nutrition (e.g., high fruit and vegetable and whole grain intake and reduced saturated and trans fat intake).

### Vitamin B-12 (Cobalamin)

Low serum vitamin B-12 levels become more common with aging. Most recent population studies indicate that approximately 10% to 15% of older adults have vitamin B-12 deficiency. Thus, low levels do not represent normal aging. Pernicious anemia, an autoimmune disorder causing decreased gastric intrinsic factor production, is a rare cause of deficiency in the older adult. Cobalamin deficiency in older adults is more commonly caused by malabsorption of cobalamin in foods, usually owing to atrophic gastritis and hypochlorhydria (Table 38-4); supplemental B-12 in crystalline form is not affected by this and continues to be well absorbed. Stomach acid helps to remove the vitamin from food and make it bioavailable. There may be other causes for deficiency in older adults that are not yet known. Disorders that interfere with enterohepatic absorption (such as ileal disease or surgery) will lead to deficiency more rapidly than low intake does because the high efficiency of the enterohepatic vitamin B-12 reabsorption will be impaired and the vitamin may be lost in the stool.

Vitamin B-12 deficiency can present clinically with two relatively independent disorders. There is a hematologic disorder that causes macrocytosis and anemia. And there is a neurologic disorder that can cause a peripheral neuropathy, including paresthesias and numbness; spinal column lesions, including loss of vibration and position sense, sensory ataxia, limb weakness, orthostatic hypotension, and plantar extensor responses; and neuropsychiatric symptoms, discussed below (Vitamins and Cognition). These signs and symptoms of vitamin B-12 deficiency are nonspecific and common in many older adults with comorbid disorders. When there are several possible causes for the neurologic signs and symptoms, vitamin B-12 supplementation

**TABLE 38-4**

### Causes of Vitamin B-12 Deficiency

Atrophic gastritis and hypochlorhydria
Chronic antacid use (histamine-2 blockers, proton pump inhibitors)
Gastric surgery
Ileal surgery
Diseases of the small intestine and terminal ileum: Crohn disease, sprue, malabsorption syndromes
<i>Helicobacter pylori</i> infection
Pancreatic insufficiency
Parasitic infections of the small bowel (e.g., fish tapeworm)
Bacterial overgrowth syndromes
Strict vegetarianism
Acquired immune deficiency syndrome (AIDS) and AIDS treatment (e.g., zidovudine)
Pernicious anemia
Possibly meformin

is usually accompanied by disappointingly little measurable neurologic or behavioral improvement. The older the patient and the more profound the signs and symptoms, the less likely the recovery. However, some patients may respond, especially if deficiency is relatively recent. Since patients with more severe hematologic signs often have less neurologic impairment, and vice versa, it is important to consider vitamin B-12 deficiency even if the patient lacks macrocytosis and anemia. Thus, screening all older adults for vitamin B-12 deficiency should be considered, and supplementation of all deficient patients is recommended.

Many patients with low normal vitamin B-12 serum levels (<350 pg/mL) have measurable biochemical abnormalities, including elevated methylmalonic acid (MMA) (>270 nmol/L) levels, which improve with supplementation. Although these patients often appear to be asymptomatic, it is probable that borderline serum vitamin B-12 levels represent an early preclinical deficiency state. If this is the case, current laboratory norms for vitamin B-12 are too low since they may not identify patients with early deficiency. Secondary tests for low B-12 status are also nonspecific; for example, MMA may also be elevated with renal failure, and homocysteine levels are also affected by folate and vitamin B-6 status. Other tests for vitamin B-12 deficiency, such as methylcitric acid or holotranscobalamin levels, may prove better (when used with vitamin B-12 blood levels), but are not yet readily available.

An approach to screening for vitamin B-12 deficiency and treatment guidelines are discussed in Table 38-5. Intramuscular or oral replacement is most common; alternative formulations (such as nasal gels) are more costly and have not been rigorously tested. There is no scientific basis for prescribing vitamin B-12 supplementation as a general tonic, and it is not recommended.

### Folate (Folic Acid)

Folate deficiency is associated with general malnutrition (particularly associated with alcohol abuse) or with specific folate antagonists, such as methotrexate, phenytoin, sulfasalazine, primidone, phenobarbital, and triamterene. Like vitamin B-12 deficiency, it can present as a megaloblastic macrocytic anemia. Folate supplementation alone may improve the macrocytosis and anemia in vitamin

**TABLE 38-5****Evaluation and Treatment of Vitamin B-12 Deficiency in Older Adults**

1. Screen with a determination of serum vitamin B-12 level any older adult who is frail, has macrocytosis or neutrophil hypersegmentation with or without anemia, has peripheral neuropathy or a gait disorder, or has otherwise unexplained neuropsychiatric symptoms.
2. Any patient with a vitamin B-12 serum level less than 200 pg/mL (150 pmol/L) can be considered to have a deficiency. A serum level between 200 and 350 pg/mL (150–260 pmol/L) indicates a borderline deficiency.
3. Most older adults with a B-12 deficiency can be treated with supplementation without further investigation. Only in rare cases is it essential to prove that an older patient has pernicious anemia by testing for antibodies to intrinsic factor or performing a Schilling test. Assessing for infection by *Helicobacter pylori* is an additional option.
4. Most older adults with a borderline deficiency can also be treated with supplementation. If it is necessary to obtain further biochemical evidence that a borderline serum vitamin level represents a significant deficiency, the methylmalonic acid (MMA) level (serum or urine) can be determined before and after treatment. (An elevated MMA level should fall to normal with correct treatment.) Assessing for infection by *H pylori* is an additional option.
5. All patients with possible symptoms of vitamin B-12 deficiency should receive parenteral supplementation. This can be accomplished by giving several intramuscular shots (100–1000  $\mu$ g) within several days to weeks and then continuing supplementation indefinitely with monthly injections. Any healthy patient whose deficiency was found incidentally and is otherwise asymptomatic can be given a trial of oral supplementation with 1 mg daily. These patients should have their serum vitamin B-12 level reassessed in a month to affirm absorption, and periodic (once or twice yearly) screening thereafter.

B-12 deficiency, without correcting the ongoing neurological disorder of vitamin B-12 deficiency, and may even cause a more rapid neurologic/cognitive deterioration. However, in patients with normal B-12 status, high folate intake is associated with protection from cognitive impairment. Although measures of both vitamin B-12 and folate status are often included in the evaluation of macrocytosis, low folate is a rare cause of this disorder. Fortification of grains with folic acid began in the United States in 1998 and has reduced the incidence of neural tube defects in developing fetuses. It was feared that this fortification (approximately 100  $\mu$ g folate/d) would mask vitamin B-12 deficiency, although this has not been proven. Consumption of a diet rich in fruits and vegetables, along with fortified grains, continues to be recommended as the best source for folic acid, but folate in supplements is more bioavailable.

Folate status may be assessed by measuring serum folate if dietary intake (diet or vitamin supplementation) has not recently changed, or with erythrocyte (RBC) folate levels if there has been a recent change in diet (as after hospital admission). Homocysteine levels can be elevated in folic acid deficiency, but may also increase with renal insufficiency and with vitamin B-12 or vitamin B-6 deficiency.

### Calcium, Vitamin D, and Bone Health

Osteopenia (loss of bone mass) is common in older adults and causes an epidemic of hip and vertebral fractures. One common cause is osteoporosis, a multifactorial disease that causes brittle bones (see Chapter 117). Another cause is osteomalacia, caused by vitamin D deficiency and inadequate calcium absorption. In older adults,

osteoporosis and osteomalacia frequently coexist. Early symptoms of vitamin D deficiency include nonspecific musculoskeletal pain, particularly in the bones and muscles of the back, hips, legs, and shoulders, as well as proximal leg weakness. A very high proportion of middle-aged and older adults have inadequate vitamin D [25(OH)D] levels. Vitamin D status is best assessed by measuring both 25(OH)D and parathyroid hormone (PTH). Serum calcium, ionized calcium, phosphate, alkaline phosphatase, and 1,25(OH)D levels do not adequately identify vitamin D deficiency. Renal failure (GFR  $\leq$  60 mL/min) increases the risk for vitamin D deficiency. All persons receiving antiresorptive treatment for bone fracture protection and those on anticonvulsants, as well as those with a fat malabsorption syndrome, need assessment of their vitamin D status.

Bone mass usually peaks around age 30 and gradually declines thereafter, with an added rapid loss in women around menopause. It has been estimated that the majority of women after adolescence do not consume enough calcium. Daily intake of elemental calcium should be approximately 1000 to 1500 mg in most persons from adolescence onwards, and many persons, and particularly older adults, consume far less. In addition, calcium absorption declines with age. There are a variety of calcium sources. A cup of milk or cup of yogurt contains approximately 300 mg of calcium. Green vegetables contain some calcium, but they also contain other phytochemicals that interfere with calcium absorption. Therefore, calcium bioavailability from vegetables may be limited. Many persons will be unable to consistently obtain the recommended intake of calcium from natural sources, and will need to take calcium supplements. Some brands of orange juice and candy now contain added calcium. In pill form, calcium carbonate is least expensive, but should be consumed with food (although high fiber foods may reduce absorption somewhat). Some formulations, like calcium citrate, are better absorbed but cost more. Calcium supplements can increase constipation in some individuals. Persons who develop calcium oxalate kidney stones should not drastically limit their calcium intake, as dietary calcium can bind with and reduce food oxalate absorption and decrease risk of stone formation.

The level of vitamin D necessary for optimum bone health is uncertain, but PTH begins to rise (that is, secondary hyperparathyroidism begins) at 25(OH)D levels between 12 and 20 ng/mL (30–50 nmol/L). Frank deficiency is considered a 25(OH)D level  $<$ 10 ng/mL (25 nmol/L), and desirable levels (to avoid hyperparathyroidism and reduce bone fractures) are  $>$ 30–40 ng/mL (75–100 nmol/L). Optimal calcium intestinal absorption occurs in older adults at 25(OH)D levels above 34 ng/mL (85 nmol/L). A 25(OH)D level  $<$ 20 ng/mL (50 nmol/L) in older adults is associated with greater risk of nursing home admission.

Vitamin D is available in two forms: ergocalciferol (vitamin D<sub>2</sub>) and cholecalciferol (vitamin D<sub>3</sub>). Vitamin D<sub>2</sub> may be used for fortification, but vitamin D<sub>3</sub> seems to be approximately two to three times more potent in raising 25(OH)D levels for longer periods of time, and this may be especially so in older adults. Thus, vitamin D<sub>3</sub>, the form made naturally from sunlight exposure to skin, is the preferred supplemental form.

Vitamin D is required for calcium absorption, and vitamin D receptors in the intestine decrease with age. The capability of the skin to manufacture vitamin D when exposed to unfiltered sunlight (UV-B, not UV-A, radiation) also decreases with age, with darker skin pigmentation (blacks have a much higher prevalence of low vitamin D levels than whites), and with the recommended use of topical sunscreen, which reduces skin production of vitamin D by as much as 95%. In addition, in the winter in many parts of the United

States, the skin makes very little vitamin D. A cup of fortified milk or fortified orange juice is supposed to contain approximately 100 IU of vitamin D (some studies of fortified milk find a high proportion of samples to have much less or even none); unfortified milk has negligible amounts. Fatty fish, particularly salmon, also has vitamin D; of note, farmed salmon has approximately 25% of the vitamin D content found in wild salmon. Supplementation of vitamin D is often necessary in older adults. Fracture reduction in older adults requires supplementing both vitamin D and calcium.

The goal in supplementation is to raise the 25(OH)D level to more than 30 ng/mL (75 nmol/L); levels above 36 to 40 ng/mL (90–100 nmol/L) may be more beneficial, but this remains uncertain. This may require vitamin D intake substantially above the RDA and, perhaps, near or above the UL of 2000 IU daily. The 2005 Dietary Guidelines for Americans recommend older persons consume 1000 IU (25  $\mu$ g) of vitamin D daily. There appears little risk for vitamin D toxicity at daily intakes up to 10 000 IU daily in persons not at risk for hypercalcemia (e.g., malignancy, sarcoidosis), despite the current RDA and UL. Vitamin D deficiency can be treated with an oral dose of 50 000 IU D<sub>2</sub>/week for 8 weeks or 2,000 IU D<sub>3</sub>/day for 6 months, and then checking 25(OH)D, PTH, and calcium levels. In individuals at high risk for vitamin D deficiency and fracture risk, it may be preferable to schedule high dose oral vitamin D<sub>3</sub> supplementation (e.g., 100 000 IU) three to four times a year; this also optimizes treatment adherence compared with daily medications. Persons taking glucocorticoids need vitamin D and calcium supplementation, but also need a bisphosphonate or intermittent PTH therapy for bone protection as well (see Chapter 117).

Vitamin D receptors are present on many different cell types, and vitamin D has many other roles beyond that in bone health: stimulates insulin production, improves myocardial contractility, modulates B and T lymphocytes, promotes TSH secretion, reduces age-related macular degeneration, and may improve periodontal health, muscle strength and muscle mass, falls risk, and physical performance in older adults. Chronically elevated PTH levels (caused by vitamin D deficiency) may be toxic to muscles and can cause adipogenesis within muscles. Current research is studying whether optimal intake of vitamin D, or vitamin D analogues, may decrease the risk for diabetes mellitus, inflammatory bowel disease, congestive heart failure, colon and prostate cancers, multiple sclerosis, and rheumatoid arthritis.

Preformed vitamin A intake (that is, not provitamin A carotenoids), at levels around twice the RDA and much less than the upper limit of toxicity, has been linked to an increased risk for osteoporosis and hip fracture. High-dose preformed vitamin A supplementation has been shown to improve morbidity and mortality in young children in developing countries so intakes above the RDA are common in this situation. More research is needed to determine whether this pediatric supplementation will subsequently be associated with decreased bone health.

Vitamin K also plays a role in normal bone metabolism. This is yet another reason to encourage eating green leafy vegetables (collards, broccoli, spinach, salad greens). Persons who are taking the anticoagulant coumadin, which interferes with vitamin K synthesis, should try to eat consistent amounts of green leafy vegetables from day to day to reduce fluctuations in coagulation times. A diet high in fruits and vegetables significantly reduces bone turnover and increases bone mineral content. High plasma homocysteine is associated with increased hip fracture risk in older adults.

## SPECIFIC DIETARY CONSIDERATIONS FOR OPTIMAL HEALTH

### Nutrients and Immunity

Malnutrition, particularly protein-energy undernutrition, is known to impair some aspects of immune status in older adults, including specific B and T cell-mediated functions and nonspecific immunity (polymorphonuclear cells and monocytes). Certain vitamins also appear to have a role in immune function. Several studies of vitamin B-6 supplementation of 2 to 50 mg/day have found that lymphocyte proliferative responses and IL-2 production increased in older adults. Supplementation of healthy older adults with 200 to 800 IU of vitamin E and 15 to 60 mg of beta-carotene has been found to increase delayed-type hypersensitivity responses and lymphocyte proliferative responses in some, but not all studies. Cell-mediated immunity may also decline in folate deficiency. It remains controversial whether ascorbic acid (vitamin C) deficiency plays a significant role in immune function. The evidence indicating that high doses of vitamin C reduce the incidence of viral infections or illness duration is very weak.

Multiple vitamin/mineral supplements may produce improvements in immune function if taken on a long-term basis. Several studies indicate that healthy older subjects who consumed a daily multiple vitamin/mineral supplement for 1 year experienced greater improvements in immune responsiveness, IL-2 production, and NK cell cytotoxicity than did nonsupplemented controls. In one study, there was a greater antibody response to influenza vaccination, a decreased incidence of infections, and less antibiotic use in the supplemented group. These improvements occurred even in those subjects who were very healthy and not vitamin deficient. In contrast, several studies with shorter treatment periods (2.5–4 months) failed to find an association between multiple vitamin usage among healthy older adults and either protection against common infections or immune status improvement.

Trace minerals also play a role in immune function. Zinc can affect immune function; however, no readily available measures of tissue zinc status are available. Serum zinc is not a good marker of tissue status; low serum zinc merely reflects low serum albumin. Older adults commonly have low zinc intakes, and low intake is correlated with poor immune function and tissue healing. However, high intakes (>100–150 mg/day zinc sulfate) may also depress immune status and copper absorption. Vitamin and mineral supplements can improve serum markers of antioxidant activity in nursing home residents, but after 2 years only supplementation of zinc (20 mg) and selenium (100  $\mu$ g), but not vitamin supplementation, was found to decrease infections. There is evidence that selenium supplementation has beneficial effects on immune markers, lipoperoxidation, and erythrocyte sensitivity to hemolysis.

### Vitamins and Cognition

Numerous vitamins have been linked to cognitive decline with advancing age and to the pathogenesis of Alzheimer's disease. The potential protective and adverse effects of antioxidants continue to be debated. According to one theory, the accumulated effects of oxidative stress contribute to the development of both Alzheimer's and vascular disease, which are common causes of dementia in older

individuals. High intakes of alpha-tocopherol alone as a vitamin E supplement have not been found to affect cognition, but intake of mixed forms of alpha and other tocopherols from foods has been associated with slowing the rate of cognitive decline with aging. Cross-sectional data have also implicated a role for carotenoids in protecting against cognitive impairment, perhaps by decreasing small vessel disease in the brain.

There is an association between neurocognitive dysfunction (including cognitive impairment without dementia, Alzheimer's disease, and vascular dementia) and elevated plasma homocysteine. It is still uncertain whether elevated homocysteine and low folate and vitamin B-12 are a contributing cause of cognitive decline rather than a consequence of it. Randomized studies of vitamin B-12 and/or folate supplementation have shown a reduction in serum homocysteine and MMA concentrations; however, most have shown no beneficial effect on cognition for either healthy or cognitively impaired subjects, although one well-designed study found improvement in memory, information processing speed, and sensorimotor speed in healthy younger patients (aged 50–70 years) who received 800  $\mu\text{g}$  of daily folate for 3 years compared with placebo.

A search for reversible causes of dementia has routinely included the assessment of folic acid and vitamin B-12 status. Vitamin B-12 deficiency can cause neuropsychiatric symptoms, including delirium manifesting as slowed thinking, depression, confusion, memory loss, and poorer language comprehension and expression that is difficult to differentiate from early Alzheimer's disease. Low serum folate is associated with atrophy of the cerebral cortex, perhaps as a result of hyperhomocysteinemia. A 3-year longitudinal study of nondemented persons older than 75 years found that those with low levels of either vitamin B-12 or folate on entry to the study had increased risk for developing Alzheimer's disease. There are very rare case reports of neuropathy associated with folate deficiency. Some studies find slowed mental processing, including poorer performance on mental status testing, and depressive symptoms (particularly impaired motivation and social withdrawal) in patients with folic acid deficiency. However, while deficiency of these vitamins is common in frail older adults with cognitive disorders, vitamin B-12 and folic acid supplementation rarely affects the course of slowly progressive cognitive decline.

## Nutrition and Cardiovascular Disease

There is a growing body of evidence that nutrition plays an important role in cardiovascular disease (CVD) prevention (also see Chapter 110). Diets that are low in saturated fat, contain modest amounts of polyunsaturated fat, and include an abundance of fruits and vegetables are associated with a significantly reduced risk of cardiovascular events. As indicated in Chapter 110, the American Heart Association Step I diet is similar and is recommended for community-dwelling elderly people with dyslipidemia and increased risk for CVD. Others may benefit from a heart healthy type diet as well.

The so-called Mediterranean diet is another example. It is characterized by the use of olive oil as the principal source of fat, an abundance of fruits and vegetables, and a moderate consumption of Mediterranean fish such as sardine, anchovy, and picarel. No one component of this diet has been shown to be more important than another in terms of CVD prevention. The benefits of the various types of oils, especially those containing omega-3 essential fatty acids, have already been discussed. Various hypotheses have been suggested

to explain the beneficial effects of increased consumption of vegetables and fruits. There are probably multiple reasons including the fact that many vegetables and fruits are low in saturated fats and contain ample amounts of vitamins, dietary fiber, and plant polyphenols, a large group of natural antioxidants. In addition to their antioxidant properties, polyphenols have been shown to elicit several interesting effects in animal models and in vitro systems: they trap and scavenge free radicals, regulate nitric oxide, decrease leukocyte mobilization, induce apoptosis, inhibit cell proliferation and angiogenesis, and exhibit phytoestrogenic activity. Whether these properties of polyphenols are important in human nutrition or contribute to the role of fruits and vegetables in CVD protection remains to be determined.

Specific vitamins may also play a role in CVD prevention. Homocysteine is associated with thrombogenicity and vascular disease throughout the body. Folic acid (and, to a lesser extent, vitamin B-12, vitamin B-6, and riboflavin) can lower homocysteine levels. Following fortification of grains in the United States in 1998, homocysteine levels have declined in the general population. A meta-analysis found no benefit of antioxidant supplementation on restenosis after percutaneous transluminal coronary angioplasty. Studies are currently underway to determine whether specific vitamin therapy will reduce clinical endpoints of heart attack and stroke, although preliminary studies have not shown a protective effect. The role of iron (a prooxidant) in atherosclerosis is under study.

Antioxidants have been promoted as protective for CVD. Many epidemiologic observational studies have shown a lower rate of cardiac death in people who consume a diet rich in the antioxidant vitamins E and C, and carotenoids. High levels of serum carotenoids are associated with a lower risk of periventricular white matter lesions on magnetic resonance imaging, particularly in smokers. These studies are difficult to interpret as diets rich in antioxidants are also higher in fiber and lower in cholesterol and saturated fat, and people who consume large amounts of fruits and vegetables, or who take vitamin supplements often have healthier lifestyles. There may also be a gender difference in the interaction of antioxidant vitamins and atherosclerosis. Randomized clinical studies for primary prevention of CVD have not found that any single vitamin is consistently beneficial. In fact, some studies have found increased mortality with the use of supplemental beta-carotene and vitamin E. There is evidence that high supplemental vitamin E may increase risk for hemorrhagic stroke and all cause mortality. Overall, current evidence is insufficient to conclude that antioxidant vitamin supplementation reduces clinically significant oxidative damage in people, although large randomized studies in the United States and Europe are continuing.

Persons at risk for CVD may still wish to consume supplemental vitamins, but should be educated to modify other more clearly associated risk factors, such as smoking, hypertension, diabetes mellitus, saturated and trans fat intake, exercise, etc. Although the toxicity of antioxidant vitamins and most B vitamins is quite low, certain subgroups, such as smokers or persons with uncontrolled hypertension, may be at higher risk for side effects. For this reason, ULs should not be exceeded.

## Micronutrients and Cancer

In observational epidemiologic studies, populations who consume foods highest in antioxidants (fruits and vegetables) have lower cancer rates. Similar to studies of antioxidants and CVD, it is difficult to determine whether these findings are because of the antioxidant

nutrients or to other reasons. Nutritional studies of supplements for cancer prevention are difficult for many reasons, including the wide range of etiologies, unknown optimum age for intervention, the long time to achieve an effect, the effect of baseline nutritional status, and the possible role for various gene–nutrient interactions. Many studies or meta-analyses of studies have not found a benefit for antioxidant supplements. On the other hand, some clinical prevention trials using micronutrients have shown promising effects: selenium in lung, prostate, and colorectal cancer; vitamin A, beta-carotene, vitamin E, and selenium in stomach cancer; and vitamin E in prostate and colon cancer. In contrast, several studies have found an increased risk of lung cancer in some persons taking beta-carotene supplements (although in persons not taking high-dose supplements, there is an inverse association between cancer mortality and plasma carotene levels), and vitamins may impair the effectiveness of cancer therapy, perhaps by protecting cancer cells during radiation therapy. Fiber intake remains unproven to be protective against colon polyps or cancer. Any protective role for other nutrients (vitamin D analogues; calcium; phytonutrients like green tea, lycopene, and soy isoflavones) and special diets (e.g., the Mediterranean diet) remain under investigation.

It is very likely that people with cancer will try alternative therapies, including mega-vitamin and mineral supplements, and herbal or folk remedies. This should be discussed proactively with patients, from the very time that their cancer is detected, so that they can have the best information available to make their decisions and toxic side effects can be prevented.

### Nutrition and Age-Related Eye Diseases

Evidence to support a protective effect of individual vitamins and minerals on age-related eye diseases is conflicting. A number of studies have suggested a possible role for zinc in preventing age-related macular degeneration, or in slowing its progression. Doses used have varied between 80 mg zinc oxide and 220 mg of zinc sulfate. At these pharmacologic doses, there is a risk for stomach upset, immune dysfunction, and impairment of copper absorption. The use of zinc and antioxidant vitamin supplementation (beta carotene, and vitamin C and E) in persons at higher risk for age-related macular degeneration may be beneficial and should be discussed with a retina specialist for appropriate dosing and to avoid toxicity. Studies in progress are evaluating lutein, zeaxanthin, omega-3 fatty acids, and lower doses of zinc. Smoking has been shown to be the strongest environmental risk factor for age-related macular disorders.

Critical assessment of related studies supports a diet rich in food antioxidants rather than vitamin supplements to possibly prevent age-related cataract. The Antioxidants in Prevention of Cataracts Study and Age-Related Eye Disease Study, using supplements of zinc with cupric oxide, beta-carotene, and vitamins C and E, did not find any reduction in cataract development and progression.

## ASSESSMENT OF NUTRITIONAL STATUS

This topic is also discussed in Chapter 40.

### Initial Screening Assessment

The risk of developing one or more nutritional disorders increases as a function of age, paralleling the age-associated increase in the

prevalence of disease and disability that are often causally related to the development of protein, energy, and micronutrient deficiency states as well as obesity. Prevention and early intervention are the best approaches to keeping older individuals optimally nourished because many forms of malnutrition, particularly protein and energy undernutrition, are very difficult to reverse.

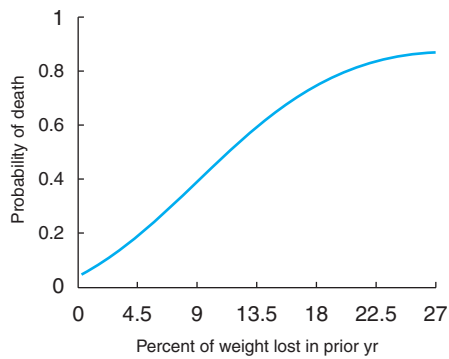

Providers should routinely screen their older patients to determine if they have or are at risk of developing nutritional problems. Ideally this should be done as part of a general health maintenance program that is automatically scheduled at least annually and whenever there is a change in the patient's health state. Like other screening instruments, the nutritional screen should use simple criteria, be relatively easy to complete, have relatively low attendant costs, and provide a valid assessment of nutritional risk with a reasonable degree of sensitivity and specificity. Components of the screening evaluation can be self-administered, completed by associate staff, or gleaned from other assessments including a routine history and physical examination. Individuals identified by the screen to be at risk of having or developing nutritional disorders should be scheduled for a more in-depth assessment.

For the purpose of the initial screening assessment, older individuals that have experienced a recent deterioration in their socioeconomic or health status should be considered at risk for the development of subsequent nutritional problems. For this reason, it is important to carefully assess for new health concerns and change in socioeconomic status as part of a nutritional screening assessment. Screening for alcohol abuse with the University of North Carolina's CAGE questionnaire or similar instrument can be included as part of the nutritional assessment.

Other known risk factors for the development of nutritional problems include a recent deterioration in physical or cognitive function and a change in the number or type of medications prescribed. Older patients who are hospitalized because of an acute illness or surgical problem are at very high risk of developing nutritional deficits prior to discharge. Prolonged bed rest, acute inflammation, and inadequate nutrient intake, which are common during hospitalization, rapidly lead to the depletion of both lean and total body mass, placing older patients at a high risk for subsequent mortality. For this reason, any hospitalization for an acute illness should be recognized as a nutritional risk factor and prompt a more in-depth assessment.

A careful weight history, possibly the most important and specific component of the nutrition screen, should be obtained from all older patients. If prior weights are available from the medical record, these should be utilized since patients often provide inaccurate accounts of their weight history. A weight loss of 5% or more within the prior 6 months or 10% or more within the prior 3 years should be considered indicative of a potentially serious nutritional problem unless the weight fluctuation can be ascribed with certainty to alterations in fluid balance. Numerous studies have demonstrated a direct correlation between the amount of weight that is lost and an increased risk of subsequent mortality (Figure 38-6). This is true even if the older individual states that he/she voluntarily lost the weight. Voluntary weight loss in frail older adults has been shown to have the same adverse implications as involuntary weight loss. This probably relates to the fact that few older individuals are successful in their efforts to voluntarily lose weight and to keep the weight off while healthy. "Voluntary" weight loss is probably the result of underlying pathology in most older individuals.

As part of the general physical examination, a weight and height should be obtained. If significant kyphosis or scoliosis is present,

**FIGURE 38-6.** The relationship between the amount of weight that was lost in the prior year and the estimated risk of mortality within the subsequent year. Based on a study of 750 patients aged 65 and older discharged from an acute care hospital.

the patient's estimate of peak adult height can be utilized for current height. From the weight and height measurements, the patient's body mass index (BMI), weight as a percentage of ideal, and weight as a percentage of usual weight can be calculated as shown in Table 38-6. Signs of dry skin, thinning hair and nails, and other dermatological findings are very nonspecific findings and probably of no value in the nutritional assessment other than indicating the need for careful review of appetite and eating patterns. Since poor oral health may contribute to the development of nutritional problems, a careful oral examination is indicated.

## Comprehensive Nutritional Assessment

### Anthropometrics

Although poor reliability limits their usefulness for monitoring change over time, anthropometric measurements provide a prognostically important assessment of an older individual's nutritional status when skillfully obtained. While the skinfold measurements (biceps, triceps, suprailiac, subscapular, and midhigh) provide a rough indication of the adequacy of subcutaneous fat stores, arm and arm muscle circumferences are indicators of both muscle mass and subcutaneous fat. Numerous studies of individuals older than 65, conducted in a variety of clinical settings, have found an indirect correlation between both types of anthropometric measurements and an increased risk of subsequent mortality. Values below

the 10th percentile for age for any of these measures should prompt a careful assessment of both nutrient intake and functional status or activity level. The value of these measures in the assessment of obesity in older individuals is less clear. Because of the age-associated changes in body composition described previously, both BMI and the skinfold measurements may provide a poor indication of total body fat mass if there is significant intra-abdominal fat accumulation as often occurs with advanced age. Waist circumference and the waist to hip ratio are reasonably useful indicators of abdominal fatness. These measurements can be obtained easily in most clinical settings and provide a useful indication of nutritional status when viewed in conjunction with the other anthropometric measures. A waist-to-hip ratio greater than 1.0 in males and 0.8 in females or a waist circumference >40 inches (102 cm) in males and >35 inches (88 cm) in females are indicators of central obesity and an increased risk of diabetes and CVD.

### Laboratory Assessment

Although serum albumin, transferrin, prealbumin, and cholesterol are commonly utilized as indicators of nutritional status, considerable caution must be exercised when interpreting the results of these serum measurements. With advancing age, it becomes increasingly difficult to differentiate the interrelated effects of natural aging, disease, and nutritive state on the physiological processes that determine the serum concentrations of these substances. Consequently, random determinations may have marginal clinical value. However, when used to supplement other data, these measurements often provide valuable clues as to the patient's nutritional status and prognosis and can help in guiding treatment decisions, including the need for nutritional support. Interpretation of these measures is aided by knowledge of what physiological and pathological factors influence their serum concentration.

**Albumin.** A random serum albumin, interpreted without regard to clinical context, has low sensitivity and specificity and only limited clinical utility as a nutritional indicator. While albumin synthesis decreases by 30% to 50% after only 24 to 48 hours of protein and energy deprivation, a decreased rate of albumin degradation and mobilization of albumin from the extravascular space may contribute to the maintenance of a normal serum albumin concentration. Conversely, a low albumin concentration has low specificity as an indicator of protein-energy undernutrition because acute stress, chronic inflammation, and other disease conditions can cause low serum albumin. This effect on the albumin concentration is probably mediated by cytokines (such as tumor necrosis factor and interleukin-6) that are believed to increase vascular permeability to albumin resulting in rapid loss of the normal concentration gradient between the intra- and extravascular space. The same cytokines also suppress albumin synthesis and may trigger an increased rate of albumin degradation. Prolonged hypoalbuminemia can be caused by advanced liver disease (cirrhosis), severe congestive heart failure, nephrotic syndrome, and protein-losing enteropathies. Since it is not currently possible to differentiate the effects of inflammation from those of nutritional deprivation, a low albumin indicates only that the patient is at risk for being undernourished. Serum albumin often does not increase with refeeding and should not be utilized as an indicator of the adequacy of nutritional support.

**Transferrin.** Like albumin, serum transferrin has relatively low sensitivity and specificity as a nutritional indicator even though its rate

**TABLE 38-6**

### Formulas for Calculating Specific Weight Indices

$$\text{Body mass index} = \frac{\text{Weight (kg)}}{\text{height (m}^2\text{)}} = \frac{\text{Weight (lb)}}{\text{height (in}^2\text{)}} \times 706$$

$$\text{Weight as a percentage of usual weight}^* = \frac{\text{current weight}}{\text{usual weight}} \times 100$$

$$\text{IBW (males)}^\dagger = 106 + (6 \times [\text{height (in)} - 60])$$

$$\text{IBW (females)}^\dagger = 100 + (5 \times [\text{height (in)} - 60])$$

$$\text{Weight as a percentage of IBW} = \frac{\text{weight (lb)}}{\text{IBW (lb)}} \times 100$$

IBW, ideal body weight.

\*Usual weight is weight before onset of illness or frailty; it may be the same as peak adult weight.

†To convert to kg, divide by 2.2.

of production within the liver is also influenced by nutrient intake. Because its half-life of 8 days is considerably shorter than that of albumin, serum transferrin is a somewhat more sensitive indicator of early changes in nutritional status. However, the serum concentration responds much more sluggishly to changes in nutrient intake than that of other proteins, such as prealbumin. Iron deficiency, acute hepatitis, and estrogen all result in higher serum transferrin levels and may mask developing nutritional problems. In addition to nutritional deprivation, advanced liver disease (cirrhosis), nephrotic syndrome, cancer, and chronic infections often produce a sustained drop in the serum concentration. As is the case with albumin, transferrin is a negative acute phase reactant, meaning the serum concentration can drop precipitously in response to sepsis, major surgery, and other forms of acute severe physiological stress.

**Prealbumin.** The prealbumin level has moderate specificity as a nutritional indicator. Prealbumin (also known as transthyretin) has a half-life of 2 days and a much smaller volume of distribution compared to albumin. Like albumin and transferrin, prealbumin is a negative acute phase reactant. In response to systemic inflammation, liver production declines and the serum concentration drops rapidly. Low levels are also found in association with end-stage liver disease, iron deficiency, and nutrient deprivation. Renal failure and high-dose steroid therapy are associated with elevated prealbumin concentrations. Because of its relative short half-life, prealbumin is more sensitive to changes in nutrient intake and disease activity than are albumin or transferrin. With resolution of the inflammatory process, the serum concentration will climb rapidly to the normal range if nutrient intake is adequate.

**Cholesterol.** The serum TC concentration is also influenced by inflammation and other disease states and has very low sensitivity and specificity as a nutritional indicator. The importance of cholesterol is as a prognostic indicator. A total serum cholesterol value less than 160 mg/dL is often seen in association with chronic debilitating disease and is associated with an increased risk of subsequent mortality. Since such disease states often induce anorexia or give rise to other pathologies that limit food intake and eventually lead to nutritional deprivation, a low cholesterol should prompt a careful assessment of the older person's nutrient intake and ongoing weight history.

### Assessment of Nutrient Intake

Although frequently difficult to obtain, a detailed nutrient intake assessment is often the most critically needed part of the nutritional assessment. In the outpatient setting where both over- and under-nutrition may be a concern, a 24-hour recall or a 3-day food intake diary can be effective tools for estimating nutrient intake and identifying where dietary modifications need to be made, especially if a dietitian or comparably skilled health care provider gives the patient and the family adequate instructions on how to collect the needed data. The employment of more accurate methods of measuring nutrient intake is often necessary within hospitals and nursing homes. Several recent studies demonstrate that many older patients are maintained throughout their hospitalization on nutrient intakes that are far less than their estimated maintenance energy requirements. Contributing to the problem, the attending health care team often overestimates how much food the older patient is consuming. In one study, more than 20% of the nonterminally ill older

hospitalized patients had an average daily nutrient intake that was less than 50% of their maintenance energy requirements. This lack of adequate nutrient intake was associated with a significant deterioration in protein-energy nutritional status by discharge and a sevenfold increased risk of mortality. Low nutrient intake may be an even more widespread problem within nursing homes. Only by carefully monitoring each older individual's nutrient intake during their institutional stays can this problem be avoided.

## COMMUNITY-BASED NUTRITION PROGRAMS FOR OLDER ADULTS

Federal, state, and local governments provide many programs designed to help meet the nutritional needs of older adults, particularly those with low incomes. Many of these programs are partially funded through the Administration on Aging (AoA) Elderly Nutrition Program (ENP). The program is designed to be a federal, state, and local partnership. For every \$1 of federal funds provided for congregate nutrition services, \$1.70 additional funding is leveraged; for every \$1 of federal home-delivered funds, \$3.35 additional funding is leveraged. The leveraged funds come from other sources including state, tribal, local, and other federal moneys and services, as well as through donations from participants. Nationally, total contributions amounted to \$170 million.

The ENP provides for congregate and home-delivered meals and other nutrition services. These meals and services are provided in a variety of group settings, such as senior centers, faith-based settings, and schools, as well as in the homes of homebound older adults. These nutrition services help to address a number of problems faced by many elders, including poor diets, health problems, food insecurity, and loneliness. They include nourishing meals, as well as nutrition screening, assessment, education, and counseling, to ensure that older people achieve and maintain optimal nutritional status and to evaluate for diseases such as hypertension and diabetes. Through additional services, older participants learn to shop, plan, and prepare nutritious meals that are economical and enhance their health and well-being. The congregate meal programs provide older people with positive social contacts with other seniors at the group meal sites.

Meals served under the program must provide at least one-third of the RDAs established by the Food and Nutrition Board of the Institute of Medicine of the National Academy of Sciences, as well as the Dietary Guidelines for Americans, issued by the Secretaries of Departments of Health and Human Services and of Agriculture. In practice, the Elderly Nutrition Program participants are receiving an estimated 40% to 50% of required nutrients from meals provided by the program. The program currently provides congregate and home-delivered meals and other nutrition- and health-related services to approximately 7% of the older population, including an estimated 20% of the nation's poor elders.

# Weight and Age: Paradoxes and Conundrums

*Tamara B. Harris*

The evaluation of weight in an older person is pathognomonic of the challenges of geriatric medicine, requiring integration of information on normative biologic change with age and past individual health behaviors to assess future risk. Although weight is one of the easiest clinical measures to obtain, the interpretation of weight in the geriatric patient and assessment of the need for intervention on weight is far more difficult. This chapter provides a rationale and recommendations for an approach to weight in older patients.

## SHOULD THE HEALTH PRACTITIONER BE CONCERNED ABOUT WEIGHT IN AN OLDER PATIENT?

Body weight is an important contributor to health in old age. However, health practitioners are often skeptical about evaluating weight in older patients because it seems unlikely that this evaluation will change clinical treatment, except in the event of clear-cut weight loss. In practice, many of the health issues of old age are linked to weight. Clinically, weight stability is used as a sign of general health status. Weight is a contributor to the most problematic syndromes in geriatric medicine, particularly comorbidity contributing to hospitalization and physical and cognitive decline, and resulting health care costs. With the development of new drugs for symptomatic relief of weight-related conditions such as osteoarthritis and with extension to older persons of established preventive treatments for hypertension and hyperlipidemia, polypharmacy is increasingly a weight-related health issue as well. Caring for older patients involves dealing with weight-related issues on a daily basis, even if not explicitly recognized as such.

Apart from weight-related diseases, change in body composition with age, particularly the loss of muscle and bone and the increase in fat, may independently contribute to decline in functional status and loss of independence. Osteoporosis, a disease of loss of bone structure and quality, is an important risk factor for fracture. The loss

of muscle with age, termed sarcopenia, is hypothesized to contribute to disability. The increase in fat mass with age may contribute as well. Adipose tissue is now known to produce multiple endocrine factors, including proinflammatory cytokines such as interleukin-6 (IL-6). IL-6 is associated with body fat, independent of weight-associated health conditions, and is also an independent risk factor for physical disability and death. Thus even accounting for body weight, change in body composition with age may independently contribute to risk.

Caloric restriction consistently promotes longevity in laboratory animals, even when restriction is instituted in adult life. Restricted animals are thinner and weigh less, reflecting their lower calorie intake, but lower weight alone does not completely explain the protection from disease and the survival advantage. Nonetheless, lower body weight appears to mediate fundamental physiological processes associated with health and longevity.

## PREDICTING WEIGHT IN OLDER PEOPLE: NOTHING SPECIAL

Prediction of body weight from metabolic measures is similar in older and younger persons. Total energy expended daily reflects resting metabolic rate, the energy used for digestion (thermic effect of food), and physical activity. Doubly labeled water studies for total energy expenditure (a gold standard technique that uses CO<sub>2</sub> production to calculate activity over a specified period of time) suggest that, in the absence of acute illness, the same general principles of metabolism pertain. Total energy expenditure does, however, generally decline with age. Although lean mass is known to decrease with age, the change in energy expenditure mainly reflects lower levels of discretionary activity. Total energy expenditure for persons aged 60 to 69 years averages  $2186 \pm 42$  kcal/day for women and  $2715 \pm 56$  kcal/day for men, while for persons in their seventies, the total energy expenditure was  $1885 \pm 286$  kcal/day for white women;  $2324 \pm 436$  kcal/day for black men and  $2521 \pm 396$  kcal/day for white men.

Decreased exercise activity coupled with a small average increase in caloric intake leads to the deposition of extra body weight over time (as little as a 1% excess caloric intake over expenditure daily for a year would result in an increase of approximately 2.5 pounds in that year). Controlled feeding studies in older and younger men suggest that appetite in older people may be relatively insensitive to imbalance between calories and energy output.

Recommendations for body weight do not vary by age or race. These recommendations are based primarily on the relationship between weight and mortality, but they also account for morbidity and some disability. Body mass index (BMI), weight in kilograms divided by height in meters squared (to increase the association of this measure with percent fat), is recommended as a measurement to follow for assessment of risk associated with weight. Normal weight is considered to be a BMI between 18.5 and 25; overweight, a BMI of 25 to 30; and obesity is defined as a BMI of 30 or more. Consideration of body fat distribution has also been advocated, primarily through measurement of waist circumference as an index of central adiposity. Although there are many studies supporting the addition of waist circumference as a measure of adiposity, there are currently no agreed on cutpoints that are clearly associated with clinical outcomes. As a result, the role of waist circumference in clinical practice is still unclear. Waist circumference may be clinically useful in identifying high-risk patients for evaluation of cardiometabolic factors or to follow as a response to weight loss.

The American Society for Nutrition and the Obesity Society convened a technical review panel to review the evidence regarding the health consequences of overweight and obesity in older persons. Review of published studies from 1966 to April 2005 led this group to the conclusion that overweight, obesity, and weight-related health conditions contribute to disability. The evidence was sufficiently strong that programs to address safe and effective weight loss in older persons were considered important. Obesity and overweight are particularly important as they contribute to age-related declines in physical activity and losses in strength and muscle mass. Thus the major motivation for addressing issues of weight in old age relate to disability and the loss of independence.

### LIFETIME WEIGHT HISTORY: CURRENT WEIGHT AND RECENT WEIGHT CHANGE ARE NOT ENOUGH

Only a small proportion of people, probably less than 10% of the population, remain approximately at the same weight over their lifetime. Most people gain weight slowly over their lifetime. In Japanese American men participating in the Honolulu Heart Program, a lean and long-lived cohort, the average pattern of weight change with age was a steady increase from young adulthood to a plateau in late middle age with a decline in old age (Figure 39-1). However, the average disguises the heterogeneity in this pattern, as subgroups continue to gain and lose weight over the entire lifetime (Figure 39-2). This late life decline may be as long as 13 to 15 years, associated with many chronic conditions that increase risk of death in old age, including Alzheimer's disease. Longitudinal studies of weight from middle age to old age show that thinner older people were often heavier earlier in life. Conversely, among heavier older people, many have gained weight since middle age (Figure 39-3). Excessive weight gain early in life was associated with premature mortality. However, as treatment

**Lifetime Weight Patterns Based on Percentile Distributions in 3,611 Japanese-American Men**

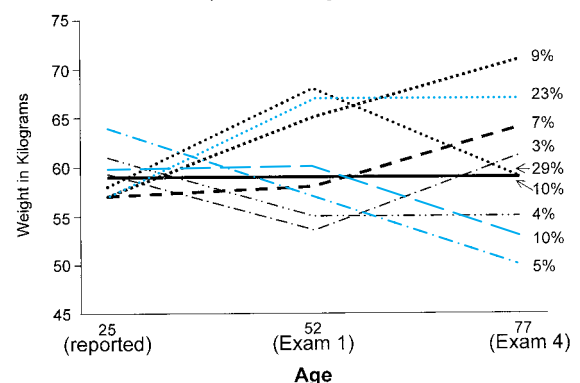

**FIGURE 39-1.** Lifetime weight patterns based on percentile distributions in 3611 Japanese American men from the Honolulu Heart Study cohort. Weight was measured at examination 1 (1965–1968) and at examination 4 (1992–1994); weight at age 25 yrs was reported at examination 1.

for weight-associated diseases improves, it is likely that more people who have had lifelong overweight or obesity will survive into old age, joining those persons who have more recently become overweight or obese.

As a result of the heterogeneity of such changes over a lifetime, the clinician should not assume the current weight is representative of a general lifelong pattern. Risk of disease, disability, and mortality in old age has been associated with change in weight from early adult weight (age 25 years) or from midlife, and with the difference between maximum and minimum weight. These two weight measures plus current weight and weight change over the prior 6 months constitute a reasonable weight history.

**Lifetime Weight Patterns Based on 5% Weight Change in 3,611 Japanese-American Men**  
(Means within groups)

**FIGURE 39-2.** Weight patterns across the lifetime from age 25 yrs to old age based on 3611 Japanese American men in the Honolulu Heart Study cohort. Each line represents one of nine weight patterns over the lifetime, with the percentages on the right side of the figure indicating the frequency of each pattern. These patterns were determined by using weight at examination 1 as the base; the position of the line for age 25 yrs and examination 4 was based on whether weight at that time was less than, greater than, or within 5% of weight at examination 1. Ten percent of the men (solid line) were within 5% of their mean weight at examination 1 on reported weight at age 25 yrs and at examination 4. Twenty-nine percent had gained 5% or more from age 25 yrs and then lost at least that much, whereas 23% had gained 5% or more from age 25 yrs and maintained that weight.

## Weight Pattern Groups within Tertiles of BMI at Exam 4 (Japanese-American Men)

**FIGURE 39-3.** The weight patterns across the lifetime from Figure 39-2 are shown within each tertile of the population based on increasing body mass index as measured in old age at examination 4. The legend refers to the type of change between reported weight at age 25 yrs and measured weight at examination 1 and change between measured weight at examinations 1 and 4. Men in the lowest third of body mass index in old age had lost weight (the most common patterns are gain-loss and stable-loss), whereas men in the highest third of body mass index had generally gained weight over time (the most common patterns are gain-gain and gain-stable).

Weight loss is associated with a diverse set of factors including depression, cancer, pulmonary disease, and inflammatory arthritides. Weight loss may also be associated with diseases thought of as associated with overweight, including diabetes, coronary heart disease, and stroke, all of which may have a wasting phase. Stressful life events, such as care giving or deaths of significant others, may also play a role in either weight gain or loss. Periods of weight loss are important also as accelerators of loss in lean mass. The issue of weight loss in older people is reviewed in greater depth in Chapters 38 and 40.

### ADIPOSIITY

Even if weight is maintained constant over life, the body becomes relatively fatter with age, with increases in total fat and losses in lean mass and bone. Fat redistributes centrally with the growth of the visceral fat compartment reflected as an increase in waist circumference. In many tissues, including muscle and bone marrow, there is a gradual replacement of tissue by fat. At any weight then, older people will have relatively more fat, less muscle, and less bone than will younger people.

Gain in weight and increases in body fat are associated with metabolic and physiological alterations that affect health and level of physical function. Cardiovascular risk factors of blood pressure, lipids, and glucose reflect increased weight and fat. Higher levels of intraabdominal fat are associated with insulin resistance, which may cause metabolic abnormalities even in the absence of overt overweight. Intramuscular fat may also contribute to these metabolic abnormalities. Adipose tissue has the potential for paracrine effects by release of molecular factors that influence the metabolism of muscle cells.

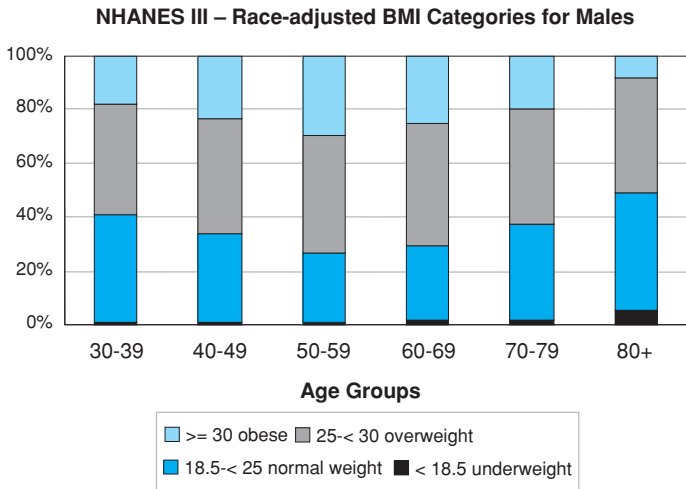

Adipose tissue may also play an important role in the promotion of inflammation and its health-related effects. In the past, fat was regarded primarily as an energy storage tissue primarily active in production of sex steroids and glucocorticoid metabolism. However, adipocytes actively produce and secrete a number of hormones and proteins, termed *adipokines*, which may have both local and systemic effects. These factors include leptin, angiotensin, resistin, adiponectin, plasminogen-activator inhibitor 1, and the cytokines,

IL-6, and tumor necrosis factor alpha. Many of these substances have been associated with cardiovascular morbidity, disability, or risk of mortality. As the importance of these and other newly identified molecular metabolic regulators is identified for obesity, we may come to understand more about physiological function in old age. For instance, leptin is highly correlated with body fat even in old age, and was thought to primarily regulate fat mass. Leptin may also play a role in the regulation of bone metabolism and in the vascular system. Activated macrophages are present in adipose tissue and related to expansion of adipose depots. Subcutaneous adipose tissue may be less able to store excess lipid in obesity and in old age. As a result, ectopic growth of fat cells may occur in and around selected organs including muscle, liver, and heart.

An imbalance between calories and activity, however, is not the only explanation for body composition changing with age. Even master athletes who maintain a high level of physical activity tend to lose muscle mass with age, albeit at a slower pace than inactive people. Hormone changes with age including estrogen, testosterone, and growth hormone may contribute to change in body composition. Genetic factors likely contribute to body composition and change with age, interacting with behavioral factors even late in life. For instance, although sarcopenia is common in old age, both men and women with preserved muscle mass and little infiltrating fat can be identified, representing part of the spectrum of genetic predisposition to muscle loss with age. Cigarette smoking also affects weight and body composition. Smokers are generally thinner, as smoking is associated with increased metabolic rate coupled with decreased appetite; smokers tend to gain weight when they stop smoking. Paradoxically, current smokers have a relatively higher waist circumference, which suggests preferential deposition of intraabdominal fat.

### STANDARDS FOR OVERWEIGHT AND OBESITY: RIGHT FOR OLDER PATIENTS?

Using current guidelines, overweight is common in both men and women, even in older people (Figures 39-4 and 39-5). Earlier data, using a slightly different cutpoint, show that the prevalence of obesity

**FIGURE 39-4.** Data for body mass index (BMI) categories for noninstitutionalized U.S. males aged 30 yrs and older from the National Health and Nutrition Examination Survey (NHANES) III. With age, the proportion of obese people (BMI greater or equal to 30) increases and then decreases in old age, while the proportion in the normal weight category follows an opposite pattern, decreasing to middle age and then increasing with age. Of those aged 80 yrs or older, 5% are underweight and 8% are obese.

in old age was increasing over time, especially in men reflecting changes in the U.S. population.

There is controversy whether the same guidelines for weight should apply across all age groups or whether there should be age-specific guidelines liberalized for older people. While overweight consistently increases morbidity risk in old age, the data on mortality are less consistent, suggesting there may be a trade-off in risks. The data are discussed below; in terms of recommendations, the appropriateness of the guidelines for geriatric patients is likely health status specific. In healthier individuals, these guidelines are appropriate

**FIGURE 39-5.** Data for body mass index (BMI) categories for noninstitutionalized U.S. females aged 30 yrs and older from the National Health and Nutrition Examination Survey (NHANES) III. With age, the proportion of obese people (BMI greater or equal to 30) increases into middle age. The proportion in the normal weight category decreases into middle age and then increases again in old age. Of those aged 80 yrs or older, 6% are underweight and 16% are obese.

ate and good clinical practice. In more frail older persons, different considerations are relevant.

### RISKS ASSOCIATED WITH UNDERWEIGHT

Undernutrition is more likely an issue than overnutrition in frail elderly people. Undernutrition is associated with poor health and weight loss. Older people who are underweight are often found in situations of dependency at home, in hospitals, or in long-term care facilities. Risks associated with undernutrition are generally related to depletion of protein stores and are exacerbated by episodes of illness. These issues are reviewed in greater depth in Chapters 38 and 40. However, frailty can occur even in persons who are overweight or obese. Frailty is characterized by extreme debility and loss of function. While more commonly associated with weight loss, these findings can occur in heavier persons.

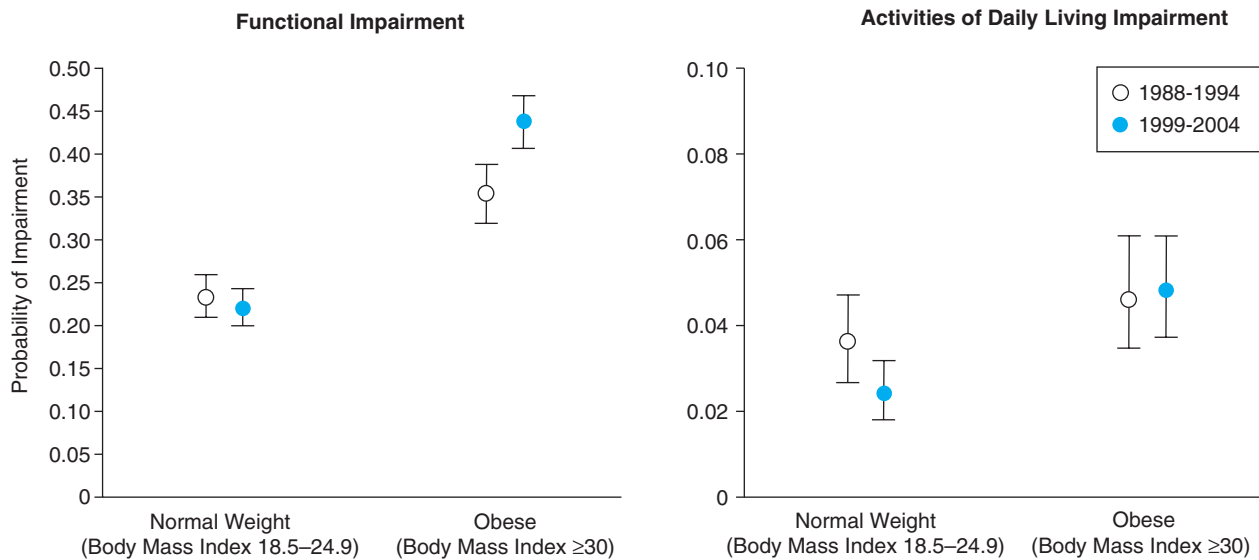

### RISKS ASSOCIATED WITH OVERWEIGHT

#### Morbidity and Disability

Overweight in old age is associated with the same risk factors and diseases as in younger populations and, for many diseases, continues to have similar relative risks. Overweight is a major contributor to osteoarthritis of knees and hips. In postmenopausal women, overweight and weight gain are associated with risk of breast cancer, and with poorer outcomes for the cancer; overweight increases the risk of colon cancer. Coronary heart disease risk is increased in heavier older persons, particularly when weight change in earlier life is accounted for and overweight is associated with incidence of diabetes. Waist circumference, independent of level of weight, may also contribute to risk of diabetes and coronary heart disease. The diseases of overweight are exacerbated by weight gain. Thus, overweight remains an important risk factor for increased morbidity in old age. Given the association of overweight with these diseases, it is not surprising that disability risk is also associated with overweight, particularly in women. While disability risk is decreasing in normal weight persons aged 60 and older, there is now evidence that disability is increasing in those who are obese (Figure 39-6).

In terms of body composition, both fat and lean mass appear to influence function. The New Mexico Aging Study found that lower lean mass is associated with disability, while other studies suggest that higher fat mass primarily is associated with disability. These are surprising results given that improved functional outcomes are associated with increased strength and muscle mass. It is possible that heavier weight and greater body fat may contribute to disability risk over a wide range of body weight, but that muscle mass is associated with a threshold of risk such that only those individuals below that threshold will be affected. Some heavier individuals have relatively less muscle mass than expected on the basis of size, a situation described as sarcopenic obesity, but risk is likely attributed to body fat rather than muscle. The association of fatty infiltration into muscle with lower strength and physical performance has now been assessed by computerized tomography. Even accounting for body size, height, and other aspects of body composition, fatty infiltration into

### Predicted Probability of Impairment by Obesity and Time

Values are adjusted for age, sex, race/ethnicity, education, and income. Error bars represent 95% confidence intervals. Note that y-axis of right figure indicates a much smaller probability range from 0 to 0.10 than the left figure.

**FIGURE 39-6.** These data from the National Health and Nutrition Examination (NHANES) III (1988–1992) and NHANES 1999–2004 show trends in functional impairment and activities of daily living disability over this time period by level of body weight. In persons aged 60 yrs and older with normal body weight, both forms of disability did not change over time, while the prevalence of functional impairment increased over time in obese persons. (Data from Flegal KM, et al. Cause-specific excess deaths associated with underweight, overweight, and obesity. *JAMA*. 2007;298:2028.)

muscle is associated with an increased risk of symptomatic functional decline, poorer physical function, and change in strength.

#### Mortality Risks

In younger populations, overweight is associated with risk of death. Some studies of older people are consistent with this result, particularly those studies in which midlife weight is used to estimate risk of death in old age or where those with significant weight loss are excluded, as in a cohort of over 500 000 persons recruited from the American Association of Retired Persons (Figures 39-7 and 39-8). However, most studies of weight and mortality in old age show a U-shaped association with increased risk associated with both lower and heavier weight. Other studies, particularly of people older than age 75 years, report either an increase in deaths, primarily in underweight individuals, or no relationship at all between weight and mortality. What might explain these results and should these studies affect the approach to the geriatric patient?

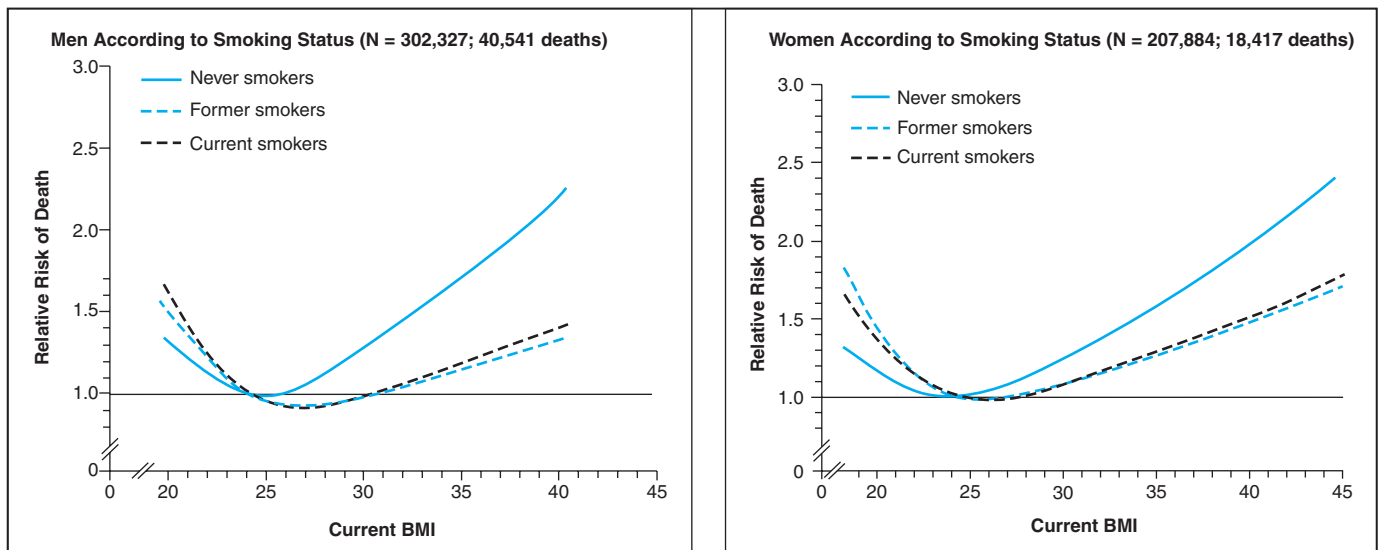

Several explanations may contribute to differing results among studies and between older and younger populations. In body weight studies, thinner persons are generally thought to be the relevant healthy contrast population. Cigarette smoking, which leads to thinner body habitus and also to increased risk of death secondary to smoking-related illnesses, tends to confound results in both younger and older populations. In addition, with increasing age, there are fewer healthy thin persons as a result of the usual age-associated gain in weight and to the tendency of individuals with chronic diseases to lose weight secondary to the illness. Therefore, in older age, those

who are ill and losing weight are overrepresented among the thinner populations and at increased risk of death. The critical factor contributing to risk of death may be low protein reserves. The loss of lean mass with age would exacerbate the risk in thinner people and the risk associated with thinness would increase with age, which is what is observed.

Among the heavier older people, there are at least theoretical protective benefits in terms of mortality risk with age. Heavier weight is associated with higher bone mineral density and with lower fracture risk. Heavier weight is associated with greater lean mass, and under catabolic stress, heavier weight may supply a functional nutritional reserve. Heavier weight is often associated with never having smoked, which may be an advantage in terms of pulmonary function; in addition, these individuals often had substantially thinner midlife weight. When risk of death in old age is estimated on the basis of weight in middle age, risk of death is consistently increased in the group whose middle age weight was heavier. Furthermore, it is clear that in old age, health appears to be associated with the ability to gain or maintain body weight in the face of physiologic stress.

The mortality risk in old age may relate to fat distribution rather than body fatness per se. Larger waist circumference is associated with increased risks of disease and mortality even when there is no increased risk observed with weight alone. Future studies using body composition should yield even better estimates.

However, without strong evidence supporting any of these hypotheses, there is no a priori reason to assume that the relationship between heavier weight and poor health outcomes should be different in old age, especially with regard to functional independence.

**FIGURE 39-7.** Data from the National Institutes of Health-AARP cohort aged 50 to 71 yrs old and followed for a maximum of 10 yrs. Men (left) and women (right) shown by smoking status in relation to their current BMI. Risks for never smokers are thought to most accurately estimate risk because they remove the effect of smoking on body weight and risk of death. Data adjusted for age, race or ethnic group, level of education, alcohol consumption, and physical activity.

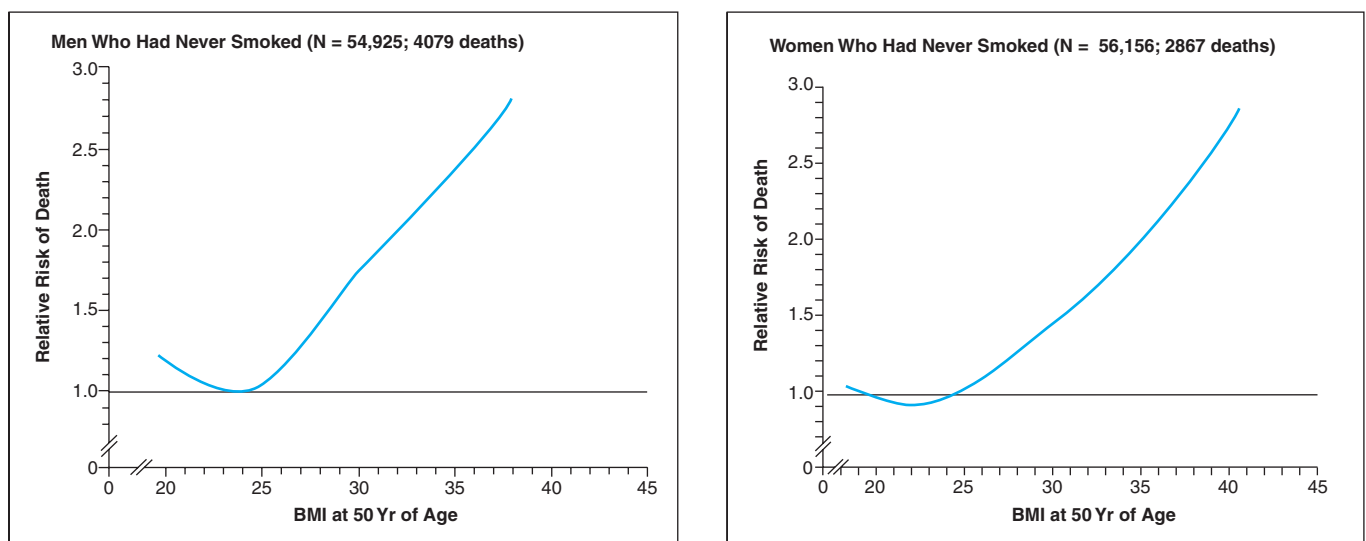

The most important issue is to judge the weight of older persons in the context of their weight trajectory and their current health status.

## INTERVENTIONS AND RECOMMENDATIONS

### Body Composition

Regardless of level of weight, interventions to change body composition hold promise, although it is unclear at present which method

will prove most effective. Ideally, these interventions would increase lean mass and decrease body fat, particularly visceral fat. Interventions attempted have included increased physical activity, which tends to decrease body fat with concomitant improvement in metabolic parameters associated with overweight, but has little effect on lean mass. Clinical trials for older patients with strength training have demonstrated increases in muscle mass, increased strength, and improvement in level of physical function. Whether these gains can be sustained over time and translated into programs applicable to larger, less-selected populations of older people is being tested. These studies have encouraged many older people to become involved in regular exercise and strength training. These interventions

**FIGURE 39-8.** Data from the National Institutes of Health-AARP cohort aged 50 to 71 yrs old and followed for a maximum of 10 yrs. Men (left) and women (right) never smokers are shown in relation to their reported BMI at age 50. The risks for overweight and obesity are steeper, caused by BMI at age 50 yrs being less confounded by illnesses that might increase risk of death but cause weight loss. Data adjusted for age, race or ethnic group, level of education, alcohol consumption, and physical activity.

are reviewed in Chapter 114. Interventions to alter body composition by using various trophic factors and pharmacologic agents show promise but are also problematic. Trials of these agents, either alone or in combination with exercise or strength interventions, are likely to inform the next generation of efforts to control body fat and increase muscle mass and strength in old age.

## Overweight and Weight Reduction

What should we counsel older patients about weight reduction? A history and physical examination related to weight should include a survey of weight-related health conditions, particularly those that are treatable with weight reduction, including hypertension, hyperlipidemia, type 2 diabetes, arthritis of the knees and hip, and peripheral vascular disease. A detailed weight history should be part of the initial evaluation of all geriatric patients and should include early adult weight, midlife weight, maximum and minimum weight, and recent weight change. In the absence of major cognitive impairment, reported weight history is reasonably accurate. Even in an overweight patient, recent unexplained weight loss should raise the need for a careful evaluation for contributory medical, psychological, or functional factors. Prevention of weight gain may be another consideration, particularly for older smokers who decide to quit or those who become disabled with diminished mobility. All older persons should be encouraged to participate in regular physical activity, including some resistance training and stretching. This can be tailored to the level of initial fitness and function, and can be adapted over time to reflect gains in capacity.

Overweight, accompanied by metabolic abnormalities or difficult-to-control symptomatic disease or polypharmacy, suggests the need for a weight-loss program. Will weight reduction benefit the older person? Short-term clinical trials of weight loss in older people show that weight loss can be achieved and results in improvements in hypertension, diabetes, and symptomatic relief of osteoarthritis of the knee. Most of the studies in which weight loss is associated with poor health outcomes are observational studies in which the weight loss was likely to be involuntary. In one of the few observa-

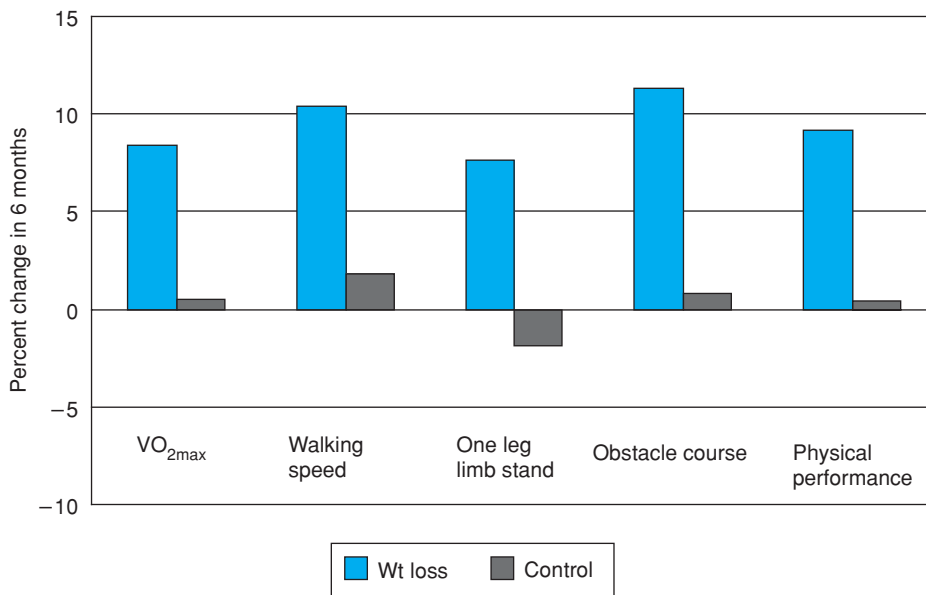

tional studies in which voluntary and involuntary weight loss could be differentiated, there was no increase in adverse outcomes with voluntary weight loss. In the absence of relevant long-term clinical trial data on outcomes with weight reduction, advice on weight loss should be guided by symptoms related to the overweight, anticipated short-term health benefits, and the general level of health status of the patient. In a patient on multiple medications for weight-related health conditions, weight reduction may be an important adjunct in weaning the patient off of the medications.

The goal of a weight reduction program should be to achieve a modest weight loss, resulting in improvement in the target weight-related health condition. Little is known about how to best achieve and maintain weight loss successfully in older adults. Efforts to increase physical activity and to decrease caloric intake are preferable to drug therapy for obesity and overweight. Drugs should be considered when it proves impossible to control the metabolic consequences of obesity (e.g., sustained hypertension or prolonged inadequate diabetic control) or under circumstances in which the obesity would constitute a major deterrent to approaching other health problems, for example, knee replacement surgery. The current set of drugs for weight reduction is limited, but active drug development is under way.

Greater numbers of clinical trials of weight loss are now focusing on older populations. Two trials have demonstrated that weight loss achieved through lifestyle interventions on energy restriction and increased physical activity improved glucose, lipids, and cytokine levels. In persons with knee osteoarthritis, a 6-month intervention of caloric restriction and exercise was associated with improvement in walking, stair climbing, and osteoarthritis symptoms. Despite the loss of lean mass as weight loss occurred, knee strength was maintained, suggesting that there may be compensatory effects from the exercise and weight loss to mitigate the loss of muscle (Figure 39-9). This mitigation of change in body composition by weight loss was supported by a 1-year trial using exercise as the primary cause of weight loss; weight loss was not associated with change in bone mineral density at key sites while caloric restriction alone, without exercise, decreased bone mineral density. These trials have been

**FIGURE 39-9.** These data are adapted from the 6-month Physical Activity, Inflammation, and Body Composition clinical trial. The weight loss intervention (identified as “weight loss” group) had a weekly education class, a weight loss diet, and exercise sessions 3 days each week. The control group had bimonthly meetings and a newsletter. The data show that weight loss in this study did not result in loss of either eccentric or concentric strength.

**FIGURE 39-10.** These data are adapted from a 6-month clinical trial for frail older persons aged 65 yrs and older with a baseline BMI of 30 or more. The weight loss intervention (identified as “weight loss” group) had a weight loss diet and participated in an exercise program. These data show that weight loss resulted in improvement in physical function by all measurements.

successfully extended to frail older persons, showing that weight loss and exercise training focused on endurance, balance, strength, and flexibility lead to better physical performance, self-reported function, and peak oxygen consumption (Figure 39-10).

If a weight reduction program is undertaken, whether by caloric restriction or by drug intervention, it is important to recognize that bone and muscle will be lost as part of this process. Older persons lose weight in similar proportions of fat and muscle as in younger people; however, because they start with less lean mass as a result of age-related changes in muscle and bone, continued losses may result in falling below thresholds of risk for fracture and loss of strength. Efforts should be made to preserve bone and muscle in the face of weight loss, including aerobic and resistance exercise components, or other short-term antiosteoporotic therapy. In addition, caloric restriction needs to be supplemented to insure adequate intake of nutrients and vitamins during a period of dieting.

The physician caring for older people also needs to identify particular times when older people are likely to be at high risk for loss of body weight, especially lean mass. These include major episodes of illness, whether inpatient or outpatient, that result in a significant period of bed rest or recuperation; changes in patterns of daily activities, such as retirement, caring for a sick spouse or friend, or minor injuries such as strains or sprains, that limit usual activity; or new medications that may prevent full activity secondary to sensory or cognitive effects including mild sedation or increased instability in balance. Encouragement of specific activities to return to the former baseline is desirable. These may include nutritional intervention, short-term physical therapy, change in medication, and an exercise prescription. It is likely far easier to intervene when the patient appears relatively healthy and can assist in a program to regain and stabilize body weight and mass than when the patient has become frail and in clear need of rehabilitation.

## CONCLUSIONS

Weight concerns remain important in old age but become increasingly complex. There is no simple set of tables that give appropriate

ideal weights for older people, especially considering that what may be ideal as a predictor of one outcome (e.g., mortality) may be quite different from what may be ideal for another outcome (functional ability). Further developments in the field will incorporate measurements of body composition and fat distribution as well as information about neuromodulation of weight to assist clinicians in rational management of this complicated problem. For the present time, most important is recognition and control of symptomatic weight-related health conditions and attention to precipitants of involuntary gains or losses in weight.

## MALNUTRITION

### Definition

Protein-energy malnutrition (PEM), the primary focus of this chapter, is present when insufficient energy and/or protein is available to meet metabolic demands. PEM may develop because of poor dietary protein or calorie intake, increased metabolic demands as a result of illness or trauma, or increased nutrient losses.

### Epidemiology

Maintenance of nutrition is an essential component of comprehensive geriatric care, particularly in the acute care setting where the presence of malnutrition is clearly associated with increased complications and other adverse health outcomes. Prevalence data, relying on a variety of measures of nutritional adequacy, suggest that deficiencies in macronutrients (protein-energy intake) and micronutrients (vitamins and minerals) are very common among older adults. National survey data indicate that 40% to 50% of noninstitutionalized older adults are at moderate to high risk for nutritional problems, and that up to 40% have diets deficient in three or more nutrients. Prevalence estimates in selected populations over 65 years old indicate that 9% to 15% of older persons seen in outpatient clinics, 12% to 50% of hospitalized elderly persons, and 25% to 60% of older persons residing in institutional settings have one or more nutritional inadequacies—with PEM being the most common. Physical and psychosocial factors that may lead to inadequate nutrition are listed in [Table 40-1](#).

Energy intake does decline significantly with age, attributable to the decrements in lean body mass and physical activity that often accompany aging. A still greater reduction in caloric intake to levels that may be below daily requirements has been a consistent finding of nutritional surveys conducted among community-dwelling el-

derly people. In the most recent National Health and Nutrition Examination Survey (NHANES III), the mean daily energy intake of persons aged 70 years and older was approximately 1800 kcal/d for men and 1400/d kcal for women, and more than 10% of elderly people reported consuming less than 1000 kcal/d. Even if this limited energy intake met the caloric needs of less-active older adults, it is unlikely that all noncaloric nutrient needs (vitamins and minerals) would be met unless the diet was extremely diverse and rich in nutrients. Although micronutrient deficiencies are common when PEM is moderate to severe, it is the PEM that tends to have the greater clinical impact. Accordingly, this section focuses primarily on PEM, with particular attention to prevention and management of PEM in the acute care setting.

Poor nutritional status and PEM are associated with altered immunity, impaired wound healing, reduced functional status, increased health care use, and increased mortality. Despite the confounding effect of coexisting nonnutritional factors, many studies indicate that poor nutrition remains an independent source of increased morbidity and mortality after adjustment for nonnutritional factors. Similarly, the efficacy of nutritional support to improve outcomes in many circumstances is unproven, but data are accumulating suggesting that there are measurable benefits from interventions to correct or prevent nutritional deficits.

### Pathophysiology

PEM may occur as a consequence of inadequate intake alone (e.g., starvation) or in association with disease-activated physiological mechanisms that affect body metabolism, composition, and appetite (i.e., cachexia). In the former (primary caloric deficiency state), the body adapts by using fat stores while conserving protein and muscle, and the resulting physiological changes are often reversible with resumption of usual intake and activity. Cachexia is marked by an acute phase response that is associated with elevated inflammatory mediators (e.g., tumor necrosis factor- $\alpha$  [TNF- $\alpha$ ] and interleukin-6) and

TABLE 40-1

## Factors Contributing to Inadequate Nutrition in Older Adults

Socioeconomic	Physiologic
Fixed income	Impaired strength/aerobic capacity
Reduced access to food	Impaired mobility/dexterity (arthritis, stroke)
Social isolation	Impaired sensory input (smell, taste, sight)
Inadequate storage facilities	Poor dentition/oral health
Inadequate cooking facilities	Malabsorption
Poor knowledge of nutrition	Chronic illness (via anorexia, altered metabolism)
Dependence on others	Alcohol
Caretakers	Drugs (e.g., SSRIs,* NSAIDs,† digoxin, opiates, levodopa, antibiotics, metformin, iron, others)
Institutions	
Psychological	Acute Illness/Hospitalization
Depression	Failure to monitor dietary intake and record weights
Bereavement	Failure to consider increased metabolic requirements
Anxiety, fear, paranoia	Iatrogenic starvation (e.g., NPO‡ for diagnostic tests)
Dementia	Delay in instituting nutritional support

\*Serotonin reuptake inhibitors.

†Nonsteroidal anti-inflammatory drugs.

‡Nothing by mouth.

increased protein and muscle degradation that may not be readily reversed by refeeding. Although cachexia is usually associated with specific chronic disease conditions (e.g., cancer, infection), this state may develop in older persons without obvious underlying disease. To some extent, these physiological changes may be adaptive. Thus, caution is necessary when devising strategies to halt the lean body mass loss and functional decline that often accompanies cachexia.

### Presentation and Evaluation

Despite its apparent clinical importance, physician recognition of malnutrition is often lacking. Effective management of frail or ill older adults mandates an evaluation of nutritional status to better allow for early recognition of PEM and consideration of appropriate interventions. Assessment of nutritional status by standard anthropometric, biochemical, and immunological measures can be complex, as both nutrient intake and nonnutrition-related factors can affect these parameters. The use of such measurements (e.g., body mass index, skinfold thickness, muscle circumferences, serum concentrations of proteins, and lymphocyte counts) to detect the presence of poor nutrition is often advocated, but may not result in earlier or more effective intervention than can be achieved by a careful history and physical examination. The close monitoring of body weight, a readily obtainable measure that reflects imbalance between caloric intake and energy requirements, maybe the simplest and most reliable way to screen for malnutrition, particularly in the outpatient setting. Body weight should be recorded at all patient visits. Weight change should be expressed as a percentage of change from past to current weight, because proportional weight change helps account for variability in baseline weight and appears to be the most clinically relevant measure. Although weight gain caused by excessive energy

intake is a common form of malnutrition, only undernutrition and weight loss caused by deficits in energy balance are considered here. Weight loss of 5% or more of usual body weight, a degree that has been associated with increased morbidity and mortality in the outpatient setting, should prompt investigation. Illness-related weight loss exceeding 10% of preillness weight is associated with functional decline and poor clinical outcomes. Weight loss of 15% to 20% or more of usual body weight implies severe malnutrition.

In the hospital setting, where acute illness or injury often coexists with inadequate intake, alterations in nutritional parameters associated with PEM may develop rapidly. Elevated levels of inflammatory mediators appear to be responsible for the greater losses in lean body mass and the rapid declines in albumin that often accompany PEM in physiologically stressed patients. While serial weight measures remain clinically relevant, early detection and correction of PEM in acutely ill hospitalized patients is enhanced by determination of dietary intake relative to metabolic requirements. Although registered dietitians often provide this information, physicians should routinely monitor dietary intake and can readily estimate caloric and protein requirements using formulas presented in Table 40-2. Biochemical and immunological measures (e.g., albumin, prealbumin, transferrin, and lymphocyte counts) are useful adjuncts in the assessment of nutritional status and can provide prognostic information, but their lack of specificity limits their utility as markers of PEM. Anthropometric measures of fat stores (skinfolds) and muscle mass (midarm muscle area) may help in the assessment of PEM, but clinicians are generally not well versed in obtaining these measures and interrater variability can be high. Although less sensitive, clinical evaluation for loss of skin turgor and the presence of atrophy in hand interosseous or head temporalis muscles can help assess for losses in subcutaneous fat and muscle mass. Because all of these parameters maybe affected

TABLE 40-2

## Estimation of Daily Energy and Protein Needs

- I. Daily energy requirements (kcal/d)
  - A. Quick estimate: maintenance 25–30 kcal/kg; stress 30–40 kcal/kg; sepsis 40–50 kcal/kg (tends to overestimate requirements for elderly and obese patients)
  - B. Estimates based on resting metabolic rate (RMR, kcal/d):
    1. First estimate RMR (using either equation below)
      - a. Harris-Benedict:  $RMR_{women} = 655 + [9.5 \times wt(kg)] + [1.8 \times ht(cm)] - (4.7 \times age)$   
 $RMR_{men} = 66 + [13.7 \times wt(kg)] + [5 \times ht(cm)] - (6.8 \times age)$
      - b. Schofield:  $RMR_{women} = [Wt(kg) \times 9.1] + 659$   
 $(age > 60 \text{ yrs}) RMR_{men} = [Wt(kg) \times 11.7] + 588$
    2. Then multiply RMR by adjustment factor to estimate total energy requirement:
 
$$\begin{aligned} \text{Total daily energy requirement} &= RMR \times 1.3 \text{ for mild illness/injury} \\ &= RMR \times 1.5 \text{ moderate illness/injury} \\ &= RMR \times 1.7\text{--}1.8 \text{ severe illness/injury} \end{aligned}$$
- II. Daily protein requirements (g/d) (may overestimate if patient obese)
 

RDA healthy adult age 51 + yrs	0.8 g/kg
Minimally stressed patients	1.0 g/kg
Injury/illness	1.2–1.4 g/kg
Severe stress/sepsis	1.4–1.8 g/kg

by nonnutrition-related factors, an effective assessment of nutritional status requires synthesis of information provided from the dietary history, physical examination, and biochemical data. There are no definitive criteria for classifying degrees of PEM. However, when weight loss exceeds 20% of premonitory weight, serum albumin is less than 21 g/L, transferrin is less than 1 g/L, and total lymphocyte count is less than 800/ $\mu$ L, PEM is generally considered to be severe.

### Assessment for Causes of Weight Loss

Initial management of patients with PEM and/or weight loss should include a thorough evaluation to identify underlying causes, and if found, to aggressively attempt to correct potentially remediable factors. In the acute care setting, the cause(s) of malnutrition are often readily evident, although depression may be a contributing factor that is frequently overlooked. In contrast, reasons for poor nutrition and weight loss among community-dwelling elderly persons may be multiple and not as readily discernible. Data available from studies on the causes of involuntary weight loss suggests that depression, gastrointestinal (GI) maladies (most often peptic ulcer or motility disorders), and cancer are the three most common causes of weight loss in older adults (Table 40-3). In these studies, when cancer was the cause of weight loss, the diagnosis was rarely obscure. Most diagnoses were readily made after standard evaluations that included a careful history and physical examination and basic screening tests (urinalysis, complete blood count, serum electrolytes, renal, liver and thyroid function tests, stool hemocults, and a chest radiograph), with additional tests only as directed by signs and symptoms. If this initial basic evaluation is unrevealing (as the data in Table 40-3 suggests will occur in around 25% of cases), it is best to enter a period of “watchful waiting” rather than pursue more extensive undirected testing. A diagnostic algorithm (Figure 40-1) focusing first on verifying actual weight loss (patients may inaccurately report a history of weight loss) and then on whether caloric intake is adequate can help guide an appropriate workup.

## Management

### General Considerations

Older persons who are not meeting their protein and caloric requirements through oral intake should be considered for nutritional support. Table 40-4 outlines approaches to nutritional support and factors to consider in deciding whether to pursue specific interventions. The urgency for nutritional interventions relates to the degree of protein-calorie depletion at the time of diagnosis coupled with the expected magnitude and duration of inadequate nutrition. In the hospital setting, clinicians must consider that patients may have been suffering from PEM for some time prior to admission. Therefore, avoidance of delays in instituting appropriate nutritional support while waiting for improved intake is desirable. One approach is to intervene after a period of 5 to 7 days of severely limited intake, or for weight loss more than 10% of preillness weight in hospitalized patients. However, attempts should be made to prevent PEM rather than wait for this degree of PEM to develop because weight loss and undernutrition are associated with worse clinical outcomes and recovery of lost lean body mass is often difficult. This is particularly important in severe stress states (e.g., sepsis, major injury) where protein catabolism can lead to losses of lean body mass that approach

0.6 kg/d. In support of early intervention when the development of PEM is likely, a trial of enteral nutrition (EN) among patients with major injury found that early (within 24 hours) enteral feeding had clinical benefits over tube feeding started later in the course of hospitalization.

### Patient Preference

The effect of the planned intervention on the patient’s quality and/or quantity of life should be addressed before proceeding with nutritional support. Although nutritional support interventions may improve weight and other nutritional parameters, evidence demonstrating their ability to improve clinical outcomes is still limited, particularly when PEM is associated with serious (e.g., critically ill intensive care unit patients) or irreversible underlying disease (e.g., cancer). While most agree that efforts to improve nutrition, even in patients with serious underlying disease, are warranted, late in the course of disease appropriate palliative care may include, if not mandate, discontinuing such efforts. Determination of the care preferences of the patient and family is a critical component of the decision-making process. Patient and family counseling prior to implementing nutritional support should include a review of the interventions being considered and their potential for adverse, as well as beneficial, effects. Figure 40-2 shows an algorithm to help guide nutritional support decisions.

### Enhancing Oral Intake

**Nonpharmacological** Although it is uncommon for elderly persons with PEM to be able to increase their food consumption sufficiently to correct their nutritional deficits, short trials of strategies to improve voluntary intake are reasonable for stable patients with mild PEM (no definitive criteria exist, but parameters consistent with mild-moderate PEM include weight 85–90% of premonitory weight, albumin 25–30 g/L, transferrin 1.5–2.0 g/L, total lymphocyte count 800 to 1200/ $\mu$ L). As previously outlined, underlying causative or contributing condition(s) to PEM should be considered and addressed. Strategies to help overcome anorexia and improve oral intake include assessing and meeting food preferences, providing frequent small meals and snacks, use of flavor-enhanced foods, and providing favorite high-calorie foods (i.e., sweets). Dietitians may aid greatly in these efforts.

High-calorie snacks and oral nutritionally complete supplements are generally recommended. Randomized trials provide some evidence that oral nutritional supplements can improve dietary intake, prevent or lessen weight loss, improve measures of immune function, and improve health outcomes of older adults with, or at high risk for, malnutrition. Higher-calorie “plus” variety nutritional supplements (1.5–2.0 kcal/mL) are preferred over standard (1 kcal/mL) formulas. Costs are only slightly higher, and because they deliver higher caloric content per milliliter ingested, patients need not drink as much volume to improve caloric intake. Supplements should be provided between, rather than with, meals as this appears to result in less compensatory decreases in food intake at mealtime, thereby more effectively increasing total daily caloric intake. However, even if total caloric intake is only marginally improved, the provision of energy from nutritionally dense supplement sources may be beneficial because of improved micronutrient intake.

A standard multivitamin supplement should also be considered for all older adults with poor intake. Evidence suggests that

improving micronutrition with multivitamins, particularly in malnourished or at-risk persons, can improve clinical outcomes (e.g., infection rates). Increased physical activity is an important adjunct that can improve appetite and sense of well-being, thereby leading to improved caloric intake, micronutrient, and functional status.

**Drugs** Pharmacologic approaches to stimulate appetite and promote weight gain may be considered on an individual basis with the knowledge that the few agents (megestrol acetate [MA], dronabinol, cyproheptadine) that can improve intake in some patient populations (e.g., cancer, human immunodeficiency virus [HIV], anorexia nervosa) have not been shown to be effective in older adults and have the potential to cause important side effects. Further, the weight gain that has been observed with these agents has usually been small, dispro-

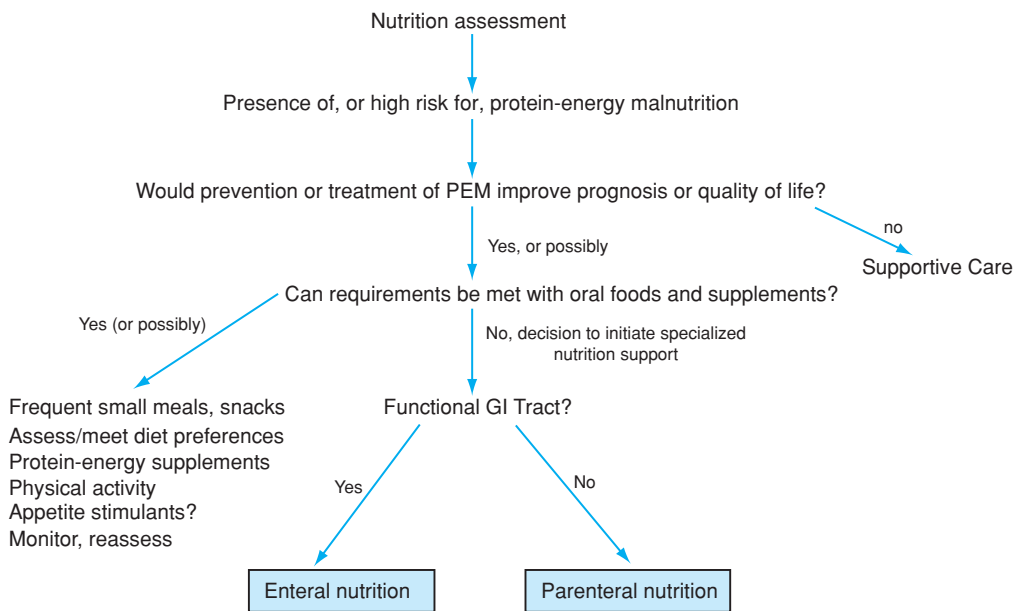

portionately fat mass, and not associated with improved function, quality of life, or decreased morbidity and mortality. MA and dronabinol have shown, at best, limited promise in relatively small studies conducted in nursing home patients. Also of note, in one small nursing home trial, MA did not increase food intake unless combined with increased mealtime feeding assistance. A head-to-head comparison trial in cancer patients found MA to be more effective than dronabinol in improving appetite and promoting weight gain. MA’s mechanism of action may involve suppression of inflammatory cytokines (e.g., interleukin-6 and TNF- $\alpha$ ), consistent with the observation that this agent appears most effective in persons with elevated cytokine levels (e.g., cancer or acquired immunodeficiency syndrome [AIDS] patients). If initiated, MA may not have a demonstrable effect on appetite for several weeks, but if no effect is seen by 8 weeks, MA should probably be discontinued. If positive effects are demonstrated without significant side effects, MA maybe continued for up to 12 weeks. Potential side effects include fluid retention, nausea, glucose intolerance, and venous thromboembolism. Treatment for more than 8 to 12 weeks can suppress the adrenal–pituitary axis, resulting in adrenal insufficiency and insufficient response to acute stressors. MA also appears to blunt the beneficial effects of progressive resistance exercise, consistent with an undesirable glucocorticoid-like catabolic effect. Only very preliminary data exists for dronabinol use in older adults. Although potential benefits of this agent include positive effects on pain, mood, and nausea, as well as appetite, further study is needed to clarify its efficacy and safety in this population. Delirium is the major side effect of concern from dronabinol.

If depression is felt to be a likely, or possible, contributing factor to poor intake, a trial of therapy is usually warranted. Selective serotonin reuptake inhibitors (SSRIs) are first-line antidepressant agents and improve appetite by improving depression. Mirtazapine and tricyclic

antidepressants (e.g., nortriptyline) have been claimed to increase appetite independent of effects on mood. However, one retrospective study did not find a difference between the effects of SSRIs versus tricyclic antidepressants on weight change.

### Maintaining Lean Body Mass and Functional Status

**Anabolic Agents** Anabolic hormones (e.g., growth hormone, testosterone, oxandrolone) have received considerable attention in the search to find strategies to help preserve or increase lean body mass in patients with malnutrition and weight loss. Although adequate nutrition is essential for patients with weight loss, a physiologically stressed catabolic patient may lose significant lean body mass despite aggressive nutritional support (and the weight gain that does occur with nutritional support and appetite stimulants maybe primarily fat and water). A trial of growth hormone in 20 undernourished elderly patients did demonstrate a slightly faster weight gain but differences in weight after 4 weeks were no longer significant. The use of growth hormone in intensive care and congestive heart failure patients has yielded disappointing results with evidence of increased mortality. The cost, need for injection, and potential side effects of growth hormone further limit its clinical utility. Testosterone increases muscle protein synthesis mass and strength, and improvements in functional outcomes have been observed in small controlled trials in selected male populations (e.g., older men after knee replacement surgery, deconditioned older men on a Geriatric Evaluation and Management unit). Although testosterone might be considered in men with documented hypogonadism, its role in the setting of malnutrition and/or cachexia remains to be clarified. Oxandrolone, a synthetic anabolic agent with an increased anabolic to androgenic effect ratio, has shown some utility for patients with weight loss in association with AIDS/HIV or burns, and preliminary data also suggests benefit in patients with chronic obstructive pulmonary disease (COPD). This agent can cause hepatitis, hirsutism, and fluid retention, and is contraindicated in patients with breast or prostate cancer. Further research is needed to define the clinical role of oxandrolone as a pharmacological intervention to be used in combination with nutrition therapy in older adults.

**Physical Activity** Efforts to increase physical activity are an important adjunct to any nutritional intervention as positive effects of exercise include improved appetite and functional status. The benefits (and safety) of exercise in older populations are reviewed in Chapter 114.

## NUTRITIONAL SUPPORT

### Enteral Nutrition

Enteral nutrition is defined as the nonvolitional delivery of nutrients by tube into the GI tract. EN should be considered for patients with PEM, or at high risk for it, who cannot meet their requirements through oral intake. However, specific indications regarding if and when to provide EN are not clearly established other than use in patients with neurological dysphagia >1 week. EN requires a functional GI tract and is contraindicated in patients with inadequate bowel surface area, intestinal obstruction, or paralytic ileus. Purported benefits of enteral tube feedings relative to parenteral nutrition (PN) include the maintenance of GI structure and function, more physiological delivery and use of nutrients, less risk of overfeeding and hyperglycemia, and lower costs. Although these advantages maybe more theoretical than actual, EN is recommended when GI function is felt to be adequate. However, enteral and PN should not be considered mutually exclusive. For patients unable to fully meet their nutritional requirements through EN, a mixture of PN and EN is preferable to moving to PN alone.

### Efficacy

EN can improve prognostically important intermediate nutritional parameters, but the effects of EN on clinical outcomes (e.g. functional status, medical complications, mortality) are unclear owing to limited and/or mixed data. EN is not often initiated until advanced undernutrition is present, which is a clear impediment to the potential positive effects of nutritional therapy. Several prospective

studies, including a randomized, controlled trial among older undernourished hip fracture patients, have suggested EN can improve both nutritional parameters and clinical outcomes (e.g., length of stay, infectious complications, and mortality). However, further study is needed to determine which elderly hospitalized patients might benefit most from aggressive nutritional support. In the interim, sufficient rationale exists to consider EN for patients who are undernourished or at risk for undernutrition and cannot meet their nutritional needs with oral intake.

### Tube Placement

The route selected for tube feeding depends on the anticipated duration of feeding, the potential for aspiration, and the condition of the GI tract (e.g., esophageal obstruction). Nasogastric or nasointestinal tubes provide the simplest approach for patients requiring relatively short-term EN (<30 days). Patient comfort and tolerance is best when a small-diameter, soft feeding tube is used rather than a standard large-bore nasogastric tube. The use of longer specialized feeding tubes also allows the tube to reach beyond the pylorus into the small intestine, which is the preferred site of placement. Methods to promote passage of the tube past the pylorus and into the duodenum or jejunum include ensuring adequate tube length, having the patient lie on their right side, and prescribing metoclopramide. If these methods fail and the risk of aspiration is felt to be high, tube placement into the duodenum or jejunum can be performed under fluoroscopic guidance. After placement, the desired tube position should be verified radiologically before starting feedings and then tubes should be marked at their exit point to help identify if subsequent movement occurs.

Percutaneous tube placement (gastrostomy, gastrojejunostomy, jejunostomy) is indicated when long-term tube feeding is anticipated (>4 weeks). However, it may also be appropriately considered earlier, especially when EN is likely to exceed 2 weeks, because such a tube is better tolerated, allows more consistent nutrition delivery, and has less treatment failures than nasointestinal tubes. Percutaneous placement of a gastrostomy tube (G-tube) can be performed either endoscopically or under radiographic guidance. The risks of major complications with either procedure are generally low, but infection,

hemorrhage, and peritonitis have each been reported at rates of 1% to 3%. Insufficient data are available to clearly favor one method over the other in terms of safety and efficacy, but one meta-analysis suggested that radiologic placement had slightly higher success rates and slightly lower complication rates. Radiological placement does offer advantages in terms of ability to navigate tubes into the jejunum or past near-total proximal obstructions (e.g., head and neck or esophageal cancers that endoscopes cannot get past), whereas endoscopic placement offers added diagnostic capabilities and possibly lower overall costs.

Tube feeding maybe associated with risk for aspiration pneumonia. However, most aspiration pneumonias are the result of difficulty in handling endogenous (oral or gastric) secretions rather than aspiration of material introduced through tube feeding. Thus it is not entirely surprising that although distal (postpyloric) feeding tube placement is generally advised, evidence is not definitive that such placement reduces rates of aspiration pneumonia (e.g., studies comparing aspiration pneumonia rates in patients with gastrostomy vs. jejunostomy tubes have had mixed results). Postpyloric feeding may offer other advantages such as less gastric residual problems in persons with gastric dysmotility and reduced esophageal reflux symptoms. Placement of feeding tubes directly into the jejunum maybe required for patients with abnormal or inaccessible stomachs (e.g., gastrectomy, duodenal obstruction). Although direct jejunostomy tube (J-tube) placement can be accomplished using percutaneous radiologic methods, a J-tube traditionally requires an open surgical procedure and is often placed at the time of laparotomy when the need for prolonged nutritional support is anticipated. Endoscopically placed G–J tubes and direct J-tubes tend to have smaller diameters and are more prone to clogging.

### Formula Selection

Adult enteral formulas fall into one of the following categories: general use, high nitrogen, high nitrogen and high calorie, fiber-enriched, disease-specific, and elemental (Table 40-5). All consist of varying mixtures of protein (often casein), carbohydrate (often cornstarch), and fat (usually vegetable oils), and most do not contain lactose. Formula variability includes digestibility, availability of

**TABLE 40-5**

**Approximate Composition of Standard and Disease Specific Enteral Nutrition Products**

PRODUCT TYPE (BRAND EXAMPLES)	CALORIC DENSITY (kcal/mL)	PROTEIN (g/L)	PERCENT ENERGY FROM		
			CHO*	Fat	Protein
General use formula (Osmolite, Ensure, Jevity)	1.0	35–45	55%	30%	15%
High nitrogen (Promote, Replete, Sustacal)	1.0	62	50%	25%	25%
High nitrogen, high calorie (Nutren 1.5, "Plus" products†)	1.5	60	50%	35%	15%
Very-high nitrogen, very-high cal (Magnacal, Nutren 2.0)	2.0	70–80	45%	40%	15%
Renal disease					
Predialysis (Suplena, Amin-Aid)	2.0	20–30	50–75%	20–45%	5%
Dialysis (Nepro)	2.0	70	43%	43%	14%
Diabetes (Glucerna)	1.0	70	33%	50%	17%
Pulmonary disease (Pulmocare, NutriVent)	1.5	60–70	27%	55%	18%
Critical care (Alitraq, Impact)	1.0	50–70	55–65%	15–25%	20%
Gastrointestinal dysfunction/elemental (Vivonex, Vital HN)	1.0	40	75%	5%	20%

\*Carbohydrate.

†For example, Ensure Plus, Resource Plus, Sustacal Plus.

nutrients, nutritional adequacy, viscosity, osmolality, and cost (costs tend to be substantially higher for disease-specific specialty formulas, and up to 10-fold higher for critical care and elemental specialty formulas). Isotonic general-use formulas with caloric densities of 1 to 1.2 kcal/mL, with or without added fiber, are usually the initial products of choice. Higher caloric density formulas (1.5–2.0 kcal/mL) maybe useful when volume restriction is paramount, but their higher viscosity increases the risk of tube clogging and their higher osmolalities increase the likelihood of diarrhea. Formulas with higher fiber content can be useful for preventing or decreasing tube-feed-related diarrhea.

Disease-specific/specialty formulas are available for patients with renal failure, liver failure, diabetes mellitus, pulmonary disease, GI dysfunction, and critical illness. Renal disease formulas are low in protein, low in electrolytes, and dense in calories to assist in fluid restriction. These formulas maybe useful before dialysis but are not necessary for most patients once on dialysis. Some formulas have been developed for diabetic patients, but use of a cheaper standard formula with adjustment in the glucose control regimen as necessary is adequate for most diabetic patients. Formulas for pulmonary patients have higher fat content, because energy utilization from fat results in less carbon dioxide production relative to the metabolism of carbohydrate energy sources. Although possibly useful for patients being weaned from ventilators, these formulas are of questionable clinical importance for most patients with chronic lung disease. Hepatic formulas have specific amino acid mixtures (high in branched-chain, low in aromatic amino acids) that are less likely to cause or exacerbate hepatic encephalopathy. They are indicated when, in spite of appropriate medical therapy, hepatic encephalopathy limits the delivery of adequate protein to a patient with liver disease.

A number of specialty formulations have been designed for critically ill patients and patients with decreased digestive and absorptive capacity. Some of these products are enriched with glutamine (an amino acid associated with improved nitrogen balance and gut barrier function as well as immune modulating effects when delivered parenterally) or arginine (an amino acid associated with improved nitrogen balance and immune function). However, a large trial of such “immunonutrition” in an intensive care unit (ICU) population failed to show any detectable clinical benefits. Thus, further study of potential beneficial effects of these amino acids in enteric formulas is needed before advocating increased use. In elemental formulas, carbohydrates are supplied primarily as oligosaccharides and proteins have been partially or fully hydrolyzed to free amino acids. Although they are promoted for patients with diminished ability to digest nutrients, it is uncommon for patients to be incapable of digesting and absorbing standard formulas unless they have significantly impaired GI function (assuming appropriate adjustments are made in rates of feedings, osmolality, and fiber content). Elemental diets can also cause, rather than reduce, diarrhea because of their high osmolality.

### Administration Guidelines

After desired tube placement is confirmed, tube feeds can be started at a rate of 25 to 50 cc/hour. Isotonic formulas can be started at full strength, whereas elemental/hyperosmolar formulas are usually diluted to half strength to improve initial tolerance. Gastric residuals should be monitored every 2 to 4 hours until the desired rate, which should be based on estimates of the patient’s total protein and energy needs (see Table 40-2), is established. Feeding rates can be advanced 25 cc every 8 to 12 hours based on individual tolerance. Feedings

should be held if residuals are more than 1.5 times the hourly rate. Once daily requirements are reached, further adjustments to deliver nutrients primarily at night maybe desirable to allow more freedom of movement during the day (nocturnal feeds probably offer little benefit in terms of decreased satiety and improved intake during the day relative to continuous feeds). Larger-bore nasogastric and gastrostomy tubes allow for intermittent feedings without requirement of a pump. Although this offers convenience advantages and maybe more physiological, intermittent bolus feedings can increase the risk of diarrhea, vomiting, and aspiration pneumonia. Attention must also be paid to water and electrolyte requirements. Basal-free water requirements for hospitalized patients are 30 to 35 mL/kg per day, or about 1 cc/kcal delivered. Free water will need to be increased if excess fluid loss is occurring as a consequence of diarrhea, urinary, or increased insensible losses. For patients with fever, an additional 300 to 400 cc of water maybe needed for each degree centigrade of temperature elevation. Monitoring of weight and electrolytes can help clarify any necessary adjustments, with additional free water given in divided boluses three or four times a day.

### Risks and Complications

Proper consideration of whether to proceed with EN entails an understanding of common adverse effects (Table 40-6). Nasogastric

**TABLE 40-6**

#### Adverse Effects of Enteral Nutrition and Management Approaches

ADVERSE EFFECTS	MANAGEMENT
Poor tolerance	Consider
Frequent self-extubation	Parenteral nutrition
Agitation	Percutaneous gastrostomy tubes
Pulmonary	Elevate head of bed $\geq 30^\circ$
Aspiration	Monitor gastric residuals, ↓ rate as needed
	Nasointestinal, G-J, J-tubes
Gastrointestinal	
Gastric retention	Low-fat formula, metaclopramide
Nausea/vomiting	Nasointestinal, G-J, J-tubes
Diarrhea	↓ Delivery rate, ↑ fiber, antidiarrheals
Metabolic complications	
Hyperglycemia	Routine monitoring glucose, electrolytes
Fluid and electrolytes	Monitor weight, volume status, free water
Refeeding syndrome*	Monitor phosphate, magnesium, potassium
Mechanical problems	
Insertion site irritation/infection	Local skin care
Tube plugging	Regular flushing, cola/cranberry flushes
G-tube, J-tube extubation	See text
Nasopharyngitis, sinusitis, local pain, epistaxis	Use small-bore flexible tube and avoid prolonged nasal intubation (>4–6 weeks)
Drug interaction considerations	
Tube feeds ↓ bioavailability (e.g., ciprofloxacin, azithromycin)	Hold feedings 15 min before and after medications
Frequent medications interrupt nutrition	Alternate medication routes (IV, IM, rectally, transdermal)

\*Abrupt, often large drops in serum potassium, phosphorous, magnesium, which may accompany initiation of nutritional support in malnourished patients.

(NG) tubes are often not well tolerated, with patient agitation and self-extubation being particularly common among patients with cognitive impairment or delirium. The subsequent need for physical or chemical restraints can increase complications and appropriately dampen enthusiasm for NG tube feedings. Also, EN in actual practice often involves delayed and inadequate nutritional support because of frequent problems with tubes (e.g., self-extubation, plugging) or GI intolerance (e.g., high residuals, bloating, diarrhea). These factors may explain why attempts to provide elderly persons with EN are often abandoned after only a short course of therapy. Some have advocated an early switch to, or starting with, PN, particularly if patients are confused or delirious and the expected duration of therapy is short (1–2 weeks). If longer-term support is likely, early use of percutaneous gastrostomy tubes, which tend to be better tolerated by uncooperative or confused patients, maybe considered (along with a reevaluation of overall patient care preferences and goals before proceeding with this more invasive approach).

Pulmonary aspiration is a relatively common and serious complication of EN. Patients with gastric retention, decreased gag reflex, and altered levels of consciousness are at increased risk for aspiration, and mechanically ventilated patients should not be considered protected by the presence of an endotracheal cuff. The risk of aspiration can be reduced as outlined in [Table 40-6](#). Gastric retention problems may respond to a change to a low-fat formula or to pharmacologic intervention with metoclopramide. Diarrhea is another GI problem that frequently complicates EN. When significant diarrhea occurs, infectious causes (particularly *Clostridium difficile*) must first be excluded. The possibility of intolerance to formulas with high osmolality or high fat content should also be considered. Interventions to reduce diarrhea include slowing the rate of infusions, diluting hypertonic formulas, increasing formula fiber content, and the use of antidiarrheal agents. In addition to the electrolyte abnormalities that can be caused by diarrhea, hyperglycemia, and other metabolic abnormalities may develop related to tube feedings. Potassium and phosphorous requirements can be very high in the first few days after nutritional support is started because of extracellular to intracellular shifts that accompany nutrient utilization, particularly among cachectic patients (“refeeding syndrome”). Fluid-retention problems are also not uncommon in older adults with impaired renal or cardiac function. To minimize these problems, monitoring protocols should include frequent evaluations of GI tolerance, daily weights, and daily monitoring of glucose and electrolytes (including phosphorus, calcium, and magnesium) until stable.

Increased problems with tube clogging often occur when more viscous higher-calorie formulas and medications (especially fiber and calcium supplements) are passed via small-bore (smaller than no. 10 Fr) catheters. Tube maintenance with regular flushing every 4 to 8 hours for patients on continuous feeds, and before and after the delivery of intermittent tube feeds or medications (with 30 cc warm water) can reduce clogging problems. When possible, give medications by mouth rather than by feeding tube. Use of cola, cranberry juice, or meat tenderizer in solution may help open clogged catheters. Another common mechanical problem is the replacement of gastrostomy or jejunostomy tubes that have fallen out. Feeding tube fistula tracts are generally not well established for at least 1 to 2 weeks after placement (and often substantially longer given malnutrition’s effect on wound healing). Tubes that come out early (in the first 2–3 weeks after placement) require replacement by the original specialist. If the fistula tract is well established, patients or care providers should be able to gently replace tubes that have

fallen out, and delay in doing so for more than 6 to 12 hours risks spontaneous closure of the tract. However, feeding should not be resumed until proper tube placement is radiologically confirmed.

## Parenteral Nutrition

Parenteral nutrition (PN), the delivery of required nutrients by vein, is generally indicated to prevent the adverse effects of malnutrition in patients who are unable to obtain adequate nutrients by oral or enteric routes. However, specific indications regarding if and when to institute PN, as well as the utility of PN once instituted, have not been clearly delineated. In general, the decision to institute PN depends on the severity and expected course of the underlying disease(s) and the severity of preexisting and anticipated undernutrition. The duration of undernutrition that can be tolerated before adverse effects occur is not clear. Some expert opinion guidelines have suggested that to preserve nutritional status and prevent starvation-induced complications, PN should be considered for even well-nourished, minimally stressed patients who are anticipated to be unable to eat for more than 10 to 14 days. PN might also be considered to prevent starvation-induced complications in critically ill or severely stressed patients in whom enteric intake is precluded for 5 to 7 or more days. The decision to institute PN requires careful consideration of the patient’s clinical condition and prognosis, clinical judgment about the patient’s ability to tolerate undernutrition, and insight regarding patient care needs and preferences.

## Efficacy

Evidence that PN can improve clinical outcomes is generally not robust. Limited data that PN can have beneficial effects comes primarily from the following settings: postoperative PN in patients with esophageal or gastric cancers; a randomized trial demonstrating that PN reduces complications in severely malnourished patients (defined in the reference study by a low nutritional risk index score, which generally was reached if weight loss exceeded 10% to 15% and albumin was <33 g/L, or, in the absence of weight loss, if serum albumin was <28 g/L) undergoing major elective surgery; and studies in selected patient populations that include bone marrow transplant recipients, malnourished critically ill patients, and patients with short bowel syndrome. There is a paucity of studies and many unanswered questions about the efficacy and safety of PN in elderly individuals. Furthermore, findings such as detrimental clinical outcomes with routine PN for cancer chemotherapy patients, along with the cost and invasiveness of PN, suggest that risks and benefits must be reviewed carefully for each patient. That PN maybe of some benefit when used in cancer patients who are severely malnourished affirms the importance of patient selection and the identification of clear goals of therapy before instituting PN.

## Administration Guidelines

**Intravenous Access** Total parenteral nutrition (TPN), the delivery of all required nutrients by vein, requires the use of hypertonic solutions that can only be tolerated when delivered into large venous vessels, preferably into the superior vena cava. Because peripheral veins are limited to solutions containing lower concentrations of amino acids and dextrose (<10% dextrose), peripheral parenteral nutrition (PPN) usually cannot deliver nutrients in sufficient quantity to meet all requirements. The infusion of lipids can improve energy

delivery and vessel tolerance to PPN, making PPN occasionally useful for short-term support or as adjunctive therapy for patients with limited tolerance of EN support. Central catheter placement has traditionally been accomplished via subclavian or internal jugular veins with associated operator-dependent risks of insertion complications that include pneumothorax, inadvertent arterial puncture, and hemorrhage. Central venous access for long-term use (weeks to months) can also be obtained via catheters advanced through peripheral vessels (usually median cubital, basilic, or cephalic veins). Such peripherally inserted central lines (PICCs) offer reduced risks of the aforementioned central placement complications and may have a reduced risk of infectious complications. Complications that may be increased with PICCs include early mechanical phlebitis, catheter occlusions, and catheter tears, although the latter two problems can be minimized with proper line maintenance. One nonrandomized study of TPN delivered through PICCs versus through subclavian vein-inserted central catheters found no difference in complication rates and concluded that PICC lines can be used safely and effectively for TPN. Regardless of the placement method used, proper line position needs to be confirmed by x-ray before initiating TPN.

**TPN Composition** Standard TPN solutions contain carbohydrate (dextrose) and protein (amino acid) concentrates, fat emulsions (soybean or safflower oil with egg phospholipids), micronutrients, and electrolytes. Knowledge of usual TPN formula composition can help provide a working framework (Table 40-7) but macronutrient and electrolyte content in particular must be individualized. Energy and protein content should be based on estimates of patient requirements (see Table 40-2). Electrolyte requirements are highly variable and often require adjustments as they are influenced by the patient's underlying disease (e.g., heart failure, renal dysfunction) and factors such as renal or GI fluid losses. Standard packages of vitamins and trace elements are added to TPN solutions daily to prevent the development of micronutrient deficiencies. Because patients on warfarin should not receive vitamin K, it is not included in standard vitamin packages and must be given separately in doses of 5 to 10 mg/wk.

The optimal proportions of fat and carbohydrate to meet energy needs are controversial. All standard formulas contain hypertonic glucose (10–70% dextrose before mixing), but because glucose tolerance declines with age, slow upward titration in delivery rates are necessary in older adults. Aggressive glucose monitoring and treatment is important as hyperglycemia is associated with increased infection risk, particularly when blood glucose exceeds 200 mg/dL. Glucose infusion rates should not exceed 5 mg/kg/min (about 500 g/d for a 70-kg person on continuous TPN) because the rate at which stressed patients can metabolize glucose as energy is limited. Overfeeding with glucose results in increased risks of hyperglycemia, increased carbon dioxide production, and the conversion of excess glucose calories into fat (which requires energy and contributes to fatty liver changes).

Lipids in the form of 10% to 20% fat emulsions are added to TPN as a source of concentrated energy and to supply essential fatty acids. Delivery of fat emulsions two to three times a week is usually adequate to prevent essential fatty acid deficiency. Fat emulsions are isotonic and are generally well tolerated, but patients occasionally develop hyperlipidemia and, less frequently, have allergic reactions (usually to the egg phospholipid component). Increasing the proportion of energy supplied by fat can reduce hyperglycemia and carbon dioxide production, but fat delivery should not exceed 2.5 g/kg/d (or 50–60% of nonprotein calories) to avoid possible adverse consequences associated with fat overload. The fat overload syndrome is characterized by hyperlipidemia with diffuse fat deposition that can cause organ and reticuloendothelial system dysfunction, impaired immune function, and increased risk of sepsis. Lipid formulations enriched with medium-chain triglycerides may have less potential for these side effects and improve nitrogen balance relative to long-chain triglycerides, but studies have not demonstrated consistent benefits and their proper role in nutritional support remains unclear.

TPN formulas with special amino acid compositions are available for patients with severe renal or hepatic disease. The renal formulas consist primarily of essential amino acids to allow delivery of necessary proteins while minimizing nitrogen loads. Their use should be restricted to predialysis renal failure patients. The hepatic failure formulas have increased ratios of branched chain amino acids to aromatic amino acids. They can reduce problems with hepatic encephalopathy, but because of their expense, they should be reserved for patients who develop hepatic encephalopathy with standard TPN formulas.

**Formula Delivery** Initial infusion rates should be at a rate of 25 to 50 cc/hour and increased every 8 to 12 hours as metabolic status allows until fluid and nutrition goals are met. At some institutions, carbohydrate, fat, and protein TPN components are mixed together into a single bag (total nutrient admixture or three-in-one formula). Although this simplifies administration, the admixed product is less stable, and concerns have been raised that the haziness imparted to the admixture by the lipids makes it difficult to detect problems that can occur with calcium and phosphorous precipitation (though inline filters should be routinely used to help prevent particulate matter safety problems). In most circumstances, daily TPN volumes are infused continuously over the full 24 hours. This allows slower delivery of carbohydrate (which can help reduce hyperglycemia) and the continuous flow may decrease the risk of catheter occlusion while avoiding interruptions that might lead to hypoglycemia. Shorter infusion schedules with brief periods off TPN (cyclic TPN) are occasionally desirable, but this is more of an issue for long-term TPN in the home care setting. Because TPN formulas (especially the lipid component) can suppress appetite, it maybe desirable to reduce or hold lipid emulsions for a few days to help improve intake prior to planned discontinuation of TPN.

**Patient Monitoring and Complications** Elderly persons receiving TPN should be monitored closely (Table 40-8). Table 40-9 details common complications and their prevention and/or treatment. Correction of dehydration and volume depletion can most readily be accomplished with standard intravenous fluids, which can be infused separately or added to TPN bags for convenience. Fluid overload can be managed by using higher concentrations of macronutrients to limit total volumes infused, with diuretics added as needed. Although insulin maybe added directly to TPN solutions as needed to control hyperglycemia, it is best to give intravenous insulin separately until caloric delivery and glucose control are stabilized. Intravenous insulin is preferred over subcutaneous insulin owing to the latter's potential for erratic absorption in malnourished patients. Infection and volume depletion need to be considered if hyperglycemia is a persistent problem. As with EN, potassium and phosphate must be monitored closely because they may drop precipitously after initiating TPN in malnourished patients. In most cases, electrolyte requirements stabilize within 1 week. The relative amounts of chloride (which can lead to metabolic acidosis) and acetate (which can be metabolized to bicarbonate and lead to metabolic alkalosis) can be adjusted as needed depending on the patient's acid-base balance. Patient monitoring should also include clinical (e.g., weight, func-

TABLE 40-9

## TPN Complications and Potential Corrective Measures

CONDITION	PREVENTION/MANAGEMENT
<b>Metabolic</b>	
Fluid overload	Restrict fluid by ↑ macronutrient concentrations
Hyperglycemia	↓ Carbohydrate delivery (rate, concentration), insulin IV; consider ↑ proportion energy from fat
Hypoglycemia	Avoid sudden cessation/ interruption of TPN
Refeeding syndrome	Start/titrate TPN slowly, avoid overfeeding
Hypertriglyceridemia	↓ Fat infusion rates and/or frequency of lipids
Hyperchloremic metabolic acidosis	↑ Acetate/↓ chloride; consider renal/gastrointestinal causes
Metabolic alkalosis	Consider renal/gastrointestinal causes; replete K+; ↓ acetate
Respiratory (hypercarbia)	↓ Total calories, ↑ proportion energy from fat
<b>Nonmetabolic</b>	
Line infection	Single-lumen catheter; dedicated TPN line; aseptic line care; rule out other fever sources
<b>Hepatic</b>	
Steatosis/↑ LFTs	Avoid carbohydrate overfeeding; rule out other causes
Biliary (cholestasis)	Enteral feed if possible; rule out other causes
Catheter occlusion	Regular flushes; no line blood draws; urokinase

LFTs, liver function tests.

tional status) and laboratory (e.g., albumin, prealbumin) assessment of the efficacy of nutritional support.

Infection of the access line is uncommon in the first 72 hours, so early fevers are usually a result of other causes. The risk of infection can be reduced with proper aseptic line care, and the line site should be monitored daily for erythema, tenderness, or discharge. Positive line cultures in the absence of other sources are usually an indication for line removal. The increased rates of sepsis that have been observed in some trials of TPN (and which possibly diminished the potential for TPN trials to demonstrate improved clinical outcomes) maybe related to overfeeding and hyperglycemia. Avoidance of hyperglycemia in particular may decrease the risk of TPN associated infections. Liver abnormalities that can occur with TPN include fatty liver with elevated liver function tests (often occurs early, maybe related to carbohydrate overfeeding, generally benign/reversible) and cholestasis (tends to occur later, after 3+ weeks). EN, even in small amounts, may reduce problems with cholestasis.

## Special Issues

## Comorbidity

Responses to nutritional support efforts may vary substantially owing to heterogeneity in underlying disease states associated with PEM (particularly the presence and severity of inflammatory/catabolic states). Limited data on the interaction between nutritional support and specific comorbid conditions and care settings include the following.

TABLE 40-8

## Guidelines for Monitoring Patients on TPN

CLINICAL DATA	LABORATORY DATA
Vital signs three times per day until stable	Glucose chemsticks qid until stable
Daily weights	Daily: Electrolytes, glucose, creatinine, blood urea nitrogen, calcium, phosphorus,
Daily fluid input and output	magnesium until stable, then twice weekly
Daily line and skin inspection	Weekly: LFTs, albumin, CBC, PT, triglyceride
Efficacy of nutritional support	

CBC, complete blood count; LFTs, liver function tests (alanine and aspartate aminotransferase, alkaline phosphatase, bilirubin) PT, prothrombin time.

**Hip Fracture** As many as half of all older patients who present with hip fractures are malnourished. Undernutrition may directly contribute to hip fracture events via increased presence of osteoporosis, increased risk of falls as a consequence of reduced muscle mass and strength, and reduced fat to “cushion” a fall. A Cochrane Library review of 21 randomized trials of postoperative nutritional support (with oral supplements or EN) in hip fracture patients concluded that there is some evidence that oral supplements improve health outcomes (reduced combined outcome measure of mortality and medical complications), but nasogastric feedings were not well tolerated and did not improve mortality. The authors concluded that oral supplements maybe effective (although the evidence is still very weak) and that the benefits of nasogastric feeding are even less certain and should probably be reserved for very malnourished patients, with extremely poor intakes not responsive to oral supplementation.

**Chronic Obstructive Pulmonary Disease** Prevalence estimates of malnutrition in patients with COPD range from 20% to 70%. Increased inflammatory activity probably contributes to catabolic processes that combine with undernutrition to cause weight loss and loss of lean body mass. Although a meta-analysis concluded that energy supplementation does not have significant effects in patients with *stable* COPD, another review indicated that 10 of 12 randomized-controlled trials have noted positive effects of nutritional support (mostly oral supplements providing 400–1000 kcal/d) on anthropometric, immune, muscular strength, and respiratory function outcome measures. Given the relative low cost and potential for benefit, nutritional support might be considered for patients with COPD and evidence of PEM.

**Nursing Home Care Setting** Very high prevalence rates of PEM and weight loss have been documented in nursing home settings. Because conditions associated with reduced intake are common in nursing home residents (e.g., dental, chewing, swallowing problems, depression, cognitive impairment, and dependence on others for feeding), it is likely that the proportion of patients with PEM caused by reduced intake (without inflammatory/cachexia states) is higher than in hospitalized patients. In this setting, simple interventions, such as high-calorie snacks and nutritional supplements, can improve nutritional parameters and help to stabilize weight. Although it is not clear that improvements in these intermediate measures translate to improved clinical outcomes, such interventions are likely reasonable and appropriate for many nursing home residents.

**Dementia** Use of tube feeds in patients with advanced dementia is generally not advised. Observational studies suggest that tube feeding such patients does not improve nutritional status, decrease pressure sores or infections, reduce aspiration problems, or improve functional status or survival. Potential adverse effects of tube feeds in these patients include increased risk of aspiration, discomfort, and complications from tube placement, potential for increased pressure ulcers from increased urine and fecal output (and possibly increased use of restraints), and diminished quality of life from decreased interaction at mealtime and loss of gustatory pleasure from food intake. Although perhaps controversial in earlier stages of dementia, the lack of proven benefits combined with considerable potential for harm argues against the use of feeding tubes in patients with severe demen-

tia who can no longer meet their nutritional requirements through oral intake.

## FUTURE DIRECTIONS

An increased understanding of the physiologic mechanisms underlying appetite, inflammatory and other systemic responses to acute stressors, illness, and aging is leading to new approaches that may help to attenuate the adverse outcomes associated with undernutrition and cachexia. Such approaches are needed. Despite aggressive nutritional support, it is often difficult to lessen the catabolic effects that occur in response to illness or injury. Also, anthropometric measures suggest that when body weight does increase with nutritional support, gains are mostly in the form of fat and water, whereas greater increases in lean body mass might lead to better functional and overall clinical outcomes. Strategies under investigation to better prevent protein catabolism and/or promote anabolism include enriched delivery of certain macronutrients (e.g., glutamine, arginine, and omega-3 fatty acids) that may have positive immunomodulating action independent of their role as nutritional substrates. Glutamine, an important intermediate for many metabolic pathways and the primary fuel source for enterocytes and other rapidly dividing cells, is probably the best studied of these nutrients. Glutamine appears to enhance stress protein and attenuate inflammatory protein responses to acute stressors, effects that might improve outcomes in ill or elderly patients. Clinical trials with TPN solutions supplemented with glutamine have found improved nitrogen retention, decreased infections, and decreased hospital days. However, a trial of an enteral formula enriched with glutamine (and arginine, omega-3 fatty acids, and antioxidants) in a heterogeneous intensive care unit population did not detect beneficial effects. The role of immunonutrition in treating undernutrition and cachexia remains to be clarified.

Aging, acute, and chronic illnesses are associated with an increased production of catabolic cytokines. It is possible that blocking the production or activity of these cytokines can improve clinical outcomes. Agents with anticytokine activity that have the potential to be useful include inhibitors of TNF- $\alpha$  production (pentoxifylline and thalidomide), anti-TNF- $\alpha$  antibodies and TNF- $\alpha$  receptor blockers (etanercept, infliximab, adalimumab). However, a potential adverse effect is interruption of necessary TNF roles. To date, no convincing data exist for the utility of these drugs in patients with cachexia. Other approaches to weight loss and cachexia may focus on overcoming anorexia by modulating effects of peptides and cytokines involved in appetite and energy regulation such as ghrelin, neuropeptide Y, and leptin. Although promising, such strategies to increase appetite, anabolism, and/or decrease catabolism require further study to better define their efficacy and safety in various disease states before considering for clinical use.

# Disorders of Swallowing

JoAnne Robbins ■ Jacqueline Hind ■ Steven Barczi

Demographic changes related to aging necessitate that clinicians have the resources to address eating and swallowing difficulties present in older adults. The capacity to effectively and safely eat or swallow is one of the most basic human needs and also can be a great pleasure. Therefore the loss of this capacity can have far-reaching implications. Many would argue that swallowing is one of the cardinal behaviors needed to sustain life. The process of swallowing requires orchestration of a complex series of psychological, sensory, and motor behaviors that are both voluntary and involuntary. Dysphagia refers to difficulty swallowing that may include oropharyngeal or esophageal problems. More specifically, there may be difficulty in oral preparation for swallowing and/or moving material from the mouth to the esophagus and from the esophagus to the stomach.

Although age-related changes place older adults at risk for dysphagia, an older adult's swallow is not inherently impaired. *Presbyphagia* refers to characteristic changes in the mechanism of swallowing of otherwise healthy older adults. Clinicians need to be able to distinguish among *dysphagia*, *presbyphagia*, and other related diagnoses such as globus hystericus to avoid overdiagnosis and overtreatment of dysphagia. Older adults can be more vulnerable and, with additional stressors such as acute illness and certain medications, they can cross over from having a healthy older swallow (*presbyphagia*) to experiencing *dysphagia*. This chapter reviews the normal swallowing process and *presbyphagia*, as a healthy aging evolution, dysphagia outcomes, multidisciplinary approaches to diagnosing and managing dysphagia, and newly recognized rehabilitation strategies for dysphagia care.

## IMPACT OF DYSPHAGIA

Dysphagia prevalence depends on the specific population sampled, with community-dwelling and more independent individuals having rates near 15%. Upward of 40% of people living in institutional settings such as assisted-living and nursing homes are dysphagic. With

the projected growth in the number of individuals living in nursing homes, there is a compelling need to address dysphagia not only in ambulatory and acute care settings but also in long-term care settings.

The consequences of dysphagia vary from social isolation because of the embarrassment associated with choking or coughing at mealtime to physical discomfort (e.g., food sticking in the chest) to potentially life-threatening conditions. The more ominous sequelae include dehydration, malnutrition, and both overt and silent aspiration precipitating pulmonary complications. For the purposes of this chapter, aspiration is defined as the entry of material into the airway *below* the level of the true vocal folds. Silent aspiration refers to the circumstance in which a bolus comprising saliva, food, liquid, medication, or any foreign material enters the airway below the vocal folds *without* triggering overt symptoms such as coughing or throat clearing. Both overt and silent aspiration may lead to pneumonia, exacerbation of chronic lung disease, or even asphyxiation and death. To gain a better understanding of the effect, these consequences have on older adults and the impact of dysphagia interventions, research in this area has aimed to develop more meaningful outcome measures. Assessments focused on pathophysiology, function, and health services are now being conducted to create more evidence-based practices in dysphagia care.

Insofar as dysphagia is a biomechanical disorder of bolus flow, signs of flow abnormality, using videofluoroscopy, have been well detailed. These include (1) the duration, direction, and completeness of bolus flow; (2) the duration and extent (range) of anatomic structural movements; and (3) the relationship between bolus flow and structural movements as well as between physiologic and anatomic parameters such as pressure generation and muscle/fat structure. More recently, the bulbar innervated swallowing mechanisms are being studied and are providing targets specific for novel treatment paradigms aimed at improving swallowing function. Other clinical outcomes of dysphagia have become important endpoints in assessing interventions that aim to make it possible for patients to eat and drink adequately and safely. These include measures of hydration,

nutrition, aspiration episodes, and emotional sequelae. Other measures have been developed that target what and how dysphagic adults eat and drink. Most of these scales are directly applicable to older adults (Table 41-1). Additionally, pneumonitis, overt aspiration pneumonia, and additional forms of evidence of pulmonary damage are monitored. Nonetheless, it has been difficult to attribute mortality directly to dysphagia because it is often a secondary rather than a primary diagnosis.

Dysphagia profoundly influences quality of life (QOL). Patients with swallowing difficulties, especially those who relinquish oral eating, manifest significant changes in psychosocial status, functional status, and emotional well-being. Eating and drinking are social events that relate to friendship, acceptance, entertainment, and communication. As such, major adjustments in the process of feeding

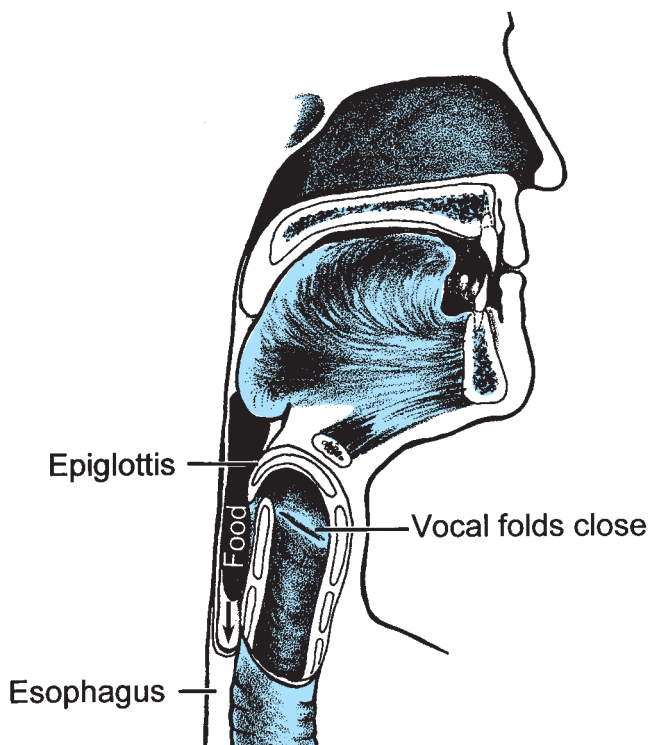

and eating can lead to distressing responses such as shame, anxiety, depression, and isolation. Only recently have practical dysphagia-specific, comprehensive, QOL measures been developed. By monitoring functional outcomes in clinical practice, physicians and other health care providers may be able to better assess and adjust their treatment of dysphagia.

## SWALLOWING PROCESS

Swallowing is an orchestrated activity that balances the competing behaviors of ingestion, speaking, and breathing. Approximately 30 oral and pharyngeal muscle pairs and multiple nerves must perform precisely on cue so that the upper aerodigestive tract is reconfigured from a mechanism that channels air for breathing and speaking (Figure 41-1) to a food-propelling mechanism that accomplishes ingestion (Figure 41-2). The four morphologic regions serving these purposes are the oral cavity, pharynx, larynx, and esophagus. Of these, the first three collectively are termed the upper aerodigestive tract because they also serve the airway-dependent functions of respiration and speech production. In humans, with our upright posture, it is the adjacent position of the anatomy for breathing to the anatomy for food passage that facilitates gravitational influences on food to flow into an unprotected airway. Such anatomy and physiology require precision to satisfy the delicate balance between swallowing physiology and breathing—each a life-sustaining

**FIGURE 41-1.** Aerodigestive tract channeling air for breathing from the nose and mouth through the open larynx into the lungs and back up and out. For speaking, air is channeled similarly, but the vocal folds vibrate to produce voice. (Adapted with permission from Weihofen D et al. *Shape. The Easy to Swallow, Easy to Chew Cookbook*. New York, New York: John Wiley and Sons; 2002.)

**FIGURE 41-2.** Aerodigestive tract reconfigured from an air channel to a food-propelling mechanism during swallowing. The tongue propels food into the throat; the epiglottis covers the larynx, which is the airway entrance; and the vocal folds close to protect the trachea and lungs from foreign material. (Adapted with permission from Weihofen D et al. *The Easy to Swallow, Easy to Chew Cookbook*. New York, New York: John Wiley and Sons; 2002.)

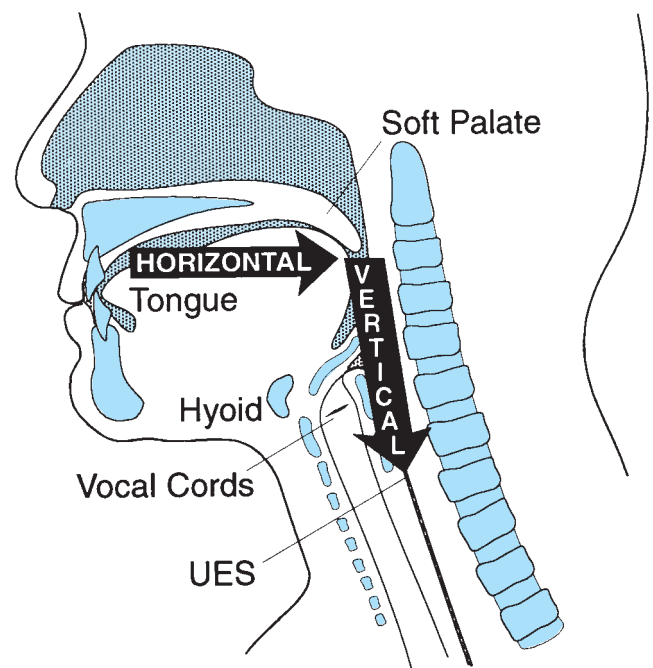

function that must occur during cessation of its counterpart. Thus, a basic understanding of the relationship between the anatomic components and the functional interaction of this mechanism is essential to an understanding of normal swallowing and the effects of age and age-related diseases on it.

### Normal Swallowing

Swallowing is an integrated neuromuscular process consisting of a combination of volitional and relatively automatic movements. Although normal swallowing is usually conceptualized as a continuous sequence of events, the process of deglutition has been conveniently described as occurring in two, three, or four phases or stages. Moreover, the system engaged in swallowing can be divided into two basic structural subsystems, horizontal and vertical (Figure 41-3), that mirror the direction of bolus flow and the potential for gravitational influence on it.

#### Horizontal Subsystem

The oral cavity components comprise the horizontal subsystem. As such, this subsystem is involved in the initial, largely volitional, processing and transport phases of swallowing—the swallow preparatory phase and the oral transport phase. The swallow preparatory phase is characterized by food acceptance, containment, and manipulation. The lips and the buccal musculature act in complex patterns, varying the size and shape of the oral opening to allow acceptance and/or containment of food within the oral cavity. The process of

**FIGURE 41-3.** The oropharyngeal swallowing mechanism can be divided into two basic structural subsystems, horizontal and vertical, that mirror the direction of bolus flow. UES, upper esophageal sphincter. (Adapted with permission from Robbins JA. *Normal swallowing and aging*. *Semin Neurol*. 1996; 16(4):309.)

chemically changing the material requires that numerous labial and lingual glands secrete into the oral cavity an enzyme-rich fluid that maintains and lubricates the mucosa and is directly incorporated into the food. This textural manipulation of food and the mechanical formation of a bolus are accomplished largely by the tongue. The tongue positions the bolus between the teeth and moves in a complex three-dimensional chewing pattern if the bolus requires mastication. The moistening of the food in the oral cavity is essential for normal bolus transit and/or flow and clearance, particularly because gravity provides no assistance until the vertical phases of swallowing.

The oral transport phase comprises movement of the cohesive bolus (masticated if necessary) posteriorly (and horizontally when the subject is in a normal upright seated posture) to the inlet of the superior aspect of the vertical subsystem, the pharynx (Figure 41-4). The intrinsic tongue muscles change the shape of the tongue, forming grooves along its body and anterior and lateral seals to facilitate containment. The extrinsic tongue muscles change the position of the tongue within the oral cavity and assist in changing its shape (Figure 41-4A), and then progressively arching the tongue posteriorly to transport the bolus to the vertical subsystem (Figures 41-4B and C).

#### Vertical Subsystem

The pharyngeal and laryngeal components, in conjunction with the tongue dorsum, comprise the superior aspect of the vertical subsystem, where gravity begins to assist in the transport of the bolus. The anatomic juxtaposition of the entrance to the airway (laryngeal vestibule) and the pharyngeal aspect of the upper digestive tract demand biomechanical precision to ensure simultaneous airway

**FIGURE 41-4.** Lateral view of bolus propulsion during swallowing. (A) Voluntary initiation of the swallow by tongue “loading.” (B) Bolus propulsion by tongue dorsum and UES opening anticipating bolus arrival. (C) Bolus entry into pharynx associated with epiglottal downward tilt, hyolaryngeal excursion, and UES opening. (D) Linguapharyngeal contact facilitating bolus passage through the pharynx and (E) UES closing and completion of oropharyngeal swallowing; then the entire bolus is in the esophagus. (Adapted from Robbins JA: *Normal swallowing and aging*. *Semin Neurol*. 16(4):309–317, Dec., 1996.)

protection and bolus transfer or propulsion through the pharynx. To this end, the pharyngeal transport phase is characterized by a sequence of rapid, highly coordinated neuromuscular events that cause pressure changes critical to bolus transport or transit in a safe, timely, efficient manner.

Linguopalatal contact sequentially moves the bolus against the posterior pharyngeal wall, contributing to the positive pressures imparted to the bolus and propelling it downward. Simultaneously, the pharyngeal constrictors begin to contract in a descending sequence, first elevating and widening the entire pharynx to engulf the bolus (Figure 41-4D and E), and clean up residue after swallowing is completed. A descending peristaltic wave then cleanses the pharynx of residue. Tight closure of the velopharynx during the pharyngeal transport phase provides a seal at the superior aspect of the vertical system, preventing nasal leakage of the bolus and contributing to the generation of high positive pressures, which are applied to the bolus.

Several mechanisms ensure the redundancy by which airway protection is accomplished. Three levels of sphincteric closure include (1) the aryepiglottic folds, (2) the false vocal folds, and (3) the true vocal folds, with closure of the true vocal folds (the lowest of the three sphincters) providing “the last line of defense” to prevent aspiration of invasive material. The hyolaryngeal complex is lifted upward and forward by the combined contraction of the suprahyoid muscles, thyrohyoid muscles, and pharyngeal elevators. This hyolaryngeal elevation and anterior movement, coupled with retraction

of the tongue base, covers the laryngeal vestibule and diverts the bolus laterally around the airway. Timely relaxation and opening of the upper esophageal sphincter (UES) permits continuous vertical passage of the bolus into the esophagus. The UES functions as a mechanical valve. For it to open normally, four criteria must be met: (1) relaxation of muscle tone, (2) compliant tissue, (3) traction force provided by sufficient hyolaryngeal excursion, and (4) pulsion force imparted by the bolus. In normal swallowing, UES relaxation and opening occur prior to bolus arrival at the hypopharynx.

### Neurophysiology of Oropharyngeal Swallowing

Historically, swallowing was largely viewed as a sequence of pharyngeal and esophageal events and was defined as reflexive. The findings from quantitative temporospatial studies on normal swallowing conducted in the last two decades, and current knowledge of the underlying neural substrates, have provided new insights into oropharyngeal swallowing, showing that it is a patterned response rather than a traditional reflex.

Sensorimotor control of swallowing requires the coordinated activity to be distributed across both the cranial and spinal nerve systems, including the peripheral nerves, their central nuclei, and their neural centers. More specifically, the neural control of swallowing involves five major components: (1) afferent sensory fibers contained in cranial nerves, (2) cerebral and midbrain fibers that synapse with the brainstem swallowing centers, (3) paired swallowing centers in

**FIGURE 41-5.** Healthy young swallowing documented with videofluoroscopy. (A) Bolus in oral cavity, ready to be swallowed. (B) Bolus appears as a “column” of material swiftly moving through the pharynx. (C) Oropharynx cleared of material when the swallow is completed. (Adapted with permission from Robbins JA. Normal swallowing and aging. *Semin Neurol.* 1996; 16(4):309.)

the brainstem, (4) efferent motor fibers contained in cranial nerves and the ansa cervicalis, and (5) muscle and end organs. Indeed, this neural network spans all levels of the neuraxis from the cerebrum superiorly to the brainstem and spinal nerves inferiorly and muscles and end organs at the periphery. This relatively diffuse network is designed to integrate and sequence both the volitional and automatic actions of swallowing.

Healthy persons depend on a highly automated neuromuscular sensorimotor process that intricately coordinates the activities of chewing, swallowing, and airway protection. To accomplish a normal swallow, which occurs in 2 seconds or less, the muscles of chewing interact with 26 pairs of striated pharyngeal and laryngeal muscles. The muscles involved in chewing include the masseters, temporalis, and pterygoids (innervated by cranial nerve V); the lip and buccal musculature, the orbicularis oris, and the buccinator (innervated by cranial nerve VII); and the intrinsic and extrinsic lingual muscles (innervated by cranial nerve XII). Optimal structural integrity and precise neural mediation result in continuous, rapid bolus flow from the mouth to the esophagus (Figure 41-5A, B and C) that accommodates variations in bolus size, texture, and temperature and the individual’s intent to swallow, chew, or just hold the bolus in the mouth.

Research on swallowing neurophysiology over the past decade has begun to reveal complex underlying neural substrates that may pro-

vide an understanding of how willful control during the early stage of swallowing allows access to the patterned response. Behavioral and sensory interventions attempting to modify a response certainly have more treatment potential than if they are aimed at a reflex. Accessing mechanisms of neural plasticity, defined as the ability of the brain to change, is becoming a focus to elicit neuroprotection relative to aging effects or recovery from dysphagia following injury such as stroke.

## SENESCENT SWALLOWING

Traditional thinking suggests that the causes of dysphagia are always disease-related, with direct or indirect damage to effector end-organ systems of swallowing. Research during the past decade has indicated that swallowing changes occur even with healthy aging. This work, with a focus primarily on the anatomy and physiology of the oropharyngeal swallowing mechanism, describes a progression of change that may put the older population at increased risk for dysphagia. This research is particularly relevant when an older healthy adult, whose functional reserve is naturally diminished, is faced with increased stressors such as central nervous system (CNS)-altering medications, mechanical perturbations (e.g., a nasogastric [NG] tube or a tracheostomy), or chronic medical conditions

**FIGURE 41-5.** (Continued)

**FIGURE 41-6.** Healthy old swallowing documented with videofluoroscopy. (A) Bolus in mouth ready for swallowing. (B) Bolus pooled in vallecula and pyriform sinus during delayed onset of pharyngeal response. (C) Bolus cleared of material when the swallow is completed. (Adapted with permission from Robbins JA. Normal swallowing and aging. *Semin Neurol.* 1996; 16(4):309.)

(e.g., frailty) that might not elicit dysphagia in a less vulnerable individual. Translation of this work into clinical practice will provide safeguards against the overdiagnosis and overtreatment of dysphagia in the elderly population.

### Age-Associated Changes in Swallowing

A major characteristic of older healthy swallowing is that it occurs more slowly. In people older than 65 years, the initiation of laryngeal and pharyngeal events, including laryngeal vestibule closure, maximal hyolaryngeal excursion, and upper UES opening, takes significantly longer than in adults younger than 45 years. Although the specific neural underpinning has not been confirmed, oral events may become uncoupled from the pharyngeal response. Thus, in older healthy adults, the bolus may remain adjacent to an open airway by pooling or pocketing in the pharyngeal recesses longer than in younger adults (Figure 41-6).

Aspiration and airway penetration are believed to be the most significant adverse clinical outcomes of misdirected bolus flow, as reflected in the high rates of pneumonia with increasing age and disease. However, airway invasion in healthy adults is commonly believed to be largely absent. The use of an eight-point scale (Table 41-2) that discretely quantifies the occurrence, the depth, and the person's reaction to airway penetration or aspiration found no significant difference between young (21- to 32-year-olds) and old

(63- to 84-year-olds) age groups in scale scores on three repeat swallows. However, when a greater number of swallows were performed, aspiration did occur in the older group, indicating fatigue or change in endurance as a possible factor that may relate in a very practical sense to eating meals.

Using simultaneous videofluoroscopy and manometry (manofluoroscopy) and a tube through the nasopharynx similar in size to a “garden variety” NG tube, a significant interaction was found for tube by age. That is, liquid penetrated the airway significantly more frequently when the tube was in place only in the *oldest* group of men and women (older than 70 years). Thus, it appears that under demanding conditions (e.g., endurance = demanding, or NG tube placement), older individuals are less able to compensate and are more at risk for aspiration. Findings such as these characterize presbyphagia or “old swallowing” which is *not* abnormal swallowing in the elderly population.

Age-related changes in the generation of lingual pressure also define presbyphagia. Healthy older individuals have reduced isometric tongue pressures compared with younger individuals. In contrast, the generation of maximal lingual pressure during swallowing (which requires submaximal pressures) remains “young” in magnitude but slows in the time necessary to achieve those “young” swallowing pressures. The relationship between maximum isometric pressure and peak swallowing pressures can be considered an indication of the functional reserve available for swallowing. As people get older,

**FIGURE 41-6.** (Continued)

**TABLE 41-2****Multidimensional Depth of Airway Invasion and Residue, Single-digit Scoring System for the Penetration-Aspiration Scale**

CATEGORY	SCORE	DESCRIPTION
No penetration or aspiration	1	Contrast does not enter the airway
P E N E T R A T I O N	2	Contrast enters the airway, remains above vocal folds, no residue
E N T R Y	3	Contrast remains above vocal folds, visible residue remains
A S P I R A T I O N	4	Contrast contacts vocal folds, no residue
	5	Contrast contacts vocal folds, visible residue remains
	6	Contrast passes glottis, no subglottic residue visible
	7	Contrast passes glottis, visible subglottic residue despite patient's response
	8	Contrast passes glottis, visible subglottic residue, absent patient response

Robbins JA, Coyle JC, Roecker EB, Rosenbek JC, Woody GL: Differentiation of normal and abnormal airway protection during swallowing using the penetration aspiration scale. *Dysphagia*, 14(4):228–232, 1999.

slower swallowing may allow time to recruit the necessary number of motor units required for pressures critical for adequate bolus propulsion through the oropharynx. However, fluids of low viscosity (e.g., water, tea), by their composition, are likely to move more quickly than the physiology to handle them safely and thus put older people at increased risk for aspiration.

### Neurophysiological Correlates of Senescent Swallowing

Neuroimaging studies using cranial magnetic resonance imaging (MRI) in normal adults have shown a relationship between slower swallowing and an increase in the number and severity of periventricular white-matter hyperintensities (PVHs) in the brain, supporting the concept that voluntary control of swallowing is mediated by corticobulbar pathways traveling within the periventricular white matter. The occurrence and degree of PVHs increase with age and may explain, at least in part, the relatively asymptomatic decline in oropharyngeal motor performance observed in older people. Cerebral atrophy, a common finding in asymptomatic older individuals, may be another contributing factor to presbyphagia.

Changes in the periphery also occur with age and may be a function of changes in various sensory mechanisms or caused by muscle atrophy. Similar to the age-related loss of limb skeletal muscle, are the changes with age in fiber density, muscle tension, muscle strength, and muscle contraction in facial, masticatory, and lingual musculature. Rather than reflecting CNS deterioration, slowed swallowing

that remains coordinated and effective, as found in most healthy old people, may represent a compensatory strategy for achieving pressure-generation values that may be critical to successful bolus propulsion.

### DIFFERENTIAL CONSIDERATIONS FOR DYSPHAGIA AND ASPIRATION

#### Etiologies

Older adults are at increased risk for developing dysphagia because of a number of age-associated phenomena. Several factors contribute to and several comorbid processes also increase the chances that older adults will suffer the adverse consequences of dysphagia—dehydration, malnutrition, and aspiration pneumonia. By targeting high-risk groups and intervening with acceptable compensatory and rehabilitative approaches, it is hoped that the ultimate burden of dysphagia on the geriatric population will decline.

A decreased physiologic reserve can combine with a number of age-related, disease-related, or iatrogenic changes to transform an at-risk individual into an older adult with dysphagia. The concept of homeostenosis, or decreased physiologic reserve, is being recognized as a crucial covariable with dysphagia. Frailty or sarcopenia may be outward manifestations of this poor reserve. Several anatomic or pathologic perturbations occurring throughout the orobuccal cavity, the laryngopharyngeal region, and the esophagus must also be acknowledged as important cofactors in the onset of dysphagia.

#### Age-Related Conditions

Age-related changes throughout the upper aerodigestive tract can influence swallowing integrity. Oral risks are also discussed in Chapter 42. During the oral phase, the food bolus may be inadequately prepared because of poor or absent dentition, periodontal disease, ill-fitting dentures, or inappropriate salivation caused by xerostomia. Musculoskeletal factors such as weakness of the muscles of mastication, arthritis of the temporomandibular joint or larynx, osteoporosis of the jaw, or changes in tongue strength and coordination of the oropharyngeal events can deter efficient swallowing. Sensory input for taste, temperature, and tactile sensation changes in many older adults. This disruption of sensory-cortical-motor feedback loops may interfere with proper bolus formation and timely response of the swallowing motoric sequence and detract from the pleasure of eating. Controversy exists regarding the predictive value of an absent gag reflex for aspiration, although many clinicians still use this criterion to screen for altered pharyngeal sensation. Davies and colleagues studied the gag reflex in 140 healthy young (mean: 27 years) and old people (mean: 76 years) and reported that 43% of the older group and 27% of the younger group had an absent gag while all but one had intact pharyngeal sensation.

Material can penetrate into the upper airway in normal individuals if the bolus is not properly prepared, if the timing of the swallow is delayed, or if the intake is too rapid. Important risk factors for aspiration include altered level of attention during feeding (e.g., delirium), altered sensory discrimination in the oropharynx, feeding problems, mechanical ventilation, and feeding tube placement. In the latter circumstance, the rate of tube feeding, the position of the patient,

**TABLE 41-3****Neurological Disorders Causing Dysphagia**

Stroke
Head trauma
Parkinsonism and other movement and neurodegenerative disorders
Progressive supranuclear palsy
Olivopontocerebellar atrophy
Huntington's disease
Wilson's disease
Torticollis
Tardive dyskinesia
Alzheimer's disease and other dementias
Motor neuron disease (amyotrophic lateral sclerosis)
Guillain-Barré syndrome and other polyneuropathies
Neoplasms and other structural disorders
Primary brain tumors
Intrinsic and extrinsic brainstem tumors
Base of skull tumors
Syringobulbia
Arnold-Chiari malformation
Neoplastic meningitis
Multiple sclerosis
Postpolio myelitis syndrome
Infectious disorders
Chronic infectious meningitis
Syphilis and Lyme disease
Diphtheria
Botulism
Viral encephalitis, including rabies
Myasthenia gravis
Myopathy
Polymyositis, dermatomyositis, inclusion body myositis, and sarcoidosis
Myotonic and oculopharyngeal muscular dystrophy
Hyper- and hypothyroidism
Cushing's syndrome
Iatrogenic conditions
Medication side effects
Postsurgical neurogenic dysphagia
Neck surgery
Posterior fossa surgery
Irradiation of the head and neck

altered intestinal transit times, and the ability of the patient to protect their airway all influence the occurrence of reflux and aspiration and are discussed in detail in Chapter 40. Gastroesophageal reflux caused by lower esophageal sphincter (LES) incompetence as well as intraesophageal reflux defined as material moving proximally within the esophagus prior to crossing the LES also predispose individuals to micro- or macroaspiration.

### Age-Related Disease

Neurological and neuromuscular disorders are one of the principal risks for dysphagia (Table 41-3). Neurologic diseases rise in prevalence in older cohorts of the population. Stroke, brain injury, Alzheimer's disease, and other dementia syndromes, and parkinsonism all place older adults at increased risk for dysphagia with its incipient consequences.

**TABLE 41-4****Warning Signs Associated With Dysphagia and Aspiration Risk**

Decreased alertness or cognitive dysfunction
Stupor, coma, heavy sedation, delirium, "sundowning," dementia, agitation
Playing with food, inappropriate size of bites, talking or emotional lability during attempts to swallow
Changes in approach to food
Avoidance of eating in company
Increase in amount of food remaining on plate
Special physical preparation of food or avoidance of foods of specific consistency
Prolonged mealtime, intermittent cessation of intake, frequent "wash downs"
Compensatory measures (head and neck movements)
Laborious chewing, repetitive swallowing
Coughing and choking on swallowing, increased need to clear throat
Manifestations of impaired oropharyngeal functions
Dysarthria
Wet, hoarse voice and other voice changes
Dysfunction of focal musculature (facial asymmetries, abnormal reflexes or dystonia, dyskinesias or fasciculations)
Drooling or oral spillage, pooling and pocketing of food
Frequent throat clearing
Patient complaints or observations of
Difficulty initiating a swallow
Sensation of obstruction of bolus in the throat or chest
Regurgitation of food or acid
Inability to handle secretions
Unexplained weight loss
Impaired breathing during meals or immediately after eating
Pain on swallowing
Leakage of food or saliva from a tracheostomy site

Because cognitive function and/or communication may be impaired, it is important for the practitioner to note the warning signs associated with dysphagia and a risk of aspiration (Table 41-4). Between 50% and 75% of patients who have had a recent acute stroke develop eating and swallowing problems, with ensuing complications of aspiration developing in 50%, malnutrition in 45%, and pneumonia in 35%. Other delayed adverse consequences have also been reported, with up to 15% of patients who have suffered a cerebrovascular accident (CVA) developing pneumonia within 1 year of the acute insult. Brainstem or bilateral hemispheric strokes predictably produce dysphagia, but unilateral lesions also can contribute to dysphagia. Daniels and colleagues identified six clinical features associated with an increased risk for aspiration poststroke. These included (1) an abnormal volitional cough, (2) an abnormal gag reflex, (3) dysarthria, (4) dysphonia, (5) a cough following a trial swallow, and (6) a voice change following a trial swallow. The presence of any two of these findings had a sensitivity of 92% and a specificity of 67% in predicting that there would be penetration and aspiration of material as evidenced with videofluoroscopy.

A host of common problems involving the head and neck can directly damage the effector muscles of swallowing and increase the risk for dysphagia. Head and neck injury, carcinoma, complex infections, thyroid conditions, and diabetes are associated with age-related dysphagia. Although vertebral osteophytes are common, these bony

growths alone rarely cause dysphagia. Dysphagia more commonly results from the presence of osteophytes in conjunction with neuromuscular weakness or discoordination. This can be caused by combinations of several underlying conditions or comorbidities such as diabetes, chronic obstructive pulmonary disease, congestive heart failure, renal failure, an immunocompromised status, and/or cachexia for which an individual no longer can draw an adequate reserve to effectively compensate.

Sometimes dysphagia can be a direct consequence of a treatment provided for another disease process. Health care interventions can result in drug-induced delirium, protracted hospital stays, and ultimately malnutrition. Indwelling NG tubes, airway intubation, and medication effects may all predispose a frail older adult with borderline airway protection to develop frank aspiration. Understanding the iatrogenic causes of dysphagia can alter medical practice and may reduce its incidence and complications.

Older adults are much more likely to be taking medications for multiple medical conditions. These medications can influence salivary flow, intestinal peristalsis, cognition, or psychomotor status, thereby interfering with normal oropharyngoesophageal function or altering airway protection. More than 2000 drugs can cause xerostomia or reduced salivary flow via anticholinergic mechanisms. The list is extensive and can include common antidepressants, antihistamines, antipsychotics, and antihypertensive agents. Likewise, a number of delirium-promoting therapies exist and similarly produce adverse consequences through either anticholinergic or other central mind-altering effects. Certain agents can directly relax the LES and increase acid reflux and esophageal problems. Finally several psychotropic drugs can produce delayed neuromuscular responses or extrapyramidal effects, thereby influencing the tongue and bulbar musculature. Table 41-5 provides a partial list of these agents and how they can contribute to dysphagia.

An altered level of attention and cognition may also produce special concerns with regard to safe eating and swallowing. As described

elsewhere in this book, delirium is frequently underrecognized and undertreated in both hospital and institutional settings. In general, testing an inattentive adult for dysphagia results in the poorest evaluation. If swallowing is assessed during one of these episodes, aspiration is likely to occur. If a staff member at a hospital or nursing home feeds a patient during one of these intervals, the outcome may be disastrous.

Several different treatments can either directly or indirectly damage swallowing effector organs as described previously. Head and neck cancer surgeries, some spinal cord surgeries, thyroid surgeries, and any intervention that can jeopardize the recurrent laryngeal nerve may result in dysphagia. A number of chemotherapy and radiotherapy regimes can cause oropharyngeal injury. The prospective outcome of dysphagia should be incorporated into the risk–benefit discussions of these procedures.

## Symptoms

Medical history plays a critical role in establishing a diagnosis of dysphagia (Table 41-6). A detailed history can elucidate the proper diagnosis in some dysphagic adults and is an important first step in

**TABLE 41-6**

### Historical Data Used for Clinical Diagnosis of Dysphagia

Site or timing of impairment
Oral (problems with chewing, bolus gathering, initiation of swallow)
Pharyngeal (problem immediately on swallowing, choking after a long delay, suggestive of passage of residue from the pharynx into the larynx)
Esophageal (seconds after swallow, behind chest bone)
Onset, frequency, and progression
Duration, sudden onset related to a specific event (stroke, pill impaction, etc.), or gradual
Frequency (constant, intermittent)
Progression and severity (including more and more foods and impairing nutrition and hydration?)
Aggravating factors and compensatory mechanisms
Food consistency (solids and/or liquids)
Temperature
Usefulness of sucking, turning, and tilting of head, and so on
Intermittent, constant, or fatiguing symptoms
Associated symptoms
Change in speech or voice
Weakness; lack of control of musculature, particularly of the head and neck
Choking or coughing
Repetitive swallows or increased need to clear the throat
Regurgitation (pharyngeal and nasal, or esophageal and gastric; immediately on swallow, or long delay, undigested food, putrefied or secretions?)
Fullness/tightness in the throat (globus sensation)
Pain, localized or radiating
Odynophagia (pain on passage of bolus)
Ancillary symptoms and evidence of complications
Loss of weight or loss of energy (including from dehydration)
Change in appetite; attitude toward food, toward eating in company; preparation of foods
Respiratory problems (cough, increased sputum production, shortness of breath, pneumonias and other respiratory infections)
Sleep disturbances (secondary to secretion management or regurgitation)
Changes in salivation (water brash or dry mouth)

**TABLE 41-5**

### Mechanisms by Which Common Medications Contribute to Dysphagia

#### Xerostomia

##### Anticholinergic effects

- Tricyclic antidepressants
- Antipsychotic agents
- Antihistamine drugs
- Antispasmodic drugs
- Antiparkinsonism drugs
- Antiemetic drugs

##### Other mechanisms

- Antihypertensives (e.g., diuretics, calcium channel-blockers)

#### Reduction in esophageal and/or laryngeal peristalsis

- Antihypertensive drugs (e.g., dihydropyridine calcium channel-blockers)
- Antianginal drugs (e.g., nitrates)

#### Delayed neuromuscular responses

- Drugs that promote delirium (e.g., anticholinergic agents, opiates, benzodiazepines)
- Drugs that have extrapyramidal side effects (e.g., antipsychotic drugs)

#### Esophageal injury and/or inflammation

- Drugs that relax the lower esophageal sphincter (e.g., calcium channel-blockers, nitrates)
- Large pills that have incomplete esophageal transit

the evaluation process. Recognizing the classic complaints associated with dysphagia and differentiating them from symptoms of common age-related diseases can be challenging. Nevertheless, a careful history may avert increased testing and potential iatrogenic complications in frail older patients. Dysphagia may also present in a more subtle fashion, without symptoms, but with recurring exacerbations of an underlying disease such as chronic obstructive pulmonary disease.

Patients may initially complain of difficulty swallowing liquids, solid food, or pills. Caregivers or nursing personnel may note such difficulties experienced by the patient including “pocketing” of pills within the oral cavity. The patient or the patient’s observant family members may complain of the increased time needed to complete a meal. The patient or the practitioner may identify weight loss without any other localizing explanation. However, clinicians must distinguish these dysphagia or aspiration symptoms from a myriad of other common health problems that may mimic dysphagia in older adults. For example, in frail individuals, depression or early parkinsonism may be manifested solely by weight loss and slowed eating. Without a complete history, these patients may be sent for a dysphagia workup before an attempt is made to manage their “root problem.”

Symptoms of esophageal dysphagia include food “hanging up” behind the sternum, neck pain, chest pain, and heartburn. This issue is also addressed in Chapter 91, which includes a discussion of esophageal disorders. A specific problem with solid food dysphagia suggests a mechanical obstruction. If the symptoms are intermittent, a lower esophageal ring may be present. If the symptoms are progressive, a peptic stricture or carcinoma is more likely. If there are difficulties in ingesting solids and liquids, a neuromuscular or dysmotility etiology must be considered.

### SCREENING ACROSS A CONTINUUM OF CARE SETTINGS

Dysphagia evaluation varies depending on the clinical setting. The comprehensive diagnostic approaches available for hospitalized older patients with dysphagia may not be logistically feasible for bed-bound nursing home residents. Likewise, interdisciplinary dysphagia teams are frequently available in academic settings or in larger hospital systems and less common in other settings. When such a team is not available, the responsibility for screening for swallowing problems falls on the primary provider or the hospital staff. Speech language pathologists, who are usually the swallowing therapists, are well trained to conduct bedside (also referred to as noninstrumental) examinations that include history taking, oral motor assessment, voice evaluation, and assessment of trial swallows. Prior to this referral though, clinicians can provide a focused secondary screening during their encounter with the patient. A number of attempts have been made to identify a simple screening tool for use in ambulatory clinics or at the patient’s bedside. None of these approaches has proven altogether effective, but certain approaches warrant mention.

A 3-oz water swallow test can be performed at the bedside. The clinician auscultates over the patient’s trachea before and after the water is swallowed. Overt coughing, choking, or a change in the character of breath sounds suggests aspiration. While this test identified 80% of poststroke patients in a rehabilitation unit who aspirated during a subsequent videofluoroscopic swallow study, in addition

to resulting false negatives, it provides no information for identifying the underlying pathophysiology of the swallow or for selecting specific interventions.

Because swallowing difficulties are very common in geriatric patients, some mechanism of primary screening should also take place within a primary care clinic setting. An example of a dysphagia screening form is provided in Table 41-7. Because swallowing is not something a patient usually mentions, it may be necessary to ask related questions until a particular word or phrase triggers an association with the patient’s experience (e.g., swallowing, chewing, moving food to the throat, coughing, choking).

Many forms of comprehensive geriatric assessment now include nutritional screening, which can be used as a surrogate screening for dysphagia. Some geriatric clinics now incorporate questions about difficulties with eating or swallowing that are included in periodic screening questionnaires. The simple question, “Do you have difficulty swallowing food?” was reported to have 100% sensitivity and 75% specificity in detecting swallowing difficulties in patients with parkinsonism. Alternatively, a practitioner’s recognition of the relationship among symptoms of weight loss, cough or respiratory decompensation, and dysphagia may serve as a start in addressing this common problem. Nonetheless, once dysphagia is suspected, a more complete assessment is necessary not only to validate its presence but also to define and construct a treatment plan that modifies the underlying sensorimotor pathophysiology.

### TEAM APPROACH TO DYSPHAGIA

Interdisciplinary health care teams play a vital role in the care of complex older adults with dysphagia. This cross-disciplinary focus helps to address not only the medical but also the functional and psychosocial consequences of this problem. The team approach offers the stated advantage of a more efficient comprehensive assessment with shared responsibility for interventions and often makes timely consultation possible. The responsibilities of team members are often divided among disciplines and can include reviewing health issues, obtaining pertinent swallowing history, and an examination (which may include instrumental studies), providing education and counseling to the patient and to the family or the care provider, conducting psychosocial screening, and reviewing advance directives. Teams can be either formal or informal in composition. Core teams frequently include a speech language pathologist, a dietitian, and either a physician or a nurse practitioner.

### Focused Assessment of Swallowing

A major function of the swallowing team is to perform a thorough assessment of the swallowing mechanism and its function. Most commonly, the speech language pathologist plays a major role, performing a two-part examination consisting first of a clinical (bedside) noninstrumental evaluation often followed by an instrumental assessment of swallowing. A brief description of both methods follows.

### Noninstrumental Swallowing Assessment

The clinical evaluation is noninstrumental and although often referred to as a “bedside” procedure can be performed in a variety of environmental settings including an outpatient office. It usually

**TABLE 41-7****Dysphagia Screening Form—University of Wisconsin and Madison GRECC**

Patient Name: \_\_\_\_\_  
 Medical record # \_\_\_\_\_ or Social security # \_\_\_\_\_  
 Primary Diagnosis: \_\_\_\_\_

1. Do you have difficulty swallowing? Yes No Chewing? Yes No
2. Do you have difficulty moving food/liquid out of your mouth into your throat to swallow? Yes No
3. Does food/liquid remain in your mouth after you finish swallowing? Yes No
4. Do you cough or choke when drinking or eating? Yes No  
 If so, how often does this occur:                      Infrequently  
    Once a day  
    1 or more times per meal
5. Does food/liquid feel like it remains in your throat after you finish swallowing? Yes No
6. Does food/liquid feel like it stays in your chest (esophagus) after you finish swallowing or eating a meal? Yes No
7. Do you bring back up food or liquid after you've swallowed it? Yes No  
 If so, how many minutes or hours after swallowing does it come back up?
8. Do you have any pain when swallowing? Yes No If so, where?
9. Is your mouth dry? Yes No
10. Any difficulty swallowing your saliva? Yes No
11. Have you noticed any drooling? Yes No Wet pillow in the morning? Yes No
12. Is it taking longer to eat a meal? Yes No
13. Do you eat everything you want to eat? Yes No
14. What have you stopped eating because of difficulty?
15. What type of foods are easiest for you to swallow:
  - A. All kinds of foods
  - B. Soft solids (e.g., pasta, soft vegetables)
  - C. Pureed
  - D. Liquids
16. Are you hungry? Yes No
17. Current weight: \_\_\_\_\_  
 Occurrence of weight loss over past 3 months: Yes No  
 If so, please specify amount: \_\_\_\_\_
18. Are you congested in your chest, throat, nose? Yes No  
 How often do you have a head cold or chest cold?

involves four types of assessment: (1) history taking; (2) speech and voice assessment; (3) oral motor assessment; and (4) performance on trial swallows. The specific methods and measures preferred and most frequently used by clinicians when working with dysphagia of neurogenic origin, which is frequently the case in older patients, are shown in [Table 41-8](#).

Although a noninstrumental assessment provides a breadth of information, it can only increase the suspicion of aspiration through findings such as increased secretions or a wet and/or gurgly voice quality. Given the possibility of silent aspiration as a result of decreased cognition or diminished sensation in older people, coughing and throat clearing, which are the characteristic signs of aspiration, may be absent. To rule out aspiration with an acceptable level of confidence, an instrumental assessment is often necessary. Moreover, effective dysphagia intervention relies on an accurate diagnosis of the specific pathophysiology. That is, the underlying movement disorder that results in disordered bolus flow in terms of direction, duration, and clearance, must be defined and remediated in order to eliminate or minimize the dysphagia. Most frequently, instrumental methods are necessary to clarify the aspects of the swallowing sequence that must be modified to effect safe and efficient bolus flow. Although clinicians must pursue a complete oropharyngeal and esophageal assessment of many dysphagic patients, this section

focuses on oropharyngeal dysphagia and the reader is referred to Chapter 50 for a discussion of the esophagus.

### Instrumental Examination

To obtain the most useful and valid representation of swallowing, an instrumental diagnostic test should

1. Depict soft tissues, air, fluid-filled cavities, and surrounding bone,
2. Produce clear images of functional changes in multiple planes and real time,
3. Allow viewing of the entire swallow,
4. Be noninvasive and risk-free,
5. Detect and quantify aspiration,
6. Allow objective and repeatable measurements, and
7. Estimate prognosis and treatment potential.

A variety of imaging methods are available for studying the swallow, including ultrasound, MRI, computed tomography scanning, and scintigraphy. The two most commonly used techniques are described in the following sections.

**TABLE 41-8****Clinical and Bedside Swallowing Methods and Measures**

<b>History</b>	<b>Oral motor</b>
Patient report of problem	Tongue strength/range of motion
Family report of problem	Lip seal/pucker
History of pneumonia	Jaw strength/lateralization
Type of neurological insult	Soft palate movement/symmetry
Nutritional status	Dysarthria
Gastrointestinal anomaly	Speech intelligibility
Structural abnormality	Oral apraxia
Previous surgery	Volitional cough
Other disease	Ability to follow directions
Medications	Management of secretions
<b>Voice</b>	<b>Trial swallows</b>
Breathiness	<i>Bolus Type:</i>

### Oropharyngeal Videofluoroscopic Swallowing Evaluation

An oropharyngeal videofluoroscopic swallowing evaluation is most commonly used to assess the integrity of the oropharyngeal anatomy, swallowing physiology, and bolus flow. Structural abnormalities and mucosal lesions are identified by the barium that is swallowed and used to outline the soft tissue structures it passes. In this manner, webs, pharyngeal diverticula, masses, and other soft tissue anomalies are revealed. Structural anomalies such as postsurgically modified anatomy, scar tissue, and osteophytes can be elucidated by radiographic means. Perhaps, the two greatest strengths of the videofluoroscopic swallow evaluation are that the swallow is recorded in motion and preserved digitally or on videotape for replay.

This method permits viewing of the dynamic swallow. All oropharyngeal structures can be examined with regard to their contribution to the coordinated (or uncoordinated) swallow in terms of timing and range of motion. Their impact on bolus flow is made apparent. Therefore, the specific pathophysiology and its impact on bolus flow are clarified and can be targeted for treatment.

An oropharyngeal videofluoroscopic swallow study is not designed simply to determine if a patient is aspirating or even why a patient is aspirating or retaining residue. It is designed also to assist a clinician in determining if a patient can safely receive oral nourishment and allows for trials of proposed interventions to maximize efficacy and safety. During the study, the clinician often varies bolus characteristics sufficiently to be able to offer a diet recommendation

(such as thickened liquid or semisolid). Additional recommendations may be simple postural adjustments, such as tucking the chin, which are shown under fluoroscopy to improve direction or efficiency of bolus flow.

Although videofluoroscopy is the instrumental method most commonly used to assess swallowing, it is limited in the following ways:

1. The amount of information obtained is restricted to a few minutes in an effort to limit radiation exposure.
2. The environment can be distracting for patients with cognitive deficits.
3. The material ingested is barium, not food, and may not simulate the swallow evoked when real food is used as a stimulus (taste, smell).

Despite these limitations and exposure to a small amount of radiation (equivalent to 2 years of natural background radiation or a set of dental x-rays), videofluoroscopy is preferred for the breadth of information it provides with regard to anatomy, physiology, bolus flow, and assessment of trial intervention.

In addition, a fluoroscopic examination can easily be extended to the esophagus when indicated. Merging of the videofluoroscopic swallow study directly into esophagography, which results in a distinct third test referred to as an oropharyngeal esophagram, may reveal anatomic or physiological findings for the referred sensation. Findings may include a Schatzki's ring, an esophagus-narrowing web or stricture, a delay in LES opening or esophageal stasis, or other esophageal etiologies for the dysphagia. Thus, an oropharyngeal esophagram permits a more organized, efficient, cost-effective process for professional personnel and for the patient. Most importantly, it optimizes the potential for comprehensive findings and facilitates immediate intervention.

### Fiberoptic Endoscopic Evaluation of Swallowing

Fiberoptic endoscopic evaluation of swallowing (FEES) is second to videofluoroscopy in frequency of instrumental approaches used with elderly patients. It combines the traditional endoscopic examination, in which the flexible scope allows direct visualization of the nasal cavity, the entire nasopharynx, the oropharynx, the larynx, and the hypopharynx, with dynamic recording of swallowing. Although FEES permits only limited observation of the pharyngeal swallow because it is "whited out" or visually obliterated during swallowing caused by constriction of the anatomy, the method provides a valuable alternative to a noninstrumental clinical assessment. It is being used with increased frequency in long-term care facilities where videofluoroscopy is unavailable and also with bariatric patients or those who cannot be moved to radiology because of medical instability. Other advantages are its repeatability, the use of real food and fluid during the assessment, and its potential as a biofeedback tool.

In addition to limited visualization of the dynamic oropharyngeal swallow, the limitations of FEES involve risks related to endoscopy, which include nosebleed, mucosal injury, gagging, allergic reaction to the topical anesthesia, laryngospasm, and vasovagal response. Laryngospasm is reported most often as patients are being extubated or by a sudden flow of refluxed gastric contents. Aspiration of food or liquid also might trigger laryngospasm. Patients with a history of significant aspiration, patients who require supplemental oxygen, and patients with acute mental status depression may be at increased risk if they are functioning on the edge of adequate respiratory status and cannot tolerate the minor laryngopulmonary

trauma caused by the endoscope. Finally, a vasovagal response, commonly manifested as fainting, is a fairly uncommon event but can be dangerous. The unlikely possibility of encountering an adverse reaction during a flexible endoscope examination must be balanced against the daily risks faced by patients with dysphagia.

## DYSPHAGIA INTERVENTION

Dysphagia clinicians and researchers have historically felt most comfortable with physiologic outcomes (movement parameters such as range of motion) and the effect on bolus flow direction, duration, and clearance as indicators of the success of an intervention. Attitudes are changing as reflected by increased concern about QOL and the development of SWAL-QOL, a dysphagia-specific patient-centered QOL instrument. Through focus group methodology, SWAL-QOL was designed to represent the patient's perspective in measuring QOL attributable to dysphagia. The questionnaire, comprising 10 domains, is completed by patients in 10 minutes on an average.

The intent is for advances in QOL measurement such as SWAL-QOL to fill a void in dysphagia care, including understanding how variations in treatment affect the human experience of living with a swallowing difficulty and documenting the effectiveness of any given treatment in terms of both physiologic function and QOL. Once data are obtained clarifying how QOL varies with treatment, the dysphagia-specific tool can be used to facilitate decision making by patients and clinicians and to monitor the longitudinal course of individual patient treatment outcomes.

Treatment for dysphagia is usually compensatory, rehabilitative, or a combination of the two approaches. Compensatory interventions avoid or reduce the effects of impaired structures or neuropathology and resultant disordered physiology and biomechanics on bolus flow. Rehabilitative interventions have the capacity to directly improve dysphagia at the biological level. That is, aspects of anatomic structures (e.g., muscle) or neural circuitry are the targets of therapy that may have a direct influence on physiology, biomechanics, and bolus flow.

### Compensatory Dysphagia Interventions

Traditionally, interventions for dysphagia in elderly patients are compensatory in nature and are directed at modifying bolus flow by targeting neuromuscularly induced pathobiomechanics or by adapting the environment. Compensatory strategies are believed by clinicians to be less demanding on the patient in terms of effort, and many of these strategies can be imposed on a relatively passive patient. A nonexclusive sampling of compensatory strategies includes postural adjustment, slowing the rate of eating, limiting bolus size, adaptive equipment, and the most commonly used environment adaptation, diet modification.

#### Postural Adjustments

Postural adjustments are relatively simple to teach to a patient, require little effort to employ, and can eliminate misdirection of bolus flow through biomechanical adjustment. A general postural rule for facilitating safe swallowing is to eat in an upright posture so that the vertical phase of the oropharyngeal swallow capitalizes on gravitational forces at work when the patient is sitting with the torso, and neck at a 90-degree angle to the horizon and the head in line with

the horizon. This posture also can assist in precluding early spillage of food or liquid from the horizontal oral phase into the pharynx and a potentially open airway as well as diminishing the probability of nasal regurgitation. A less obvious postural adjustment is useful for patients with hemiparesis. For this group of patients, a common strategy is a head turn toward the hemiparetic side, effectively closing off that side to bolus entry and facilitating bolus transit through the nonparetic pharyngeal channel. If the pathophysiologic condition is the uncoupling of the oral from the pharyngeal phase of the swallow, a simple chin tuck (45 degrees) reduces the speed of bolus passage, thereby giving the neural system the time it needs to initiate the pharyngeal and airway protection events prior to bolus entry. Other postural adjustments facilitate safe swallowing and are designed to specifically compensate for pathophysiologic conditions analyzed and treated by a swallowing clinician on referral for a swallowing assessment and treatment.

#### Food and Liquid Rate and Amounts

Although we live in a “fast food” society, older individuals and especially those with dysphagia take longer to eat. Eating an adequate amount of food becomes a challenge not only because of the increased time required to do so but also because fatigue frequently becomes an issue. Typically, smaller amounts per swallow are less likely to enter or block the airway, but in individuals who experience a sensory loss in the mouth or throat, larger amounts of food or liquid may be necessary to trigger a swallow. To promote a safe, efficient swallow in most individuals with swallowing and chewing difficulties, the following recommendations are useful:

- Eat slowly and allow enough time for a meal.
- Do not eat or drink when rushed or tired.
- Take small amounts of food or liquid into the mouth—use a teaspoon rather than a tablespoon.
- Concentrate on swallowing—eliminate distractions like television.
- Avoid mixing food and liquid in the same mouthful.
- Place the food on the stronger side of the mouth if there is unilateral weakness.
- Alternate between liquids and solids.
- Use sauces, condiments, and gravies to facilitate cohesive bolus formation and prevent pocketing or small food particles from entering the airway.

#### Adaptive Equipment

Eating and drinking aids can assist in placing, directing, and controlling the bolus of food or liquid and in maintaining proper head posture while eating. For example, modified cups with cutout rims (placed over the bridge of the nose) or straws prevent a backward head tilt when drinking to the bottom of a cup. A backward head tilt, which results in neck extension, should be avoided in most cases because when the head is tilted back, food and liquid are more likely to be misdirected into the airway. Spoons with narrow, shallow bowls, or glossectomy feeding spoons (spoons developed for moving food to the back of the tongue) are useful to individuals who require assistance in placing food in certain locations in the mouth. More importantly, these utensils and devices promote independence in eating and drinking. A speech pathologist or swallowing clinician

can make suggestions regarding appropriate aids for optimizing swallowing safety and satisfaction. Occupational therapists are experts in the area of adaptive equipment and can be helpful in obtaining products that are often available only commercially.

### Diet Modification

The most common compensatory intervention is diet modification, a totally passive environmental adaptation. Withholding thin liquids such as water, tea, or coffee, which are most easily aspirated by older adults, and restricting liquid intake to thickened liquids is almost routine in nursing homes in an attempt to minimize or eliminate thin-liquid aspiration, presumably the precedent to the long-term related outcome, which is pneumonia. Despite the huge impact these seemingly unappealing practices may have on patient QOL, they have been commonly implemented in the absence of efficacy data.

A large National Institutes of Health (NIH)-funded multisite, randomized clinical trial (RCT) was designed as two sequential RCTs to compare the efficacy of two of the most commonly prescribed dysphagia interventions: chin-down posture and thickened liquids (nectar and honey viscosity) for patients with Parkinson's disease (PD) and/or dementia in the short term and over a longer period of time. Seven hundred eleven patients were enrolled in a short-term arm of the study (Part I) in which each intervention was evaluated using videofluoroscopy to assess its effectiveness in preventing the primary outcome: immediate aspiration. In Part II of the study, the long-term follow-up, 515 patients were randomly assigned to use one of these common interventions for 3 months and were monitored for incidence of the primary outcome: pneumonia. The primary outcome of Part I showed that aspiration was significantly reduced with honey-thick liquids as compared with both nectar-thick and chin-down posture interventions. The primary outcome of Part II showed equal value in chin-down posture and thickened liquids in pneumonia prevention. Several secondary outcomes also are of great importance. Patients with dementia (with or without PD), regardless of intervention, had significantly greater incidence of pneumonia than patients with PD only. Patients who aspirated more frequently with all of the interventions during the videofluoroscopic evaluation of swallowing also were more likely to incur pneumonia during Part II. Of the individuals who did get pneumonia, those randomized to drink honey-thick liquids (defined as 3000 centipoise, which is very thick) for 3 months were hospitalized for an average of 13 days longer than patients drinking nectar-thick liquids (4 days) or those performing the chin-down posture (6 days) while drinking.

With the recent appearance of SWAL-QOL on the clinical scene, some of these ongoing practices can be evaluated from the patient's perspective as well as by the clinicians who, with good intent, recommend them. In the NIH RCT, significantly more patients who were cognitively intact reported preferring chin-down posture with thin liquids over nectar or honey-thickened fluids. Between the thickened fluids, they found nectar more satisfactory, or pleasant to drink, than honey.

Additional diet modifications include a pureed diet, and a soft food diet in which the bolus maintains itself in a cohesive mass during transit but has more texture than the pureed diet. The use of sauces and gravies to minimize the formation of dry particles that may easily be misdirected into the airway is a common practice. Other strategies within this category as interventions are available, and the dietitian should work closely with the team to ensure that the

safest diet is provided and that it is effective in maintaining adequate nutrition and hydration, while also acceptable to patients in order to insure compliance.

### Knowing the Heimlich Maneuver

Educating care providers and family members about the signs of choking and the standard first-aid technique for clearing the airway, namely, the Heimlich maneuver, is essential. While the Heimlich maneuver can be self-administered, it is recommended that individuals with dysphagia eat in the company of someone who knows this first-aid technique. Family members should be trained in emergency techniques for clearing the airway.

### Rehabilitative Dysphagia Interventions

Rehabilitative exercises are, by nature, more active and rigorous. Often a rehabilitative approach to dysphagia intervention is withheld from elderly patients because such a demanding activity is assumed to deplete any limited remaining swallowing reserve, thus potentially exacerbating dysphagia symptoms. Sufficient treatment efficacy data are unavailable, and so assumption-based patterns of practice prevail.

Although progressive resistance training appears to be safe and effective for limb musculature in older adults, such training has only begun to be systematically applied to the muscles of swallowing. A description of two different exercise regimens that are supported with efficacy data for improving swallowing-related function in the elderly follow.

One is a simple isotonic/isometric neck exercise performed over a 6-week period in which the patient simply lies flat on his back and lifts his head (keeping shoulders flat) for a specified number of repetitions. The improved physiologic outcome of UES opening that affects swallowing is speculated to result from strengthening the mylohyoid/geniohyoid muscle groups and possibly the anterior segment of the digastric muscle.

Another exercise regimen demonstrating effectiveness in older dysphagic patients comprises an 8-week isometric resistance exercise for the tongue and was shown in acute and chronic stroke patients to improve swallowing safety by reducing airway invasion, increasing lingual pressure generation both isometrically and during swallowing and increasing lingual structure, specifically volume or size, as measured via MRI. Such findings suggest that older, dysphagic individuals are able to benefit from rehabilitative exercises focused on bulbar-innervated head and neck musculature. The methods hold promise for not only influencing safe, efficient bolus flow with significant functional gains but also may restore health and improve QOL as well.

## OPTIMIZING SWALLOWING AND RELATED HEALTH THROUGH PREVENTION

### Medications

Minimizing medications that may, most often in combination, put a patient at risk for dysphagia is an important goal. Furthermore, pills are often described by patients as being difficult to swallow. Patients should be informed about medications that can be crushed,

can be mixed with foods, or are available in liquid form. Pill-induced damage to the esophagus can occur if pills are taken when lying down or with inadequate amounts of liquid.

On the other hand, some medicines can enhance the swallow. For example, in parkinsonism, the timing of medication can be adjusted to decrease bradykinesia, thereby achieving the greatest effect in improving swallowing coordination at mealtimes.

## Oral Hygiene

Poor oral hygiene is a risk factor for pneumonia, and aspiration of saliva, whether or not it is combined with food or fluid, can increase the likelihood of infection. Therefore, patients should be encouraged to perform oral hygiene several times a day and undergo periodic dental examinations. Furthermore, products to relieve oral dryness, as well as alcohol-free mouth care products, can be recommended.

## TuBe or Not TuBe—Oral Versus Nonoral Intake

Oropharyngeal dysphagia is potentially life-threatening. In the older population, critical decisions often must be made that impact on the patient's safety, health, and QOL. Among these perplexing issues is the question of continuing oral intake or providing nonoral enteral or parenteral nutrition. This dilemma is also reviewed in Chapter 40.

Enteral nutrition, the delivery of nutritive products to the digestive system through nonoral means, is often selected for the temporary prevention of aspiration in acutely ill patients. It also is chosen for longer-term nutritive supplementation or permanent replacement in patients whose disease process results in confirmed or suspected swallowing-related aspiration or malnutrition and dehydration. In the case of the latter, older patients whose chronic disease processes are overlaid on a system with a reduced functional reserve for safe, sufficient swallowing, the clinician's impressions often direct decisions relating to tube feeding for weeks, months, or even years. Rabenek et al. wrote: "No explicit guidelines for percutaneous endoscopic gastrostomy (PEG) tube placement are available to guide clinical decision-making. In the absence of such guidelines, the decision to place a PEG tube focuses mainly on the patient's ability to take food by mouth." However, it would clearly be narrow and short-sighted to make decisions with such an impact solely on the basis of empirical swallowing abilities or even instrumental physiologic and bolus flow test results. For an issue that may be a critical source of a patient's sense of autonomy, self-respect, dignity, and QOL, swallowing ability is merely one factor in a decision-making formula that is yet to be determined. Unfortunately, the current situation remains as stated by Logemann: "An important decision is whether the patient should continue to be fed orally, or be placed on a nasogastric tube or given some type of gastrostomy or jejunostomy. At this time, there are no absolute guidelines the clinician can use to make the decision."

Therefore, both published evidence and the practitioner's own clinical experience must contribute to such decision making. One study involving an elderly population followed for 11 months documented the incidence of complications of tube feeding. At 2 weeks postintubation, 43% of patients fed by NG tube and 56% of those fed by gastric (G) tube had been diagnosed with aspiration pneumonia. Sixty-seven percent of patients fed by NG tube and 44% of those fed by G tube had become agitated and/or self-extubated, requiring restraints or sedative medications to maintain the integrity

of enteral nutrition. Late complications in patients in the NG tube group included a 44% incidence of aspiration pneumonia and a 39% incidence of self-extubation, whereas a 56% incidence of aspiration occurred in the gastrostomy group.

These data and others have led to comparisons between the outcomes of parenteral (intravenous) and enteral modes of feeding. Findings suggest advantages in safety and somewhat equivocal physiologic and clinical outcomes, whereas costs may be less for the latter mode.

In summary, while oropharyngeal dysphagia may be life-threatening, so are the alternatives, particularly for frail elderly patients. Therefore, contributions by all team members are valuable in this challenging decision-making process, with the patient's family or care provider's point of view perhaps being the most critical second, of course, to the competent patient, himself. The state of the evidence calls for more research, including RCTs in this area. Until (and perhaps after) these data are collected and have been analyzed, the many behavioral, dietary, and environmental modifications described in this chapter and being further refined are compassionate and, in many cases, preferred alternatives to the always present option of tube feeding.

# Oral Cavity

*Jonathan A. Ship*

The oral cavity serves three essential functions in human physiology: (1) the production of speech, (2) the initiation of alimentation, and (3) protection of the host. A discussion of oral–pharyngeal health and function throughout the human life span must consider the impact of any disturbance of these three functions on an older person’s life.

In order to speak, process food, and protect the host from pathogens and trauma, many specialized tissues have evolved in the oral–facial region (Table 42-1). The teeth, the periodontium, and the muscles of mastication exist to prepare food for deglutition. The tongue occupies a central role in communication, and is also a key participant in food bolus preparation and translocation. Salivary glands provide a secretion with multiple functions. Saliva, in addition to lubricating all oral mucosal tissues to keep them intact and pliable, moistens the developing food bolus, permitting it to be fashioned into a swallow-acceptable form. All these tissue activities are finely coordinated, and a disturbance in any one tissue function can significantly compromise speech and/or alimentation and diminish the quality of a patient’s life (Table 42-2).

The oral cavity is exposed to the external world and is vulnerable to a limitless number of infectious, traumatic, and environmental insults. Extensive mechanisms have evolved to protect the mouth and permit normal oral function. The oral cavity is richly endowed with sensory systems that contribute to the enjoyment of food and alert an individual to potential problems. These systems include mechanisms for taste (and its inextricable relationship with smell); thermal, textural, and tactile sensation; and pain discrimination. Also, saliva plays an important protective role and contains a broad spectrum of antiviral, antibacterial, and antifungal proteins that modulate oral microbial colonization. Other proteins maintain the functional integrity of the teeth by keeping saliva supersaturated with calcium and phosphate salts and provide the first role in repairing incipient caries (tooth decay) via a remineralization process.

The use of dental services among older cohorts has improved over the past 40 years in the United States. However, findings from several national surveys indicate that a significant proportion of the

elderly population does not see a dental professional on a regular basis and may thus be at risk for developing severe oral medical problems. For example, patients of all ages report more physician visits per year than dental visits, and this difference increases with greater age. More than 25% of the U.S. population aged 65+ years has not seen a dental professional in the past 5 years. In addition, elderly persons who wear complete dentures are four times less likely to visit a dentist than are those with remaining teeth.

These trends may change, however, for several reasons. First, future cohorts of older persons will have experienced improved oral health earlier in life, which will result in more patient visits than previous older-aged cohorts. Second, dental insurance coverage and retirement assets are more available for older-aged dental care than for previous generations of retired individuals. Third, nearly one-third of the elderly population is edentulous, but the prevalence of edentulousness has been decreasing steadily for the past four decades. This has resulted in an increased retention of the natural dentition, and therefore dental caries and periodontal diseases will remain substantial oral health concerns for older individuals in the future.

Half of adults aged 55+ years in the United States wear an oral prosthesis (partial or full denture), and 60% of them report problems with their appliances. This includes oral–fungal infections, traumatic lesions, and alveolar bone loss, yet edentulous adults are less likely to see dentists than their dentate counterparts. Oral and pharyngeal cancers develop in both dentate and edentate older adults, especially individuals with long-term alcohol and tobacco use, and regular cancer screening examinations are essential to diagnose and treat these tumors at early stages. Therefore, adequate oral health care for the elderly people should include preventive dental treatment and increased availability and use of dental health services. Most oral diseases are preventable and treatable at every age.

Accordingly, physicians, nurses, and aides who care for older patients need either to recruit dental expertise routinely as part of the overall assessment or to familiarize themselves with the appearance of oral health and disease states. Patient well-being is optimized

**TABLE 42-1****Oral Tissues and Their Functions**

ORAL TISSUE	FUNCTION
Teeth	Mastication, bone regeneration
Periodontium	Mastication, bone regeneration, host defense
Salivary glands	Lubrication, buffering acids, antimicrobial activity, mechanical cleansing, mediation of taste, remineralization of teeth, oral mucosal repair
Taste buds	Taste, host defense
Oral mucosa	Host defense, mastication, swallowing, speech
Muscles of mastication and facial expression	Mastication, swallowing, speech, posture

when nondentists detect oral disease and recommend preventive and interventional services. Similarly, dentists should refer patients to physicians for previously undiscovered or inadequately controlled medical problems (e.g., diabetes, hypertension, cardiovascular disease). Communication is critical between dental and medical practitioners regarding medically complex patients who may need individualized health care planning to maintain oral health at minimal risk.

This chapter focuses on specific oral tissues and their functions. It summarizes “normal” oral physiologic status in older adults and explains how common systemic diseases and their treatments may affect the oral tissues during aging (Table 42-3). It also briefly reviews the evaluation and management of oral disorders frequently encountered in the elderly population. Additional information on the diagnosis and treatment of these disorders is available in several comprehensive reviews cited in the reference section.

**TABLE 42-3****Oral-Pharyngeal Processes in Older Adults**

PROCESS	HEALTHY OLDER ADULTS	MEDICALLY COMPLEX OLDER ADULTS
Taste	Unaffected	Diminished
Smell	Diminished	Diminished
Food enjoyment	Unaffected	Diminished
Salivary output	Unaffected	Diminished
Chewing efficiency	Slightly diminished	Diminished
Swallowing	Slightly diminished	Diminished

**DENTITION**

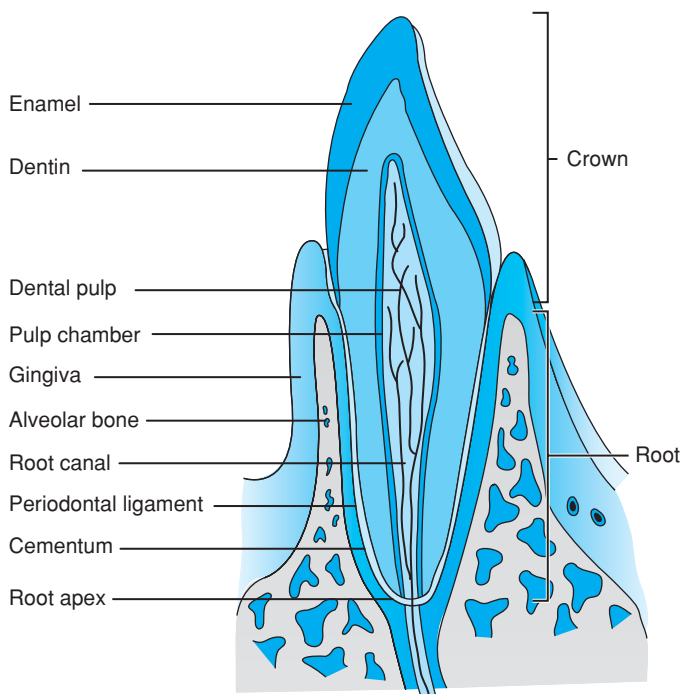

The loss of teeth has long been associated with aging. National health surveys in demonstrate that approximately one-third of Americans older than age 65 years are edentulous. Although the prevalence of edentulous adults has decreased dramatically over the past 50 years, the population older than age 65 years still has an average of 11 missing teeth. Advances in dental treatment, disease prevention, increased availability of dental care, and improved awareness of dental needs have resulted in significant gains in dental health.

Tooth loss is attributed to two major processes: dental caries (discussed below) and periodontal diseases (discussed in the next section). Caries affects the exposed dental surfaces, and periodontal diseases are confined to the supporting bony and ligamentous dental structures. With the current trends toward increasing tooth retention in aging populations, there is a correspondingly greater risk for the development of both of these disease entities.

A tooth consists of several mineralized and nonmineralized components supported by the periodontal ligament and the alveolar

**TABLE 42-2****Clinical Manifestations of Oral Infections**

DISEASE	ORAL MANIFESTATIONS
<i>Dental and periodontal infections</i>	
Dental caries	Soft to hard discolored defect on tooth surface
Gingivitis and periodontitis	Erythematous, edematous, and hemorrhagic gingiva, which may be accompanied by gingival recession and tooth mobility
<i>Viral infections</i>	
Primary herpes simplex infection	Clear to yellow vesicles that rupture and form shallow, painful ulcers on all mucosal surfaces; gingival tissues inflamed, edematous, and painful
Recurrent herpes simplex infection	Burning or tingling prodrome in lesion sites (lip, hard palate, attached gingiva); whitish-gray vesicles rupture to form painful ulcers, which then develop a crust
Herpes zoster	Unilateral vesicular eruptions in areas following the distribution of ophthalmic, maxillary, or mandibular divisions of trigeminal sensory nerves
Cytomegalovirus	Mononucleosis-like symptoms, petechial hemorrhages, enlarged salivary glands, pharyngotonsillitis
<i>Fungal infections</i>	
Pseudomembranous candidiasis	Soft, white or yellow plaques that can be wiped off to expose an underlying erythematous mucosa
Hyperplastic candidiasis	Leukoplakic or keratotic lesions that cannot be removed by scraping
Erythemic or atrophic candidiasis	Painful erythematous oral mucosal lesions; tongue appears “bald”; diffuse inflammation of denture-bearing areas
Angular cheilitis	Erythematous cracked or fissured lesions at the lip commissures
<i>Salivary gland infections</i>	
Acute sialoadenitis	Tender salivary gland swelling with purulent discharge on palpation of the gland duct
Chronic sialoadenitis	Recurrent, tender swellings of salivary gland progressing to a firm and atrophic gland

**FIGURE 42-1.** Dental, periodontal, and alveolar bone anatomy. (From Ship JA, Heft M, Harkins S. Oral facial pain in the elderly. In: Lomranz J, Mostofsky DI, eds. *Handbook of Pain and Aging*. New York, New York: Plenum Press; 1997:1214.)

bone (Figure 42-1). The outer dental structure is enamel and is the hardest, most mineralized component, consisting of ~90% hydroxyapatite. Enamel covers the coronal aspect of the tooth and is the first hard tissue exposed to caries-causing bacteria. Dentin constitutes the main portion of the tooth structure, extending almost the entire length of a tooth. It is covered by enamel on the crown and by cementum on the root. Cementum is the least mineralized of the three components (50%) and is the component most susceptible to caries-causing bacteria. The central, nonmineralized portion is the dental pulp, which houses the vascular, lymphatic, and neuronal supply to the tooth.

Tooth loss in children and young adults is caused predominantly by dental caries, whereas in middle-aged and older adults, periodontal diseases play a greater role in the loss of teeth. Longitudinal studies of generally healthy adult males have found that the principal cause of tooth extraction is dental caries. Furthermore, caries activity continues throughout life and is not a phenomenon confined to any single period.

There are two classifications of dental caries, depending on the dental surface affected. Coronal caries is characteristic of caries in young adults and children. This occurs when the enamel and dentin of the coronal portion of the tooth are affected. In older adults, if gingival recession or periodontal disease causes the root surfaces of the tooth to become exposed to the oral environment, root surface or cervical caries may occur.

The primary caries-causing microorganism is *Streptococcus mutans*; oral *Streptococcus*, *Actinomyces*, and *Lactobacillus* organisms are also associated with coronal and root surface lesions. These bacteria reside on the tooth surface in dental plaque, a soft, firmly adherent mass that contains bacteria, food debris, desquamated cells, and bacterial products. Acid production by plaque bacteria dissolves the

mineral content of the enamel, dentin, or cementum. The exposed protein constituents are destroyed by hydrolytic enzymes, and caries results. Dental plaque is considered a primary etiologic factor in dental caries, as well as a principal source of pathogenic organisms in periodontal diseases.

As a dentate individual gets older, there is susceptibility to coronal caries as a result of recurrent decay around existing restored surfaces, and the prevalence of root surface caries increases. For example, there is an 18-fold increase in the average number of tooth surfaces with root caries between persons aged 20 years and those aged 64 years (thus root caries often begins well before old age). There are many risk indicators for root surface caries: increased age, decreased exposure to fluoride, coronal caries, periodontal attachment loss, diminished oral-motor skills required for proper oral hygiene, and additional medical, behavioral, and social factors.

Studies in the United States reveal an increase in the mean number of decayed and restored teeth among older-aged dentate adults over the last 50 years. These trends probably reflect the increased retention of the natural dentition and a greater use of dental services by older adults; it is unlikely that they represent a true increase in dental caries activity. However, epidemiologic projections suggest that significant increases in the prevalence of root surface caries will occur in aging populations in the future.

For an older person with teeth, caries is a significant concern and may be a source of pain, infection, and malnutrition. Dental caries will appear as darkish lesions that frequently are associated with dental plaque (Figure 42-2) (Color Plate 7). Long-standing caries ultimately results in the destruction of the tooth with the possibility of a disseminated infection to the maxillofacial tissues and ultimately into the systemic circulation (septicemia). Once teeth have been destroyed from dental caries or periodontal disease, mastication, phonation, and deglutition may be perturbed. Also, social contact and nutritional status may be affected in a substantially edentulous aging individual.

The prevention of dental caries in an older adult is no different from that in a younger individual: fluoride, daily effective oral hygiene, and regular visits to dental professionals. Adult tooth surfaces can become resistant to decalcification and decay through repeated exposure to fluoride in water supplies, toothpaste, rinses, and gels. However, even resistant tooth surfaces can become carious when oral hygiene is inadequate and the mouth is exposed repeatedly to

**FIGURE 42-2.** Severe dental caries and associated dental plaque.

fermentable carbohydrates. When detected early, caries can be debrided from a tooth, and the missing tooth structure can be restored with a wear-resistant, insoluble restorative material (e.g., amalgam or composite resin). Some restorative materials contain fluoride (glass ionomer cements) and can help reduce caries risk. Untreated dental caries, however, in most circumstances progress to severe or even total loss of tooth structure and possibly pain, abscess formation, cellulitis, and bacteremia. Replacements for lost teeth are available with removable prostheses (partial dentures) or fixed prosthodontic appliances (crowns, bridges, implants).

## PERIODONTIUM

The periodontium consists of the tissues that invest and support the tooth. It is divided into the gingival unit (gums) and the attachment apparatus (cementum, periodontal ligament, and alveolar bony process) (see [Figure 42-1](#)). Gingivitis occurs when the gingival unit is inflamed. Periodontitis (or periodontal disease) exists when there is inflammation and an appreciable loss of the attachment apparatus as a result of the presence of pathogenic microorganisms. Microbial species (e.g., *Bacteroides*, *Fusobacterium*, *Prevotella*, *Actinobacillus*, *Capnocytophaga*, *Streptococcus*) cross the gingival epithelium and enter subepithelial tissues, where they activate specific host defense mechanisms. Eventually, this causes tissue destruction, including bone loss and tooth morbidity.

Certain periodontal changes occur in aging individuals. For example, cross-sectional studies demonstrate that older adults show an increase in dental plaque, calculus (calcified dental plaque), and the frequency of bleeding gingival tissues. Older persons also experience greater gingival recession and loss of periodontal attachment ([Figure 42-3](#)) (Color Plate 8). Longitudinal studies report that periodontitis is more prevalent and usually more extensive among black people, subjects with less education, those who have not seen a dentist recently, and those with gingivitis and certain pathogenic organisms. Currently, it is believed that periodontal disease proceeds through a series of episodic attacks rather than occurring as a slowly progressing continuous process. Furthermore, periodontal bone destruction results from an overly aggressive local immune reaction to the pathogenic organisms, triggering a cascade of cytokine and immuno-

**FIGURE 42-3.** Gingival recession and loss of periodontal–alveolar bone attachment in an older adult.

logical events that can produce irreversible loss of alveolar bone. It is not known whether older age cohorts are more susceptible to periodontal destruction than are younger populations. Among healthy adults, periodontal attachment loss occurs at small increments in all age cohorts and does not occur in greater amounts in older healthy adults. However, many systemic diseases and therapeutic regimens commonly found in older individuals may affect adversely periodontal health. Therefore, an older medically compromised adult is especially susceptible to developing periodontal diseases and is at risk for associated dental–alveolar infections, pain, and tooth loss.

Several classes of medications commonly prescribed for older people are associated with gingival enlargement and hyperplasia, a condition that if left untreated predisposes to both caries and destructive periodontitis. The family of calcium channel-blockers can cause this unwanted drug side effect, which may require periodontal surgery for definitive treatment. The antiseizure medication phenytoin and the immunosuppressant cyclosporine also have also been associated with gingival enlargement.

Periodontal diseases have oral and systemic effects on health. They are directly associated with halitosis, gingival bleeding, tooth mobility, and tooth loss. Untreated periodontitis has been reported to interfere with blood glucose control in diabetic patients, and recent investigations suggest associations between cardiovascular disease and periodontitis after controlling for traditional risk factors such as weight, gender, tobacco use, age, and blood lipid levels. Gram-negative bacteria are implicated in the pathogenesis of periodontal disease, and colonization of the oropharynx with gram-negative bacilli predisposes a patient to pneumonia. Aspiration pneumonia can occur when oropharyngeal secretions are aspirated into the lungs, causing infection. Periodontal bacteria from the gingival sulcus in dentate individuals have been isolated from patients with pneumonia. Risk factors for aspiration pneumonia include older age, immunocompromised state, mechanical ventilation, feeding problems and/or feeding tubes, and deteriorating health status. Importantly, many debilitated older patients have received inadequate oral hygiene and are therefore highly susceptible to aspiration pneumonia.

For an older person with teeth, periodontal diseases can cause pain, difficulty with mastication, infection, and possibly social isolation. Gingivitis may be detected by the presence of erythematous and/or edematous gingival tissues with occasional hemorrhage, as well as halitosis. Gingival recession produces exposed dental root surfaces, a sign of periodontitis. This ultimately causes tooth mobility, a condition that necessitates definitive treatment. The systemic health of an already compromised individual may be further threatened by bleeding and suppurating gingiva, dental alveolar infections, and the potential transmission of oral bacteria via bacteremias and/or oral–pharyngeal secretions.

Treatment of gingivitis and periodontitis starts with regular oral hygiene in the form of toothbrushing and flossing after each meal. Electric toothbrushes and mechanical irrigation systems can assist older patients who have motor and/or cognitive disorders. Periodontal therapy ranges from local (e.g., dental prophylaxis, local debridement) to pharmacological (e.g., use of intrasulcular antimicrobial solutions, systemic low-dose doxycycline as an immunomodulator) to surgical techniques (e.g., debridement, excision of hyperplastic tissue), depending on the extent of periodontal infection and bony destruction. Numerous antimicrobial and anticollagenase pharmaceuticals have been approved for treatment as well: oral rinses (e.g., chlorhexidine 0.12%), subgingival antimicrobials (e.g.,

minocycline hydrochloride 1 mg microspheres), short-term antimicrobials (e.g., clindamycin 300 mg qid or metronidazole 400 mg tid for 7 to 10 days), or long-term anticollagenases (e.g., doxycycline 20 mg). While periodontal healing after surgery tends to be slower even in healthy older persons, the long-term results of periodontal therapy are indistinguishable from those in younger adults. The decision either to save the dentition and restore periodontal health or to extract teeth with moderate periodontal disease should be determined after all oral and systemic factors have been evaluated. Therefore, the health of a person, rather than age per se, should determine the extent of periodontal treatment.

## SALIVARY GLANDS

There are three major pairs of salivary glands (parotid, submandibular, and sublingual) and numerous groups of minor glands (e.g., labial, palatal, and buccal), all of whose principal function is the exocrine production of saliva. Each gland type makes a unique secretion derived from either mucous or serous cell types, forming the fluid in the mouth termed *whole saliva*. Saliva includes many constituents that are critical to the maintenance of oral health. Its most important functions are lubrication of the oral mucosa, promotion of the remineralization of teeth, and protection against microbial infections. Although the role of saliva in digestion is limited, saliva helps prepare the food bolus for deglutition and is responsible for dissolving tastants and delivering them to taste buds.

It was previously thought that salivary output diminishes with increasing age. This was based on the clinical observation that older individuals frequently have a dry mouth and complain of xerostomia. However, investigations reveal that, in general, there is no substantial diminution in salivary production across the human life span in healthy adults. Thus, in the absence of complicating factors (e.g., certain systemic diseases, medications), there is no generalized age-related perturbation in the production of salivary fluid. In addition, there appear to be no significant alterations in the composition of saliva in older, healthy persons.

These physiologic findings contrast with the morphologic changes seen in aging salivary glands. Major salivary glands lose ~30% of their parenchymal tissue over the adult life span. The loss primarily involves acinar or fluid-producing components, while proportional increases are seen in ductal cells and in fat, vascular, and connective tissues. Because acinar components are primarily responsible for the secretion of saliva, it is not known why, in the presence of a significant reduction in the gland acinar volume, total fluid production does not diminish with increasing age. It has thus been deduced that salivary glands possess a functional reserve capacity that enables them to maintain fluid output throughout the human adult life span. There is evidence that with a reduced reserve capacity, additional burdens placed on aging salivary glands (e.g., anticholinergic medications) increase their vulnerability to functional decline. Therefore, salivary hypofunction and complaints of a dry mouth (xerostomia) should not be considered to be normal sequelae of aging but instead are indicative of a host of conditions and their treatments (Table 42-4). The most common etiology of salivary gland hypofunction is iatrogenic. Many medications taken by older persons reduce or alter salivary gland performance. In addition, radiation for head and neck neoplasms and cytotoxic chemotherapy can have direct and dramatic deleterious effects on salivary glands.

**TABLE 42-4**

### Causes of Salivary Hypofunction in Older Adults

CATEGORY	EXAMPLES
Medications	Anticholinergics Antidepressants Antihistaminics Antihypertensives Anti-Parkinson's disease Anxiolytics Diuretics
Oncological therapy	Cytotoxic chemotherapy Head and neck radiotherapy
Oral conditions	Bacterial and viral infections Salivary gland obstructions Traumatic lesions Neoplasms
Other conditions	Alzheimer's disease Cerebrovascular accidents Dehydration Diabetes mellitus Late-stage liver disease Sjögren's syndrome Systemic lupus erythematosus Thyroid disorders (hyper and hypo)

The single most common disease affecting salivary glands is Sjögren's syndrome, an autoimmune exocrinopathy that occurs predominantly in postmenopausal women. Alzheimer's disease, diabetes, dehydration, rheumatoid arthritis, and cerebrovascular accidents may also affect salivary output. Several oral inflammatory and obstructive salivary gland disorders (e.g., bacterial infections, sialoliths, trauma, neoplasms) result in salivary dysfunction, as well as benign and malignant salivary tumors.

A clinician is likely to encounter many older patients with oral complaints related to salivary gland hypofunction. A brief clinical examination should include palpation of all major glands and inspection of the duct orifices to ensure patent glands. The application of a mild solution of citric acid or lemon juice to the tongue can help determine whether a patient's salivary glands will respond to a gustatory stimulus. Regardless of etiology, any of the major oral physiologic roles influenced by saliva (see Table 42-1) may be affected adversely. With impaired glandular output, increased dental caries will ensue rapidly, increasing the possibility of tooth loss. The oral mucosa becomes desiccated and cracked, leaving the host more susceptible to microbial infection (Figure 42-4) (Color Plate 9). Older adults experience difficulty in swallowing or speaking at length, pain (which may arise from either the teeth or the oral soft tissues), impaired denture use, altered taste, and diminished food enjoyment.

Treatment of salivary dysfunction starts with identification of the etiology. Medication-induced salivary problems can be eliminated by stopping unneeded drugs, modifying drug use and dose, or substituting one drug with another drug that has fewer anticholinergic side effects. Even when no reduction in the daily dose is recommended, the splitting of a dose into several smaller and more frequently taken doses may alleviate or diminish the sensation of oral dryness. To enhance salivary production, gustatory (sugar-free mints, candies), masticatory (sugar-free gums), and pharmacologic (pilocarpine

**FIGURE 42-4.** Dry mouth and salivary hypofunction caused by external beam radiotherapy used for tongue cancer. Remaining salivary output is viscous and difficult to swallow, caused by destroyed serous-producing salivary glands.

5 mg tid and qhs, cevimeline 30 mg tid) stimulants can be useful in a patient who has remaining salivary function. Salivary substitutes, rinses, and moisturizing gels can assist a patient who has little or no remaining salivary function. Prevention of dry-mouth problems is essential and can be achieved with the frequent use of sugarfree beverages, topical fluoride, and regular oral hygiene after meals. Removable prostheses must be kept clean and out of the mouth during sleeping hours. Frequent lubrication of the lips helps prevent lip cracking and infections.

## SENSORY FUNCTION

Many reports suggest that food enjoyment, recognition, and sensory function decline as a function of age and that this can produce significant nutritional deficits. It has been suggested that there is a true anorexia (loss of appetite) associated with aging, although this is confounded by the many comorbidities that cause anorexia, and which are so common in elderly people, as well as other social and psychological factors that may reduce oral food and fluid intake. Perturbations in taste, smell, other oral sensory modalities can occur with age, and with dental/periodontal problems, increasingly reduce the rewards of eating, thus contributing to a diminished interest in food among many elderly persons.

The taste receptors of the human gustatory system are distributed throughout the oropharynx and are innervated by three cranial nerves: VII, IX, and X. It appears that the number of lingual taste buds does not diminish with age. The registration of a taste phenomenon is complex, because multiple factors are involved: gustation, olfaction, and central nervous system function. The ability to taste is often evaluated at two levels: (1) *threshold*, the most common measure, a “molecular-level” event, which reflects the lowest concentrations of a tastant that an individual can recognize as being different from water and (2) *suprathreshold*, a measure that is reflective of the ability to taste the intensity of substances at functional

concentrations encountered in daily life. In addition to detection, recognition, and intensity, the normal sensation of taste involves a hedonic component: the degree of pleasantness.

Many earlier studies citing a higher frequency of taste complaints among older persons examined institutionalized individuals rather than healthy elderly people. It now appears that subjective reports of taste function among generally healthy, community-dwelling persons demonstrate that only modest changes occur with increased age, in comparison to studies revealing a threefold increase in the frequency of subjective complaints among older persons who take prescription medications. Objective threshold and suprathreshold evaluations of gustatory function in healthy older adults have been reported for all four taste qualities (sweet, sour, salty, and bitter), and in general, the decremental changes detected with increased age have been modest and taste-quality-specific. For example, the ability of older persons to detect salt decreases slightly with age, while no changes in the detection threshold for sucrose (sweet) are noted. The importance of medication usage and place of residence in the evaluation of taste dysfunction has been confirmed in clinical studies in which institutionalized persons and those using more prescription medications had significantly elevated taste thresholds.

Older individuals perform less well in the more complicated problems of flavor perception, food recognition, and food preference. This is probably a result of diminished olfactory performance rather than the modest changes that accompany taste function with aging. The available data on olfactory performance clearly indicates declines in thresholds, suprathreshold intensity judgments, and odor recognition in both men and women with increasing age. Among older adults, average thresholds are higher, the ability to perceive suprathreshold intensities is blunted, odor recognition is impaired, and the judgment of pleasantness is reduced compared with younger subjects. Moreover, longitudinal studies demonstrate that as people get older, recognition decrements become even more severe.

However, in the real world, people do not typically taste a single tastant in aqueous form and foods that contain solely olfactory cues are not consumed. Foods are chemosensory mixtures, and the most relevant but most difficult to obtain measures of gustatory and olfactory function involve the use of complex food analogs. In one study, younger subjects were significantly better than were elders at recognizing stimuli in blended food. However, when younger persons repeated the test with their nasal airways occluded, their performance dropped to the level of elderly individuals. One conclusion from this finding is that the daily life chemosensory functions of older individuals are handicapped by diminished olfactory performance. Moreover, it has been suggested that for many persons, the “anorexia of aging” can be reduced or reversed by adding flavor enhancers to foods.

Many other sensory cues (temperature, texture, pressure) participate in the experience of food enjoyment. Little research attention has been dedicated to these phenomena. One study demonstrated no age-related changes in the ability of subjects to distinguish fluids of varying temperatures and viscosities; however, a specific decline was observed in the perception of localized lingual pressure.

Normal chemosensory function cannot operate independently of good oral health. Numerous oral conditions can directly or indirectly affect smell and taste by altering the underlying biology of the taste or smell system or by introducing exogenous stimuli into the mouth or nose. Many oral conditions, including fungal/bacterial/viral infections, vesiculobullous diseases, salivary gland hypofunction, poorly

**FIGURE 42-5.** Asymptomatic erythematous candidiasis (denture stomatitis) caused by an ill-fitting oral prosthesis. This mycotic infection combined with a poorly fitting removable prosthesis contributes to impaired taste, smell, chewing, and swallowing.

fitting prostheses, and oral manifestations of systemic diseases, can cause chemosensory dysfunction. For example, inadequate removal of food particles can allow their breakdown or metabolic conversion by oral microorganisms to noxious, unpleasant substances. Periodontal diseases can result in accumulations of putrefied acidic materials that may leak into the oral cavity and alter taste sensation. Similarly, dental–alveolar bacterial infections with subsequent fistula formation may contribute continuously low levels of purulent matter in the mouth.

The complaint of a smell or taste problem may be indicative of a chemosensory disorder or could be the manifestation of an oral and/or systemic medical problem. For example, the sudden loss of either smell or taste may be a sign of brain tumor. Alternatively, gradual diminishment in food enjoyment may be related to multiple sources (e.g., a poorly fitting removable prosthesis, an oral fungal infection, decreased smell identification, a drug) (Figure 42-5) (Color Plate 10). Older subjects are more likely to have chemosensory complaints, but unfortunately those complaints are very poor predictors of olfactory dysfunction. A patient should be asked if he or she can specifically identify the four basic tastants and distinguish between different odorants; such patients can be given the University of Pennsylvania Smell Identification Test. A thorough multidisciplinary approach is required for a patient presenting with chemosensory complaints because of the wide range of potential oral, systemic, physiologic, cognitive, and pathologic factors that are involved in oral sensory functioning.

## ORAL MUCOSA

The soft-tissue lining of the mouth may be characterized by three general types: (1) well-keratinized tissue with a dense layer of connective tissue and firmly attached to underlying bone (e.g., marginal gingiva, palatal mucosa), (2) slightly keratinized and freely movable tissue (e.g., labial and buccal mucosa, floor of the mouth), and (3) specialized mucosa (e.g., dorsum of the tongue). The primary function of the oral mucosa is to act as a barrier to protect the underlying structures from desiccation, noxious chemicals, trauma,

thermal stress, and infection. The oral mucosa plays a key role in the defense of the oral cavity.

Aging frequently is associated with changes in the oral mucosa similar to those in the skin, with the epithelium becoming thinner, less hydrated, and thus supposedly more susceptible to injury. The reasons for these changes (if they are normally a sequela of aging) are complex and include alterations in protein synthesis and responsiveness to growth factors and other regulatory mediators. Cell renewal (i.e., mitotic rates) and the synthesis of proteins associated with oral mucosal keratinization occur at a slower rate in aging individuals. Alternatively, the normal tissue architecture and patterns of histodifferentiation, which probably are dependent on complex interactions with the underlying connective tissue, do not display any changes with age. Overall, changes in the vascularity of oral mucosa probably contribute to an alteration in mucosal integrity because of reductions in cellular access to nutrients and oxygenation. Mucosal, alveolar, and gingival arteries demonstrate the effects of arteriosclerosis. Varicosities on the floor of the mouth and the lateral and ventral surfaces of the tongue (comparable to varicosities on the lower extremities) are also observable in geriatric patients.

The maintenance of mucosal integrity depends on the ability of the oral epithelium to respond to an insult. Insults can be caused by physical factors (eg, trauma), exposure to chemical or microbiological toxins, microbial infections, and oral and/or systemic conditions. Many studies have documented that the immune system undergoes a decline with age (see Chapter 3), and it is likely that this decline extends to mucosal immunity. Therefore, the oral mucosa may be more susceptible to transmission of infectious diseases as well as delayed wound healing. Similar findings have been reported for healing gingival tissues.

Cross-sectional studies have demonstrated that age per se has no effect on the clinical appearance of the oral mucosa. However, considerable evidence suggests that the use of removable prostheses has a potentially adverse effect on the health of the oral mucosa. The denture-bearing mucosa of aged maxillary and mandibular ridges shows significant morphologic changes. Ill-fitting dentures can produce mechanical trauma to the oral tissues (see Figure 42-5) as well as cause mucosal hyperplasia. Oral candidiasis frequently is found on denture-bearing areas in an edentulous individual, often occurring with angular cheilitis (deep fissuring and ulceration of the epithelium at the commissures of the mouth). Therefore, the clinician should ask the patient to remove all removable prostheses before conducting an adequate oral examination.

Oral mucosal alterations in an older person are often a result of multiple oral and systemic factors (Table 42-5). Numerous medications have been associated with oral mucosal changes. For example, long-term use of antibiotics frequently results in oral candidal infections, while drugs with xerostomic side effects (see above) increase the potential for mucosal injury. Bisphosphonate drugs used for cancer metastasis and osteoporosis (primarily those administered IV, but possibly those delivered orally) have been associated with an unusual but severe destruction of oral mucosa and bone referred to as osteonecrosis. Drugs commonly used in older patients for arthritic conditions, hypertension, cardiac arrhythmias, seizures, and dementia are associated with lichenoid-like reactions. The withdrawal of a causative drug usually results in complete resolution of the lesion within 2 to 3 weeks, but if there is no clinical improvement, a definitive diagnosis should be obtained with a biopsy specimen.

TABLE 42-5

## Conditions Associated with Oral Mucosal Changes

CLASSIFICATION	DISEASE/DISORDER	EXAMPLES
Oral conditions	Infections	Candidiasis, herpes simplex, herpes zoster
	Ulcerative conditions	Recurrent aphthous stomatitis
	Cancer	Oral squamous cell carcinoma
	Periodontal diseases	Gingivitis, periodontitis
	Prosthetic problems	Poorly fitting dentures, denture stomatitis
	Salivary gland hypofunction	Dessicated oral tissues
	Food allergies	Lichenoid changes
Systemic diseases	Trauma	Traumatic fibroma, mucocele
	Dermatological disorders	Systemic lupus erythematosus, lichen planus, pemphigus vulgaris, cicatricial pemphigoid, erythema multiforme
	Endocrine disorders	Diabetes mellitus
	Neurologic disorders	Alzheimer's, Parkinson's, CVA
Medical therapies	Immunocompromising disorders	HIV, AIDS, rheumatoid arthritis
	Medications	Diuretics, calcium channel-blockers, antibiotics, antiseizures, immunomodulating drugs, bisphosphonates
	Radiotherapy	Head and neck radiotherapy
	Cytotoxic chemotherapy	Methotrexate, 5-FU, cyclosporin

AIDS, acquired immunodeficiency syndrome; CVA, cerebrovascular accident; 5-FU, 5-fluorouracil; HIV, human immunodeficiency virus.

Numerous oral mucosal disorders affect the elderly population, ranging from benign (e.g., recurrent aphthous ulcers and traumatic lesions) to malignant (e.g., squamous cell carcinomas) (Figure 42-6) (Color Plate 11). The diagnosis of mucosal diseases requires a detailed history and a thorough head and neck and oral examination, including all mucosal tissues. For vesiculobullous and erosive diseases, a simple three-item classification is helpful: (1) acute multiple lesions (e.g., erythema multiforme, herpes simplex, herpes zoster, allergic reaction), (2) recurring oral ulcers (e.g., recurrent aphthous stomatitis, traumatic ulcer), and (3) chronic multiple lesions (e.g., pemphigus vulgaris, mucous membrane pemphigoid, lupus erythematosus, lichen planus, dysplasia, squamous cell carcinoma). If a lesion does not resolve after 2 to 3 weeks, a tissue biopsy is required. For lesions that are suspected to be oral manifestations

of autoimmune connective tissue disorders (e.g., pemphigus, pemphigoid, lichen planus), biopsies should also include specimens for direct immunofluorescence. If trauma from an injury or an ill-fitting denture is suspected, removal of the etiology should allow the lesion to heal. Many of these conditions have an immunological etiology, and therefore management strategies involve topical and/or systemic immunomodulating agents (Table 42-6).

TABLE 42-6

## Treatment of Common Vesiculobullous and Erosive Diseases in Older Adults

MEDICATION	REGIMEN
<i>Topical treatments*†‡§</i>	
Fluocinonide gel 0.05%	Apply to affected regions tid and qhs
Triamcinolone acetonide in gel base 0.1%	
Clobetasol propionate gel 0.05%	
<i>Oral rinses†¶</i>	
Dexamethasone elixir 0.5 mg/5 mL	Rinse and spit 10 mL qid for 5 min
Diphenhydramine elixir 12.5 mg/5 mL	
<i>Systemic medications†**</i>	
Prednisone 5 mg	12 tabs qod × 2 days, decreasing by 2 tabs every other day
Azathioprine 50 mg	1 tab bid

\*If extensive gingival lesions are present, use with a custom-fabricated tray.

†Oral candidiasis may result and concomitant antifungal therapy may be necessary.

‡Taper as indicated by clinical response.

§Can be combined in a 1:1 mixture with orabase.

¶Can be combined in a 1:1 mixture with sucralfate, kapectate, or maalox.

\*\*Dose and duration depend on severity of disease and concomitant systemic diseases.

Azathioprine in combination with prednisone permits use of lower doses of prednisone.

**FIGURE 42-6.** Squamous cell carcinoma of the right lateral border of the tongue. The lesion is characterized by unhealing erythematous, ulcerative, and leucoplakic regions, poorly defined margins, and regional lymphadenopathy.

The oral mucosal disease with the greatest potential morbidity and mortality is cancer. For example, 2.4% (more than 34 360 cases) of all cancers in 2007 in the United States were in the oral cavity and pharyngeal region, resulting in nearly 8000 deaths per year. The three greatest risk factors for developing oral cancer are age, alcohol, and tobacco use; nearly half of all oral cancers occur in persons older than 65 years of age. The average age at the time of diagnosis is approximately 60 years, and males are more than twice as likely to develop oral cancer as are females. While attempts to diagnose and treat oral cancer have improved in the last 30 years, 5-year survival rates have not improved dramatically, and the average 5-year survival rate is only ~50%.

Neoplasms may arise in all oral soft and hard tissues and in the oropharyngeal and salivary gland regions. The clinical appearance of an oral carcinoma is quite diverse (ulcerative, erythematous, leukoplakic, papillary) and may be innocuous as well as asymptomatic (see Figure 42-6). If a patient presents with an unusual and suspicious lesion with no readily apparent etiology (such as a denture sore), the patient should be referred to a specialist more familiar with the appearance of the oral mucosa. Any oral lesion that does not heal completely in 3 to 4 weeks after removal of suspected etiologies (e.g., ill-fitting denture) should undergo a diagnostic biopsy procedure. Importantly, carcinoma should be considered part of the differential diagnosis of any oral lesion.

The treatment of oral cancers involves oral, head, and neck surgery, radiotherapy, chemotherapy, or a combination of any of these three modalities, depending on the tumor's histopathology and stage. Before receiving definitive therapy, the patient should have a comprehensive oral examination so that focal areas of infection or potential infection (dental caries, periodontal disease, dental-alveolar infections, soft and hard tissues lesions) can be treated before surgery, radiotherapy, or chemotherapy. The patient must be educated about many potential risks: surgery-related sensory, esthetic, and functional problems; radiotherapy-induced mucositis, salivary gland hypofunction, and osteoradionecrosis; and chemotherapy-induced mucositis and immunosuppression.

## MOTOR FUNCTION

The oral motor apparatus is involved in several routine yet intricate functions (speech, posture, mastication, and swallowing). Regulation of these activities may occur at three levels: the local neuromuscular unit, central neuronal pathways, and systemic influences. In general, aging is associated with changes in neuromuscular systems. Animal studies strongly suggest that age-associated deficiencies in motor function are not related to the composition and contractile function of skeletal muscles. Instead, these changes probably are related to other factors such as neuromuscular transmission and propagation of nerve impulses.

Studies of oral motor function have shown that some alterations in performance (mastication, swallowing, oral muscular posture, and tone) can be expected with increased age. These changes appear to be more common among predominantly edentulous persons than among those with a natural dentition. The most frequently reported oral motor disturbance in the elderly population is related to altered mastication, and even fully dentate older persons are less able to prepare food adequately for swallowing than are younger individuals. Older persons are more likely to be partially or completely

edentulous than are persons in other age groups, and therefore the geriatric population is susceptible to altered chewing. It also has been reported that older persons tend to swallow larger-sized food particles than do younger adults. This suggests that there is a diminution in masticatory efficiency that can be further exacerbated among individuals with a compromised dentition (those with dental caries, periodontitis, missing teeth). Furthermore, older individuals may be more susceptible to aspiration pneumonia resulting from chewing and swallowing problems in addition to periodontal pathogens. In summary, the majority of research findings suggest that dentition, not age per se, has a direct influence on mastication.

After mastication, a food bolus is ready for swallowing. A thorough review of swallowing problems in older people is provided in Chapter 41. Normal aging has minor adverse effects on swallowing, although in a healthy older person, advanced age per se does not appear to cause any clinical dysfunction. However, a host of conditions common in the elderly population will cause clinically significant swallowing deficiencies. Salivary hypofunction (see earlier) impairs swallowing times and under severe conditions increases the likelihood of aspiration. Patients with neuropathies have been reported to have oral swallow times four- to sixfold longer than those in healthy controls, and these persons may not even be able to produce the recognizable characteristics of an oral swallow. Neurovascular conditions (e.g., cerebrovascular accidents, dementia, motor neuron disease) are likely to cause dysphagia and predispose a person to the danger of aspiration. Therefore, swallowing changes in older persons are usually caused by sensory, muscular, and neurologic deterioration.

The temporomandibular joint (TMJ) is located between the glenoid fossa and the condylar process of the mandible, and exhibits a functionally unique gliding and hinge-like movement. It is of particular interest to clinicians, for it is the focus of several craniofacial pain disorders. Using radiographic and postmortem evaluations, several studies have reported that various components of this joint undergo degenerative alterations with increasing age. However, research reports confirm that TMJ functional impairment is not a "normal" age-associated event. Conversely, many oral and systemic conditions commonly seen in the elderly population are linked with temporomandibular disorders (TMD). Orofacial pain in the elderly patient may be a result of a variety of problems of the cranio-mandibular-oral complex and other extraoral diseases, making diagnosis and treatment challenging and frequently requiring a multidisciplinary approach.

In general, two types of pathology are associated with the TMJ: *articular*, related to the joint itself, and *nonarticular*, pathology occurring in structures unrelated to the joint but causing similar or referred symptomatology. Several articular abnormalities common to all joints also affect the TMJ, including trauma, ankylosis, dislocation, and arthritis. Nonarticular disorders may result from a variety of clinical entities, including trigeminal neuralgia, headache, migraine, otitis, dental-alveolar pain/infection, and masticatory myalgia. Orofacial habits (e.g., jaw clenching and tooth grinding) and poor head and neck posture can produce muscle fatigue and subsequent spasm. Moreover, psychological conditions (stress and depression) can exacerbate underlying articular and nonarticular disorders. Clinically, the patient will present with pain in many regions: TMJ, temporal, cervical, or neck region, masticatory muscles, and the oral cavity. Diagnosis is also challenging since symptoms may occur primarily in any of these sites with regular, irregular, or no pain referred to the

TMJ region. Limited jaw opening (less than 40 mm from the maxillary central incisor to the mandibular central incisor) and pain on mastication or during jaw movements may be indicative of TMD. Treatment, as with other arthritic or muscular disorders, requires the elucidation of an appropriate diagnosis and ranges from conservative and reversible regimens (anti-inflammatories, analgesics, muscle relaxants, physical therapy, oral bite splints) to more invasive procedures for unresolved painful conditions (e.g., TMJ surgery).

The National Health Interview Survey indicates that older adults report considerable amounts of orofacial and TMJ pain. The estimated prevalence rates among adults 75 years and older were 1.2% for burning mouth pain, 1.6% for face pain, 3.4% for toothache, 3.9% for jaw joint pain, and 6.2% for oral sores. While toothaches, oral sores, and jaw joint pain decreased with age, face pain was age-independent, and burning mouth pain increased with age. Interestingly, similarly aged adults are approximately five times more likely to visit a physician than a dentist in a year. This finding suggests that people may be more likely to visit a physician even for orofacial problems and/or that a considerable number of older adults may not seek stomatological treatment from dentists for their pain.

Speech production is another function subserved by the oral structures, and it undergoes some changes with increasing age, including significant alterations in activities such as tongue shape and function during specific phoneme production and frequency variability. However, among healthy older persons, these changes do not compromise or alter speech in any perceptible way. Tongue strength undergoes decreases with age, even among healthy adults, yet tongue endurance is similar between younger and older persons. There are also age-associated alterations in intraoral and maxillofacial posture. Drooping of the lower face and lips in the elderly person results not only from the loss of supporting hard tissues, but also from a diminished tone of the circumoral muscles. The latter changes may elicit esthetic concerns and can lead to embarrassment from drooling or food spills caused by the inability of an older individual to close the lips competently while eating or speaking. Often, drooling caused by reduced circumoral muscle tone can result in complaints of excess salivation.

Significant oral motor disorders also may result from a number of therapeutic drug regimens, such as the frequent association of tardive dyskinesia with phenothiazine therapy. These dyskinesias may include diminished performance and speech pathoses as well as alteration in movement (chorea, athetosis).

## SUMMARY

The health of the oral cavity and its ability to fulfill its function of communication, nutritional intake, and host protection can be

impaired in older adults. Age alone does not appear to play a strong role in the impairments. Instead, oral and systemic conditions and their treatments with drugs, chemotherapy, and radiation compromise oral health and function. This will predispose an older person to develop oral microbial infections including dental caries and periodontal diseases, pain, salivary hypofunction, altered chemosensation, dysphagia, difficulty chewing and speaking, greater risk for disseminated systemic infections, and, importantly, a diminished quality of life. All health care providers should attempt to identify older persons at risk for developing oral diseases, be able to recognize existing oral diseases, and either treat or refer patients who have stomatological disorders.

# Assessment and Rehabilitation of Older Adults with Low Vision

*Gale R. Watson*

## DEMOGRAPHICS

Many large, population-based, cross-sectional studies have documented the increase in prevalence of eye disease and visual impairment with increasing age, particularly in persons over the age of 75 years. U.S. population estimates indicate that more than 26 million people over the age of 40 years are affected with some type of visual disorder and that more than 4 million individuals in the U.S. aged 55 years or older are currently experiencing severe vision loss.

Estimates of the prevalence of visual impairment per 1000 persons in the United States demonstrate the significant increase in vision problems with age. A 2001 study estimated that 14% of persons aged 70 to 74 years have serious difficulty seeing, even with their spectacle correction, and this increases to 32% among persons aged 85 years or older. Centers for Disease Control and Prevention (CDC) and the National Centers for Health Statistics (NCHS) estimate the prevalence of severe visual impairment among persons 70 to 74 years of age at about 1% of the elderly population, but by age 85 years, nearly 2.5% of persons are severely visually impaired. After age 85 years, one in four older people cannot read a newspaper even with best-corrected vision.

Age-related visual impairment is not only challenging to the person in whom it develops, but also affects society as a whole. Medicare beneficiaries with coded diagnoses of vision loss have been shown to incur an additional \$2.14 billion in 2003 in noneye-related medical costs, incurring significantly higher costs than those with normal vision. Additional eye-related costs per patient yearly are approximately \$345 for those with moderate vision loss, \$407 for those with severe vision loss, and \$237 for those who are blind. Additional noneye-related costs per patient yearly are \$2193, \$3301, and \$4443, respectively. Prevent Blindness America, a national volunteer eye health and safety organization, puts the medical loss for

visual impairment at \$5.48 billion for persons 40 years and older. Their number includes increased medical expenditures, as well as increased informal care days. They define informal care as unpaid care provided by people not living with the older person, and valued it according to minimum wage dollars. Health utility (distress, pain, depression, lack of mobility, social limitations) was converted into quality-adjusted life years and the total lost value for this factor was \$10.5 billion. Thus, preventing vision loss among older persons is not only a medical imperative, but also an economic one.

Vision loss is reason enough for a decline in function among older persons, but vision loss has also been associated with cognitive decline, heart disease, arthritis, hypertension, falls and hip fracture, depression, reduced overall quality of life and mortality. Older visually impaired persons are twice as likely to have difficulty walking as do sighted peers, three times more likely to have difficulty getting outside, more than twice as likely to have difficulty getting in and out of a bed/chair, and three times more likely to have difficulty preparing a meal.

The most prevalent age-related causes of visual impairment in the United States are macular degeneration, diabetic retinopathy, glaucoma, and cataract. Approximately 60% of persons with visual impairments who are not institutionalized have one or more additional impairments. These include the loss of hearing, impaired mobility, decreased energy and stamina from respiratory and heart disease, and cognitive changes resulting from stroke or dementia. Vision loss has been ranked third, behind arthritis and heart disease, among the most common chronic conditions causing older persons to require assistance with activities of daily living (ADLs). Because the majority of people with visual impairments have useful vision, rehabilitation services and vision-enhancing techniques and devices offer opportunities to increase their visual and general functional capacity.

## AGING AND LOSS OF VISION

### Normal Age-Related Changes in Vision

Every older person experiences age-related changes in vision. [Table 43-1](#) summarizes the age-related changes that cause functional declines for older persons. Decreased transmission of the ocular media, increased scatter in the cornea, lens, vitreous body, and retina as well as decreased pupil size are related to anatomic changes in the aging eye. The age-related changes discussed here are those that have the greatest impact on function in daily life. These common changes in vision function must be taken into account when considering the daily living, quality of life, and the design of facilities for all older persons.

The ability to accommodate for focus on visual targets from distance to near, which is dependent on a flexible crystalline lens and the ciliary muscle, is altered with age, beginning around age 45 years. During this change, an increasing amount of plus in a concave lens (usually prescribed in bifocal lenses or reading glasses) is required to boost the focusing power of the eye to compensate for the loss in refracting ability of the lens for near tasks.

The visual acuity of normally sighted older persons shows only a modest decrease under high-contrast conditions, but reducing the

illumination of an acuity chart, reducing the contrast of the acuity chart, and/or adding surrounding glare, produces drastic age-related acuity losses, as compared to young observers. For example, in a sample of 900 older observers, for those at age 82 years, the median high-contrast visual acuity was 20/30, low-contrast high-luminance acuity was 20/55, low-contrast, low-luminance acuity was 20/120, and low-contrast acuity in glare conditions was 20/160. A young observer loses only about one line of acuity under similar conditions.

Because of anatomic changes in the eye and media, older persons are more sensitive to glare in the environment, more likely to experience disabling glare, and have reduced glare recovery time. This may have the most impact on activities such as walking outdoors or driving, but may also affect indoor activities as well, if very bright and dim environments are adjacent, such as restaurants, movie theaters, and atriums. Visual discomfort may arise because of glare, and disabling glare may hide important targets that must be viewed for the sake of safety. Glare sensitivity has been associated with motor vehicle accidents for older drivers.

Attentional visual field, the visual field area over which one can process rapidly presented visual information, declines with age. Unlike conventional measures of visual field that assess visual sensory sensitivity (such as static flashing lights), attentional visual field relies on higher-order processing skills such as selective and divided attention and rapid processing speed. Decreased attentional visual

**TABLE 43-1**

#### Normal Age-Related Changes in Vision

CHANGES	REASON	IMPLICATIONS FOR DAILY LIFE
Loss of accommodation	<ul style="list-style-type: none"> <li>• Crystalline lenses lose flexibility</li> <li>• Ciliary muscles lose tone</li> </ul>	<p>Increasing inability to focus on close targets beginning around age 45 yrs.</p> <p>Plus lenses prescribed in a bifocal, reading glasses, or contact lenses; required to compensate for loss of accommodative ability.</p>
Loss of low-contrast acuity	<ul style="list-style-type: none"> <li>• Decreased transmission of ocular media</li> <li>• Decreased pupil size</li> </ul>	Functional loss of acuity under glare or low lighting may cause small targets to be missed, bumping or tripping into low-lying objects.
Increased sensitivity to glare	<ul style="list-style-type: none"> <li>• Increased light scatter in cornea, lenses, vitreous body, and retina</li> </ul>	<p>Discomfort even in low glare conditions such as cloudy days. High glare causes decreased acuity and difficulty in seeing targets in the environment.</p> <p>Sun lenses, hats, visors, and umbrellas provide more comfort outdoors; tinted lenses may be prescribed for indoors.</p>
Increased difficulty with dark adaptation	<ul style="list-style-type: none"> <li>• Losses in ocular transmittance and pupillary miosis</li> </ul>	<p>Difficulty moving from bright to dim environments. Risk for stumbling or falling is greater under these circumstances.</p> <p>Fear of balance problems or falling may cause compensatory behaviors such as shuffling, reaching for hand-holds, etc. Change environmental lighting to avoid light/dim areas.</p>
Loss of color discrimination	<ul style="list-style-type: none"> <li>• Smaller pupil diameter, reduced light transmission through the lens, changes in photoreceptors and neural pathways</li> </ul>	Difficulty detecting differences in dark colors and pastels; adding lamps or identifying matching colors near a sunny window helps.
Loss of attentional visual field	<ul style="list-style-type: none"> <li>• Decline of higher order visual processes such as selective and divided attention and rapid processing speed</li> </ul>	Risk factor for balance and mobility problems and vehicle crashes in driving. Training improves performance.
Increased difficulty with visual reading ability	<ul style="list-style-type: none"> <li>• Related to attentional visual field and low contrast acuity and slower saccadic performance in eye movements.</li> </ul>	Reading speed of older readers reduced by one-third that of younger readers; text navigation skills decline with age. Training improves performance.

field has been correlated to a greater incidence of driving accidents and is related to a greater risk for balance and mobility problems for normally sighted older persons. Attentional visual field can be improved with training, but such training is not widely available.

Visual reading ability decreases with age as well. The reading rate of older persons who are normally sighted and have good high-contrast visual acuity decreases by as much as a third of that of young readers. Accuracy of reading, however, can remain comparable to that of younger readers. Reading performance among older persons with good acuity (20/30) is highly correlated with attentional visual field; those with good reading performance into very old age also retain good attentional fields as well. Low-contrast visual acuity is also correlated with reading performance for this population; older persons with poor low-contrast acuity tend to read more slowly. Even when high-contrast acuity is good, older persons, especially the oldest old, are at risk for reading difficulties that may arise from a combination of reduced attentional visual field, slower saccadic performance in eye movements, and poor low-contrast visual acuity. Reading rate for normally sighted older adults with good high-contrast acuity and good comprehension skills can be improved with training. Training in reading efficiency that emphasizes improvements in eye movements for reading similar to those exercises used to improve reading for school children has given good results for this population. Such training, however, is not widely available.

Color discrimination is another aspect of vision that declines with advancing age. Persons who are older have greater difficulty detecting differences between dark colors such as brown, black, or navy, and also have difficulty with pastels. Loss of color vision in old age is related to smaller pupil diameter, reduced light transmission through the lens, and changes in photoreceptors and neural pathways.

Dark adaptation declines as a result of losses in ocular transmittance and pupillary miosis resulting from the aging process. Difficulty with dark adaptation can be limiting to older adults moving from light to dim environments and vice versa. The risk for stumbling or falling may be greater under these circumstances. The normally sighted older person may function as if severely visually impaired when first adjusted to a drastic change in illumination.

Although not related to a change in vision per se, care must be taken in providing refractive correction in spectacle form for geriatric patients. Multifocal spectacle lenses either in the form of bifocals or varifocals are commonly prescribed but are associated with a higher risk of “edge of step” accidents, and multifocal lens wearers are twice as likely to fall as single focus lens wearers. A large percentage of these falls are reported to occur outside the home, perhaps as a result of tripping or stumbling resulting from obstacles not seen in the near vision correction of the lower visual field. The bifocal portion of a spectacle correction provides additional dioptric power to provide vision at near distance for reading, etc. This means that objects outside this near-focal range such as steps, curbs, stairs, house cats, etc. are blurred and indistinct. This effect is greatest in older patients, as the need for extra dioptric power for near vision increases with age. Patients with multifocal correction are encouraged to tuck their chins and look over the top of the bifocal correction when moving so that they can look through the distance correction in the upper portion of the lenses, but head flexion significantly increases postural instability. Encouraging those who are at risk for falling to explore these issues with their eye care specialists can be an important aspect of falls prevention.

## PREVALENT AGE-RELATED CAUSES OF VISUAL IMPAIRMENT

### Age-Related Macular Degeneration

Functional vision loss because of age-related macular degeneration may include metamorphopsia (visual images appear distorted and wavy), relative scotomas, and result in dense central scotomas for those whose pathology progresses to visual impairment. Individuals with central scotoma usually develop a strongly preferred retinal locus (PRL) that performs as the primary fixation reference, although the patient may not always be aware that there is a scotoma present. The loss of central visual field results in loss of visual acuity and contrast sensitivity. The ability to use the PRL that develops for fixation may be difficult for many persons. The effects of macular degeneration on daily life include difficulty with reading print, inability to recognize faces (that can lead to reluctance to participate in social activities), difficulty with distance and depth cues (that adversely affect safe mobility), and loss of color and contrast sensitivity (that interfere with a variety of household and work/leisure tasks) (Table 43-2).

### Diabetic Retinopathy

The progression of diabetic retinopathy includes macular edema that may cause blurred vision if the fovea is involved, retinal hemorrhages (and/or laser treatments), which may result in scattered central, peripheral, and/or midperipheral scotomas, and retinal detachment, which can cause larger areas of field loss if not reattached. Diabetic retinopathy can progress to total blindness. Loss of function can include decreased visual acuity, scattered field loss over the retina, metamorphopsia across the retina, increased sensitivity to glare, and loss of color and contrast sensitivity. If the fovea is lost to scotoma, then a PRL will develop. Vision fluctuations can be manifested over time as macular swelling increases or subsides, and can also be related to hemorrhage. Sudden vision loss is common following hemorrhage, with the patient describing episodes of smoky vision, a dropped veil over the eye(s), or seeing black or red strings across the field of view. Treatment and absorption of blood can improve acuity, though not usually to normal levels. The effects on daily life include difficulty reading print materials, difficulty recognizing faces, increased sensitivity to glare and light/dark adaptation, difficulty with distance and depth cues, loss of color and contrast sensitivity, and fluctuating vision.

### Cataract

Age-related cataract is manifested by gradual opacity of the lens, which interferes with the passage of light, causing reduced visual acuity, light scatter, sensitivity to glare, altered color perception, and image distortion (straight lines appear wavy). Persons with cataracts may experience trouble with glare and loss of contrast, may have decreased acuity, and report areas of metamorphopsia or small scotomas in the visual field. When the cataract has begun to interfere with lifestyle, surgery may be performed to remove either the entire lens or the posterior portion. Correction for the removal of the lens

**TABLE 43-2****Age-Related Causes of Visual Impairment**

CONDITION	COMMON CLINICAL PRESENTATION	IMPLICATIONS FOR REHABILITATION
Macular degeneration	<ul style="list-style-type: none"> <li>• Reduced visual acuity</li> <li>• Loss of central visual field and contrast sensitivity</li> </ul>	Difficulty with tasks requiring fine detail vision such as reading, inability to recognize faces, distortion or disappearance of the visual field straight ahead, loss of color and contrast perception, mobility difficulties related to loss of depth and contrast cues.
Diabetic retinopathy	<ul style="list-style-type: none"> <li>• Reduced visual acuity</li> <li>• Scattered central scotomas</li> <li>• Peripheral and midperipheral scotomas</li> <li>• Macular edema</li> </ul>	Difficulty with tasks requiring fine detail vision such as reading, distorted central vision, fluctuating vision, loss of color perception, mobility problems because of loss of depth and contrast cues.
Cataract	<ul style="list-style-type: none"> <li>• Reduced visual acuity</li> <li>• Light scatter</li> <li>• Sensitivity to glare</li> <li>• Altered color perception</li> <li>• Loss of contrast sensitivity</li> <li>• Image distortion</li> <li>• Possible myopia</li> </ul>	Usually remedied by lens extraction and implant, except in extreme cases. If not managed by implant, difficulty with detail vision, difficulty with bright and changing light, color perception, decreased contrast perception, some mobility problems caused by loss of perception of depth and distance, sensitivity to glare, and loss of contrast.
Glaucoma	<ul style="list-style-type: none"> <li>• Degeneration of optic disk</li> <li>• Loss of peripheral visual fields</li> </ul>	Mobility and reading problems because of restricted visual fields, people suddenly appearing in the visual field seen as “jack in the box.”
Traumatic Brain Injury	<ul style="list-style-type: none"> <li>• Loss of hemi/quadrant visual field, or paracentral scotoma</li> <li>• Possible visual neglect</li> <li>• Visual perceptual difficulties</li> <li>• Visual agnosia</li> </ul>	Mobility and reading problems owing to visual field loss and spatial perceptual difficulties that reduce ability to drive, reach correctly, and execute eye movements related to reading, difficulty with visual and cognitive processing. Visual neglect may include inability to complete shaving and/or dressing. Difficulty completing other rehabilitation assessments and interventions because of neglected visual impairment.

is provided through intraocular lens implants, eyeglasses, or contact lenses. Cataract surgery is the most common major surgical procedure done for persons older than age 65 years who are receiving Medicare. Cataract surgery with lens implantation is associated with improved objective and subjective measures of function in ADL, as well as improved levels of vision to normal acuity in most cases.

### Glaucoma

Glaucoma is an increase in intraocular pressure caused by an abnormality in flow of aqueous fluid from the anterior chamber. It can cause a degeneration of the optic disk, loss of visual fields, and severe visual impairment. When left untreated, or if treatment is not successful, glaucoma results in a loss of peripheral fields and can lead to blindness. The effect of peripheral field loss on daily life is most problematic in safe ambulation. Because of field restrictions, the patients may not see objects in their path and may bump into objects that fall outside the field of view in any direction (street signs, tree branches, etc.). In addition, a person outside the patient's field of view may suddenly be seen as a “jack-in-the-box” and create a startle effect. Peripheral field loss may also create problems in reading and writing as only a small portion of the page can be seen at once.

### Traumatic Brain Injury

Head injury to older adults such as cerebrovascular accident, falls, or automobile accidents resulting in traumatic brain injury can lead to visual impairment. Between 20% and 40% of stroke results in visual disorder that can inhibit cognitive functioning and may reduce the effectiveness of rehabilitation of traumatic brain injury. Visual field disorders can result from injury to the visual pathway anyway between the retina and the striate cortex. The optic chi-

asm is used as an anatomical landmark to differentiate between the peripheral (prechiasmatic) and the central (postchiasmatic) visual pathway. Unilateral injury to the prechiasmatic pathway affects the ipsilesional field only, but postchiasmatic injury causes visual deficits in both monocular hemifields and are referred to as homonymous. Visual field disorders must be discerned by visual field measurement techniques called perimetry; patients are often unaware of them and do not report the defect, but may suffer from their effects, for example, bumping into objects, tripping, falling, being unable to read, etc. Vision can be completely lost in the missing field, or some vision function (for example, light detection) may remain. The most common visual field losses are hemianopsia (loss of half the visual field), followed by quadrantanopsia (loss of one quadrant) and paracentral scotoma (island of vision loss in the parafoveal region), and rarely results in central scotoma. Recovery of some visual field following injury may be spontaneous, and some patients learn spontaneously to adapt to visual field loss by oculomotor strategies; shifting gaze may reveal what is missing in the field of view of a street scene (such as an oncoming car) or the missing portion of a line of text. Systematic training in oculomotor adaptation and visual perceptual training can improve vision function and has limited ability to improve the visual field. Visual field loss may also be accompanied by visual neglect. Older adults with neglect may not spontaneously be able to attend to the neglected side. Traumatic Brain Injury (TBI) may also result in disorders of visual space perception, which affect reach (over- or underreaching for objects, knocking things over), driving (accidents resulting from inability to judge distance and depth), and reading (inability to plan and execute accurate eye movements). Visuospatial localization and orientation may be improved through training, but may not reach pre-TBI thresholds. Visual agnosia, a failure to visually recognize an object because of “mistaken identity,” is a disorder that is based in both visual-perceptual and visual-cognitive functions.

Typically, misidentifications result from the incomplete or inappropriate use of object features such as size, shape, or color. Older adults with TBI may be unaware that they are ignoring other features that might assist with correct identification. Cognitive and/or communication disorders can make visual impairment more difficult to detect following TBI. Undetected or untreated visual impairment in TBI can limit the effectiveness of other rehabilitation (e.g., many cognitive and functional assessments use visual items that cannot be appropriately identified by older persons with TBI-related vision loss, visual motor assessments require eye–hand coordination). If TBI vision loss is not detected and treated to the extent possible, the examiner or therapist may get a false-negative impression of the level of TBI disability. In addition, the TBI patient will be frustrated and troubled unduly by participating in rehabilitation that does not simultaneously address the vision deficit.

## ROLE OF THE GERIATRICIAN IN VISION REHABILITATION

After diagnosis and medical management of the patient's vision loss by an ophthalmologist, the geriatrician can play an important role in assuring that visually impaired persons receive rehabilitation services that are of high quality, are sought in a timely manner, and provide all the benefit that the patient might be able to derive from them.

A geriatrician can provide the following services for their patients related to vision rehabilitation:

1. A visual acuity evaluation. Current best practice includes the use of a logarithmic visual acuity chart.
2. A contrast sensitivity function evaluation. The Pelli–Robson chart is recommended for its ease of use and reliability.
3. A referral to a low-vision eye care specialist (ophthalmologist or optometrist) for the appropriate clinical low-vision evaluation and prescription of optical low vision devices for tasks the older person can no longer perform such as reading, writing, watching television, and recognizing street signs.
4. A referral to vision rehabilitation professionals for assessment and instruction of vision and magnification devices for literacy, ADLs, and safe travel. These therapists can also provide environmental analyses and teach the use of environmental cues.
5. Assistance to patients in preparing for rehabilitation by providing information and encouraging them to consider the goals they would like to achieve. The National Eye Institute: Visual Functioning Questionnaire-14 is a modified 14-item questionnaire that is effective in assessing the impact of vision loss on quality of life and is helpful in assisting patients in setting goals for rehabilitation.
6. Counseling or referral for coping with psychosocial issues related to visual impairment. Patients may not be forthcoming about these issues, so the physician must ask. Adjustment disorder and depression are associated with visual impairment for older persons. When patients are dealing with loss of independence and control, lowered self-esteem and strained social relations, counseling and/or psychotherapy may be recommended for both patients and family members.
7. Reinforcement of simple strategies, such as the use of saturated colors and contrast in the home environment, and the use of

simple devices, such as sun lenses outdoors and brighter indoor environments.

8. Information to the patient and family about the variable nature of low vision, its effect on daily life tasks, and the variable nature of visual abilities according to fluctuations of light and contrast.
9. Sponsorship of, or referral to, support groups where older persons with vision loss and their families can discuss problems, coping, and rehabilitation strategies they have learned with other patients.
10. Assistance in community awareness efforts about the prevalence, treatment, and rehabilitation of visual impairment among older persons.

Patients likely to benefit from vision rehabilitation include those with reduced acuity of less than 20/50 in the better-seeing eye, central or peripheral field loss with intact visual acuity, reduced contrast sensitivity, glare sensitivity, and/or light/dark adaptation difficulties as well as those with traumatic brain injury. Candidates for cataract surgery with macular disease might also benefit from preoperative low-vision assessment and coincident rehabilitation training that enhances postoperative visual performance and satisfaction with a cataract procedure.

## ADAPTATIONS OF CLINICAL AND FUNCTIONAL EVALUATIONS FOR OLDER ADULTS

The clinical and functional low-vision examinations for older persons should distinguish aging from treatable disease processes; focus holistically; be multidisciplinary and incorporate family and caregiver support; and identify and set realistic goals to improve functional status and quality of life.

In health care service, delivery to older adults with low vision, certain aspects of the examination sequence is adapted to accommodate these principles.

### Case History Interview

Because most age-related visual impairments result in a central scotoma, most patient complaints will be related to the loss of acuity, loss of central visual field, and resultant decrease in contrast sensitivity and color sensitivity. Patient goals for rehabilitation will usually include reading, writing, ADLs such as meal preparation and household maintenance, management of glare and other illumination concerns, leisure activities, and safe independent movement and travel. If older persons also have specific health-related activities that require the use of vision (e.g. loading a syringe with insulin, changing an ostomy bag), these will be goals as well.

This information may be taken by a preexamination telephone interview to lessen the amount of time a first visit might require. Because low-vision rehabilitation requires a great deal of energy and motivation from the patient, it will be guided by their personal goals for rehabilitation and by those tasks that are difficult or impossible to perform because of low vision. In this regard, the intake interviewer may find that some education is necessary in order to set reasonable goals for low-vision treatment. Because most low-vision interventions are “task-specific,” it is important to state treatment goals as specifically as possible.

Because of the nature of the older person's vision loss, professionals should become familiar with some of the courtesies and accessibility issues that assist in providing quality health care. Unless there is a problem with the person's hearing, always speak directly to the older adult with visual impairment. Allow the older adult to take your arm when moving from place to place in the environment, and use appropriate sighted guide techniques. If you are guiding a person with visual impairment on your arm, you are responsible for assuring that the path you are taking is wide enough to accommodate both of you. If the path is not wide enough (e.g. a crowded hallway), ask the person to step behind you, while still holding your arm with his other hand when walking. Say your name when first coming into the room, and tell the older adult when you are leaving the room. Do not leave the older adult with low vision standing alone in a hallway or room without a wall or furniture near to touch for orientation and balance. Avoid using directional cues that are visual in nature such as pointing or giving directional references that are unclear to those with low vision. For example, instead of saying, "take that chair over there," say, "take the red chair against the white wall to your immediate right."

### Clinical Low-Vision Evaluation

The low-vision eye care specialist (who may be an ophthalmologist or an optometrist) must be flexible and adaptable to a variety of different environments, schedules, and communication styles. The conventional pattern of the low-vision examination will be followed including distance and near acuities; internal and external ocular health examination; retinoscopy; tonometry and slit-lamp biomicroscopy; ophthalmoscopy; ophthalmometry; determination of central and peripheral fields; color vision and contrast-sensitivity testing; glare testing; and near and distance testing of vision-enhancing devices, including optical, electronic, and nonoptical devices. For many older adults, especially those in long-term care facilities, a careful refraction and updating conventional spectacles may provide significant improvement in vision. Table 43-3 summarizes the aspects of the clinical low-vision examination.

Because of the nature of medical and long-term care service delivery to older adults, it is often necessary to take the low-vision

examination and therapeutic intervention out of the office or clinical setting. There is a growing trend of providing low-vision services as a part of outpatient hospital care, comprehensive outpatient rehabilitation facilities, and long-term care facilities, such as nursing homes and private homes of older adults.

### Nursing Homes

Despite the fact that an estimated 26% of persons in nursing homes have visual impairment, few nursing home residents receive low-vision care. For example, one study estimated only 25% of visually impaired patients at a long-term care facility who were in need of vision rehabilitation were referred by their attending ophthalmologists. Another study found that there was no difference in the referral rate for vision services for nursing home residents between those who complained about their vision and those who did not. Another study found that only 11% of all residents in 19 nursing homes had received eye examinations in the last 2 years. Providing information about vision and vision impairment to the nursing home staff is important for assisting residents in using their remaining vision effectively. Because stroke is another common medical condition requiring rehabilitation for older adults, it is important that the low-vision team work closely with those professionals who diagnose, treat, and rehabilitate older adults who have experienced cerebrovascular accident. A curriculum in low vision for in-service training for long-term care staff has been developed and is effective in increasing staff knowledge and positive outcomes for patients.

### Hospital Settings

Low-vision care is routinely provided to older veterans in the hospital system of the Veterans Health Administration. In the Blind Rehabilitation Centers, the veteran who is legally blind is seen for up to 10 weeks of rehabilitation, including low vision rehabilitation. Preliminary results from a national outcomes study indicate positive outcomes and veteran satisfaction from these programs. The Veterans Health Administration (VHA) also provides low-vision services to veterans who have low vision but who are not legally blind. Recently, the VHA has expanded low-vision services and provided an additional \$40 million in funding for clinical vision rehabilitation services closer to veterans' homes. Outcome studies of all VA vision rehabilitation services indicate that veterans who are provided low-vision services regain their ability to perform independent activities of daily living (IADLs) independently and become active community participants. Hospitals in the private sector are increasing services to older persons as a part of outpatient services, and low-vision rehabilitation is often provided.

### Community Service Agency Settings

The Older Americans Act mandates the provision of supportive community resources for older adults. Some examples of community agency settings include senior centers, nutrition centers, senior clubs, adult daycare centers, and senior rehabilitation centers. These services may be contacted through the local telephone book yellow pages. For example, in Atlanta, the services are clustered in the BellSouth Yellow Pages under the heading, "Senior Services." The explanation of the local county services contracts is provided and a

**TABLE 43-3**

contact number for each county is listed. Low-vision services might be provided onsite at these community service settings because of the prevalence of visual impairment among older adults.

### Private Home Settings

Approximately 70% of the older population requiring long-term care reside in the community. Senior residential retirement centers have increased in number. Most frail older persons requiring care are living at home with family members, and not in long-term care facilities. Interactions with family members and caregivers become very important in these situations. It is crucial that family members and caregivers understand the sometimes contradictory nature of visual impairment; for example, visual performance varies widely under different levels of illumination and can decline if the older person is fatigued. Comorbid conditions such as dementia, mobility impairment, depression, etc. can affect how the older person uses vision or interprets visual images. Understanding the interaction of these factors will help the family in supporting the older adult achieve their goals for vision rehabilitation.

### Functional Visual Assessment

Whenever possible, the functional assessment should take place in the older adult's daily environment. Specific goals stated by the older adult will guide the functional assessment to discover what visual target size, target distance, and visual skills are required to achieve that goal. For example, if the patient's goal is to read the newspaper again, the target size requires approximately 20/40 or better visual acuity with magnification, the target distance will be determined by the magnification device, and the visual skills required are precise fixation and saccades while maintaining the focal distance of the magnification device. The functional assessment can also uncover the need to address other goals, the need for environmental assessment and modification, and provide ongoing opportunities to educate the older adult and their significant others about vision and rehabilitation. Table 43-4 presents the key aspects of the functional vision assessment.

The functional low-vision assessment may be completed by a wide variety of rehabilitation professionals. Traditionally, the functional low-vision assessment of older persons has been provided by a low-vision therapist, a rehabilitation teacher for the visually impaired, an orientation and mobility specialist, or some other professional from the field of visual impairment. Now, as low vision is increasingly a part of hospital services and comprehensive outpatient rehabilitation facilities, the functional assessment may be provided by a rehabilitation nurse, an occupational therapist, or some other rehabilitation professional who has received specialized training in low vision.

Regardless of the background of the rehabilitation professionals, they should be well versed and experienced in basic optics of the eye, lenses and low-vision devices, methods of observation and evaluation of visual skills for all ADLs, the causes and functional implications of visual impairments, basic techniques of sighted guide and orientation and mobility, assessment of reading, assessment of the environment, and basic techniques of assessing and using technology such as low-vision devices (e.g., magnifiers, spectacles, monoculars) and electronic devices (e.g., Braille writer, Kurzweil reader, closed-circuit television system [CCTV]). The rehabilitation professional providing the evaluation may also be the rehabilitation therapist,

**TABLE 43-4**

#### Key Aspects of the Functional Visual Assessment

Functional visual acuities	Distance and lighting required for discriminating detail of objects in the environment
Functional visual fields	Ability to perceive objects in the environment in central and peripheral quadrants of the visual field at near and distance
Color/contrast discrimination	Ability to detect objects, their color, and contrast with the background at varying distances
Ocular motor skills	Ability to maintain fixation and move the eyes/head/body to fixate, scan, track, and localize targets in the environment
Visual perceptual skills	Ability to make sense of what is seen; recognize critical features, perceive part-to-whole relationships, figure-ground, etc.
Lighting	Analysis of the usefulness of environmental lighting; need for illumination and control
Use of visual and nonvisual cues	Availability and use of visual and nonvisual cues in the environment for task performance
Performance of activities of daily living and instrumental activities of daily living that are affected by vision	Observe for ability to perform, ease and speed of performance, comfort and stress level, safety

in which case they must be familiar with techniques of instructing visual-motor skills for all ADLs and IADL with and without low-vision and electronic devices, task analysis, teaching basic orientation and mobility, and teaching basic techniques of reading and writing with low-vision devices. The professional must also be familiar with tools and techniques that do not require the use of vision in order to assist the older person with low vision in developing other mechanisms for performance when using vision is not the safest or most efficient mechanism (e.g., slate and stylus that are used for writing Braille). This rehabilitation professional will work closely with the eye care specialist providing the clinical low-vision examination, and the low-vision team may also include a counseling professional and any other professionals who are providing care associated with the use of vision. Because many older persons are at risk for multiple impairments, this team may also include other physicians, such as a geriatrician or physiatrist, orthopedist, speech, physical, respiratory, and recreational therapists, other nurses, and technicians.

## MANAGEMENT OF LOW VISION

### Developing a Vision Rehabilitation Plan

The clinical low-vision examination and functional visual assessment culminates in a vision *rehabilitation plan* that summarizes the information obtained in the evaluations into clearly stated goals and objectives. If Medicare is funding the low-vision services, the plan will follow that format and requirements. In many cases, family members also may be involved. The implementation of the vision

rehabilitation plan should emphasize a process using the principles of andragogy, or adult learning, that incorporate the older person's values, beliefs, attitudes, and life experiences.

Following the clinical examination and functional assessment, the low-vision team will recommend low-vision devices (including optical, electronic, nonoptical, and environmental modifications) that will be evaluated to assess their usefulness to the older adult. There should be additional focus on the rehabilitation program and its adaptation for older individuals. Successful use of low-vision devices is related to the intensity of the instructional program. Research shows that specialized therapy in the use of visual skills and low-vision devices improves the abilities of low-vision individuals who are older to a greater extent than do the services provided by eye care specialists alone.

### Instruction and Guided Practice Using Remaining Vision and Low-Vision Devices

Working with a low-vision therapist will provide an opportunity for the older adult to develop the appropriate visual skills, as well as learn the benefits, limitations, and uses of low-vision devices, and apply principles of color, illumination, and contrast that make the environment as conducive as possible to the use of remaining vision. It is important to assist caregivers in understanding how remaining vision and low-vision devices aid the older adult in accomplishing visual tasks. Family members and caregivers can provide important social support in this regard, but must understand the process in order to be most helpful. In a study of visually impaired older veterans, a supportive caregiver was the most strongly correlated variable to continued use of low-vision devices 1 to 2 years after they were prescribed. If at all possible, low-vision devices should be loaned for use in the daily environment before they are prescribed to assure that they are useful.

Some aspects of instructing the use of vision and devices are particularly important when working with older persons with low vision. Because of the potentially devastating consequences of falling, the low-vision therapist must be certain to address safety issues related to using low-vision devices that will prevent falls. Nausea, dizziness, and other aspects of motion sickness are common side effects of using magnification, and reducing these effects is an important aspect of instruction. Monoculars and binoculars should be used as spotting devices only, and older adults must never attempt to walk while viewing through them. If the older person's goal is watching television or spectator sports, binoculars that are spectacle-mounted may be provided and the older person will use them only while seated.

Another factor to be explored in the use of low-vision devices for older adults is hand tremor. Hand tremor may be severe enough that handheld magnifiers or telescopes are not useful. The low-vision team may want to explore spectacle-mounted devices to avoid the difficulty of maintaining focus if hand tremor is problematic.

Postural support and ergonomic considerations are an important aspect to using devices for persons who are older. Because of the prevalence of back and neck pain, as well as limited stamina, it is important that the therapist be able to keep the older person as comfortable as possible. The low-vision therapist will evaluate and teach the use of appropriate ergonomic devices such as the appropriate chair and table, lumbar and cervical support, footstool, lamps, and reading stands.

Cognitive decline may limit the usefulness of low-vision devices for independent functioning; however, an additional goal can be added for rehabilitation—reducing caregiver burden. Assuring that vision rehabilitation includes ergonomic solutions for safe functioning by providing good lighting for ambulation and other visual tasks, judicious use of bold color and contrast for cuing activity and movement and use of simple devices for common activities (e.g., watching television, reading, getting a snack from the refrigerator).

Finally, illumination is an important aspect of the instruction. Most older persons need more light, but some may be extremely sensitive to light. An evaluation of a variety of lamps and overhead lighting situations is necessary, with the use of illumination controls that are individually recommended such as filters, absorptive lenses, hats with brims and pinhole glasses.

### Low-Vision Devices

Low-vision devices are optical devices, electronic devices, lighting devices, ergonomic devices, and other tools that enhance the use of vision. Some devices, such as those optical devices that incorporate refractive correction, require special prescription. Others are more simple and straightforward in their assessment and recommendation, such as lamps, reading stands, or large-print books. During the clinical evaluation and functional assessment, the low-vision team will discover whether magnification, minification, or other nonoptical devices (such as large print books, lamps, reading stands, etc.) will be useful for enhancing the vision. [Table 43-5](#) summarizes the types of devices available and their uses. Devices are prescribed based on the goals of the older person and most persons require instruction and practice in their use.

Magnification devices may be categorized as four types: relative distance, relative size, angular, and electronic. Relative distance magnification is provided by bringing the device to be viewed closer to the eyes. Often older adults who want to recognize someone will move more closely to the face they want to see, exhibiting this type of magnification. Spectacle-mounted magnifiers focus the target image, such as print for reading, at ranges closer than the older eye can accommodate, and allow very close distances to be maintained. These lenses must be prescribed by an eye care specialist experienced in low vision in order to incorporate the refractive correction of the older person when required. Typically, these devices require a close focal distance and a short depth of focus. Depending on the power and focal distance, they can be used for near tasks such as reading, writing, and viewing photographs.

Magnification may also be provided by stand or handheld magnifiers, which are often more familiar to older adults who may have used them previously for maps or coins. These devices do not require a close eye-to-lens distance, but the closer to the eye the lens is held, the wider the field of view. Some are available with built-in illumination, which overcomes the problem of illuminating the target the older adult is viewing. Handheld magnifiers require a steady hand to maintain focus and may be fatiguing to use for long periods. Older adults who use stand magnifiers must wear their bifocal correction for visual accommodation, as the lens is set slightly inside the true focal distance of the lens in order to provide a better optical image at the periphery of the lens.

Relative size magnification is used whenever a target to be viewed is made physically larger. Examples of this are phone dials with enlarged numbers or large print in magazines and newspapers.

**TABLE 43-5****Low-Vision Devices**

<b>OPTICAL/ELECTRONIC DEVICES</b>	<b>TYPICAL USE</b>
Stand or handheld magnifiers	Short-term reading or writing tasks such as checking a price tag or recipe, signing a check
Spectacle-mounted magnifiers	Long-term reading such as newspaper; used for writing in low powers
Handheld monoculars or binoculars	Traffic or street signs, spectator events
Spectacle-mounted monocular or binocular telescope	Television viewing, spectator events, possible driving Short-focus telescope can be used for cards, reading music, games, woodworking, etc.
Closed-circuit television system	Reading, writing, independent activities of daily living, with distance camera, can be used like a telescope
Field-expansion devices: • Reverse telescope • Field-expansion prisms • Hemianopic mirrors	Field expansion for ambulating or obstacle detection, identification, and/or avoidance  Best with normal or near-normal acuity
<b>NONOPTICAL DEVICES</b>	<b>TYPICAL USE</b>
Lamps	Provide brighter illumination, primarily used as task lighting
Illumination control devices	Control glare, may increase contrast: sun lenses, hats, visors, colored filters
Handwriting implements	Felt-tip pens, bold-line paper, check- and letter-writing stencils, allow user to stay on line and write legibly
Posture and focal distance support	Upright reading stand, footstool, chair with arms and high back Cervical and lumbar support: provide comfort and allow user to read or write for a longer period
Large print	Large-print books and news, large phone dials, etc., to enhance visibility
Color/contrast aids	Brightly colored tape/paint for marking dials, edge of steps, etc., to enhance visibility and safety

Environments such as older adult high-rise apartments or condominiums and planned communities may also use enlarged signage, another example of relative size magnification.

Telescopic devices provide angular magnification by the use of a positive and negative lens in housing (galilean) or by the use of two positive lenses with an erecting prism (keplerian). Older adults may have used monoculars or binoculars in the past for sporting or other events, and may have developed basic skills in their use. Older adults use telescopic devices for identifying targets that are further away, such as street signs or television. The telescope may be handheld or may be mounted into spectacles for hands-free viewing. Mounted short-focus telescopes may be used for tasks that are closer, such as reading music from a stand or identifying cards on a table. Some older adults with visual impairment who meet visual

and driving requirements may use miniature mounted telescopes for driving.

The CCTV is an example of electronic magnification. The CCTV provides a camera to focus on the visual task and the older adult sees the image projected onto a monitor. The visual task may be reading and writing from a desktop or the camera may be positioned for visual tasks at a greater distance such as seeing the minister and choir at church. The advantages of the CCTV include more magnification than any other device, a wider field of view, and contrast enhancement via reversed polarity. CCTV offers a mechanism for the development of new technologies such as miniaturization, head-worn devices, and contrast enhancement.

A variety of software and hardware packages have been developed that produce enlarged print as well as speech-out on a computer. Computer use in conjunction with CCTV can use multiple cameras to provide split-screen images for designing a workstation that simultaneously accesses computer, print viewing, word processing, and distance viewing.

Expanded field devices are helpful to older adults who maintain normal or near-normal acuity while experiencing decreased field of view, such as that caused by glaucoma or hemianopsias. Expanded field devices provide the ability to find targets by increasing the perceived view of a scene. For example, an older adult with restricted fields wishes to find the arriving and departing flight monitors in an airport. By using a field-expansion device, these monitors can be more easily located and the user then moves closer to them in order to read the information without the device. A reverse telescope functions similar to a peephole in a door, but with better optics. Another type of field-expanding device minifies in the horizontal meridian only. The visual field may also be expanded by the use of base-out prisms incorporated into spectacles. The base-out prism shifts the image in, allowing a small eye movement to see the expanded field. Small mirrors attached to spectacles may also be used for field expansion.

Nonoptical devices that enhance the use of vision may also enhance the use of optical and electronic devices. Illumination controls in the form of lamps, filters, absorptive sun lenses, and environmental lighting are of vital importance to visual functioning for older adults. Setting up kitchen and living room “workstations” for visual activities that include ergonomic considerations enhances the use of vision and all devices. Simple devices that use large features, large print, and the judicious use of bold color and contrast can enhance the vision and independence of older adults.

### Instruction in the Use of Low-Vision Devices

A sequence of instructional procedures covers several areas:

- Use of visual skills without low-vision devices
- Use of visual skills with low-vision devices
- Use of vision and low-vision devices for individualized functional tasks that lead to the accomplishment of defined goals.

Instruction in the use of visual skills without devices covers fixation, spotting, localization, scanning, tracing, and tracking. Individuals with maculopathy (such as age-related macular degeneration or diabetic retinopathy) may require additional instruction in the development and maintenance of visual skills using the PRL.

Instruction in the use of visual skills with low-vision devices includes integrating unaided visual abilities with the unique demands

of a low-vision device such as maintaining the focal distance or focusing the device, and adjusting eye and head movements to compensate for a restricted field of view through the lens. If the individual is using eccentric viewing (the use of a PRL other than the fovea), the instructor assures that the device selected allows the opportunity to maximize field and acuity in the eccentric position.

### Reading and Writing with Low-Vision Devices

Reading is a task that is so fundamental to our society and so disrupted by age-related visual impairment that it is the primary goal for vision rehabilitation among older adults. Readers with low vision can develop visual skills that are well-adapted to reading if they receive appropriate intervention. Most readers develop a strongly PRL following the onset of central scotoma. The PRL is an area that will take over the function of fixation in an eccentric, nondamaged area of the retina. The reader may require instruction and practice in using the PRL for reading, especially because of the demands of using magnification to compensate for acuity loss. A Swedish study found that 71% of older adults with low vision could read the newspaper following rehabilitation, although at a 3-year follow-up that number had dropped to 48%. However, the number of fluent readers (70 words per minute or better) had increased from 41% to 48% over the 3-year period. These results indicate that those older adults with vision loss who persevere with rehabilitation strategies are able to continue improving their skills over time. In another study, persons with macular loss who had a PRL below the scotoma exhibited faster reading rates, and the size of the atrophic area in the macula was the predominant limiting factor in reading; the larger the atrophy, the lower the reading rate. Reading rate is also related to visual span (number of characters available in the field of view) and the reserves of acuity and contrast sensitivity provided by the visual system and low-vision device. Accuracy of word identification and comprehension of reading, however, can remain near normal for readers with macular loss despite their slow rates. Readers with low vision often supplement visual reading with speech output devices such as spoken computer programs and books on audiotape.

Older adults with low vision can write effectively using a combination of magnification devices, lighting devices, stencils (templates for checks, envelopes, letters, etc. that assure that writing is spatially correct), and pens that provide more visibility.

## ENVIRONMENTS FOR OLDER PERSONS

The onset of visual impairment for older adults can make even the most familiar environment seem strange and hazardous. It is important that older adults be oriented to familiar and unfamiliar environments, and that the environment be as “user-friendly” as possible to increase independence and safety. There are a variety of rehabilitation techniques that assist in accomplishing this task. [Table 43-6](#) presents the basic strategies.

### Improving the Lighting

Most older persons require two to three times more light than do younger persons for the same tasks, but those with cloudy media (cataract, keratoconus, vitreous floaters, etc.) are more sensitive to glare. The challenge is to get enough light without creating glare,

**TABLE 43-6**

### Ways to Make an Environment More Visually Accessible

Change the real or perceived size of objects to be viewed	<p>For loss of detailed vision:</p> <ul style="list-style-type: none"> <li>• Increase size (large print)</li> <li>• Move closer (move chair closer to the television)</li> <li>• Use magnification</li> </ul> <p>For loss of peripheral fields with normal acuity:</p> <ul style="list-style-type: none"> <li>• Minify image (reverse telescope)</li> <li>• Move further away</li> <li>• Use field-enhancement devices such as mirrors</li> </ul>
Improve lighting	Use appropriate environmental lighting to decrease glare and increase overall light level; use illumination controls such as sunlenses, hats with brims, visors, colored filters; use task lighting such as flex-arm lamps
Increase contrast between objects and background	Eliminate busy background patterns, mark down steps with contrasting color on risers; increase contrast between furniture, china, and background
Use bright, clear colors	Mark light switches, dials, etc. with colored tape; use large areas of bright color for discrimination of objects
Organize the environment for ease and safety	Doors completely open or closed, chairs under table when not in use, furniture against the wall, organize clothing for color and function, etc.
Consider alternative strategies that do not use vision	Use of other senses for task performance, such as audiotaped reading materials, use of long cane for safe travel, olfactory cues for doneness of food, etc.

which can be disabling. For example, the glare from a sunny window onto a waxed floor, tabletops, and glass could cause objects in the dining room of a senior community to be obscured. An older person with low vision might function as if blind in that environment and be unable to find a chair, recognize his friends, serve his plate, or even see the food in a buffet line.

In an environment that is conducive for the function of older persons, it is important to manage not only light, but also shadow, which can be conducive to function, for example, a triangular shadow at the end of a step indicates the height and depth of the step as well as how many steps are there. But shadow can also be hazardous, such as the shadow of a garden wall that obscures a sidewalk curb, causing a person to trip or fall.

Lighting is best if controllable, no matter what type it is. Most older persons with low vision will require task lighting that can be positioned closer to reading/writing material or craft activity. Because the intensity of light is inversely related to the square of distance from its source, adding light at ceiling height will not provide adequate task illumination for older viewers. Task lights must be used that can be positioned closely, and therefore flex-armed lamps are best in this regard.

There are a variety of different types of bulbs that are useful and recommended for older viewers with low vision.

- Fluorescent lighting spreads evenly, is inexpensive and energy efficient, but provides less contrast because of that evenness and

produces less shadow. It is a harsh light and flickers and may be bothersome to some viewers, causing headache and eye strain. Covering or shading fluorescent bulbs or bouncing the light from the ceiling to the eye may be helpful.

- Incandescent light is easily directed and provides more contrast and shadow. But the light can pool, especially if provided by one bulb suspended from the ceiling, causing pinpoint glare or pools of light within relative darkness. Using multiple incandescent fixtures can eliminate this problem. Incandescent lamps are good for task lighting such as reading, sewing, or hobbies.
- Halogen light uses the glow of halogen gas, as well as the incandescent filament to create a brighter light. The light is more blue and therefore may require filtering. Ultraviolet or blue light may generate superoxide and hydroxide free radicals that may be related to damage in the eye. Although controlled clinical studies have not been done, blue light has been suggested as increasing risk of cataract and macular degeneration. Subsequent studies have not shown a correlation to visible light exposure and risk, but many rehabilitation services are cautious about “blue light hazard.” An Australian study suggests that persons with less melanin (i.e., light-colored iris, fair skin) are at more risk from light.
- Neodymium oxide and incandescent bulbs are currently touted as “full-spectrum lighting.” These bulbs emit fewer ultraviolet and infrared rays and provide a sharp drop in the emission of yellow light. The effect is a more vivid “true” color, similar to sunlight, so contrast is increased.

These types of lighting can be mixed to achieve effects that are most pleasing and comfortable for older people with low vision. A study exploring these types of lighting in reading lamps found strong preferences among older readers with low vision, but no differences in objective measures of reading performance based upon the type of light. Thus, informed reader choice should guide the selection of the type of light for older readers.

Light/dark adaptation is another aspect of environmental lighting that must be considered. Most older persons have difficulty traveling from bright areas to dim ones because their dark adaptation is not as efficient as in young adults. Persons with severely restricted field loss (e.g., advanced glaucoma) become functionally blind in dim lighting. Avoiding light/dark areas in the environment such as a bright dining room and dim hallway is helpful. When these areas are unavoidable, the older person could use illumination controls such as sunglasses or brimmed hats to assist with light/dark adaptation. Persons with severely restricted visual fields who are at risk for falling when ambulating at night may use lightweight, very bright, portable lamps with long battery life that have been designed for night hunters.

### Increasing Contrast

Light/dark contrast is produced by the amount of light that is reflected from different surfaces (a light object is brighter than a dark one). A greater contrast between objects and their backgrounds make them easier to see. Therefore, providing an area of dark background and an area of light background in the bathroom, kitchen, and bedroom can help a person more easily identify possessions. For example, if a comb and brush are of light color, they may be kept on a dark tray. Most TV remotes are black, so they should be placed on

a very light background. Similarly, marking the edge of stairs with contrasting colored tape makes each step more visible.

### Using Color

The ability to identify colors, especially darks and pastels diminishes with age. Certain visual impairments, especially those that affect the cones, such as macular degeneration, also reduce color vision. However, bright, clear colors can be seen by most older persons with low vision. For example, yellow against navy blue is very visible, because it combines both color and contrast cues.

### Using Organizational Strategies

Organization can be extremely helpful for the person with low vision. For example, always making sure that doors are completely open or completely closed, and placing chairs under the table when not used increases the safety of the environment. Organizing and labeling clothing by color and function in closets and drawers and organizing the kitchen can assist an older person in continuing to live independently. Learning new ways of performing daily tasks can make the loss of vision less of a problem in independent living. For example, retrieving a pair of spectacles that have fallen onto a light carpet might be difficult for some older adults. Learning a visual scanning pattern that begins at the site where the spectacles seem to have fallen and then continues in a circular pattern outward until they are found will assist in retrieving them.

Using color coding can be helpful as well. For example, chicken soup cans could be marked with wide yellow rubber bands, and tomato soup cans could be marked with wide red rubber bands. These markers could be quickly identified, avoiding the necessity for identifying the soup with a magnifier each time a can is retrieved from the cabinet. Brightly colored and nubby stick-on “dots” may be provided that provide both contrast and tactual cues for marking dials, buttons, and controls of appliances.

### Alternative Strategies

Even when an older adult with low vision retains useful vision for a wide variety of tasks, it is sometimes helpful to use alternative techniques that do not require the use of vision because vision may not be the most efficient or safest way of accomplishing some tasks. For example, even though an older adult may have useful vision for walking, he may find it best to use a long white mobility cane in order to detect drop-offs, so that vision can be used to seek landmarks for orientation. An older adult with low vision may use speech output (a program that speaks symbols or words) for most computer word processing so that limited stamina for reading and writing may be used for reading mail, which must be done visually. A metal plate called a “flame-tamer” may be placed on the eyes of a gas stove in order to avoid burns in the kitchen. Knowledge of a wide variety of rehabilitation strategies and tools will assist older adults with low vision in developing a repertoire of techniques and devices that allows them to complete tasks safely, efficiently, and effectively.

Orientation to a new setting requires some basic alternative techniques that can be used anywhere. Some older adults may be able to use all of the techniques, some may only need one or two. It is important to remember not to rush the older adult in orientation, whether it is a long-term care facility or physician’s office. These exercises

**TABLE 43-7****Orientation to a New Setting for Older Adults with Vision Loss**

Using a starting/ending point	Begin at one starting/ending place in the room, such as the door. Have the older adult reach out and feel both sides of the doorway, then describe the contents of the room, while leading him around the room via sighted guide and trailing and allowing him to feel features. Give simple names to the walls using some feature of the wall (example, the wall to the right is the bed wall, the wall opposite is the window wall).
Using compass directions or clock face	Some older adults will be more familiar with compass directions. Using the same starting points as previously explained, use north wall, south wall, east wall, and west wall to name the four sides of the room. Proceed using compass directions as the way of finding and naming locations in the room. Use clock face numbers in a similar manner for those who can more easily understand them.
Using landmarks and cues	Use familiar landmarks for orientation to a new environment, for example, the smell of food is a landmark for the dining room. The audible hum and red glow of a soft-drink machine may be another landmark.

may be repeated as often as necessary. Teaching family members these techniques may be helpful when new environments come up in the future. [Table 43-7](#) presents an overview of these techniques.

## PSYCHOSOCIAL CONSIDERATIONS

### Adaptation to Vision Loss

Anxiety and depression are common reactions to loss, and age-related visual impairment is complicated by the other losses associated with aging. There are two schools of thought on the timing of rehabilitation related to adaptation. Some rehabilitation professionals subscribe to a “loss theory” of psychological adjustment. This theory proposes that the person must “die” as a sighted person, and be “reborn” as a visually impaired person, incorporating the visual impairment into the sense of self. According to this theory, attempting rehabilitation would be fruitless until the process is complete. Others subscribe to the theory that anxiety and depression are related to a person’s negative stereotypes about visual impairment and a lack of confidence and motivation to attempt rehabilitation, but that if rehabilitation is successful, depression and anxiety should be reduced.

Older adults may hold many negative stereotypes associated with visual impairment: increased helplessness, inhabiting a world of darkness, increased vulnerability to crime, the perception that use of devices mark them as different, or to be pitied. Older adults with low vision may attempt to pass as fully sighted in order to avoid having others project these negative stereotypes onto them. But attempting to pass as fully sighted may cause other difficulties. For example, older adults with low vision do not recognize faces well, and the lack

of a friendly hello when passing acquaintances may be interpreted as unfriendliness. Failure to use alternative techniques for identifying targets and moving in the environment may lead to falls, burns, or other safety hazards.

Support groups and peer counseling for older adults with low vision can be extremely helpful in coping with vision loss. Support groups may be found through local multiservice agencies for persons who are visually impaired or may be started by senior citizen’s centers or other groups. Short-term professional counseling in conjunction with rehabilitation may be very helpful.

### Family and Social Support

In a recent study of low-vision device use among veterans, most of whom were older males with macular degeneration, family support was the most powerful predictor of continued use of devices up to 2 years following their prescription. Providing information and support to family members who are experiencing the impact of an older member’s vision loss can be powerful. Visual impairment is experienced by the entire family or caregiving system, not just by the older person, and both social and psychological concerns must be addressed. The loss of vision by one family member can disrupt roles in the family, create economic demands, and add stress when tasks previously performed by the older adult must be performed by someone else.

For family members who understand the functional implications of visual impairment, understanding the behavior of their older adult with low vision is easier. For example, understanding the effect of changing lighting conditions, the effects of glare, the adaptation times when traveling from dim light to bright and vice versa, can help explain behaviors like shielding the eyes, shuffling the feet, hesitation, fear of falling, and ceasing previously enjoyed activities. The fact that an older adult with restricted visual fields may pick up a dime from the floor, then bump into a partially open door seems contradictory, but is perfectly explained by the functioning field of view.

Assisting older adults with low vision in continuing social activities, such as hobbies, crafts, games, and traveling can aid them in maintaining important contacts with family and peers. Social support and contact is associated with less depression in older adults with low vision. Support groups can assist older adults with low vision in completing and using their rehabilitation, as well as facilitating adaptation to vision loss. Peer support, or mutual aid groups who meet regularly to share their concerns may be especially beneficial for older adults who may be overprotected, abused, or treated paternalistically by those who do not understand visual impairment or aging. Facilitating assertiveness for older adults with low vision is recommended because it is linked to less depression and more social support. Social skill training in assertiveness for older adults with low vision has been shown effective in decreasing depression, and deriving greater satisfaction in life.

## FUNDING FOR LOW-VISION REHABILITATION

Traditionally, vision rehabilitation services have been funded through private pay, or through vocational rehabilitation services for individuals who were preparing for the work force. Funding for services to older adults with vision impairment has been a critical health care issue in the United States. Public funding for the Independent

Living Services for Older Individuals Who are Blind program under the Rehabilitation Act is minimal, with approximately \$32.9 million allocated nationally in fiscal years 2006 and 2007. The funding remains at this level in the President's appropriations for 2008. These funds provide services in the traditional "blindness" system—state or private agencies for the visually impaired that are serving persons of all ages who have visual impairments.

Prior to 2002, only older veterans with low vision who served in the U.S. military and whose disability is service-connected had full access to comprehensive blindness and low-vision services through the Department of Veterans Affairs Medical Centers. However, most visually impaired veterans have age-related vision loss and their income is such that a copayment is required from them or from their private insurance carrier. Vision rehabilitation services were developed initially to meet the needs of blinded veterans returning from World War II. Young war-blinded men had few other medical problems, so efforts to rehabilitate them for the work force spawned the professions of orientation and mobility instructors, rehabilitation teachers for the blind, and low-vision therapists in order to meet their unique needs. This specialized "blindness and low-vision" rehabilitation was not considered part of the broader medical rehabilitation. Credentialing of vision-rehabilitation professionals developed separately from occupational or physical therapists, and their practice was autonomous, requiring neither medical referral nor supervision. As a result, many medical professionals are unaware of their services and do not understand the "blindness" rehabilitation system in which their practice began. The Department of Veterans Affairs model of service delivery in vision rehabilitation continues today in the same vein. Services are provided nationally by teams of professionals. Ophthalmologists or optometrists provide the medical eye care services, and the rehabilitation professionals are orientation and mobility specialists, rehabilitation teachers, and low-vision therapists. Recently the Department of Veterans Affairs appropriated \$40 million to provide vision rehabilitation services in a continuum of care to patients who have low vision as well as those who are legally blind, in recognition that veterans are aging in place and require services close to home. The vision/blind rehabilitation service in this milieu is also unique in that prosthetic devices are included. Low-vision devices such as magnifiers, telescopes, binoculars, closed circuit television systems, computer equipment, etc. are dispensed according to VA policy at no cost to veterans as a part of the VA's commitment to vision/blindness rehabilitation services.

The rise in older adults with low vision has spurred Medicare to produce a national policy of reimbursement as well. In 2002, the Centers for Medicare and Medicaid Services (CMS) released a national program memorandum to alert the provider community that Medicare beneficiaries who are blind or visually impaired are eligible for physician-prescribed rehabilitation services from approved health care professionals on the same basis as beneficiaries with other medical conditions that result in reduced physical functioning. This memorandum was issued in response to the committee report accompanying the FY 2002 Labor/Health and Human Services/Education appropriations bill.

The memorandum further directed that the patient receiving services must have a potential for restoration or improvement of lost

functions, and must be expected to improve significantly within a reasonable and generally predictable amount of time. The rehabilitation that is covered was short-term and intense; maintenance therapy was not covered. Applicable Health Care Common Procedural Coding System therapeutic procedures are outlined in the memorandum, as are applicable International Classification of Diseases (ICD)-9 codes that support medical necessity.

The effect of the program memorandum has been to increase the visibility of Medicare provisions for vision rehabilitation, but it is not a national coverage decision. Medicare carriers are not compelled by the memorandum to develop a Local Medical Review Policy as a result, and are still able to deny all claims that the local carrier does not deem medically reasonable or necessary.

In 2003, Congress authorized the Secretary of Health and Human Services to carry out a nationwide outpatient vision rehabilitation services demonstration project. The purpose of this demonstration project is to examine the impact of standardized national coverage for vision rehabilitation services in the home by physicians, occupational therapists and certified vision rehabilitation professionals. Medicare beneficiaries who are diagnosed with moderate to severe visual impairment may be eligible to receive covered vision rehabilitation services under this demonstration project. The demonstration covered services will only be available to Medicare beneficiaries who live in New Hampshire, New York City, Atlanta, Georgia, North Carolina, Kansas, and Washington state and must be prescribed by a qualified physician, such as an ophthalmologist or an optometrist who also practices in one of the specified demonstration locales. Eligible beneficiaries can be covered for up to 9 hours of rehabilitation services provided in an appropriate setting, including at home. Two notable aspects of this project are that (1) vision rehabilitation professionals are covered to provide services under the general supervision of the qualified physician (optometrist or ophthalmologist) and (2) for purposes of this demonstration, CMS is waiving the usual "incident to" rules in order to allow occupational therapists who are in private practice and certified vision rehabilitation professionals to provide services under general supervision of the physician. Neither the 2002 Medicare policy nor the 2003 Demonstration Project provides coverage for adaptive equipment (low-vision devices) as does the Department of Veterans Affairs.

# Age-Related Changes in the Auditory System

Su-Hua Sha ■ Andra E. Talaska ■ Jochen Schacht

## INTRODUCTION

The sense of hearing is unequalled by our other sensory modalities in terms of its sensitivity, dynamic range, and discrimination of the finest nuances in stimuli. It does serve us well through a part of our lifetime, but beginning in our forties (slightly earlier for men and later for women), our inner ears suffer the influence of aging in a very subtle yet progressive manner. Age-related hearing impairment (ARHI) affects most people aged 65 years and older and represents the predominant neurodegenerative disease of aging. Hippocrates had already noted deafness to be more prevalent among his elderly patients and in *The Comedy of Errors*, Shakespeare's elderly merchant, Aegeon, complains of his own "dull deaf ears." Thus, ARHI or presbycusis is not a disease of modern societies but has been accepted for centuries as one of Lord Byron's inevitable "woes that wait on age" that it still appears to be.

It was the New York otologist, St. John Roosa, who first drew the attention of his colleagues to hearing loss of the elderly as a medical condition. In 1885 he proposed the name presbycusis that he had coined from the Greek *πρέσβυς*, old man, and *ακούειν*, to hear. Systematic studies of the anatomical pathology began in the late nineteenth century, leading by the 1930s to the realization that the decreased auditory acuity could be attributed to deterioration of the auditory sensory cells and the auditory nerve. These changes frequently affect the perception of the upper frequencies first, resulting in high-frequency hearing loss as a hallmark of presbycusis. However, age-related hearing loss is not a uniform condition, but a multifactorial one combining genetic predispositions with a plethora of lifetime insults to the hearing organ because, in all its versatility and efficacy, our sense of hearing is also uniquely vulnerable to environmental influences. These may include noise, chemicals, and solvents at the workplace, lifestyle (e.g., smoking), and leisure activities (from iPods to rock concerts and target shooting), diseases (e.g., diabetes, respiratory disorders), viral or bacterial infections, and even the adverse effects of the very medications designed to cure the diseases and

infections. This spectrum of potential abuse of our auditory organ yields an exceedingly intricate etiology and pathology of hearing loss in the elderly. Age-related pathology of the central auditory system adds to the complexity of the problem. Presbycusis has been defined as "hearing impairment associated with various types of auditory dysfunction, peripheral or central, that accompany aging and that cannot be accounted for by extraordinary ototraumatic, genetic, or pathological conditions" but it is almost impossible in practice to separate the confounding factors from a "true" effect of aging. It has therefore often been debated whether presbycusis indeed exists in populations that are isolated from adverse environmental influences.

Animal models provide hope to resolve some of the basic mechanisms that underlie the deterioration of hearing and point to ways and means to delay or prevent presbycusis. By virtue of the availability of molecular and genetic information and of transgenic and knock-out animals, mice have become one of the preferred model animals although, as we shall point out later, caveats do apply here too. This review will illustrate the features of human presbycusis and draw on animal models to discuss its potential molecular basis.

## Epidemiology of Age-Related Hearing Impairment

ARHI is the most frequent sensory impairment in the elderly and the prevalence of the disorder increases with age. In humans, as in most other species, age-related hearing loss begins at the high frequencies and progresses gradually into the lower speech range. Males suffer age-related hearing loss earlier than females, beginning in the late thirties to early forties while women will match the males' deficits in the later decades of their lives. Approximately 44% of people suffer from a significant hearing loss in their sixties; this number rises to 66% between the ages of 70 and 79 years, and skyrockets to 90% after age 80 years. With an increased life span of the population worldwide, especially in developed countries, the impact of ARHI will continue to increase in the future.

The individual rate of decline in hearing, however, is exceptionally variable and some people may maintain excellent hearing with “golden ears” late into life as a result of genetic traits that have yet to be elucidated. Superimposed on the gender differences, race apparently also plays a role, although whether this role is causative or correlative is unknown. One study of over 2000 elderly Americans aged 73 to 84 years found the incidence of high-frequency hearing loss that met their criteria to be 91.8% in Caucasian American men, 76.1% in African-American men, 74.2% in Caucasian American women, and 59.2% in African-American women. In addition to genetic differences, each group had tendencies toward particular risk factors, suggesting that the incidence of hearing loss across groups is presumably caused by a combination of genetic and risk factor diversity.

## Risk Factors Modulating Age-Related Hearing Impairment

### Genetics

Family history plays a role in predisposition to presbycusis. An analysis of hearing thresholds in sibling or parent/child pairs versus spousal pairs (control) in Framingham Heart Study patients found that the inherited genetic effects were significant. The predictive power of family history appeared stronger for females than males and stronger for “metabolic” type rather than sensory type hearing loss (see Schuknecht’s classification of age-related hearing loss in section “Peripheral Pathology of Age-Related Hearing Impairment in Humans”). Overall, the study suggested that about 55% of the variance in age-related hearing loss can be ascribed to genetic factors. This influence is then modulated by external risk factors.

### Environmental Factors

The great variation in the progression and severity of hearing loss has long led to the recognition of ARHI as a complex genetic disorder with environmental risk factors. Major environmental risk factors that may contribute to the manifestations of ARHI, briefly mentioned above, include exposure to excessive noise, ototoxic medications (primarily aminoglycoside antibiotics and anticancer agents of the cisplatin class), and industrial solvents. These environmental factors appear to damage the auditory system by oxidative injury and thus may aggravate the age-related changes in the auditory system. Animal experiments bear out the accelerating influence of these factors, which do not necessarily have to inflict damage by themselves. When mice at 3 months of age received a mild noise exposure causing only temporary threshold shifts, their hearing recovered to normal within 3 days. These mice, however, developed a significantly greater hearing loss with age than control animals.

### Gender Differences and Hormonal Factors

Age-related hearing loss sets in earlier in males than in females, both in the human population and experimental animals. In the later decades of life, however, these differences diminish, suggesting that differences in hormonal levels between male and female contributes to onset of ARHI. Receptors for steroid hormones are indeed present in the cochlea. In support of a link between ARHI and hormonal levels, fluctuations in hearing thresholds have been observed during

the menstrual cycle and estrogen therapy slowed the development of ARHI in postmenopausal women. Furthermore, in patients (and mouse models) with Turner syndrome who do not synthesize estrogen, ARHI sets in early. A correlative study in human saw a protective effect of elevated serum levels of aldosterone on auditory thresholds and an improvement of “hearing-in-noise” in older individuals. Aldosterone receptors in the inner ear influence the ionic homeostasis of inner ear fluids, which is essential for cochlear homeostasis and the transduction of sound.

### Diabetes Mellitus

Both type I and type II diabetes promote hearing loss and cochlear pathology in humans and in animals. Deficits in several aspects of auditory function were significantly more pronounced in a group of people with type II diabetes aged 60 years or older compared with a group of age- and sex-matched controls and excluding those with other significant health problems or a history of hearing problems. Diabetes mellitus and associated deregulated blood glucose levels, in fact, exact a multitude of stresses on a cellular level, which could lead to loss of function in the delicately balanced hearing organ with time and age. Fundamentally, increased blood glucose levels leads to cellular hypoxia and build up of reactive oxygen species and other metabolic by-products, as well as changes in the collagen and microtubule structure of the cells. Also, the effects of diabetes on vasculature are profound, including atherosclerosis and vessel wall dystrophy. In the inner ear, which depends on the stria vascularis to carefully maintain the endocochlear potential, this could result in impaired sensory function and apoptosis.

### Cardiovascular Disease

All conditions that affect the function of blood vessels such as hyperlipidemia, hypercholesterolemia, hypertension, hyperlipoproteinemia, and cardiovascular disease have been implicated in ARHI. Specifically, stria ARHI (see next section) appears to be aggravated because stria vascularis is most vulnerable to any restriction of blood flow. Just as in diabetes, any cardiovascular disease leading to vascular compromise will impair the function of this tissue and, by way of decreased endolymphatic potential, decrease the sensitivity of the cochlear organ to sound.

### Lifestyle

Poor health habits with regard to exercise, smoking, and diet are also considered risk factors for ARHI based on data of population studies. Since some of these habits influence cardiovascular function and other potential risk factors for ARHI, it remains open how much lifestyle acts directly on the auditory organ or secondary to general health.

### Psychology

Interestingly, adherence to negative stereotypes about the elderly, i.e., the concept in many societies that aging is met with an inevitable decline in function of all faculties, demonstrates as a predicting risk factor for ARHI. External stereotyping (the prevalence of stigmata with aging in the subject’s culture) and negative internal perception (extent of internalization of these stigmata) acted as independent

risk factors on hearing loss with age, and had a stronger impact than gender or race. This predicts an observable phenomenon wherein cultures with positive concepts of aging do not expect their elders' hearing to become enfeebled and, in fact, the incidence of ARHI is then lower. Here again, an influence on the auditory system maybe secondary to the effect of stigmata on general well-being.

### Hearing Loss Basics: Frequencies and Sound Intensity

A significant hearing loss of any origin will eventually lead to difficulties in communication and a decreased awareness of the environment. In addition to the social isolation at all ages, subjects with early-onset presbycusis may suffer economic consequences from difficulties in employment or professional advancement. The question of what constitutes a significant hearing impairment is complex as it involves consideration of both the magnitude of sensitivity loss and the frequencies at which the loss occurs. Although the most convenient assessment criterion for age-related hearing loss is a subjective one—that is, posing the question, “do you have a hearing problem?” or a more elaborate questionnaire like the Hearing Handicap Inventory for the Elderly-Short (HHIE-S)—a more quantitative evaluation can be obtained by an audiogram (see section on “Functional Assessment of Hearing”). While there is not one set paradigm for classification of audiograms into handicapping and nonhandicapping hearing thresholds, the American Medical Association/American Academy of Otolaryngology—Head and Neck Surgery sets the bar at an average threshold shift (hearing loss) of 25 dB or above at frequencies between 500 and 3000 Hz.

What does a loss of 25 dB hearing acuity mean in practical terms? The bel or decibel scale of sound pressure (“intensity”) is logarithmic, such that an increase in 3 bels (30 dB) confers approximately a doubling of the sound intensity ( $10^{3/10} = 1.995$ ). Therefore, a reduction of sensitivity of 25 dB, as is required for some definitions of occupational hearing impairment, is considerable. In rough terms, a difference of 25 dB in threshold makes normal conversation equivalent to a whisper, and a whisper equivalent to silence (Table 44-1). The crying baby would still be heard—albeit subdued—but the leaves rustling in the forest or the crickets in summer would not be heard.

ARHI poses a specific problem as the hearing loss mostly sets in at the high frequencies. As a result, many with age-related hearing loss do not recognize their condition for a long time. The frequency spectrum of human hearing, at its best, ranges from about 60 Hz to 16 kHz. A hearing loss at the very high frequencies may not produce any communicative disadvantages since frequencies over 4 kHz contribute little to speech (Table 44-2). Even musical instruments have a limited range in their fundamental frequencies. Since the progression of ARHI is also gradual, the subject maybe unaware of the gradual loss of overtones in speech or instrumental music, which can extend two or three octaves higher than the fundamentals, i.e., to two or three times the frequencies.

Although basic hearing needs center on the 1000 to 2000 Hz range, higher frequency losses like those in ARHI cost the ability to discriminate between many words with f, p, k, s, t, th sounds (Table 44-2). For example, to a person with high-frequency hearing loss, “sick” and “thick” maybe difficult to differentiate, and “three socks” may sound like “free fox” unless the listener has developed the ability to read the speakers lips for more information. Such communication errors may seem trivial, but can cause enormous social disability when they happen in work situations or become cumulative.

**TABLE 44-1**

#### Typical Sound Levels

dB	SOUND
15	Pin drop at close range
15–20	Rustling leaves, dripping faucet
35	Whisper
50–60	Normal conversation
60–70	Vacuum cleaner
70–90	Screaming child
85	<i>Safety limit for an 8-h workday</i>
100	<i>Safe for 15 min or less</i>
105–110	Gas engine mower, chain saw
110	Car stereo at maximum volume
110	<i>Safe for 1 min 29 s</i>
115	Maximum volume from an iPod
116	<i>Human body perceives low frequency</i>
120	Front row at a rock concert
120–130	Jet plane taking off
127	<i>High risk of tinnitus</i>
130–140	Gun shot from a hunting rifle
140	<i>Hearing deficit at exposures &lt; 1 s</i>

Intensity levels of some familiar sounds can provide a guide to understanding the impact of hearing loss as discussed in the text. The comparison of these levels to safety standards also illustrates the potential impact of environmental noise exposure on the complex manifestations of presbycusis.

*Safety levels are taken from DHHS (NIOSH) Publication No. 98-126 on Occupational Noise Exposure.*

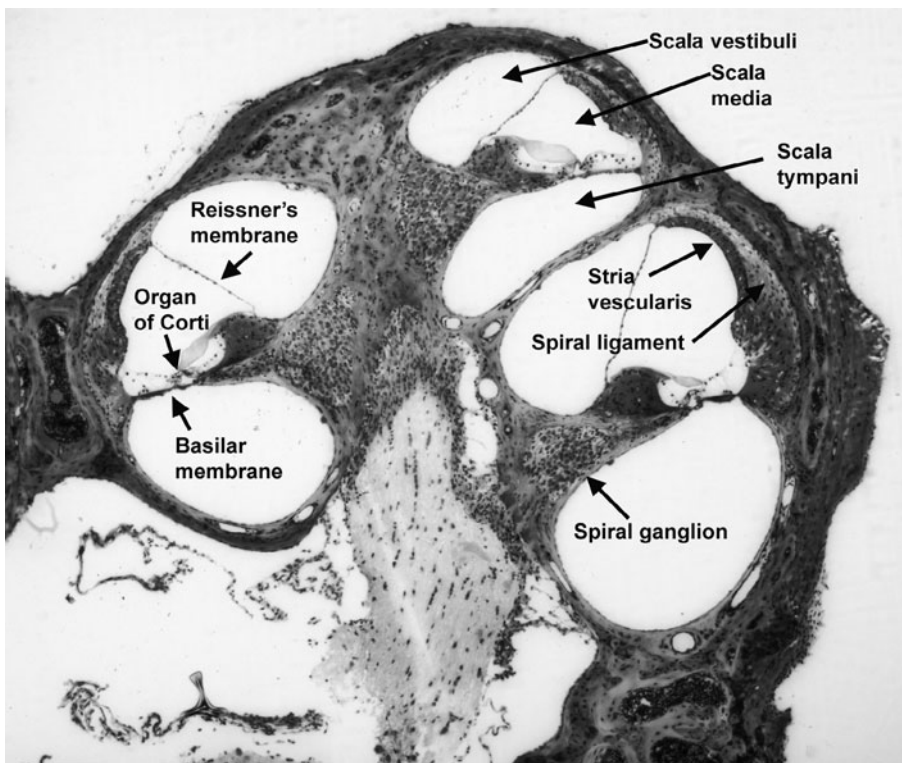

The high frequencies are also important for auditory discrimination in the presence of background noise. A common and often the first noticed signal of presbycusis is the “party effect” when an individual with good one-on-one communication experiences difficulties in speech perception in a noisy environment such as a

**TABLE 44-2**

#### Frequency Ranges of Common Sounds

SOUND	APPROXIMATE FUNDAMENTAL FREQUENCY RANGE (Hz)
Guitar	82–1175
Truck engine	125–250
Dog's bark	200–300
Violin	196–4400
Soprano singer	200–1400
Most spoken consonants	250–500
Middle C of the musical scale	264
Spoken vowels	500–750
Crying baby	750–1000
Consonants: c, p, ch, g, h, sh	1000–2000
Telephone ring	3000–4000
Consonants: f, k, s, t, th	3000–8000
Birds chirping	4000–8000

In addition to these fundamental frequencies, most sources of sounds and musical instruments in particular, produce overtones that add to the richness of the sound. These overtones reach two to three times the fundamental frequencies. Comparison of the frequencies to the classical pattern of high-frequency age-related hearing impairment illustrates the early impact on specific speech features and the quality of music appreciation.

**FIGURE 44-1.** Anatomy of the cochlea. A low magnification light micrograph of a near midmodiolar cross-section illustrates the tissues and fluid-filled spaces of the  $2\frac{1}{2}$  turns of the mouse cochlea. As indicated in the upper turn, the fluid spaces are the scala tympani and scala vestibuli filled with perilymph, and scala media filled with endolymph. They are separated by the thin Reissner's membrane and the basilar membrane upon which the organ of Corti is located. When sound reaches the ear, the vibrations of the tympanic membrane (ear drum) are passed along the middle ear ossicles to the cochlea where they initiate a traveling wave in the fluids which, in turn, move the basilar membrane. The tectorial membrane, an acellular structure, rests on the stereocilia of the hair cells. Spiral ganglion neurons run from the organ of Corti where they make contact with the hair cells through the modiolus to the central auditory system. The stria vascularis and spiral ligament, tissues involved in setting up the ionic composition and high (+70–100 mV) potential of the endolymph, lie along the lateral wall of the cochlea.

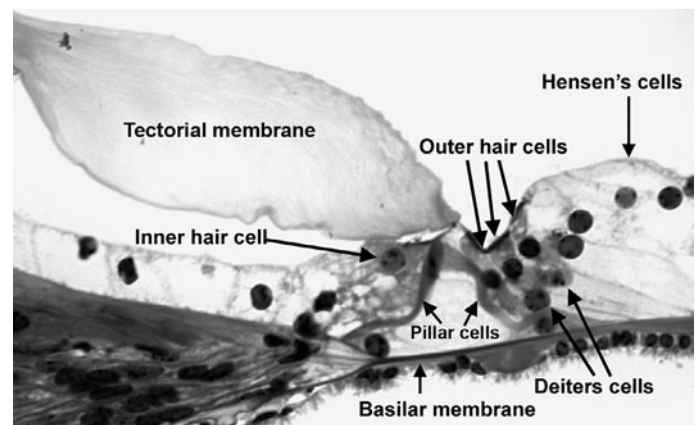

restaurant, a party, or a conference. Audiological examinations routinely include frequencies up to 8000 Hz and would reveal the presbycusis changes although the individual may still be told by the audiologist that their hearing is “normal for the age.”

### Anatomy of the Auditory Periphery

Not only is age-related hearing loss shaped by many influences, it also shows a variety of morphological manifestations. The present framework for classifying age-related hearing loss was proposed by Schuknecht in 1964 based on the histopathology of human temporal bones. In order to understand its age-related changes, we should first sketch the structure of the mammalian auditory organ, the cochlea (Figure 44-1). Encased in bone, the tissues and fluids of the cochlea of different species coil “snail-like” for  $2\frac{1}{2}$  to  $4\frac{1}{2}$  turns and a total length of a few centimeters without any relationship to body size. A human cochlea, for example, extends for 33 mm in  $2\frac{1}{2}$  turns while the dimensions in the guinea pig are 20 mm and  $4\frac{1}{2}$  turns. The cochlea is tonotopically organized in all species, and high frequencies are processed in the base, low frequencies in the apex.

Several structures with distinctly different functions and susceptibility to environmental and age-related insults can be discerned within this membranous labyrinth and best seen in a midmodiolar section that transverses the length of the cochlea. The lumen of the cochlea is separated into three fluid-filled compartments by the basilar membrane and Reissner's membrane. Scala vestibuli and scala tympani contain perilymph, similar in composition to extracellular fluids. Scala media contains endolymph, unique among body fluids by its high concentration of  $K^+$  and low  $Na^+$ , creating a large positive endolymphatic potential as a driving force for the transduction current, which is used by the sensory cells. Scala media is bounded laterally by spiral ligament and stria vascularis, the tissues that are responsible for maintaining endolymph. These tissues

are highly vascularized and provide most of the oxygen and nutrient supply to the cochlea. The organ of Corti (Figure 44-2), located on the basilar membrane, is the auditory end organ containing sensory cells and supporting cells. Sensory cells include the inner hair cells and three rows of outer hair cells, numbering several thousand in all species. The name “hair cell” is derived from the stereocilia that protrude from the apical end of the cells (Figure 44-3). Inner hair cells are the primary sensory cells that convert the mechanical acoustic input into receptor potential and release of neurotransmitter, triggering action potentials that are carried to the brain by the spiral

**FIGURE 44-2.** The organ of Corti. A cross section shows details of the mouse organ of Corti located on the basilar membrane. The sensory cells are arranged in one row of inner hair cells and three rows of outer hair cells. Inner hair cells are the primary transducers of sound and receive most of the afferent innervation of the spiral ganglion nerve. Outer hair cells amplify transduction and receive most of the efferent innervation. Supporting cells include Deiters', Hensen's, and pillar cells. The tectorial membrane does not extend to its full length because of preparation artifacts.

**FIGURE 44-3.** Hair cells and their stereocilia. A scanning electron micrograph of a “surface preparation” gives a top view of the organ of Corti, presenting the apical aspects of hair cells and supporting cells. The hair cells are clearly distinguished by their stereocilia, the white tufts arranged in linear (inner hair cells, IHC) and W-like (outer hair cells, OHC) form. In the process of sound transduction, the stereocilia are deflected by a shearing motion generated between the basilar membrane and the tectorial membrane, causing transduction channels to open and allow influx of potassium from the endolymph. This influx triggers a receptor potential and release of neurotransmitter (glutamate) at the synapse between the inner hair cell and the spiral ganglion nerve. Scale bar: 20  $\mu\text{m}$ . (Scanning electron micrograph from mouse cochlea kindly provided by Dr. Andrew Forge, Institute of Laryngology and Otology, University College London, UK.)

ganglion neurons. Most of the afferent innervation by this auditory nerve converges on the inner hair cells. The major function of outer hair cells is to enhance the performance of the cochlea, particularly at low intensities of sound. They receive mostly efferent innervation from auditory centers in the brain. Supporting cells include the inner pillar, outer pillar, Deiters', Hensen and Claudius' cells, about whose function we know relatively little.

The cells in the sensory epithelium are highly differentiated. Hair cells, once lost, are not regenerated by other cell types in the mammal and replaced by permanent “scars” (Figure 44-4). Consequently, any damage to these cells leads to irreversible hearing loss.

### Functional Assessment of Hearing

From a clinical functional aspect, pure tone audiometry, tympanometry, acoustic reflex measurements, and word recognition scores with behavioral tests are the most common and important methods for hearing assessment. Tympanometry and acoustic reflex (stapedius reflex) test the integrity of the middle ear while audiometry yields information about acoustic thresholds at distinct frequencies. Word recognition and behavioral tests explore more complex interactions

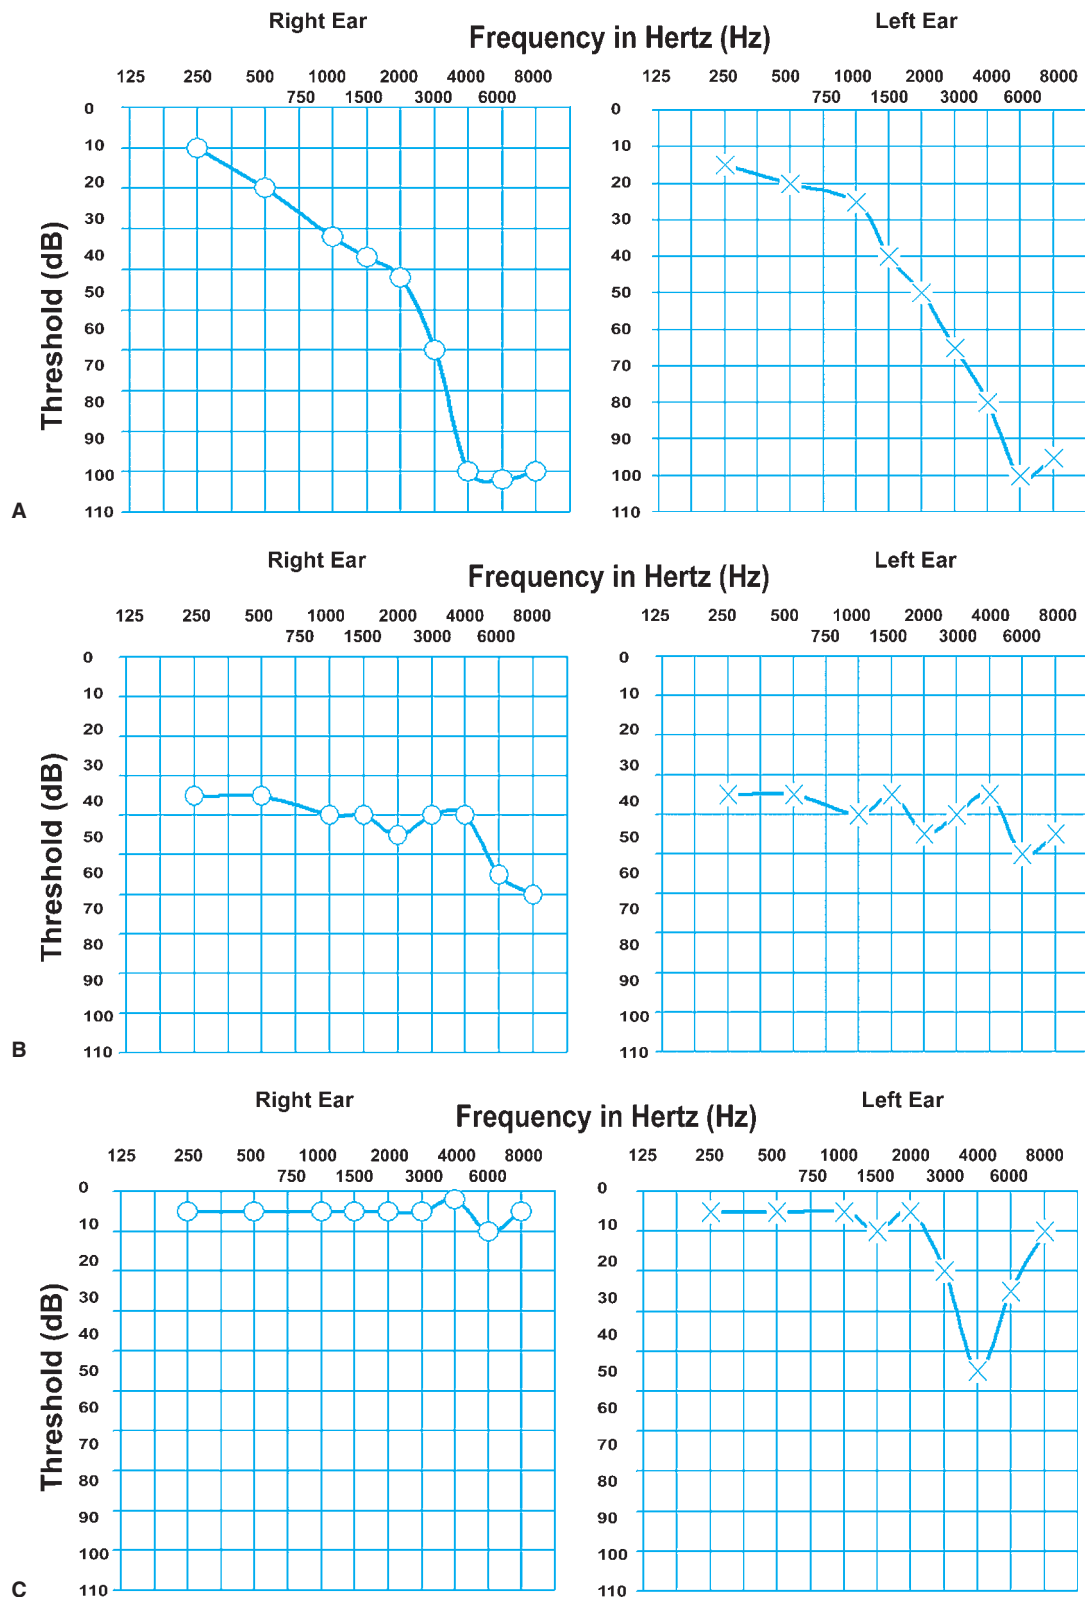

that involve both the auditory periphery and the central processing of the information. Auditory brainstem response (ABR) and otoacoustic emission measurements are passive sound-evoked responses and therefore most easily adapted to routine testing in animals, providing information on the integrity of the auditory pathway and outer hair cells, respectively. Some invasive methods, essentially limited to animal experimentation, such as recordings of cochlear microphonic potential (largely derived from outer hair cells), cochlear whole nerve action potential, and single unit recordings can be used to assess hair cell transduction and synaptic activity, the function of auditory afferent nerves, and individual neurons of the cochlear and vestibular nerves in experimental animals.

### Peripheral Pathology of Age-Related Hearing Impairment in Humans

Schuknecht's classification of 1964 is still a valuable guideline today for the various forms of presbycusis although the framework has limitations. The broad categories of ARHI are as follows: (1) *Sensory* ARHI refers to a primary degeneration of hair cells of the organ of Corti that begins in the base, yielding an audiogram that is abnormal only at the high frequencies (Figure 44-5A). Current data suggest that ARHI in humans largely follows such a pattern of a high-frequency hearing loss. (2) *Neural* ARHI mainly reflects loss of afferent neurons while cochlear structures remain relatively normal, leading to a loss of word discrimination ability. In general, aging people lose afferent neurons only slowly and significant changes in the audiogram may require a loss of 90% of neurons. The incidence of neural ARHI is low and the existence of a purely neural ARHI is even controversial. As hair cells degenerate, secondary neuronal degeneration follows, so that the term “sensorineural” ARHI is favored over a separation of sensory and neural ARHI. (3) *Strial*, or *metabolic*, ARHI is caused by a degeneration of the stria vascularis (primarily a “flattening,” reduction of volume) resulting in a decrease of the endocochlear potential. This decrease of the driving force for transduction affects the entire cochlea and therefore all frequencies. The audiogram shows a flat hearing loss (Figure 44-5B). Strial ARHI may account for 20% to 35% of ARHI according to Schuknecht, who also noted that strial ARHI tends to occur earlier in life than other forms. Others peg the incidence of this form of hearing loss much lower. Although Schuknecht did not include the spiral ligament in the hallmarks of strial ARHI, human and animal studies have tied strial pathology to that of the adjacent spiral ligament. (4) *Cochlear conductive* ARHI or *mechanical* ARHI is caused by changes in the stiffness of the basilar membrane. An audiogram of this type shows a linear decline of over 50 dB at all frequencies without degeneration of any cochlear cells or structures. Only a small portion

**FIGURE 44-4.** Loss of hair cells with age. Surface preparations of the mouse cochlea are stained with phalloidin to visualize F-actin, a major component of stereocilia and hair cells. Three rows of outer hair cells are complete and arranged in an orderly fashion in an animal of 3 months of age. At 23 months, the structure is disturbed and some cells are missing.

**FIGURE 44-5.** Audiograms of different forms of hearing loss. Pure-tone audiograms record the auditory thresholds, i.e., the minimal sound level necessary to elicit a response in the listener at specific frequencies. Typical audiograms cover the range from 250 to 8000 Hz and the increasing intensity of the sound is plotted downward on the y-axis. A normal ear (Figure 45-5c, right) would yield an audiogram with flat responses around 0 to 10 dB; if the threshold is increased in a subject, the curve drops lower. Thresholds of 25 to 30 dB constitute a subjectively noticeable impairment, 70 dB and above would make perception at this frequency difficult to impossible. (A) The sloping audiogram from a 62-year-old male shows progressive high-frequency hearing loss in both ears. Fundamental speech frequencies are moderately affected but the threshold of 65 dB at 3000 Hz renders speech discrimination in noise difficult. (B) The flat audiogram from a 64-year-old male shifted to higher thresholds is indicative of a “metabolic” presbycusis. (C) The audiogram from a 32-year-old male shows a sharply defined hearing loss of 45 dB only at 4 kHz in the left ear. Such a “notch” in the audiogram is typical for noise damage, here from target shooting or hunting.

of ARHI is estimated to fall into this category. (5) Mixed ARHI in which multiple forms of pathologies overlap. About 25% of cases may be of mixed pathology.

In evaluating age-related hearing loss, it is oftentimes difficult to determine the contributions of environmental influences that also damage the hair cells in the organ of Corti, such as exposure to noise, industrial solvents, or ototoxic medications. Aminoglycoside antibiotics (exemplified by streptomycin, gentamicin, kanamycin, and related drugs), in particular, destroy hair cells in a base-to-apex progression, causing an initial high-frequency hearing loss reminiscent of sensorineural presbycusis. Noise-induced hearing loss usually differs in its pattern as the site of cochlear damage relates to the frequency of the exposure. Furthermore, a fingerprint of noise trauma in hunters and shooters is a unilateral hearing deficit in the 4 kHz region (Figure 44-5C). Damage from industrial noise would be expected to be bilateral and show a broader area of hearing loss.

### Central Auditory Aspect of Age-Related Hearing Impairment

Central auditory changes with aging can essentially be classified into two major types. The first is referred to as “peripherally induced central effects,” which presents with changes in the cochlear nucleus driven by the decline of peripheral cochlear inputs that occur with age, typically starting with hearing loss at high frequencies. The other is referred to as “true aging” neurodegenerative changes in the brain. In this case, ARHI share similarities or common mechanisms with other central nervous system conditions of the aged such as Alzheimer’s and Parkinson’s diseases. Age-dependent changes in auditory structures include declines in the number of ventral cochlear nucleus and lemniscal nerve fibers.

The elderly often present with difficulties in speech recognition, rather than an inability to hear sound. Despite audiograms within the normal range, the subjects still require a stronger speech signal, particularly, in a noisy environment. These subjects may have deficits in processing sound in the higher auditory centers. Specific comprehension tests (e.g., a speech perception in noise (SPIN) test) can be used to diagnose such a condition.

Animal models have illuminated some central consequences of peripheral degeneration. Neurons with low thresholds for high-frequency tones (e.g., in the ventral inferior colliculus) cease to respond and the locations of frequency representation change. Synaptic connections may change in number, spontaneous activity, or their inhibitory or excitatory properties. Such changes do not bode well for a rehabilitation of the hearing impaired with, for example, cochlear implantation (see section on “Management of Age-Related Hearing Impairment”). The adult auditory system, however, shows surprising plasticity and electrical stimulation by implants can reverse some of the central changes.

### Animal Models of Peripheral Age-Related Hearing Impairment

A large variety of species has been studied for age-related auditory pathology including chinchillas, guinea pigs, primates, dogs, and rodents. These species cover the range of cochlear pathologies, including organ of Corti, neural and stria degeneration, as is noted for humans, and the majority of animals show a complex mix of cochlear pathologies. Mongolian gerbils are considered a model for stria pres-

bicusis, presenting with stria atrophy, decrease in the endocochlear potential, and decreased cochlear blood flow. Degeneration of spiral ganglion cells and fibrocyte vacuolization and interstitial edema in the spiral ligament are also observed. In cats and rats, the underlying pathology has been linked to a combination of hair cell loss and spiral ganglion cells. Recently, a stria type of hearing loss was also observed in the rat underscoring the fact that a singular “pure” type of hearing loss maybe rare in any species.

Mice have become favored for study of ARHI, because of availability of molecular and genetic information and of transgenic and knock-out animals. A caveat, however, is that each mouse strain differs significantly in its rate of hearing loss, ranging from those such as CBA and CAST, which exhibit minimal hearing loss by 18 months of age, to those such as C57BL/6 and DBA, which exhibit significantly accelerated hearing loss by approximately 8 and 3 months of age, respectively. The accelerated loss of hair cells and hearing found in C57BL/6 and BALB/cJ mice correlates with the presence of a recessive locus on proximal mouse Chr 10, the age-related hearing loss (*Ahl*) gene. The *Cdh23<sup>ahl</sup>* allele (cadherin 23 or otocadherin) promotes degeneration of the organ of Corti in the cochlear base and high-frequency hearing loss beginning after 1 year of age as shown in congenic B-6.CAST-*Cdh23<sup>ahl</sup>*. Furthermore, *Cdh23<sup>ahl</sup>* also promotes noise-induced hearing loss, suggesting a connection between noise and ARHI. Since BALB/cJ and C57/BL mice are genetic mutations, they may not reflect a normal biological aging process.

The CBA/J mouse loses hearing sensitivity late in its life span progressively from high frequencies to low. ARHI begins around 12 months of age and progresses slowly until 18 months after which point a more rapid rate of hearing loss is seen. The hearing loss at high frequencies is accompanied by loss of outer hair cells and a moderate degeneration of spiral ganglion cells. Since the CBA/J strain maintains a normal morphology of stria vascularis and normal endocochlear potential in aging, a sensorineural origin of the observed auditory deficits can be inferred.

### Molecular Mechanisms of Age-Related Hearing Impairment in Animal Models

Recent work places “auditory aging” in animals—at least for sensorineural presbycusis—into the category of oxidant-stress related events. Reaction products of reactive oxygen species are elevated in the cochlea of the aging CBA/J mouse including markers for increased activity of hydroxyl radicals, peroxynitrite, and  $H_2O_2$ . At the same time, antioxidant defense systems including mitochondrial superoxide dismutase and apoptosis-inducing factor, both radical scavengers, decrease. Other suggestive evidence comes from heterozygous mice lacking superoxide dismutase. Age-related hearing loss developed earlier and with greater severity, as evidenced by increased hair cell loss following the canonical base-to-apex progression. The imbalance of oxidant stress in the cochlea then stimulates redox-regulated signaling pathways, leading to apoptotic and necrotic cell death. Strong support for the notion of oxidant stress as a contributing factor in cochlear aging comes from dietary manipulations in which antioxidants slow the progression of cochlear degeneration and hearing loss (see section on “Prevention of Age-Related Hearing Impairment”).

Deletions in mitochondrial DNA are also an established indicator of cumulative oxidative damage to a tissue and have been observed in the aging cochlea. The mtDNA<sup>4977</sup> deletion is the most common

mutation, which affects cells' capacity for oxidative phosphorylation and appears to accumulate with age. A strong correlation exists between these signs of free radical-inflicted injury and the hearing ability of rats.

Vascular abnormalities are another pathological change with aging potentially affecting oxygen supply and mitochondrial respiration thus adding to oxidant stress in the inner ear. As a case in point, suppression of cochlear blood flow promotes mitochondrial DNA mutations and may impact hearing loss. In addition, reduction of cochlear blood flow from age-related degeneration could lead to a compromised function of the stria vascularis and an inability to maintain cochlear homeostasis for the maintenance of transduction currents and tissue integrity.

### Genetic Contributions to Age-Related Hearing Impairment in Animal Models

The vast majority of known mouse models of genetic hearing loss exhibit sensory dysfunction soon after birth. Analysis of these models has implicated a diverse array of genes required during early embryonic development and postnatal maturation of the auditory sensory neuroepithelium. However, the utility of these models for understanding later-onset hearing loss is unclear. The few studies that have directly examined the influence of genetic variation on later hearing acuity in the mouse indicate that ARHI combines contributions from several genes in addition to environmental influences. For example, the aforementioned *Cdh23* gene locus modifies other loci related to calcium metabolisms. Calcium is not only a second messenger in homeostatic mechanisms but it is a universal signal responsible for controlling a plethora of cellular processes, including cell death pathways. Calcium also plays a central role in mitochondrial function and a dysregulation of mitochondrial calcium can impair energy metabolism and enhance free radical generation, triggering further mitochondrial dysfunction, cytochrome *c* release, and apoptotic pathways. Although it has been postulated that many genes will participate in the etiology of ARHI, little research data are available on the identity of such genes. Some candidate genes include a gene responsible for a carcinogen metabolizing enzyme, *N*-acetyltransferase 2 (*NAT2*), polymorphism, and a single-nucleotide polymorphism within gene *KCNQ4* that codes for a potassium voltage-gated channel expressed in hair cells.

### Prevention of Age-Related Hearing Impairment

As discussed above, several environmental and personal behavioral factors are associated with the overall manifestations of ARHI. Therefore, avoiding noise, ototoxins and smoking, regular exercising, and maintaining a healthy diet will aid in attenuating progressive hearing loss as it will contribute to general health. The question as to what extent interventive strategies can specifically delay ARHI cannot yet be conclusively answered but some data point to the general concept that the rate of ARHI can be influenced.

"Augmented Acoustic Environment" is a concept to influence the progression of presbycusis by exposure to controlled stimuli. This environment could be created by an enhanced ambient acoustic background or by delivery of specific stimuli through hearing aids. Studies in mice, mostly on inbred strains with accelerated hearing loss, confirm that the auditory system responds to such treatment but not necessarily in predictable ways. While amelioration of some

forms of age-related changes was found, other effects were detrimental, leaving final judgment to future experimentation.

Dietary restriction has been widely used in aging studies and can slow certain age-related physiological declines and extend longevity. For the auditory system, results of such studies are inconclusive and emphasize the point that organ-specific effects of a generalized treatment are impossible to predict. Caloric restriction had positive effects on the progression and magnitude of ARHI in rats but was ineffective in rhesus monkeys. A comprehensive study of 15 mouse strains brought every conceivable result from an apparent amelioration of the rate or severity of presbycusis to no effects and to an acceleration of hearing loss. Such results indicate a major influence of genotype on the outcome, cautioning that similar problems might be encountered in presbycusis therapy in humans.

Antioxidant therapy in animal models, based on the premise that oxidant stress is a contributor to ARHI, has shown promise but also inconsistencies. Rats that were placed on vitamin supplementation (vitamins C and E) shortly after birth outperformed their placebo controls in hearing tests at old age. When the supplementation with antioxidants (acetyl carnitine and lipoic acid) was started later in life and upheld for 6 weeks, results were less convincing. Dogs, on the other hand, fed an antioxidant diet (*DL*- $\alpha$ -tocopherol acetate, *L*-carnitine, *DL*- $\alpha$ -lipoic acid, and ascorbic acid) for the final 3 years of their life had better preserved auditory neurons. The key to success, aside from a suitable combination of compounds, seems to be the long duration of treatment.

Human studies corroborate the hypothesis that ARHI can be manipulated by therapeutic intervention. Daily supplementation of folic acid for 3 years affected the hearing of elderly participants. There was a small but significant positive effect on low-frequency hearing while changes in high-frequency hearing, the area normally most afflicted by aging, were not affected by the treatment. Nevertheless, since low-frequency hearing is important for speech, the result is encouraging. The underlying mechanism of this protection has yet to be established but the effect goes hand-in-hand with controversial observations that patients with higher erythrocyte and serum concentrations of folate maintain lower hearing thresholds. It should be noted however that routine folic acid supplementation of foods is not permitted in the Netherlands where the study was carried out. Results may differ in countries where basic folate levels in the population maybe higher.

Quite intriguingly, several surveys indicate alcohol consumption as a possible modulator of ARHI. Moderate use of alcohol was associated with better hearing in the elderly, an effect in line with observations that low alcohol intake can be beneficial for general health. Heavy drinkers, in contrast, had a tendency toward more pronounced high-frequency hearing loss.

### Management of Age-Related Hearing Impairment

The major cause of ARHI is the loss of hair cells and cochlear neurons. Since hair cells, as mentioned, cannot regenerate, restoration of normal hearing is not possible. The choice for rehabilitation of ARHI is hearing aids. Digital hearing aids present a wide range of user options and have advanced technologically in all aspects including the tolerance of a noisy environment and improved cosmetology. Hearing aids, individually tailored to a subject's audiogram, provide clearly increased hearing ability and speech discrimination (Figure 44-6). However, knowledge about the benefits and

**FIGURE 44-6.** Typical effects of a hearing aid. The unaided audiogram (open circles) shows presbycusis high-frequency hearing loss. With hearing aids in place (closed circles), acuity is improved to near-normal levels for frequencies up to 3000 Hz. Note that low frequencies deliberately are not boosted and that rescue of the elevated thresholds at high frequencies is not possible.

acceptance of hearing aids is low. About one-half of elderly people who could benefit from a hearing aid never try; others are dissatisfied after short use and only 10% to 30% wear hearing aids. While rejection to a large extent depends on personal idiosyncrasies, health care, and cultural aspects, it can in some instances have a pathophysiological basis. “I can hear but I can’t understand” may point to a central auditory deficit that cannot be easily corrected by enhancing the peripheral stimulus.

If the magnitude of the hearing loss exceeds the corrective capability of hearing aids, cochlear implants are recommended with increasing frequency to older subjects. Such “bionic ears” are indicated for persons with bilateral hearing loss and 50% or poorer word recognition. While a hearing aid essentially amplifies sound to the cochlea and therefore depends on remaining sensory cells, the cochlear implant bypasses the cochlea and stimulates the auditory nerve directly. To achieve an effective transformation to an electrical stimulus, the acoustic information needs to be preprocessed and delivered to the nerve via an electrode implanted into the cochlea. The success depends on appropriate coding paradigms and a healthy complement of cochlear nerve innervation. Since the degeneration of the cochlear nerve is slow in humans, much of the aging population presenting with presbycusis would be good candidates. The outcome of implantation is variable but almost all of the patients greatly improve speech perception and most even acquire the ability to carry on telephone conversations. Challenges that remain are speech recognition in unfamiliar contexts and the enjoyment of music.

## Outlook

Age-related hearing loss is an exceedingly complex disease besetting an organ of even greater complexity. It appears to be a sequel to numerous morphological and molecular changes that befall the auditory system as we age, and which are being characterized with

increasing acuity by basic and clinical research. Our understanding and ability to design interventive and curative therapies will much depend on advances into the molecular mechanisms of auditory pathologies.

Given the partial success of pharmacological protection, this approach should yield the first practical results. Appropriate agents for and timing of interventions will be explored in animal models, both independent of and tied into interventions in extending life span and general health. Gene therapy also shows promise as a possible strategy to protect hair cells. To date, research has successfully focused on prevention of hearing loss caused by acute trauma like drugs and noise. Such model systems can easily be applied to hearing loss from aging as the etiology of these insults can be strikingly similar to age-related sensorineural hearing loss. As the caveats in the preceding sections point out, we have to be careful in translating results from models to humans, and lengthy trials may prevent the immediate implementation of prospective solutions.

In the area of rehabilitation, technological advances of hearing aids and cochlear implants will improve not only speech recognition but also music appreciation, an area of difficult rehabilitation. A direct nerve implant, already successfully tested in an animal model, may replace the cochlear implant for better efficacy of stimulation and a wider range of frequency and intensity perception. The following generation of prostheses will bypass the cochlea and its nerve and stimulate higher auditory centers. Although clinical application of auditory midbrain implants is in its infancy, a handful of patients have already been treated. Such prosthetic therapy could prove advantageous for patients with massive degeneration of the auditory periphery and/or degeneration of the auditory nerve as in a severe neural type of ARHI.

Lastly, functional hair cell regeneration is the final frontier in the field. Recent studies have shown that cells in the organ of Corti, such as supporting cells, may mitose or transdifferentiate into hair cells if appropriately stimulated. The challenges, however, are highly complex: not only hair cells need to be (re)generated, they also have to be incorporated into the intricate cytoarchitecture of the cochlea and find their appropriate connections to the central auditory structures. Stem cell research may likewise provide new insights for replacement of hair cells and the regeneration of the auditory nerve.

Although presbycusis is not yet preventable or treatable, progress in basic and clinical research promises hope for the future. Most realistic in the near term seem protective pharmacological strategies to delay or attenuate age-related hearing impairment and improved rehabilitation through next-generation hearing aids and implants. A plausible clinical therapy for the regeneration of new and functional hair cells may, despite recent encouraging advance, still be decades away.

## ACKNOWLEDGMENT

Dr. Schacht’s and Sha’s research on age-related hearing loss is supported by program project grant AG-025164 from the National Institute on Aging, NIH.

# Sex and Gender Across the Human Life Span

*William R. Hazzard*

John Anderson, My Jo \*

*John Anderson, my jo, John,  
When we were first aquent:  
Your locks were like the raven,  
Your bonie brow was brent.  
But now your brow is beld, John,  
Your locks are like the snaw;  
But blessings on your frosty pow,  
John Anderson, my jo.  
John Anderson, my jo,  
We clamb the hill thegither;  
And mony a cantie day, John,  
We've had wi' ane anither;  
Now we maun totter down, John,  
And hand in hand we'll go,  
And sleep thegither at the foot,  
John Anderson, my jo.*

*Robert Burns, 1789*

Do you recall this poem above from your high school English literature course? I certainly do, for its romantic depiction of a couple's idealized journey together through this life and perhaps beyond. Little did I dream at the time that the central theme of this chapter would define a paradox that would provide a focus throughout my career in gerontology and geriatric medicine: women outlive men even as they experience greater levels of morbidity, health care utilization, and functional impairment throughout their lives.

A visit to almost any long-term care facility will prompt an obvious question from even the most casual observer: "Where are the men?" This chapter attempts to answer this intriguing question on the basis of both practical and theoretical considerations and extrapolate its conclusions and speculations to considerations of the health

and social care of the elderly in this century of an unprecedented "age wave" in America and the world at large.

The principal questions addressed in this chapter include:

- What is the magnitude of the sex differential in longevity in the United States?
- How universal is this differential among different populations? Among ethnic groups in the United States? Among different nations, especially by degree of socioeconomic development?
- Has this differential always existed? If not, when did it emerge? And why?
- Are there genetic determinants of this differential? Are these mediated by sex hormones? How do these change across the life cycle?
- What are the extragenital consequences of the sex differential in sex hormone physiology at various stages in the life cycle? What are these consequences, notably in the:
  - Nervous system?
  - Endocrine/metabolic system?
  - Immune system?
  - Cardiovascular system?
- What are the social, psychological, and behavioral implications of these differentials at various stages in the life cycle?
- What are the age-specific mortality rates of men and women (commonly expressed as the ratio between the two)—both all-cause and cause-specific?
- What are the age-specific morbidity rates in men and women—both all-cause (especially as expressed in functional status) and cause-specific?
- How do these differentials affect the lives of older persons, with specific implications for the duration and quality of life for elderly men and women? For the prevalence and duration of widowhood? For the health—physical, psychological, social, functional, and

---

\*Joy.

financial—and social and living circumstances of elderly widows and widowers?

- Are these trends changing? If so, how and why? And if so, what are the implications of those changes for the lives of elderly Americans in the twenty-first century?
- Finally, on a more macro level, what are the planning and policy implications of those changes (with special reference to health care and long term care)?

## DEFINITIONS

Throughout this chapter the following definitions are used, conforming to the recommendations of the Committee on Understanding the Biology of Sex and Gender Differences formed by the Board on Health Sciences Policy of the Institute of Medicine of the National Academy of Sciences as explicitly advanced in their landmark 2001 report, edited by Wizeman and Pardue, entitled *Exploring the Biological Contributions to Human Health: Does Sex Matter?*:

- **Sex:** The classification of living things, generally as male or female according to their reproductive organs and functions assigned by chromosomal complement.
- **Gender:** A person's self-representation as male or female, or how that person is responded to by social institutions based on the individual's gender presentation. Gender is rooted in biology and shaped by environment and experience.

It is noteworthy that simply to clarify use of the terms *sex* and *gender* was one of the principal recommendations of this report. As will become evident, this distinction is important in consideration of the central issues in this chapter wherein sex and gender interact dynamically across the lifespan. This is evident perhaps most dramatically during periods of exceptional rates of change, notably during adolescence and across the menopause, transitions that will be highlighted in the discussion that follows. For both sex and gender contribute significantly to the longevity, function, and quality of life of elderly Americans and both must be considered in responsible planning efforts for their health and social care in the twenty-first century.

## HISTORY OF THE SEX DIFFERENTIAL IN LONGEVITY

The sex differential in longevity from birth in contemporary American society is currently over 5 years (Table 45-1). However, this differential has changed dramatically over the past century and continues to evolve. At the beginning of the twentieth century, when the United States was still a developing nation, the sex differential in human longevity was just 2 years, and the overall age-adjusted male:female mortality ratio was only 1:1 (Figure 45-1). Throughout the first 70 years of that century, the ratio climbed steadily (except for a brief decline to near unity during the period 1918 to 1919, which was attributable to the [still unexplained] greater female mortality during the influenza pandemic of that era). This continuous increase translated into a sex differential in expected longevity at birth that reached a maximum at 7.5 years during the period 1969 to 1971. During those seven decades, the nation experienced progressive and dramatic socioeconomic development, a series of cataclysmic wars, and major changes in the roles of men and women in society. The social

progress of women in the post-World War II and Vietnam war era and the rise of the feminist movement led some cynics (mostly men) to predict that women would begin to suffer the health and mortality consequences of the lifestyles and social roles historically considered as “masculine” (the so-called “they’ll get theirs” scenario). In this author’s experience, all persons, both lay and professional, have strong opinions as to why women outlive men. These opinions, however, are more often rooted in personal biases than objective scientific consideration. To illustrate this point, a 1996 survey of more than 500 college-aged students confirmed a distinct sex difference in attribution of the sex differential in longevity: young males ascribed the difference to the traditionally greater physical labor of men and the less stressful life of women, while the females attributed it to better self-care and attention to health by women.

While there is very little evidence to support any of the predicted deterioration in health or longevity of women in the present climate of changing lifestyles and occupational status (women in the

## Average Life Expectancy at Given Ages for White Adults, United States, 1980, Presented by Gender

AGE	LIFE EXPECTANCY (YEARS)		MALE/FEMALE RATIO, %
	Male	Female	
At birth	70.7	78.1	90.5
At 60 yrs	17.5	22.4	78.1
At 65 yrs	14.2	18.5	76.8
At 70 yrs	11.3	14.8	76.4
At 75 yrs	8.8	11.5	76.5
At 80 yrs	6.7	8.6	77.0
At 85 yrs	5.0	6.3	79.4

Adapted from Wylie CM: *Contrasts in the healths of elderly men and women: An analysis of recent data for articles in the United States. J Am Geriatr Soc. 1984;32:670.*

workforce generally experience considerably fewer health problems, seek medical attention substantially less often, and carry less mortality risks than women who are not employed), there can no longer be any doubt that the sex differential in longevity in America has begun to narrow and, in retrospect, has been doing so progressively over the past 30 years. Harbingers of this trend were apparent in mortality data from the late 1960s, when a plateau in the previous linear rise in the sex differential in age-specific death rates began to emerge (see Figure 45-1), and the absolute difference between the sexes in expected longevity subsequently began to decline (see Table 45-1). However, as this trend has continued, it has reflected a greater gain among males than females (compare Table 45-2 with Table 45-1), even as both sexes have experienced continuing moderate increases to unprecedented average longevity. Should this pattern continue, it will introduce an important change in demography of the aging population, as the sex differential progressively narrows. This will reduce the burden of widowhood on survivors and hence the vulnerability of those survivors, especially widows, to loss of independence and consequent institutionalization (discussed further below).

Nevertheless, a certain minimum sex differential in longevity appears to be a fundamental, perhaps immutable, principle of human gerontology. In America, this appears to hold true across ethnic groups with a broad range of average longevity. Nor is this phenomenon confined to the United States: the gap that developed in the United States in the twentieth century simultaneously emerged in all nations that underwent similar socioeconomic development (albeit with considerable variance in the magnitude of those changes; see Ory and Warner), with accompanying increases in average longevity of both sexes. Indeed, as detailed in the insightful review by Austad, women outlive men in 103 of the 104 demographic units tracked in the *United Nations Demographic Yearbook*, the lone recent exception being Bangladesh. These longevity increases are attributed principally to improvements in nutrition, education, housing, transportation, sanitation, public health, and health care, all leading to reductions in the diseases and conditions that predispose to the vastly premature deaths of infants and children. These developments also reduced the deaths of women of reproductive age associated with childbearing (including reduced numbers of pregnancies and deliveries). The same societies also generally experienced simultaneous advances in the status of women in general, a trend that appears

TABLE 45-3

## Genetic Factors That May Differentially Affect the Basic Biochemistry of Male and Female Cells

Female specific:

- Expression of some genes from both X chromosomes
- Defect in initiation or maintenance of X chromosome inactivation
- Changes in estrogen-responsive genes (e.g., the HER2 gene in breast cancer) in germ line or somatic cells

Male specific:

- X-chromosome-linked recessive mutations
- Expression of Y-chromosome-specific genes
- Changes in androgen-responsive genes in germ line or somatic cells

Reprinted with permission from Institute of Medicine, *Exploring the Biological Contributions to Human Health: Does Sex Matter?* Washington, DC: National Academy Press; 2001.

to parallel reductions in premature mortality of women wherever it occurs (see Table 45-3 and concluding section).

## WHEN DOES THE SEX DIFFERENTIAL IN MORTALITY BEGIN?

The sex differential in mortality (Figure 45-2) appears to begin at conception, when the ratio of male to female zygotes may be as high as 170 to 100 (for reasons that remain unclear, Y-bearing sperm are more likely to fertilize an egg than are sperm with the X-chromosome). Because of greater in utero male fetal death, however, by 10 to 12 weeks of gestation (as determined in abortuses), the gender ratio has declined to approximately 130:100. This decline in male survival continues throughout fetal life such that by birth this

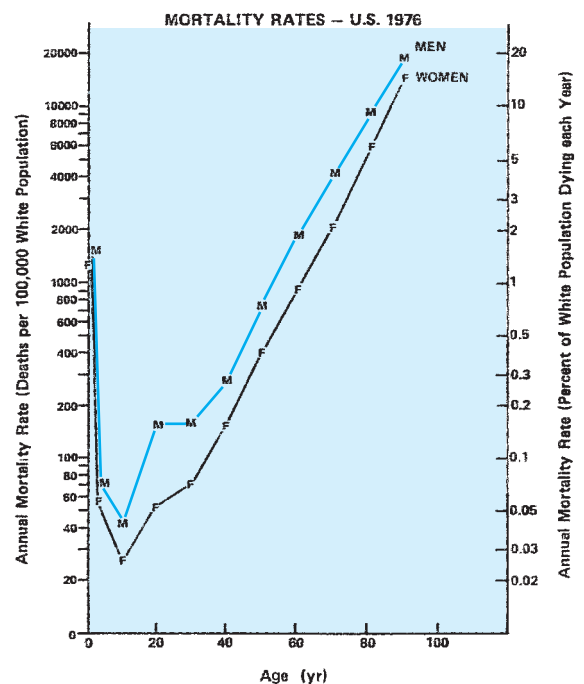

FIGURE 45-2. Mortality rates by gender, United States, 1976. (Compiled from data presented in Gee EM, Veivers JE: *Accelerating sex differential in mortality: An analysis of contributing factors. Soc Biol. 30:75, 1984.*)

ratio has decreased yet further to 106:100 (see chapter by Neel in the volume edited by Ory and Warner).

This trend continues throughout the remainder of the human life span, albeit less dramatically with advancing age. And because the sex ratio of the population at every age reflects the cumulative survival of the sexes from each preceding birth cohort, the sex differential among survivors progressively favors females over males with every passing year of life. After the initial 6% excess of males over females at birth, the continued surplus of male deaths produces parity in numbers between the sexes during adolescence. However, at every age beyond that era, women outnumber men with an ever-growing sex disparity. This leads to a progressive rise in the ratio of women to men with advancing age, a pattern that appears to grow almost exponentially in old age, to a female:male ratio of approximately 3:2 among community-dwelling elderly persons older than age 85 years.

Somewhat paradoxically, this sex differential in the population grows with age in spite of a progressive narrowing in the gap in expected remaining longevity between the sexes, especially beyond middle age. This dwindles to little more than 2 years at age 75 years (see Table 45-2) and 1 year at age 85 years. Of practical utility to clinicians (e.g., in counseling aging couples), the ratio of remaining expected longevity between men and women remains relatively constant beyond middle age, stabilizing at approximately 80% (men compared with women) (see Table 45-1) even as the absolute difference narrows with each passing year of survival. Thus, a strategy designed to minimize the duration of widowhood should place special emphasis on survival of men through youth and middle age, the phases of life in which their greater vulnerability to premature death contributes most to the sex differential in longevity and protracted widowhood of their spouses.

By contrast with the situation among community-dwelling older persons, however, the sex ratio among residents of long-term care facilities (except, of course, those in the Veterans Affairs system) is far higher than 3:2. Ratios of 6:1 or 7:1 are not unusual in community nursing homes. This reflects in part the more vulnerable functional status of elderly women, as compared with men of similar age, and the common reality that they have outlived their husbands (even in nursing homes—in spite of the greater risk of death in the men in such facilities, measures of the performance of activities of daily living (ADLs) display lower average scores in female than male residents—one of many paradoxes raised in the sex/gender/longevity domain). Thus older women demonstrate greater musculoskeletal weakness and disability than do men of comparable age. They have more osteoporosis and are at greater risk to fractures from falls than their male counterparts. They also experience more urinary incontinence, an impairment that especially raises their risk of long-term institution utilization. Women older than age 85 years also have a greater prevalence of dementia, a pervasive disorder among the elderly that greatly increases their risk of institutionalization and often has devastating consequences to function and quality of life in the nursing home environment.

However, just as important, the social circumstances of elderly women, who often live alone, also contribute to their preponderance in long-term care institutions. As emphasized by Wylie, this reflects their more frequent single marital status: at the time of his review in 1980 approximately 80% of American men older than age 65 years were married, only 40% of women older than age 65 years were married, and the widow to widower ratio was 4:1, all figures that grew by each year of advancing age. Thus, given that for both

sexes the person most likely to provide close and continuing support for a vulnerable older individual is the spouse, an elderly man who requires social and health care support to remain in the community is much more likely to have the help and companionship of his wife (who is also usually younger and more vigorous). However, an elderly woman who requires such support is much less likely to have an able spouse in attendance, often having outlived her husband, and she is a candidate for long-term institutional care unless alternative sources of social and health care support can be identified. Widowhood is the normative last phase of life for women: it often lasts more than a decade and is a reality that deserves serious consideration in responsible planning for the care and welfare of older persons for both individual couples and also as social policy.

This differential in caregiving needs and provision of care to elderly men and women is an example of how the terms *sex* and *gender*, as defined earlier, differ in a meaningful way: caregiving is culturally (as well as, arguably, genetically and hormonally) determined; the care provided by wives to their husbands represents an extension of their traditional and normative female nurturing role, a role that carries major implications for the care and welfare of aging persons, both male and female.

## MECHANISMS OF THE BIOLOGICAL BASIS OF THE SEX DIFFERENTIAL IN LONGEVITY

The universal nature of the sex differential in mortality across ethnic and geographic lines suggests that this phenomenon may be rooted in the biology as well as the sociology of the human species. The nature and possible biological mechanisms of this differential have recently been concisely summarized by Federman. As recently reviewed by Austad, examples from comparative zoology suggest that the greater longevity of the female versus the male generally predominates in the animal world. An important and instructive caveat prevails here, however: to observe this differential, the environment must be sufficiently protected as to mitigate the harsher consequences of “survival of the fittest” according to strict Darwinian principles, circumstances that prevail in the wild as well as during more primitive stages of human evolution. This cushioned environment, in turn, will permit survival of both sexes to an age approaching the maximum lifetime potential (MLP) of any given species. This is notably the case in zoos, in which aged animals are protected from inimical forces such as predation and malnutrition, and there females generally outlive males. As noted by Austad, in arguably the nonhuman primate most closely resembling the human, the chimpanzee, in zoos or similar protected environments females typically live longer than males by 3 to 4 years, a difference representing about 10% of their MLP. In this example, however, this reflects a dramatic decrease in male survival during relative youth (4–7 years of age), with parallel rates of survival thereafter.

## BASIC MOLECULAR GENETICS OF SEX DIFFERENCES (see Table 45-3)

The following systematic review of potential mechanism that mediate the sex differential in human longevity begins with the examination of the genetic platform of both sexes as concentrated in the sex chromosomes and upon which sex and gender dimorphism

**FIGURE 45-3.** The human sex chromosomes. (Reprinted with permission from Institute of Medicine. *Exploring the Biological Contributions to Human Health: Does Sex Matter?* Washington, DC: National Academy Press; 2001.)

is played out across the life span and focus upon general biological regulators, notably levels of oxidative stress.

The sex chromosomes constitute but approximately 5% of the human genome (Figure 45-3). The Y chromosome is much smaller than the X chromosome and codes for only about two dozen different genes. Of those, the SRY gene determines development of the male gonadal phenotype, while spermatogenesis is related to a small number of other genes, mutation or deletion of which has been associated with certain cases of male infertility. Another class of Y chromosomal genes code for ribosomal proteins in Y-bearing cells (RPS4Y in Figure 45-3), while homologous genes on the X-chromosome code for those proteins in XX cells; thus certain ribosomal proteins throughout the organism differ between male and female cells. However, the functional consequences of these differences remain to be determined.

Male and female genomes differ in another important respect: females have twice the dose of X-chromosomal genes (i.e., “heterogametic”). This difference has led to the heterogametic sex hypothesis that the lack of a second X-chromosome in the male underlies at least a portion of his diminished longevity compared with the female. Here information from comparative zoology offers tantalizing mechanistic insight; for example, in the bird, the female has one long and one short sex chromosome and is thus the heterogametic sex (while the male has the two long [“Z”] sex chromosomes). According to the heterogametic hypothesis, male birds would be predicted to have a longevity advantage over females—which as cited by Austad is indeed the case for several species listed (budgerigars, zebra finches, and Japanese quail)—once again, however, explicitly specific to those raised in captivity.

In the human the X chromosome has approximately 160 000 DNA base pairs encoding an estimated 1000 to 2000 genes (see Figure 45-3). Only a few of these, the “pseudoautosomal,” have homologues on the Y chromosome. Products of these genes, like those on the autosomes, play a role in virtually every aspect of cellular function, metabolism, development, and control of growth and turnover. Especially germane to this discussion are those that play specific roles in particular tissues at particular points in development, several of which have been demonstrated to play critical roles in gonadal differentiation.

The twofold increase in X-chromosomal genes in females is in general offset by X-chromosomal inactivation, a complex, carefully regulated process unique to female cells marked in each by one of the two X-chromosomes becoming heterochromatic (identifiable on microscopy as the Barr chromatin body in the nucleus of female cells). This process renders genes on the inactivated X-chromosome functionally silent. It occurs in every somatic cell of XX females but not in XY males. Thus, not only must XX cells maintain the state of cell-specific X-inactivation throughout life but also, because the same X-chromosome is not inactivated in every cell, XX females are “epigenetic mosaics.” Not surprisingly, the process of X-inactivation is itself controlled by multiple factors, including genes. However, this may vary widely; in some families, sisters may show nearly identical patterns of X-inactivation, whereas in other studies of female identical twins, such patterns differ widely within twin pairs.

Directly germane to the focus of this discussion, female mosaicism underlies the dramatic sex difference in the severity and risk of death from diseases that are transmitted in a sex-linked recessive mode. For whereas a mutation in a gene on the X-chromosome will be

expressed in every cell of an affected male, only half of the cells of the female will experience the consequences of that mutation, and her heterozygous state may carry no functional significance. However, given the rarity of X-linked recessive diseases with major physiologic consequences (e.g., classical hemophilia), the aggregate contribution of all the premature deaths of males from such sex-linked autosomal recessive diseases to the sex differential in longevity is miniscule.

Perhaps more relevant, however (at least theoretically), it appears that in cells grown in culture that at least 10% to 15% of X-linked genes appear to be expressed from the inactive chromosome and hence have “escaped” X-inactivation, contributing to a net increase in activated X-chromosomal gene products in females. This differential X-inactivation may have implications for vulnerabilities to certain diseases in affected individuals; for example, the suspected relationship between gastrin-releasing peptide receptor and smoking-related lung cancer, which is released by both active and inactive X chromosomes, with elevated levels hypothesized to lead to increased risk of lung cancer in women smokers. And, at the purely theoretical level, is X-inactivation maintained constantly throughout life? Could reactivation of the silenced X provide “back-up” genetic resiliency for women in later life?

### SEX DIFFERENTIALS DURING FETAL, CHILDHOOD, AND ADOLESCENT DEVELOPMENT

All humans—XX, XY, or with an atypical sex chromosome configuration—begin development from a common starting point *in utero*, with similar, phenotypically female genitalia until 6 to 7 weeks of gestational age. After that point expression of the SRY gene on the Y chromosome in males induces development of the testes. At about 9 weeks, this results in the secretion of testosterone. This, in turn, as modulated by multiple genes (at least 70 on sex chromosomes and autosomes), results in the development of the reproductive tract and masculinization of the male fetus as expressed most notably in the genitalia and the brain. In the absence of testosterone, the female phenotype is expressed; ovarian hormones are not required for this development. Moreover, animal studies and research on human dizygotic twins have suggested that testosterone secreted by a male fetus can exert a masculinizing influence on adjacent female fetuses, with anatomic, physiologic, and behavioral consequences. Thus events during intrauterine life, especially the secretion of testosterone by the fetal testis, exert powerful and enduring effects on postnatal life.

During late fetal life and infancy, however, the hypothalamic–pituitary–gonadal axis is largely suppressed, giving rise to relative hormonal stability throughout childhood (the “juvenile pause”). Adolescence, the gradual coming of age that transpires during most of the second decade of life, is the next phase of development during which the sex and gender differentials in growth and behavior are dramatic. Within that phase, puberty constitutes the transitional period between the juvenile state and adulthood during which the adolescent growth spurt occurs, secondary sexual traits appear (producing the dramatic sexual dimorphism of adult men and women), sexual activity is commonly initiated, and profound psychological changes occur. This tends to be conceptualized as a series of changes arising from reactivation of the hypothalamic–pituitary–gonadal axis.

However, despite the relative hormonal quiescence during the juvenile phase, small pulsatile patterns of follicle-stimulating hormone (FSH) and leuteinizing hormone (LH) can be detected as harbingers of coming adolescence in prepubertal children, and a striking eight-fold difference in estradiol levels is demonstrable in girls. This is associated with a 20% advancement in bone age in girls versus boys and maybe related to their earlier onset of puberty. The development of breasts, which begins in white girls at an average age of 10.6 years, is under the control of estrogen, whereas growth in axillary and pubic hair is influenced by androgens secreted by the adrenals and ovaries. The age at which the benchmarks of pubertal development appear is also influenced by ethnicity (breast development begins about a year earlier on average in African-American girls than in white girls). Whether or not there has been an earlier age of breast development in recent decades remains a subject of controversy. However, contrary to much popular opinion, the average age of menarche appears to have remained constant for at least the past four decades. In boys, the beginning of puberty is marked by an increase in testicular size, which begins at a mean age of approximately 11 years (in both white and African-American boys).

One of the most striking sex differentials associated with puberty is the earlier onset of the growth spurt in girls (Figure 45-4), in whom it may actually begin prior to breast development or growth of axillary or pubic hair. In boys, peak height velocity is reached approximately 2 years later than in girls, although boys are taller than girls at the onset of the spurt and finish, albeit later, with a mean height that is 12.5 cm (about 5 inches) greater. This differential reflects the greater prepubertal growth of boys and their taller status when their pubertal growth spurt takes off as well as their greater growth during the pubertal phase. The principal hormonal determinants of the growth spurt are growth hormone, insulin-like growth factor-1 (IGF-1) (hypothesis #3 in Table 45-3), and triiodothyronine in the prepubertal phase (accounting for 50% of the height increase during the subsequent pubertal phase), while estradiol is the main sex hormone involved in the pubertal phase in boys as well as in girls (the estrogen in boys arising principally by extragonadal conversion from testosterone).

Another hormonal feature of puberty is the phenomenon of adrenarche, which begins before age 8 years and is marked by progressive increases in adrenal androgen secretion and plasma dehydroepiandrosterone (DHEA) and DHEA-sulfate. Adrenarche is independent of the mechanisms that regulate the secretion of sex steroids from the gonads (gonadarche). Clinically adrenarche is signaled by the appearance of axillary and pubic hair and is considered premature when it occurs in white girls before age 7 years and in African-Americans before age 5 years. In contrast to the circumstance in boys, in whom premature adrenarche is a benign variant of normal puberty, in girls it is associated with a 10-fold increased risk of the polycystic ovary syndrome (PCOS) and its associated (and pathophysiologically important) features of ovarian hyperandrogenism and insulin resistance. These lead to an increased incidence of central obesity, type 2 diabetes, hypertension, and dyslipidemia (with a male-type pattern of higher low-density lipoprotein [LDL] and lower high-density lipoprotein [HDL] cholesterol levels prior to the era of the menopause), all cardinal features of the “metabolic syndrome.” PCOS, which has been estimated to occur in as many as 10% of women, appears to attenuate the sex-specific relative immunity to cardiovascular disease (CVD) otherwise enjoyed by women. As such, its understanding may provide special insights

**FIGURE 45-4.** The relationship between age and height velocity through adolescence in human females and males. (Reprinted with permission from Institute of Medicine. *Exploring the Biological Contributions to Human Health: Does Sex Matter?* Washington, DC: National Academy Press; 2001.)

into the mechanism whereby men are at increased CVD risk, as compared with women, and the role of hormones, including insulin and sex hormones, in mediating that sex differential. Such insight may also provide opportunities to intervene with both behavioral and pharmacologic strategies to prevent premature CVD in men (and potentially in women as well, especially those with PCOS).

Of special relevance to the premise of this chapter that the sex differential in longevity originates in events in the life cycle long before old age, an intriguing body of evidence suggests that there is an association in girls between retarded in utero growth, the risk of premature adrenarche, and their subsequent development of PCOS; certain recent studies suggest that girls with antenatal growth retardation and low birth weights have fewer primordial ovarian follicles and a smaller uterus and ovaries at puberty and subsequent hyporesponsiveness to FSH, which may mediate (or at least be a marker for) the pathophysiology of PCOS. Thus, PCOS may be a classic example of a disorder of adolescence and adulthood that is programmed during fetal life but which holds important implications for health and longevity in middle and late life—as well as providing major insight into the general mechanism whereby nonandrogenized women enjoy longer (and more CVD-free) lives than their male counterparts.

These hormonal and physical changes at puberty also hold important implications for the sex differences in behavior during adolescence that are the subject of such intense contemporary public interest and concern. Some of these differences appear to proceed from the direct effects of gonadal hormones on the brains of adolescent boys and girls. For example, in studies of early adolescents, increasing levels of testosterone were associated with increasing aggression and social dominance in boys, while changes in estrogen levels correlated with changes in behavior patterns in girls during the pubertal transition. In various studies, certain behaviors appear to relate to absolute levels of sex hormones, others to the ratio of testosterone to estrogen, and still others to fluctuations in hormone levels. Still other

studies reported changes in sex hormones in response to behaviors, such as increases in testosterone following athletic successes.

Such changes may have important, even life-altering, effects on the adolescents who experience them. Earlier maturation by girls, for instance, has been associated with social adjustment problems during puberty, earlier initiation of sexual activity and pregnancy, and later problems with eating disorders, depression, and substance abuse.

Boys may not have the same extent of social and behavioral problems, partly because of the recognition they receive from precocious physical strength and athleticism. However, there can be little doubt but that the risk-taking behavior of adolescent and young adult males contributes importantly to the stark contrast in mortality rates between young men and women (see below), and it seems logical to attribute such behaviors to hormonally mediated sex differentials across the adolescent transition. These become manifest not only in differentials mediated by sex in the sense of the definition urged by the Institute of Medicine report, but, importantly, also in how adolescents present themselves to the world and how its social institutions respond to them; that is, their gender manifestations. These issues are explored in depth in the provocative essay by Courtenay. Again the physical, psychological, behavioral, and social sex and gender differentials that present such stark contrasts during adolescence are rooted in the antecedent genetic, hormonal, and environmental lives of those boys and girls and also continue to modulate individual and group sex and gender differentials in health and longevity throughout adolescence and the remainder of the life span.

A practical consideration regarding the earlier maturation of girls than boys is also germane to the central theme of this chapter: that the duration of widowhood is an important determinant of the long-term care needs of elderly persons, especially women who have outlived their husbands. Because there is a normative sex differential in the age at marriage of bride and groom (generally about 2 years, likely reflecting the earlier maturation of females), this adds a

commensurate period to the duration of widowhood, which may average nearly a decade (2–3 years difference in age at marriage plus approximately 5 to 6 years in the sex differential in longevity).

### SEX MAY AFFECT REGULATION OF REDOX STATE AND OXIDATIVE STRESS

An attractive strategy in gerontological research examines mechanisms of homeostatic regulation that apply broadly across tissues and organ systems and which impact function across the life span. As such, they may converge with advancing age to become final common pathways that may mediate age-related comorbid diseases and ultimately frailty and demise in old age. One such mechanism that may contribute to the greater longevity of females is their reported superior regulation of redox balance and level of oxidative stress. As noted by Austad, this appears most evident in studies of rats (as apposed to mice), in which certain (notably the Wistar and Fischer 344) strains demonstrate substantially (ca. 16%) longer female longevity. Especially notable in this regard have been the reports from the laboratory of Vina, where studies of male (vs. female) rats demonstrated more oxidative DNA damage in isolated mitochondria. Yet more intriguing, these investigators reported that ovariectomy in females increased the production of oxygen-free radicals (hydrogen peroxide) in liver and brain mitochondria, an increase that was prevented by estrogen replacement. These findings were extended in measurement of endogenous mitochondrial antioxidant levels of glutathione peroxidase (mRNA and protein activity), which as predicted was higher in females than males. These authors interpreted these findings to attribute the greater longevity of female rats to attenuation of the age-related increase in reactive oxygen species (ROS) by estrogen, enhancing their antioxidant protection against age-related tissue damage. However, this provocative line of research clearly requires much further confirmation and investigation.

### SEX AFFECTS NEURAL ANATOMY AND FUNCTION

Another fundamental strategy of gerontologic investigation looks to biological integrating systems for insights into the aging process. This strategy examines how changes in those systems with aging render the organism progressively more vulnerable to insults from the environment in a stochastic cascade that limits survival of the individual and determines average and maximum longevity of a given species. Hence, consideration of the determinants of the sex differential in longevity (as well as of the causes of morbidity at various stages of the life cycle) have focused upon modulation of the neural, endocrine, and immune systems by sex hormones across the life span and how these might explain that differential.

As introduced in the immediately preceding sections and well-summarized in the 2003 Institute of Medicine report, fundamental differences in genetics and physiology between males and females result in important differences in neural anatomy and circuitry as well as in cognition and behavior at all points across the life span. While these differences begin during fetal life, they are amplified and modulated continuously at each age and each stage in a fashion that interacts dynamically with the environment, including sex and gender-sensitive interactions between children and their parents and other aspects of the different “male/masculine” and “female/

feminine” cultures in which boys/men and girls/women develop and live.

These sex and gender differences can increasingly be demonstrated in the central nervous system and brain as investigative techniques in neuroanatomy, physiology, and neural imaging become more sophisticated. The brain is increasingly appreciated as an endocrine organ, too, with behavioral and anatomical consequences of exposure to hormones, including sex steroids, especially testosterone (e.g., greater aggression in male than in female mice). Such exposures are also being examined in relation to the gender identity of children. For example, case studies report that certain children with an XY-karyotype raised as girls because of mutilated or ambiguous genitalia may ultimately develop a male gender identity, presumably because of their intrauterine testosterone exposure. This challenges the belief that individuals are born with the potential to develop either male or female gender identity as determined by the sex of rearing.

Other sex differences in human behavior are also becoming increasingly documented in studies of males and females at various stages across the human life span. Many have focused on childhood play behavior and related activities and interests, personality (such as aggression and interest in babies), nonverbal communication, and cognitive abilities. These differences carry over into adult life and notably in patterns of health and health care. Here there are well-documented sex differences in frequency of visits to health professionals, use of complementary medicine, both higher in women than men, and incidence and course of certain mental disorders, notably depression, also substantially more frequent in women, as contrasted with substance abuse, notably of tobacco and alcohol, which is far more common in men. Underscoring the confounding of such behavioral differences by cultural definitions of what constitutes behavior appropriate to one’s gender, such contrasts in health status and behavior have been hypothesized to represent gender-“appropriate” responses to a common pathophysiology of depression in women versus men.

These sex differences also apply to cognition, differences that are more marked at the extremes of the distribution of any given ability. In general, women more often demonstrate greater abilities in the verbal domain: verbal fluency, speech production, the ability to decode a language, spelling, and perceptual speed and accuracy. Suggestive of a hormonal basis of such abilities, these variations in performance, especially verbal skills, have been observed in women across the menstrual cycle; for example, during the preovulatory phase, when estrogen levels are high, women have demonstrated deterioration in spatial abilities, while manual coordination and skills in articulation improved.

Women also generally excel in fine motor skills. Men, on the other hand, more frequently demonstrate better performance on tests of spatial and quantitative abilities, as well as gross motor strength. These sex differences may be reflected in the performance of certain tasks highly relevant to certain conditions common in old age (e.g., dementia), because women typically perform better than men in tests of working memory of both verbal and nonverbal information. Mathematical abilities of males are greatest at the highest levels of performance (e.g., boys outperform girls on the mathematics SATs by 2:1 at a score of 500 and above, 5:1 at 600 and above, and 17:1 at 700 and above). However, such differentials are confounded by the important contribution of experience to performance on such tests, and because boys are enrolled in advanced mathematics courses far

more often than girls, their superior performance, especially at the highest levels, may reflect that exposure more than their sex, gender, or sex hormone physiology (a general caveat for interpreting all such studies).

Recent technologic imaging advances are translating these descriptive studies into visual images of differential performance in cognitive tasks between men and women. For example, functional magnetic resonance imaging (fMRI) studies of cerebral blood flow during performance of certain activities have revealed differences between the sexes: men typically rely upon the left inferior frontal gyrus (Broca's area) to carry out phonologic processing, while women generally employ both left and right frontal gyri (extrapolated perhaps to why women may experience less loss of speech function than men after a stroke involving the left frontal gyrus).

Another area of differential neural function with major implications for health and function of women versus men across the life span that was a focus of the Institute of Medicine report is the reported increased perception of pain by women (Table 45-4). This bears much further investigation but clearly impacts morbidity in old age and the care of the elderly. Not only are older persons preponderantly women but women also have a greater prevalence of many of the disorders listed in Table 45-4, the management of which commonly falls into the domain of the geriatric clinician.

## SEX AFFECTS IMMUNE FUNCTION

Just as there is a general "domino hypothesis" of aging and longevity regarding general physiological regulation across the life span, there is an analogous hypothesis regarding the immune system and aging: involution of the thymus, which begins at puberty, is associated with a progressively reduced thymic cellular output that leads to fewer naïve T cells contributing to the peripheral T-cell pool. In the steady state, the number of T cells within that pool is held constant within narrow limits by homeostatic mechanisms. These induce the proliferation and extend the survival of resident T cells to fill niches left by declines in naïve T cells. According to this hypothesis, however, with the passage of time (and perforce aging), as T-cell population is maintained constant through proliferation, increasing proportions of T cells come to reach their replicative limit. This, in turn, renders the organism vulnerable to infections and certain cancers as the immune response to those challenges progressively fails. Relevant to the theme of this chapter, comparison of sex differences in life span and death rates at each age from infectious and parasitic diseases suggests that the immune system works more efficiently and is effective longer in females than males (implying in turn that thymic involution occurs at a more rapid rate in males).

This sex differential applies more to the adaptive than the innate immune system (granulocytes and their products). The adaptive system includes activation and suppression of T and B lymphocytes, macrophages, and dendritic cells; secretion of their cytokine products; production of immunoglobulin antibodies; and activation of the complement and coagulation systems. As a general rule, although the sex differential in these functions is relatively narrow, estrogens upregulate and androgens downregulate these systems. Accordingly, modest variation in these functions can be seen at various phases of the menstrual cycle. In general, these differences have been sufficiently subtle as to present a challenge to providing mechanistic insights through research. And whereas studies of animals in con-

trolled circumstances have demonstrated that males are more susceptible to infections with parasites, bacteria, fungi, and viruses than females, this has not been clearly demonstrable in humans, in whom the sex differentials in such infections have generally been attributed to sex differentials in exposures rather than in a sex differential in the individual's response to those exposures.

In contrast to the relatively subtle hypothesized greater vulnerability of males to infections, the far higher risk of females to diseases of autoimmune origin stands out as a major cause of the greater morbidity of women than men from these afflictions across the adult life span (summarized in Table 45-5). Indeed, as well-summarized and

referenced in the Institute of Medicine report, autoimmune diseases may well constitute the prototypical domain of greatest contrast between the sexes and hence provide unique insights into mechanisms of the sex differential in many other diseases as well as in overall morbidity and longevity. However, research to date demonstrates great complexity in the determinants of the sex differential in this domain as well, with sex differentials in exposure at different stages of the life cycle and of hormonal modulation (including that related to pregnancy in females) playing important roles. Especially germane to the sex differential in health and function across the life span, because those autoimmune diseases with greatest female preponderance arise in young adulthood and generally carry over throughout the remainder of life (e.g., rheumatoid arthritis), the contribution of those disorders to the greater lifelong morbidity of women and their greater burden of chronic illness in old age is substantial. However, as is proving to be the case in most diseases that differ by sex, the role of sex hormones in their pathophysiology and management is not clear; for example, many of the autoimmune diseases appear to be ameliorated during pregnancy and not aggravated by female hormone replacement therapy (HRT). Thus a simple, cohesive theory to explain the sex disparity is lacking, and caution is urged in attributing the difference in both auto- and isoimmune functions to either physiological or pharmacological effects of the sex hormones.

## SEX AFFECTS SEX HORMONE PHYSIOLOGY ACROSS THE ADULT LIFE SPAN

Review of the changes in sex hormone physiology across the adult life span is distributed among several other chapters in this textbook, notably, regarding the aging of the endocrine system (Chapter 65), menopause (Chapter 99), male HRT (Chapter 103), and female

HRT for osteoporosis prevention and treatment (Chapter 75). These chapters focus on aspects with implications for the aging process and approaches to HRT as part of a strategy to mitigate some of the age-associated declines in physical and functional status.

Female HRT is also addressed in the present chapter in the section devoted to that subject as related to thromboembolism and CVD, cancer, and gall bladder disease. For details of other aspects of sex hormone physiology such as reproductive function, the reader is referred to standard textbooks of endocrinology (e.g., *Williams Textbook of Endocrinology*, 9th ed.) Suffice it to summarize here that such changes are likely to influence the physiology and pathophysiology of human aging across the entire adult life span. Such differentials in sex hormone physiology are also likely to underlie much of the sex differential in longevity, as well as the health status of elderly adults in cumulative, complex patterns in multiple organ systems and diseases of those organs. However, it must be stressed that sex differences in the physiology of sex hormone regulation and the attributed effects of those differences on the function, health, and longevity of men and women cannot be not legitimately extrapolated to HRT (for either women or men), which differs from physiologic hormone regulation both quantitatively and qualitatively. Attempts to obviate the changes in sex hormone physiology with aging through HRT remains a controversial approach in both sexes, an “antiaging” strategy that lacks consistent validation through rigorous research and evidence-based practice. Indeed, a lesson of history learned once again in the early termination of the Women’s Health Initiative (WHI) (see below) is that HRT—as with all such hopeful gerontologic interventions—must be formally tested in randomized clinical trials (RCTs) before any such treatment can be recommended for widespread clinical use. Furthermore HRT, especially using the regimens employed in the WHI, is currently quite definitely not recommended for this purpose.

## SEX DIFFERENTIAL IN LONGEVITY

An empirical approach to the sex differential in human longevity begins with inspection of the sex ratio in longevity from all causes across the life span in the United States. This displays a bimodal pattern, with a peak (“spike”) of approximately 3:1 at age 20 years and a plateau (“dome”) of approximately 2:1 in late middle age (and a decline toward unity in old age). A similar pattern is seen in nearly all developed nations (although the ratios under the spike and plateau/dome vary by country), with the late sex mortality ratio being notably higher (and more in a dome-like configuration) and the sex differential in longevity growing, not declining in the nations of Eastern Europe and the former Soviet Union, where male mortality rates are increasing at an alarming rate. Perhaps providing insight to the genesis of this “spike and dome” configuration, it seems germane to note that this pattern emerged in the United States and these other nations in the twentieth century in parallel with their socioeconomic development as well as their involvement in major military conflicts.

To pursue the possible mechanisms of the evolution of the sex longevity disparity at the next level of inquiry, the sex ratio for the top 12 causes of death in 1980 (Table 45-6 and Figure 45-5) can be reviewed. This exercise reveals that men have a higher age-adjusted death rate than do women for nearly all causes. Diabetes is the one clear exception to this rule: men and women are at virtually identical age-adjusted mortality risk (i.e., diabetes nullifies the otherwise

TABLE 45-6

powerful reduction in all-cause mortality enjoyed by women versus their male counterparts especially in the pre/perimenopausal period). However, such inspection also readily allows grouping of those causes of death into ones that are frequent in adolescence and young adulthood—notably, those related to violence and the risks of a youthful lifestyle—and those that are prevalent in middle and old age, the chronic and progressive “degenerative” diseases of complex etiology that increasingly dominate the practices of primary care

physicians and geriatricians. In the first group, neurobehavioral gender differentials clearly appear causative—“macho” behavior involving considerable risk constituting the most obvious factor increasing male vulnerability. There is increasing acknowledgment that such behavior is determined at least in part by hormonal factors, although modulation—exaggeration or dampening—by sociocultural forces is clearly also important (i.e., sex plus gender issues). This risk-taking behavior also extends to sex differentials in drug abuse and sexual

FIGURE 45-5. practices, with consequences that could have a dramatic impact on the sex differential in longevity especially if the human immunodeficiency virus (HIV) epidemic continues to affect more men than women (see Chapter 87). However, narrowing in the sex differential in HIV-related deaths has recently become apparent as the viral infection spreads to women by heterosexual contact and intravenous drug abuse and through more effective antiviral treatment, HIV has become more of a chronic disease. Indeed, HIV disease is now the fastest-growing cause of death in young American women, while men from earlier cohorts are now experiencing chronic, especially metabolic and CVD accelerated by side effects of retroviral agents.

The causality of the diseases clustered under the plateau of greater male mortality in late life, which in the aggregate account for approximately 90% of the sex differential in longevity (see Figure 45-6 from Ory and Warner), is more complex and certain to prove multifactorial. An attractive hypothesis, advanced principally by social scientists, has, as with the spike in youth, focused on behavioral-cultural factors. Men in western societies have traditionally adopted lifestyles with greater risk to their health throughout mid-life: more miles driven, more cigarettes smoked, less focus on health promotion, disease prevention, and early detection. Men also historically have made fewer visits to physicians and taken fewer prescription drugs. Indeed, as reported by Courtenay, these differences in attitudes and health behaviors that undermine men's health often serve as signifiers of masculinity and instruments that men use in the ne-

gotiation of social power and status. Put another way, denial of their vulnerability to disease and death is part of the masculine tradition and gender identity, an attribute that presents a cultural and behavioral barrier to effective strategies of "preventive gerontology" for men (see Chapter 6).

This barrier is especially imposing to boys/men of lower socioeconomic and vocational strata, who have less access to the advantages enjoyed by males in the higher strata, which include greater positive reinforcement of healthy behaviors that positions of economic and social power bring (including greater access to health care and control over time and schedule). These phenomena have tended to confound the issue of sex/gender and health, introducing an intriguing paradox: women experience greater morbidity (often reported in terms of numbers of encounters with the health care system), but men have higher mortality rates at every age. The bases for these sex and gender differentials in health behavior have been widely investigated (although with little definitive outcomes and notably relatively little correlation with quantitative biomarkers of disease risk or measurements of sex hormone physiology or effects). These have been reviewed elsewhere (see especially chapters by Wingard and by Nathanson in the volume edited by Ory and Warner and the recent Institute of Medicine report edited by Wizemann and Pardue).

The behavior with the greatest potential impact on the sex differential in longevity—and a behavior that remains flux—is cigarette smoking. To illustrate this point, it was reported by Waldron in the

Ory and Warner volume that mortality in middle-aged nonsmoking men exceeds that in nonsmoking women by only 30%, as compared with a male excess of greater than 120% for the total population studied (put another way, nonsmoking men and smoking women have more equal age-adjusted mortality rates). Cigarette smoking became fashionable in the United States in the twentieth century, and until recently, was predominantly a masculine habit—men started earlier in life and smoked more heavily than women. This behavioral sex differential was reinforced by incentives that encouraged cigarette smoking by servicemen during the World Wars of that era. The clear parallel between increases in male cigarette smoking and the rising sex ratio in mortality in the twentieth century would seem causally related. Review of the sex ratios in mortality from the leading causes of death in America (see Table 45-6) strongly suggests that the historical sex differential in cigarette smoking constituted a major factor in the majority of such causes, notably vascular disease, both coronary heart disease (CHD) and stroke, cancer, especially lung cancer, and nonmalignant lung disease. Indeed, it was estimated by consensus at the NIA conference that produced the volume by Ory and Warner that the historical sex differential in cigarette smoking behavior might account for as much as 4 years of the 7-year U.S. sex differential in longevity at birth when it reached its peak in 1970.

In this context, it is relevant to examine more recent trends in cigarette smoking in both sexes and parallel trends in mortality rates from diseases related to smoking. Cigarette smoking reached its peak prevalence and intensity in the United States shortly after World War II, when nearly half of the adult population was smokers. At that time not only did more men than women smoke, but also heavy cigarette use was far more prevalent in men. From that time until the present, cigarette smoking has declined progressively in the United States (although recent reports disclose that this trend is slowing, especially in younger persons and notably in younger women). The beginning of this decline closely paralleled the release of the first Surgeon General's Report on Smoking and Health in 1963, the first clear public statement linking cigarette smoking with lung cancer and other feared diseases. Initially, the decline in smoking appeared to be greater in men than women, but by the late 1960s, women were also giving up smoking at a comparable rate. The decline has been most notable among those older than age 35 years in both sexes. When the decrease in CHD mortality first received public attention in the early 1970s (the "epidemic" having reached its peak at the time of the Surgeon General's report), a significant proportion of that reduction was attributed to the decline in cigarette smoking. This decline, which has continued to the present (albeit at a diminishing rate), has generally been equivalent as expressed in relative (percentage) terms in both genders. However, because the previous absolute levels of CHD mortality were far greater in men, their absolute decrease in CHD deaths has been greater. In parallel fashion, because the level of cigarette smoking in men was far higher, their absolute reduction in cigarette consumption has been greater (see especially the chapter by Nathanson in the volume edited by Ory and Warner). Hence, recent trends show a decrease in the difference in the number of CHD deaths in men versus women, in parallel with the decrease in the number of cigarettes smoked by men as compared with women. That women are as vulnerable as men to the untoward effects of cigarette smoking—given the lag between exposure to tobacco carcinogens and the onset of lung cancer—is evident in the narrowing of the historical sex differential in lung cancer, which surpassed breast

cancer as the most common cause of cancer-related death in women in the 1980s (see Figure 45-5), as well as in other smoking-related diseases, such as chronic obstructive lung disease and peptic ulcer disease. However, these trends appear likely to stabilize as cigarette smoking rates become equivalent in both sexes, and both men and women, especially those of higher income and educational levels, have adopted healthier lifestyles in response to the widespread public health educational campaigns against cigarette smoking.

## THE SEX DIFFERENTIAL IN ATHEROSCLEROSIS

Review of the sex differential in the leading causes of death (see Table 45-6) clearly places atherosclerosis and its clinical consequences—CHD, cerebrovascular disease, aortic aneurysm, and peripheral arterial disease—at the center of any consideration of the sex/gender gap in longevity: in the aggregate, these diseases account for more than 40% of the total (Figure 45-6). Moreover, it has been estimated that elimination of all atherosclerotic disease could add up to 10 years to average longevity beyond age 65 years in the United States, raising the mean age at death to nearly 85 years (a popular estimate of the maximum possible average human longevity according to the essays by Fries and by Olshansky et al.). Furthermore, by deferring death among men to beyond middle age, when the sex ratio is highest, a reduction in ages at death between marriage partners (and a decrease in duration of widowhood) would be important by-products.

## SEX DIFFERENTIAL IN CARDIOVASCULAR DISEASE RISK FACTORS

Although sex differentials may exist in the most basic aspects of atherogenesis (e.g., arterial intimal integrity, vasomotor response, lipoprotein uptake, or other aspects of arterial wall biology—see Chapter 34), evidence for all such possibilities, albeit intriguing, must at present be considered preliminary. A more practical approach is to review sex differentials in the traditional atherosclerosis risk factors across the life span during stages as defined in general and convenient terms by this author: childhood and adolescence (infancy to age 25 years); middle age (ages 25–75 years, conveniently bisected at age 50 years [approximately the age of menopause for women] into first and second halves); and old age (older than age 75 years).

Here population studies suggest at least subtle differences at each stage that provide a pathophysiologic basis for earlier clinical expression of CVD in men. These studies demonstrate that sex differentials begin in childhood and adolescence, as well documented in the Bogalusa community studies led by Berenson (which also demonstrated early atherosclerosis in the arteries of adolescents killed in vehicular accidents in that community). In middle age, blood pressure, both median systolic and diastolic, is lower in women than men during the first half (25–50), beyond which a crossover occurs such that hypertension (especially isolated systolic hypertension) is more common in older women than men. Regarding control of blood glucose levels, glucose tolerance tests applied to population samples (e.g., in Tecumseh) demonstrate a pattern of change in efficiency of glucose disposal with age also favoring women until midlife, with convergence between the sexes beyond middle age. This carries over into an overall age-adjusted excess male prevalence of diabetes of

greater than 10%, a disparity still evident in old age. Regarding median levels of blood lipids (cholesterol and triglyceride), these change with age in a biphasic pattern, increasing in both sexes (albeit at a lower rate in women) until the midpoint of middle age, when a plateau is reached, and declining thereafter (see [Figure 45-6](#)). Except for the abrupt increase in cholesterol levels in women older than age 50 years (the “postmenopausal overshoot”), these changes in lipids, blood pressure, and glycemic control in the first half of middle age are in general correlated with and maybe mediated by gains in relative body weight, which normatively continue until the middle of middle age, when a plateau is reached (although adiposity may continue to accrue, it is offset by decreases in lean body mass). A decline in median relative body weight during old age ultimately follows, perhaps signaling the onset of frailty and terminal decline (the continued increases in blood pressure and blood glucose beyond middle age require a different explanation).

Close inspection of such curves reveals patterns that are subtly different between men and women, the middle-aged weight plateau being achieved approximately a decade later in women than in men (during their sixties rather than their fifties). Thus, a slower accretion of weight and a later achievement of peak weight in women than men may at least partly explain the more favorable CVD risk profile of women prior to age 50 years and their relative infrequency of clinical CVD prior to that age, a benefit that may carry over into the succeeding postmenopausal era by virtue of the slower rate of atherogenesis to that point.

A sex differential in regional patterns of midlife weight gain is another possible explanation of the lower CVD risk in women (see also Chapter 92). Beyond adolescence, women prototypically gain more adipose mass about the hips and buttocks (producing “lower body,” “pear-shaped,” or “gynoid” obesity), whereas adult men prototypically add fat about the waist (leading to “upper body,” “apple-shaped,” or “android” obesity). The latter pattern confers extra CVD risk, exaggerating the known interaction between relative body weight and the traditional risk factors in population studies such as in Framingham. Moreover, those atypical women who develop upper-body obesity—especially those with hyperandrogenism and the PCOS—have CVD risk profiles resembling those of men, and they are at substantially increased risk of type 2 diabetes (presumably because of increased insulin resistance and compensatory hyperinsulinism) and its attendant increased risk of atherosclerosis and its complications.

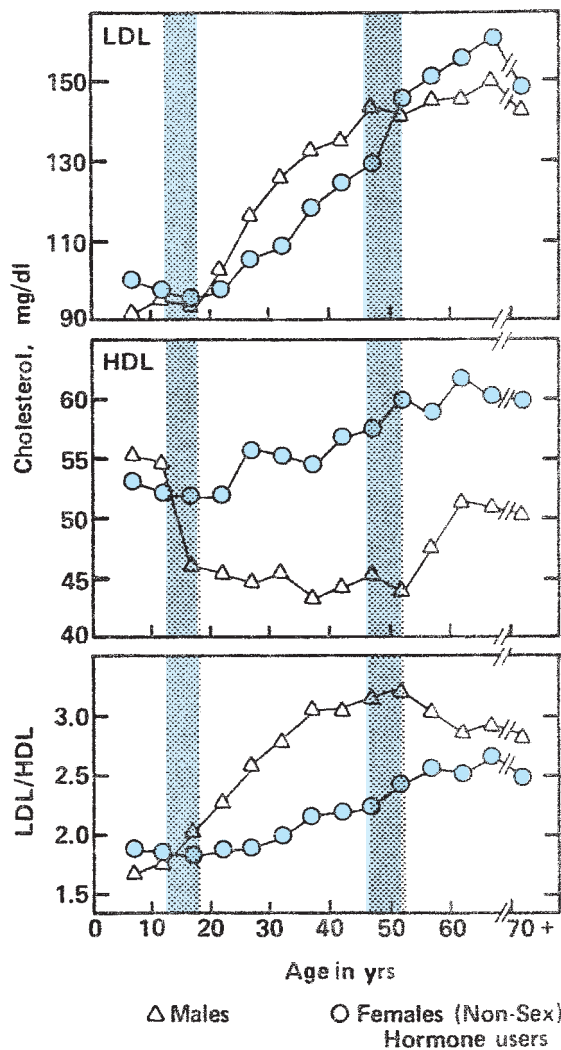

These phenomena are coming under increasing scrutiny in the present, accelerating worldwide pandemic of obesity afflicting both men and women. This advancing wave of progressive obesity is not only lowering the age of the onset of type 2 diabetes to young adulthood and even childhood but also threatens to negate continuing advances in average longevity of both sexes. With its associated, pathophysiologically important increase in insulin resistance, this trend also calls increasing attention to the “metabolic syndrome” as a major risk profile associated with premature atherosclerotic cardiovascular disease (ASCVD) and other sequelae of diabetes, hypertension, and dyslipidemia. Here, however, the disproportionate accumulation of visceral (central, upper body) adiposity by men especially in the first half of mid-life (25 to 50 years) would appear to place them at continuing disadvantage compared with women in ASCVD risk as well as overall longevity as this epidemic progresses.

Additional insight into the role of sex hormones in mediating the sex differential in atherosclerosis may be afforded by inspection of the sex ratio in cardiovascular mortality across the adult life

span (see [Figure 45-5](#)). After the peak in this ratio is reached in the premenopausal era, there occurs a major, progressive decline with advancing age, from nearly 5:1 at age 35 years to but 1.2:1 at age 85 years (it never drops below unity). Viewed from another perspective, women enjoy an approximately 10-year relative immunity to CVD, as compared with men (the rate in women ages 55–65 years, for instance, is equivalent to that in men ages 45–54 years). Consideration of this delay in women reaching equivalent CVD mortality risk as men is important in resolving an apparent paradox in popular media presentations on population aging and especially the wave of post-World War II female baby boomers currently passing through the menopause and contemplating HRT (see discussion on HRT below). Whereas at any given age women are at lower risk to CVD mortality than are men, CHD remains the leading cause of death in women beyond reproductive age. However, because of their greater longevity, and survival to an age of high risk, the percentage of women dying of CHD ultimately equals that of men (nearly 50% in both sexes). Moreover, because with advancing age, the population becomes progressively skewed toward surviving women, the annual numbers of women who succumb to CHD death may actually come to exceed those in men. As death rates from CHD progressively decline (unless nullified by increasing obesity and the metabolic syndrome), those deaths will occur in older and older persons (already the majority of CHD events occur in Medicare recipients, older than the age of 65 years), and cardiology will focus on progressively older patients and especially older women.

## ROLE OF SEX HORMONES IN MEDIATING THE SEX DIFFERENTIAL IN CORONARY HEART DISEASE RISK

Population studies such as those from Framingham, which have reported a higher prevalence of CHD in pre- versus postmenopausal women of comparable age, suggested a physiologic role for sex hormones (specifically estrogen and progesterone) in mediating the sex differential in CHD between women and men. Other population studies, such as those of the Lipid Research Clinics in the early 1970s, carefully examined average cholesterol levels (total, LDL, and HDL) in males and females (more of whom were taking HRT) between childhood and old age ([Figure 45-7](#)). These studies revealed that average lipid levels are equivalent between the sexes until puberty. However, at that point (and in parallel with the Tanner stage of pubertal development) HDL concentrations begin to decline in boys, and average levels of HDL remain relatively stable at lower concentrations in men than women (by approximately 10 mg/dL) from the twenties through the seventies. This suggests that this gap is principally attributable to an HDL-lowering effect of testosterone in men. This hypothesis is supported by studies of the effect of testosterone replacement in hypogonadal men, which suppressed HDL levels. This hypothesis has also received direct experimental support in studies of normal men rendered hypogonadal with a gonadotropin-releasing hormone (GnRH) agonist, in whom HDL levels rose (a rise that could be prevented with simultaneous testosterone administration). However, this consequence of testosterone therapy is not a pure androgenic effect, because a substantial fraction of testosterone is converted to estrogen by aromatase in various tissues. Consistent with this mixed effect, treatment with testosterone with coadministration of aromatase inhibitors results in a greater decrease in HDL levels. Moreover, androgenic anabolic steroids, which are incapable of conversion to estrogen, invariably produce a profound suppression

**FIGURE 45-7.** Median North American population high-density lipoprotein (HDL) cholesterol, low-density lipoprotein (LDL) cholesterol, and the ratio between the two versus age in white subjects. (Data from *The Lipid Research Clinics. Population Studies Data Book. vol. 1. The Prevalence Study. DHHS (NIH); 1990;80:1527.*)

of HDL levels: experimental studies of women given such agents for osteoporosis or endometriosis have demonstrated a 50% reduction in total HDL levels, ominously especially marked (85%) in the more atherogenic HDL2 subfraction.

On the other side of the coin, prospective studies of HDL levels in women followed across the menopause (Chapter 99) have also disclosed a slight average decline (especially in HDL2) coincident with ovarian failure. This suggests at least a mild effect of endogenous estrogen in raising HDL and specifically HDL2.

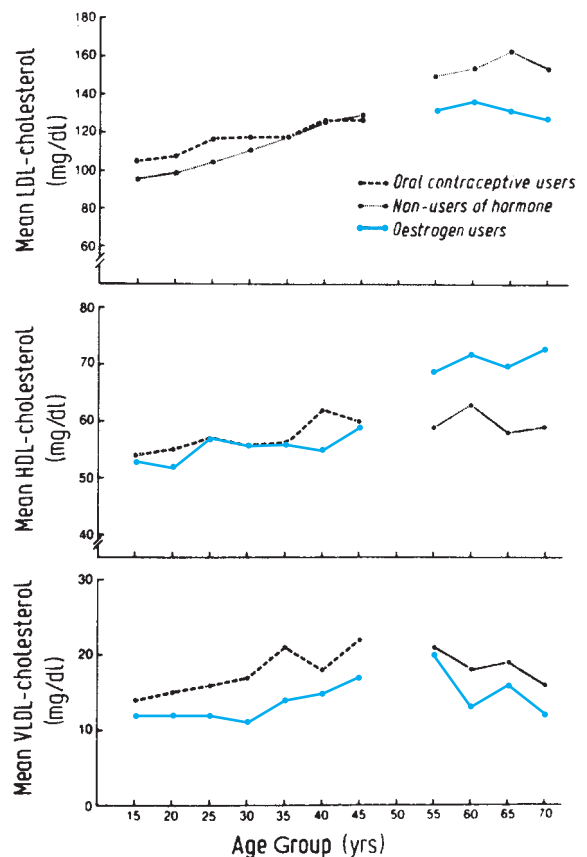

With regard to LDL, whereas mean levels rise in both sexes between puberty and the menopause (perhaps attributable to increasing adiposity), they remain substantially lower in women than men until the menopausal era, when they rise significantly, average levels in postmenopausal women actually coming to exceed those in men of comparable age. These trends in women seem most likely to be attributable to the physiological effects of estrogen in premenopausal women and the lack of estrogen beyond the menopause.

The net effect of these changes in lipid levels across the adult life span produces a more favorable pattern in women than men at all stages, with the lower HDL levels in men overriding the higher

LDL levels in postmenopausal women as to associated CHD risk. However, the sex differential in the LDL:HDL ratio (a convenient single index of lipid-associated risk) is greatest in the premenopausal era, when the sex differential in CHD is also the greatest, declining following menopause in parallel with the declining magnitude of that differential.

However, the mechanism of these putative effects of endogenous, physiologic sex hormones on plasma lipids remains largely conjectural, since there is a notable lack of association between plasma levels of those hormones and plasma lipoprotein concentrations in either population-based or carefully controlled metabolic investigations. Further investigations may reveal correlations with mechanistic implications for atherogenesis beyond lipoprotein metabolism, as suggested in analyses of the American Atherosclerosis Risk in Community (ARIC) cohort study by Golden et al. However, these may prove counterintuitive. In the ARIC study of carotid atherosclerosis, for example, intimal-medial thickening was inversely related to testosterone levels in postmenopausal women.

Thus mechanistic conclusions to date are largely extrapolated from results of pharmacologic interventions, which at best produce but a caricature of the effects of endogenous sex hormones and their physiologic regulation. Perhaps the most insightful of these on a population basis were the same Lipid Research Clinic Prevalence studies (Figure 45-8). Compared to women not taking hormone supplements, in premenopausal women taking oral contraceptives, average LDL levels were higher, while HDL concentrations were equivalent. However, closer examination of the data revealed that women

**FIGURE 45-8.** Plasma lipoprotein cholesterol levels in users and nonusers of oral contraceptives and estrogens. (Reprinted with permission from Wallace RB, et al. *Altered plasma lipid and lipoprotein levels associated with oral contraceptives and oestrogen use. Lancet. 2:11, 1979.*)

consuming contraceptives with more powerful androgenic progestational components had lower HDL than those taking contraceptives containing less androgenic progestins. In the postmenopausal women taking HRT (in that era, almost all ingesting unopposed conjugated equine estrogens (CEE) in a dose of 1.25 mg/day) average LDL levels were lower and HDL levels clearly higher than in women not taking estrogens.

These population studies have been widely confirmed in the intervening decades. Furthermore, careful metabolic studies of postmenopausal women such as those reported by Applebaum-Bowden et al. have quantitatively documented the powerful effects of exogenous (oral) estrogen in both lowering LDL levels and raising HDL (and selectively HDL<sub>2</sub>) levels.

Other studies have identified multiple additional mechanisms by which exogenous HRT in postmenopausal women might sustain their relative immunity to CHD. Indeed, for several decades, observational population studies suggested that the changes in lipid levels seen with HRT were insufficient to account for the degree of relative protection enjoyed by women who took such preparations. Studies at the mechanistic level reported beneficial effects of estrogens in decreasing arterial wall LDL uptake, perhaps retarding LDL oxidation and hence its atherogenic potential, and protecting against the paradoxical vasoconstrictive effects of such agents as acetylcholine in the presence of atherosclerosis (likely mediated by enhanced NO synthesis by arterial endothelial intimal cells induced by estrogen).

## SEX DIFFERENTIAL IN ATHEROSCLEROTIC CARDIOVASCULAR DISEASE

Thus a biological rationale for a slower rate of atherogenesis in women as compared to men would seem to emerge from their more favorable CVD risk profile, especially in the premenopausal era, and the demonstrated effects of sex hormones in mediating the lipoprotein dimension of that differential—albeit clearly demonstrable only with exogenous sex steroid administration.

Other studies of subclinical atherosclerosis, such as the 15-year prospective population study of the middle-aged men and women of Tromsø, Norway, as reported by Stensland-Bugge et al., have confirmed a sex differential in progression of atherosclerosis as reflected in ultrasound measurements of carotid artery intimal–medial thickness. Here age, blood pressure, total and HDL cholesterol, and body mass index were independent long-term predictors of intimal–medial thickness in both sexes, while triglycerides were predictive only in women and physical activity and smoking predictive only in men (though the trend was also apparent in women with heavy smoking exposures). Moreover, as in many other studies of CVD risk factors, CVD risk was associated with the number of such factors in a stepwise fashion. Of note with regard to the central message of this chapter, in this study the mean intimal–medial thickness was less in women than men at all cholesterol levels. Thus women may be relatively spared by factors in addition to their more favorable lipid profiles.

Similar trends were apparent in the ARIC studies reported by Chambless et al. Conducted in four populations of middle-aged subjects (45–64 years of age) over an 11-year period, these studies demonstrated that increased carotid intimal–medial thickness was associated with baseline diabetes, (diminished) HDL-cholesterol, pulse pressure, white blood cell count, and fibrinogen levels, as well

**TABLE 45-7**

### Prevalence of Cardiovascular Disease in the Cardiovascular Health Study

PREVALENCE (%)	MEN		WOMEN	
	Blacks	Whites	Blacks	Whites
Any clinical CVD	37.2	37.2	36.4	28.2
Subclinical CVD	43.7	41.9	39.7	41.3
Neither	19.1	20.9	24.9	32.5

CVD, cardiovascular disease.

as with changes in LDL-cholesterol (most dramatic in women passing through menopause), triglycerides, and new-onset diabetes and hypertension.

Most germane to geriatric medicine, these trends seem to carry over into old age. This was demonstrated in the Cardiovascular Health Study (CHS), a longitudinal, population-based study of men and women older than age 65 years from four communities (Table 45-7). By using a combination of clinical disease and indices of subclinical atherosclerosis (including carotid ultrasound and ankle–brachial blood pressure index), this epidemiologic research disclosed detectable, significant CVD in up to 80% of the men, but in only 67% of the women. Of special note, in this study, subclinical disease carried a prognostic significance equal to that of clinical disease in predicting incident CVD events in the 5-year follow-up (while conversely, the absence of atherosclerosis predicted a continued low risk of such events, even in the oldest segments of the cohort). Thus, even as atherosclerosis comes to affect the great majority of elderly Americans, women continue to enjoy a relative, albeit modest, protection compared with their male counterparts of equivalent age.

## FEMALE HORMONE REPLACEMENT THERAPY

Despite the biological plausibility of an important role for sex steroids in mediating the relative immunity of women to CVD and the clear effect of exogenous HRT in sustaining and even magnifying the putative role of endogenous estrogen in conferring more favorable lipid profiles, this does not translate into HRT being recommended for postmenopausal women for either primary or secondary prevention of CVD. As with all studies based upon epidemiologic associations, these must be confirmed in formal clinical trials before such recommendations can be justified. The recent dramatic change in the trend toward widespread postmenopausal HRT is perhaps the most compelling case in point, as well-summarized in the reviews by Manson and Martin and the landmark report from the WHI Writing Group.

At the time these reports were released around 2002, it was estimated that approximately 38% of U.S. postmenopausal women were using HRT. This was not only for relief of menopausal symptoms, where the benefit continues to remain clear, but also in the belief that such therapy would reduce the burden of several chronic diseases in the remaining over one-third of their lives spent in the postmenopausal state. Such putative benefits included reductions not only in CVD, but also all cancer, osteoporosis (see Chapter 75)—where the benefit also continues to remain clear—and even risk of cognitive impairment (although associated increased risks of breast cancer, thromboembolism, and gall bladder disease gave pause to

many women contemplating HRT). This hopeful, pleiotropic preventive intervention strategy was increasingly embraced by an “age wave” cohort of midlife baby boomers, notably the more highly educated and health-conscious women from higher socioeconomic strata who were more likely to receive such supplements. Their enthusiasm for HRT was buttressed by numerous (more than 40) clinical and observational epidemiologic studies that reported substantially less CVD in women taking HRT. As reviewed earlier, such benefit from HRT is biologically plausible, estrogen-exerting effects at multiple levels from the genome to whole populations that, on balance, might support their widespread use in postmenopausal estrogen replacement (as reviewed by Mendelsohn and Karas). RCTs confirmed that oral estrogen reduces LDL cholesterol by 10% to 14% and increases HDL cholesterol by 7% to 8%. Estrogen was also shown to favorably affect other indices of CVD risk: lipoprotein levels were reduced, LDL oxidation inhibited, and plasminogen-activator inhibitor-1 (PAI-1) levels decreased. However, other indices appear to be adversely affected: triglyceride levels rise; coagulation is promoted through increases in factor VII, prothrombin fragments 1 and 2, and fibrinopeptide; and—perhaps most germane to CVD in old age—C-reactive protein (CRP), a marker of immune system activation, is increased (specifically by oral [but not trans-cutaneous] HRT). Thus at the level of basic biology, a mixed scorecard in support of HRT for CVD prevention was being assembled even as more and more postmenopausal women elected to take such agents as the WHI was being designed and initiated (Table 45-8).

However, the wisdom of this trend began to engender skepticism among professionals and the lay public alike when the results of the Heart and Estrogen/Progestin Replacement Study (HERS) were reported in 1998 by Hulley et al. HERS was a 4-year RCT of HRT in the secondary prevention of CVD, which compared continuous daily CEE (Premarin) combined with medroxyprogesterone acetate (MPA; Provera) versus placebo in 2673 women with established CHD. This study demonstrated no overall effect of the HRT on coronary death rate and nonfatal myocardial infarction. In the first year of the trial, however, there was a 50% *greater* incidence of coronary events in the women taking HRT. Nevertheless, by the termination of the study this had abated, and even a trend toward a later benefit of HRT appeared to emerge in years 3 through 5, suggesting a biphasic pattern of response to the hormones. During subsequent unblinded follow-up, however, this possible later benefit did not prove sustained. Thus after 6.8 years, neither net benefit nor increased risk of HRT for secondary prevention of CHD was apparent. This disappointing outcome was subsequently echoed in the Estrogen Replacement and Atherosclerosis (ERA) secondary prevention trial of estrogen either alone or in combination with progestin on angiographically quantified coronary atherosclerosis: here too no net effect was seen. Subsequently, a review of 22 primary prevention trials of HRT, albeit mostly small and of short duration, also failed to disclose net benefit.

Subsequently the impact of these limited trials, especially as related to the potential for primary CHD prevention, was overwhelmed in 2002 when the first principal results of the WHI RCT of the effect of HRT on all-cause and cause-specific morbidity and mortality were released. This arm of the WHI was a large, community-based, placebo-controlled, RCT of continuous oral CEE (0.625 mg/day) plus MPA (2.5 mg/day). Involving 16 608 postmenopausal women with intact uteri aged 50 to 79 years (average age 63 years, including 21% older than age 70 years) recruited to 40 clinical cen-

ters in 1993 to 1998, the study had a planned duration of 8.5 years. The primary favorable targeted outcome was CHD (nonfatal myocardial infarction and CHD deaths), with invasive breast cancer as the primary adverse predicted outcome. A global index was also developed reflecting these two primary outcomes plus stroke, pulmonary embolism, endometrial cancer, colon cancer, hip fracture, and death from other causes.

After just 5.2 years of average follow-up, the study was terminated prematurely because the test statistic for invasive breast cancer exceeded the stopping boundary and the global index statistic indicated that the risks exceeded the benefits of the HRT (Figures 45-9 and 45-10). The estimated hazard ratios (HRs) and nominal 95% confidence intervals (CIs) (in parentheses) included CHD 1.29 (1.02–1.63); breast cancer 1.26 (1.00–1.59); stroke 1.41 (1.07–1.85); pulmonary embolism 2.13 (1.39–3.25); colorectal cancer 0.63 (0.43–0.92); endometrial cancer 0.83 (0.47–1.47); hip fracture 0.66 (0.45–0.98); and death as a result of other causes 0.92 (0.74–1.14). The corresponding HRs and CIs for composite outcomes were: total CVD (arterial and venous), 1.22 (1.09–1.36); total cancer, 1.03 (0.90–1.17); combined fractures, 0.76 (0.69–0.85); total mortality, 1.02 (0.82–1.18); and global index, 1.15 (1.03–1.28). Absolute excess risks per 10 000 person-years attributable to the combination HRT were 7 more CHD events, 8 more strokes, 8 more cases of pulmonary embolism, and 8 more invasive breast cancers, while absolute risk reductions per 10 000 person-years were 6 fewer colorectal cancers and 5 fewer hip fractures. The absolute excess risk of events in the global index was 19 per 10 000 person-years. The WHI writing group concluded that “this regimen should not be initiated or continued for primary prevention of CHD.”

Subsequent analyses reported in 2004 evaluated the effect of treatment of 10 739 trial participants with prior hysterectomy treated with CEE alone in the same 0.625 mg/day dosage for an average of 6.8 years. This disclosed no significant effect of the estrogen on hazard ratios for: CHD, 0.91 (0.75 to 1.12); pulmonary embolism, 1.34 (0.87 to 2.06); or colorectal cancer, 1.08 (0.75 to 1.55), while providing suggestive benefit for breast cancer, 0.77 (0.59 to 1.01) and confirming reduced incidence of hip fracture, 0.61 (0.41 to 0.91). Results for composite outcomes with CEE alone suggested no effect on: total CVD, 1.12 (1.01 to 1.24); total cancer, 0.93 (0.81 to 1.07); total mortality, 1.04 (0.88 to 1.22); and the global index, 1.01 (0.91 to 1.12), while total fractures were reduced, 0.70 (0.63 to 0.79). For the outcomes significantly affected by CEE, there was an absolute excess risk of 12 additional strokes and an absolute risk reduction of 6 fewer hip fractures per 10 000 person-years.

This important addendum to the initial, “blockbuster”, counterintuitive report from WHI illustrates the dynamic, continuing, and no doubt still incomplete nature of the substantive reports that will continue to emanate from this landmark study. In this particular instance, it is tempting to deduce that the different outcomes from combined CEE and MPA regimen in the initial report and the less ominous findings from the CEE alone substudy must be attributable to the MPA, a progestational and weakly androgenic component in the combination regimen. However, it is important to bear in mind that the participants in the CEE-alone trial had all undergone hysterectomy, and those who have had that procedure are unlikely to be similar in health and socioeconomic parameters, which confounds such a simplistic interpretation. Furthermore, the unexpected relative protection (and clearly without the increased risk of breast cancer) found with CEE–MPA in the initial report is

TABLE 45-8

## Benefits and Risks of Postmenopausal Hormone-Replacement Therapy (HRT)

VARIABLE	EFFECT	BENEFIT OR RISK		SOURCE OF DATA
		Relative	Absolute	
<b>Definite benefits</b>				
Symptoms of menopause (vasomotor, genitourinary)	Definite improvement	>70–80% decrease		Observations studies and randomized trials
Osteoporosis	Definite increase in bone mineral density; probable decrease in risk of fractures	2–5% increase in bone density; 25–50% decrease in risk of fractures	172 fewer hip fractures (402 vs. 574) per 100 000 woman-years	Observation studies and limited data from randomized trials
<b>Definite risks</b>				
Endometrial cancer	Definite increase in risk with use of unopposed estrogen; no increase with use of estrogen plus progestin	Increase in risk by a factor of 8–10 with use of unopposed estrogen* for >10 yrs; no excess risk with combined estrogen-progestin	Excess of 46 cases (52 vs. 6) per 100 000 woman-years of unopposed estrogen use (>10 yrs of use); no excess with use of combined therapy	Observational studies and randomized trials
Venous thromboembolism	Definite increase in risk	Increase in risk by a factor of 2.7	Secondary prevention: excess of 390 cases per 100 000 woman-years; primary prevention: excess of 20 cases per 100 000 woman-years	Heart and Estrogen/Progestin Replacement Study Observational studies
<b>Probable increase in risk</b>				
Breast cancer	Probable increase in risk with long-term use (>5 yrs)	Overall increase in risk by a factor of 1.35 with HRT use of >5 yrs	Excess of 20 cases per 10 000 women using HRT for 5 yrs; 60 excess cases after 10 yrs of use; 120 excess cases after 15 yrs of use	Meta-analysis of 51 observational studies
Gallbladder disease	Probable increase in risk	Increase in risk by a factor of 1.4	Excess of 360 cases per 100 000 woman-years	Heart and Estrogen/Progestin Replacement Study
<b>Uncertain benefits and risks Cardiovascular disease</b>				
Primary prevention	Could range from net benefit to net harm	Uncertain	Uncertain	Observational studies and randomized trials <sup>†</sup>
Secondary prevention	Probable early increase in risk	Uncertain	Uncertain	Observational studies and randomized trials
Colorectal cancer	Possible but unproven decrease in risk	20% decrease	24 fewer cases (96 vs. 120) per 100 000 woman-years	Observational studies
Cognitive dysfunction	Unproven decrease in risk (inconsistent results)	Uncertain	Uncertain	Observational studies and randomized trials

\*The term "unopposed estrogen" refers to the use of estrogen without medroxyprogesterone acetate.

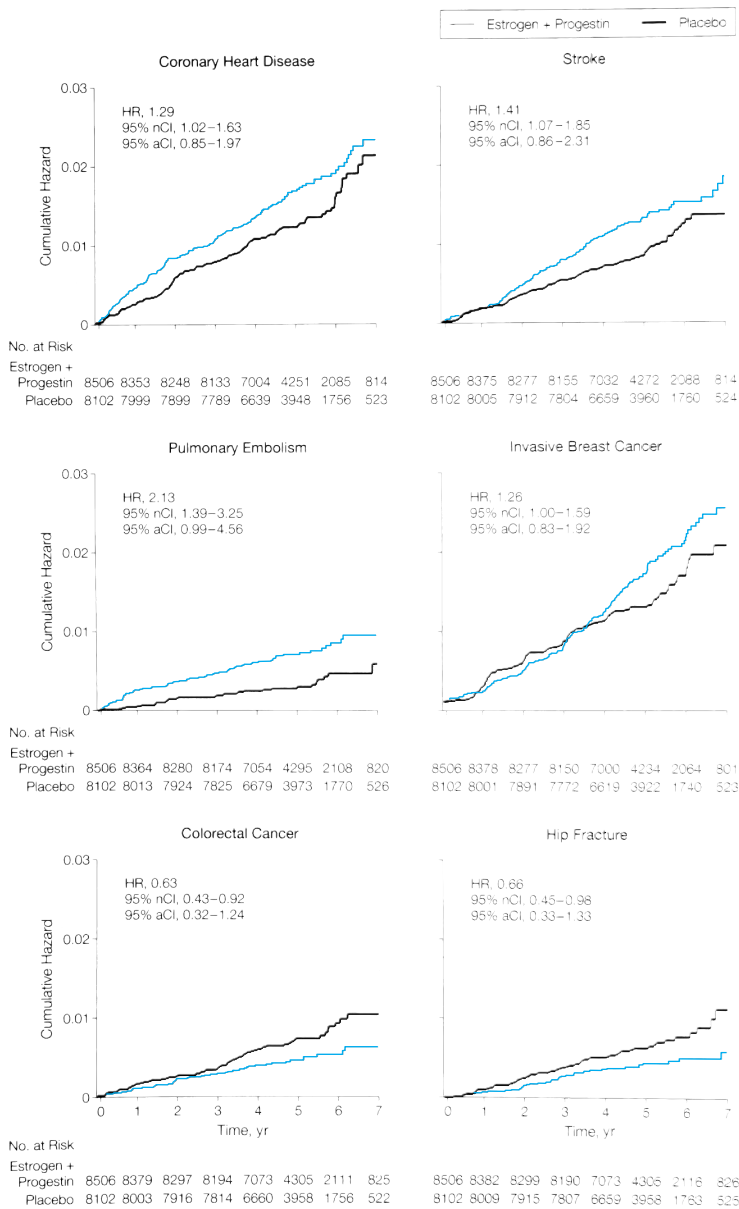

<sup>†</sup>Observational data suggest a decrease in risk of 35 to 50 percent, whereas randomized trial data show no effect or a possible harmful effect during the first 1 or 2 yrs of use. Most studies have assessed conjugated equine estrogen alone or in combination with medroxyprogesterone acetate.

Reproduced with permission from Manson JE, Martin KA: Postmenopausal hormone replacement therapy, *N Engl J Med*. 2001;345:34.

counterintuitive regarding the effect of estrogen on this important outcome.

An additional dimension from the WHI study of CEE–MPA of special interest to physicians caring for elderly persons was a substudy focused upon the effect of the combined hormone therapy on cognitive function, the Women's Health Initiative Memory Study (WHIMS). Analogous to the hope for HRT engendered by observational epidemiological cohort studies that suggested reduced inci-

dence of dementia (and Alzheimer's disease) in women taking HRT, this substudy examined a substantial fraction (4894) of the WHI participants to test the hypothesis that this HRT regimen would reduce decline in cognitive function as assessed by Modified Mini Mental State Examinations (MMMSEs). Contrary to the predicted effect, more women in the estrogen–progestin group (6.7%) experienced a substantial and clinically important *decline* in MMMSE (25% or more) compared with placebo (4.8%). Thus, as with CHD

**FIGURE 45-9.** Kaplan-Meier estimates of cumulative hazards for selected clinical outcomes of the Women's Health Initiative randomized controlled trial. (Reproduced with permission from Rossouw JE, et al. Writing Group for the Women's Health Initiative Investigators: Risks and benefits of estrogen plus progestin in healthy postmenopausal women. Principal results from the Women's Health Initiative randomized controlled trial. *JAMA*. 288:321, 2002.)

prevention, the WHIMS demonstrated an unpredicted adverse outcome, and hence postmenopausal combined HRT could not be justified in a strategy to reduce cognitive decline or prevent dementia, including Alzheimer's disease.

Thus for both primary and secondary prevention of CHD (or dementia), combination HRT cannot presently be recommended, especially in the form of continuous treatment with CEE and MPA in a woman with an intact uterus. Nor do these studies engender enthusiasm for the use of CEE alone to prevent CHD in postmenopausal women after hysterectomy. However, individualized regimens for women at increased risk for, for example, colon cancer or osteoporosis, may be prescribed. And doubtless many women will elect at least short-term HRT for control of menopausal symptoms; some may even choose long-term treatment because of strongly held beliefs as to the long-term benefits of HRT (and perhaps especially estrogen alone in the posthysterectomy state).

Nevertheless, these largely unanticipated results had a rapid, profound impact on the prevalence of HRT in postmenopausal women in the United States and worldwide. The conservative, almost ni-

hilistic conclusions published by the writing group have met with skepticism and at most grudging acceptance by longtime proponents of HRT and especially perhaps by gynecologists and reproductive endocrinologists. As to the focus of this chapter, these outcomes have served to highlight the paradox that is one of its central features: while pre-menopausal women clearly enjoy a major relative immunity to CHD, the exogenous replacement of the hormones that putatively mediate that protection in the postmenopausal state appears not only ineffective but downright hazardous. Consequently post-WHI research by determined researchers has increasingly sought to resolve this enigma, especially as related to the peri- and postmenopausal era when a myriad of symptoms, vasomotor in particular, cause women to seek relief through estrogen replacement in spite of WHI (which was not sufficiently powered to focus in this era).

Thus the relative immunity to CHD enjoyed by women, especially premenopausally, continues to suggest that a regimen of postmenopausal HRT more accurately reflecting premenopausal female hormone physiology might provide enduring benefits to women over their remaining life span. Indeed, the discrepancies between

**FIGURE 45-10.** Kaplan–Meier estimates of cumulative hazards for global index and death, Women’s Health Initiative randomized controlled trial. (Reproduced with permission from Rossouw JE, et al. Writing Group for the Women’s Health Initiative Investigators: Risks and benefits of estrogen plus progestin in healthy postmenopausal women. Principal results from the Women’s Health Initiative randomized controlled trial. *JAMA* 288:321, 2002.)

endogenous physiology and exogenous HRT suggest that important mechanistic insights might be provided by careful examination of the differences. For example, current research in atherosclerotic CVD is focusing on the role of inflammation in the pathogenesis of this disease, with special emphasis on the CRP and other proinflammatory markers even as potential mediators. Here research suggesting contrasting effects of oral versus transcutaneous or vaginal estrogens are especially intriguing, as reported for example by Modena et al. Oral estrogens, subject to magnification of their effect on hepatic metabolism by their “first pass” exposure, induce increases in CRP, while transdermal estrogens, which enter the systemic circulation directly, actually suppress CRP levels in healthy postmenopausal women.

Finally, this area of intense interest to gerontologists who consider the entire life span as the domain of their investigation and concern will endure as a focus of important research to unravel the principles as well as the paradoxes that underlie the sex and gender determinants of longevity and morbidity across the life span. The WHI itself will continue to generate important studies germane to resolution of this conundrum. Recently, for instance, Manson and her coworkers reported findings regarding coronary artery calcification from the substudy of CEE-alone. This disclosed significantly lower calcification scores (an important index of coronary artery atherosclerosis) in the women assigned to the CEE (vs. placebo) arm, especially those who adhered to their assigned CEE by 80% or more. Similarly supportive of continued HRT for perimenopausal women and as buttressed by findings from more basic research in nonhuman primates, a more finely grained analysis of the WHI-CEE substudy by Rossouw et al. in 2004 reported a potential benefit of the oral estrogen on heart disease among participants 50 to 59 years of age (the study was terminated, however, before a statistically significant

advantage could be demonstrated). And more recently, this possibility is being tested in RCTs of similar regimens in subjects recruited in the perimenopausal years. So the story is far from complete and will continue to bear watching in the years to come.

All in all, however, at least for the present, long-term, combination estrogen–progestin HRT cannot be generally recommended for prevention of postmenopausal CVD. Specifically in the realm of geriatric medicine—for example, in women older than age 75 years—the paucity of current or contemplated future research regarding HRT for CHD prevention seems certain to make this an area of uncertainty for the indefinite future and render the taking of HRT by elderly women distinctly uncommon.

## PREDICTING THE FUTURE: THE SEX DIFFERENTIAL IN LONGEVITY IS DECLINING

By the end of the 1960s, the progressive rise in the sex differential in average American longevity that marked the first seven decades of the twentieth century had begun to abate (see [Figure 45-2](#)). Subsequently, this trend has converted to a clear and progressive decline in the differential (see [Table 45-2](#)), even as the expected longevity of both sexes continues to rise (albeit at a slower rate in women than in men). Thus by the advent of the twenty-first century, the United States (and other developed countries) were entering the fourth and final, “posttransitional” stage of convergence in longevity by sex hypothesized.

The reasons for this convergence remain uncertain and controversial. As suggested earlier in this chapter, these are perhaps most focused in the narrowing sex ratio in cigarette smoking exposure in the past four decades and hence in the various disease risks

attributable to such an exposure. Of the factors, CVD contributes the greatest proportion of that decrease: the decline in CHD in the United States in both sexes during that interval has been continuous and cumulatively profound. In the ARIC surveillance study of more than 360 000 men and women aged 35 to 74 years in the four communities as reported by Rosamund et al., for example, the reduction in CHD applied both to hospital admissions and deaths caused by CHD both in and out of the hospital. Between 1987 and 1996, the age-adjusted CHD mortality rate fell 3.2% in men (CI 2.0–4.3) and 3.8% in women (CI 1.9–5.6). However, this produced a somewhat greater reduction in the absolute number of such deaths in men than women (adjusted for age) because of the greater risk in men at the beginning of the study. The reductions in both hospitalizations and in-hospital mortality were consistent with earlier studies of national data that attributed declines in CHD mortality equivalently to improved population preventive strategies and risk factor profiles as well as more effective treatment of CHD once clinically manifest. It should also be noted, however, that these reductions were more evident in the earlier years of the ARIC study, 1987 to 1991, than subsequently. This raises the question as to whether the decline in CHD will continue indefinitely or whether and when a floor effect will be observed, below which further decreases may not be possible, especially in an aging population.

### FUTURE OF THE SEX DIFFERENTIAL IN LONGEVITY AND ITS IMPLICATIONS FOR GERIATRIC MEDICINE AND GERONTOLOGY

Population health data in the United States and worldwide suggest that these CHD benefits accruing especially to men extend to other causes of death as well as to overall mortality rates, and indeed, longevity.

This raises the more general issue as to whether the greater advances in longevity among men than women in the past three decades reflect greater relative improvements in health behaviors and medical interventions in men over that time span or the reality that women are approaching the upper limit of the average potential longevity of the human species, the “barrier to immortality” described by Fries as  $85 \pm 4$  years (recently modified to  $85 \pm 7$  years, with a preterminal phase of “compressed morbidity” of 2–3 years).

Regardless that the sex differential in longevity in the United States is declining is no longer a subject of debate. This is clearly evident in [Tables 45-1 and 45-2](#) (the latter continuing to document this narrowing trend since the last edition of this textbook). Projecting these trends forward has suggested that the sex differential in United States longevity will decline to only 2.2 years by 2025 in the United States, a trend that will be replicated in most industrialized nations and attributed principally to diminishing rates of vastly premature death in men (in the 25- to 59-year age group). Perhaps the most encouraging aspect of this progressive narrowing in the sex/gender longevity gap to gerontologists and geriatricians are its implications for institutional long-term care services in the upcoming decades. As men live longer, couples can expect to live independently together longer, the duration of widowhood will decline, and the need for long-term care services will decrease accordingly. There is already mounting evidence that this hopeful sequence of events has begun. Even as the number of persons most likely to require such services continues to increase (notably those older than age

85 years), American nursing home bed capacity has for decades been at a plateau. Nor is this trend confined to the United States. Other nations at comparable levels of socioeconomic development (e.g., Sweden and Australia) are experiencing a similar relative decline in long-term institutional care. Careful deconvolution of the curves of decline in per capita nursing home utilization by elderly citizens has fractionated these trends into multiple components, including those that reflect improved health and reduced age-adjusted disability of the population as well as the development of noninstitutional alternatives to nursing home care. These encouraging trends continue in the early twenty-first century, especially in the United States, where serial studies of aging populations have disclosed progressive decrements in disability among the elderly, especially those older than age 80 years, as well as declining mortality rates for both sexes in this age group. Importantly, such studies have suggested that the greater longevity gains in men than women in recent decades may well be the predominant factor contributing to the decline in nursing home utilization, particularly in the 1990s.

This optimistic trajectory is also likely to continue well into the twenty-first century in developed nations. This prediction is reinforced by the association between enhanced longevity of both sexes and increased educational level, and because the cohort of elderly citizens with low levels of educational attainment born in the first half of the twentieth century will be succeeded by later cohorts with higher average educational levels. This might also disproportionately favor men, given the relationship between attained educational level and the adoption of more healthy lifestyles in both genders and the probability that men of higher educational level (and often higher socioeconomic status) seem especially likely to embrace health attitudes and behaviors (such as decreased cigarette smoking) and effective management of CVD and other risk indices consistent with the practice of effective “preventive gerontology” (see Chapter 9). Or to put it otherwise, since men have been traditionally so disadvantaged in longevity by their “macho” image and behaviors, they will disproportionately benefit by relaxation of that attitude as gaps in educational and socioeconomic status and the health behaviors of men and women become more closely approximated in developed nations in this current century.

Thus the poetic dream of Robert Burns that serves as the preamble to this chapter may yet become reality in a future wherein average longevity of both sexes might approach the MLP of our species.

Nevertheless, given the evidence and theoretical projections gathered to date, as a gerontologist, geriatrician, and endocrinologist, I would predict that because of fundamental and immutable biological differences between the sexes, women will always outlive men. However, in the steady state, the gap will be substantially narrower than at present—perhaps 2 to 3 years (the estimate of Kranczer for the year 2025), and the average duration of widowhood for married women will remain at least that long.

Thus, in the early twenty-first century, presented by Lopez in the volume edited by Ory and Warner (see [Table 45-3](#)) America and other developed nations may be entering the hypothesized fourth and final, steady-state, posttransitional stage in the evolution of the sex differential in longevity.

# Menopause and Midlife Health Changes

*MaryFran R. Sowers*

The profile of female geriatric patients will be changing considerably over the next decade. A substantial number of women born during the baby boom following World War II are at or beyond midlife, resulting in an increasing number of women who will be seeking treatment for symptoms associated with menopause and for chronic conditions that have their origin in midlife (see Chapter 5 for details on demographics). Further, the cohort of U.S. women who are now at midlife is unique. More than three-quarters are in the workforce; more than one-third have college degrees; and family composition has changed remarkably as evidenced by the number of live births that have declined by almost half.

For many of these women, the midlife, which encompasses the menopausal transition, will be a significant milestone and a harbinger of their health status and their interaction with health care systems for the ensuing decades. Thus, it is important to understand the events of the menopause transition and that these events are likely to affect health, the perception of health, and the perception of the contribution of the health care provider to health maintenance.

The initiation of the menopause transition (that time from active reproduction to the cessation of significant estrogen secretion because of the depletion of functional ovarian follicles) is an ill-defined period that commences with the onset of menstrual irregularity or skipped menses and ends 12 months following the final menstrual period (FMP). The median age at FMP is currently estimated to be 51.4 years. The menopause itself is the permanent cessation of menses and is clinically diagnosed following 12 continuous months of amenorrhea.

This geriatrics textbook includes a chapter on menopause because exposure to declining levels of ovarian hormones appears to modify risk factors associated with the development of debilitating diseases and health concerns of the geriatric patient. Furthermore, the menopause transition may represent an optimal time for clinical intervention. These clinical interventions can address two potential patient groups: (1) the 12% to 25% of women who already have some evidence of disability (see the physical limitations section) and

for whom active interventions are critical and (2) the majority of women who are not disabled and are open to information about preventive care, risk factor screening, and maybe seeking care for menopausal symptoms.

## PHYSIOLOGICAL BASIS OF REPRODUCTIVE AGING

Aging of the female reproductive system is unique because the time-frame for the permanent cessation of menses has changed little over time, while the average life expectancy of women now extends to more than 30 years after the FMP. Further, women have a finite period of reproductive capacity. Unlike men, who usually retain reproductive capacity throughout their lifetime, women are born with a set number of primordial follicles, whose depletion begins prior to birth (Figure 46-1). At menopause, when a woman's ovarian reserve is depleted, the number of available follicles recruited to form preovulatory follicles has dwindled to a point where ovarian-based hormones, including estrogens and progesterone, are no longer predictably produced. A progressively greater rise in gonadotropin, such as follicle stimulating hormone (FSH), is observed with the diminution of the follicular pool and the increasing nonresponsiveness in regulation of hormone secretion.

It is likely that changes in lipid, bone, or immunological functioning, among others, are related to those marked changes in estradiol and FSH concentrations during the menopause transition and occur when the hormone changes around the FMP are most pronounced. The Michigan Study of Women Across the Nation (SWAN) evaluated FSH values in relation to time and identified that there was an accelerated rise in FSH levels between 5 and 2 years prior to the FMP. FSH levels further accelerated from 2 years prior to 1 year after the FMP; thereafter, the FSH levels tended to plateau (Figure 46-2).

Because of the complexity and the cost of measuring these hormone-driven menopausal transition events in the clinical setting, progress through the transition is frequently estimated with

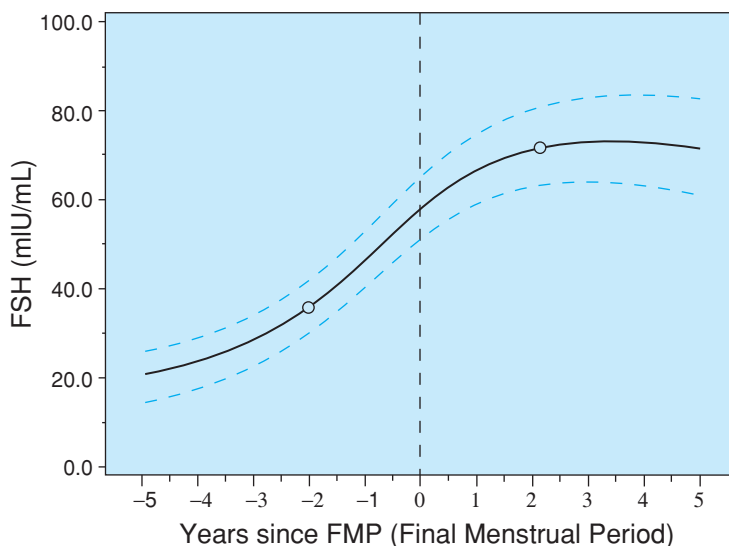

**FIGURE 46-1.** Biexponential model of declining follicle numbers in pairs of human ovaries from neonatal age to 51 yrs old. Data were obtained from the studies of Block (1952, 1953) (X,  $n = 6$ ; +,  $n = 43$ ), Richardson et al. (1987) ( $\square$ ,  $n = 9$ ) and Gougeon (1987) (\*,  $n = 52$ ). (Faddy MJ, Gosden RG, Gougeon A, et al. Accelerated disappearance of ovarian follicles in mid-life: implications for forecasting menopause. *Human Reprod.* 7:1342–1346, 1992. With permission from Oxford University Press.)

menstrual cycle characteristics. In 1996, the World Health Organization suggested definitions of the stages describing the transition to natural menopause. A broader and simpler staging system, including earlier stages of reproductive aging and later stages of post-menopause, was proposed at the International Stages of Reproductive Aging Workshop (STRAW). The STRAW staging definitions are based primarily on bleeding changes with the acknowledgment that discriminating hormone levels, specifically FSH, would add precision when sufficiently described (Table 46-1).

Based on menstrual calendar diary data of women undergoing the menopause transition, cycle lengths in excess of 60 days are a sensitive indicator of an impending FMP. This represents a pragmatic marker for use by patient and clinician alike in characterizing the menopause status of the woman. Further, these timeframes are consistent with our understanding that there are two follicle pools, one recruitable pool in which follicles, when stimulated, are immedi-

ately available for growth and a second pool of follicles insensitive to gonadotropin signals. The growable pool is refreshed approximately every 60 to 90 days. As the follicle supply decreases, the growable pool of follicles can no longer replenish itself to those numbers seen in mid-reproductive life. As the follicle reserve becomes critically diminished and few remaining responsive follicles are present, menstrual cycles become more irregular and are more likely to be anovulatory.

Aging of the reproductive system is frequently only considered in the context of the ovary; however, it actually involves all three levels of the reproductive axis—the brain, pituitary, and the ovary. While the hypothalamus and pituitary play extensive roles in all aging processes, the exact mechanisms by which gonadotropin releasing hormones (GnRH) change with age with respect to biosynthesis, transport, release, and receipt of feedback from neurotransmitters or steroids is incompletely understood. The total numbers of GnRH neurons

**FIGURE 46-2.** Average FSH values (with 95% confidence intervals from bootstrapping) in relation to final menstrual period (FMP). (Sowers M, Zheng H, Tomey K et al. Changes in body composition in women over six yrs at mid-life: ovarian and chronological aging. *J Clin Endocrin Metab.* 2007;92:895–901. Copyright 2007, The Endocrine Society.)

**TABLE 46-1****Comparison of the Definition of Reproductive Stages and the Transition to Menopause: WHO and STRAW****World Health Organization (WHO)***Natural Menopause*

The permanent cessation of menstruation resulting from the loss of ovarian follicular activity. It is recognized after 12 consecutive months of amenorrhea, for which there is no other pathological or physiological cause. An adequate independent biological marker for the event does not exist.

*Perimenopause*

The period when the endocrinological, biological, and clinical features of menopause begin through the first year after the menopause.

*Menopausal Transition*

The period of time before the final menstrual period (FMP) when variability in the menstrual cycle is usually increased.

*Premenopause*

The period ambiguously referred to as either the 1 to 2 yrs immediately before the menopause or the whole of the reproductive period prior to the menopause. It is recommended that this term be used consistently in the latter sense to encompass the entire reproductive period up to the FMP.

*Induced Menopause*

The cessation of menstruation following either surgical removal of both ovaries or iatrogenic ablation of ovarian function.

*Simple Hysterectomy*

At least one ovary is conserved. It is used to define a distinct group of women in whom ovarian function may persist for a variable period after surgery.

*Postmenopause*

The period dating from the FMP, regardless of whether the menopause was induced or spontaneous.

*Premature Menopause*

Menopause that occurs at an age less than two standard deviations below the mean estimated for the reference population. In the absence of reliable population estimates, 40 yrs is frequently used as an arbitrary cut-off point.

**Stages of Reproductive Aging Workshop (STRAW)***Reproductive Stage*

The period from menarche to the beginning of the perimenopause.

*Menopausal Transition*

The time of an increase in follicle-stimulating hormone and increased variability in cycle length, two skipped menstrual cycles with 60 or more days of amenorrhea or both. The menopausal transition concludes with the final menstrual period (FMP) and the beginning of postmenopause.

*Postmenopause*

Begins at the time of the FMP, although it is not recognized until after 12 months of amenorrhea.

WHO Technical Report Series No. 866; Soules MR, Sherman S, Parrott E et al. *Executive Summary: Stages of Reproductive Aging Workshop (STRAW)*. *Fertil Steril*. 76:874–878, 2001.

do not appear to be the critical factor in determining reproductive senescence. Rather, changes in intermittent hormone secretion (i.e., luteinizing hormone (LH) or FSH) or glycoprotein free  $\alpha$ -subunit (FAS) in pre- versus postmenopausal women result in a change in gonadotropin levels, characterized as a change in their pulse amplitude and, possibly, their pulse frequency. These changes in pulsatile

release may reflect an unappreciated aging process or a greater insensitivity to feedback during the menopause transition.

In the aging hypothalamus, dopamine secretion into the portal vasculature declines and, with aging, the stimulatory action of estrogen is absent. In addition to dopamine, it is thought that norepinephrine, acting primarily through the  $\alpha$ -adrenergic receptor, stimulates GnRH release, a process that declines with aging. This aging phenomena may explain why some of the symptoms commonly associated with the menopause transition (including potential cognitive changes) are more likely to reflect chronological change while other symptoms, such as vasomotor symptoms, appear to be more reflective of the events of change in ovarian hormone concentrations.

## Disaggregating Menopause Symptoms and Chronological Aging

The onset or exacerbation of a constellation of symptoms, including vasomotor problems, vaginal dryness and other sexual symptoms, urine leakage, changes in skin, fatigue, and problems with sleeping, negative mood, and decline in cognitive acuity, is frequently attributed to the menopause. Further, many women choose to begin hormone replacement therapy in an effort to combat these menopausal symptoms and to replace the endogenous hormones that have been declining. These symptoms are described below in relation to their development, frequency, and degree of bother during the menopause transition and, when relevant, the effect of hormone therapy (HT).

## MENOPAUSE SYMPTOMS AND CLINICAL FEATURES

### Vasomotor Symptoms

Vasomotor symptoms, including hot flashes, cold sweats, or night sweats, have been consistently associated with the menopause transition, occurring to some degree in more than 70% of women during midlife, with more than 50% of women reporting their presence for more than five years. Vasomotor symptoms are defined physiologically as a disruption in the hypothalamic central thermoregulation, causing the core body temperature to change by at least 0.2 degrees Celsius. In SWAN, the pattern of increasing perimenopausal hot flashes compared to the premenopause was consistent among African-American, Japanese, and Hispanic women. More vasomotor symptoms are found in those with increasing body mass index (BMI), current smoking status, baseline depression, and premenstrual symptoms. In a study evaluating symptom constructs in more than 500 Caucasian women, increasing frequency and amount of bother from vasomotor symptoms and sexuality were predicted by the transition from a premenopause to a postmenopause state over time. Low estradiol concentrations and higher FSH concentrations were significantly predictive of having vasomotor and sexual symptoms, but not other symptoms commonly identified with the menopause transition including urinary leakage and negative moods. Consistent with the findings from SWAN, this study found that higher BMI and current smoking behavior were highly related to increased bother with many symptom constructs, but especially vasomotor symptoms.

## Sleep Disturbances

Investigators at the 2005 National Institute of Health (NIH) State-of-the-Science Conference, Management of Menopause-Related Symptoms, reported that sleep problems are identified by 16% to 42% of premenopausal women, 39% to 47% of perimenopausal women, and 35% to 60% of postmenopausal women. Although aging, in general, is associated with decrements in sleep quality, gender differences in sleep disturbances that emerge at midlife suggest that the increase in sleep difficulties may not be simply an aging effect. However, the majority of published studies are limited by small sample sizes, cross-sectional data, and limited assessments of sleep and menopausal status. In the SWAN multiethnic sample of 12 603 Caucasian, African-American, Chinese, Japanese, and Hispanic women, aged 40 to 55 years, almost 40% reported difficulty in sleeping. Age-adjusted rates for difficulty in sleeping were highest in the late perimenopause (45%) and in women with surgical menopause (48%). Menopausal status was associated with greater difficulty in sleeping, even following adjustment for age, race/ethnicity, vasomotor and psychological symptomatology, self-perceived health status and health behaviors, arthritis, and education, all factors that were also associated with sleeping difficulty (Table 46-2).

Factors that might trigger acute sleep disturbances during the menopause transition may include the onset and exacerbation of vasomotor symptoms, rate of changing hormone levels (especially FSH), and increases in symptoms of stress associated with acute and chronic ongoing life events. There is considerable overlap between sleep disturbances and vasomotor symptoms. A study by Dzaja et al. found that 68% to 85% of symptomatic menopausal women have vasomotor symptoms and 51% to 77% report insomnia.

In some studies comparing HT users and nonusers, HT users report more sleep disturbances suggesting that preexisting sleep disturbances influence the association between HT and the exacerbation of sleep disturbances. In a longitudinal study, Matthews et al. found that twice as many incident sleep complaints (28%) occurred among HT users compared to nonusers (14%). The greater increase in sleep problems among women who used HT may have been because of the preexisting characteristics of the women or to particular HT formulations or doses.

Worsening sleep during the menopausal transition is important because this sleep is associated with decreases in quality of life and poorer work performance. Persistent insomnia has been associated

with an increased incidence of mood and anxiety disorders. Further, subjective sleep complaints and polysomnography-described sleep disruptions are associated with many negative health outcomes, including susceptibility to upper respiratory tract infections, immunosuppression, cardiovascular disease (CVD), and stroke and their attendant health care costs.

## Sexuality Dysfunction (also see Chapter 47)

Sex steroids are postulated to affect sexual function (desire, arousal, orgasm, and pain) either directly through their neurohormonal effects on pain or desire or indirectly by maintaining the anatomic competence that allows arousal to occur. Atrophic changes in the vagina, including a decrease in lubrication accompanying sexual arousal, thinning of the endothelium, and loss of rugation, which are associated with dyspareunia have been well described. Because the menopausal transition is a time of significant change in sex steroid hormones and in sexual function, it has been speculated that the menopause leads to a diminution in sexual functioning, apart from the simultaneous potential effects of normal aging. However, the evidence linking sexual function to individual endogenous hormones or changes in hormones over time remains largely circumstantial.

The few large longitudinal studies of sexual functioning and menopause suggest that domains of sexual functioning change differentially, over time with some changes resulting from aging and others from menopause. The most consistent decrements in sexual functioning have been associated with rising FSH concentrations rather than declines in estradiol, androgens, or dehydroepiandrosterone sulfate (DHEAS). In SWAN, with more than 3000 African-American, Caucasian, Chinese, Hispanic, and Japanese women, testosterone and higher FSH were associated with the desire domain, higher FSH with less arousal and lower estradiol with the pain domain, consistent with findings in the Melbourne Women's Midlife Health Program (MWMHP) and the Massachusetts Women's Health Study. The negative association of estradiol with vaginal coital pain is consistent with the described effects of estrogens on vaginal integrity and the utility of estrogen treatment for vulvo-vaginal atrophy. SWAN has reported that testosterone was positively associated with sexual desire among women with a partner, but the differences in testosterone levels among women within different desire categories are small and all within the midportion of the normal testosterone

**TABLE 46-2**

**Adjusted Odds Ratio for Reporting Difficulty Sleeping by Menopausal Status, All Women vs. Women Without Vasomotor Symptoms, Study of Women's Health Across the Nation, 1995-1997**

MENOPAUSAL STATUS	ALL WOMEN (n = 11 222)		WOMEN WITHOUT VASOMOTOR SYMPTOMS (n = 7338)	
	Odds Ratio	95% CI	Odds Ratio	95% CI
Premenopausal	1.00	Reference	1.00	Reference
Early perimenopause	1.11	0.99-1.24	1.10	0.96-1.26
Late perimenopause	1.33	1.07-1.65	1.40	1.01-1.92
Natural postmenopause	1.21	1.03-1.43	1.26	1.01-1.58
Surgical postmenopause	1.55	1.25-1.92	1.19	0.87-1.62
Postmenopause with hormones	1.12	0.95-1.31	1.03	0.83-1.27

range for women. FSH has not been postulated to have a direct role in sexual function but to be an indirect marker of gonadal function; however, its association with sexual function domains argues for an expanded view that incorporates neuroendocrine signaling into the study of complex sexual behavior.

While concurrent annual serum reproductive hormone levels and change in those concentrations over time have been associated with major domains of sexual function during the menopausal transition, the magnitude of these associations is consistently modest. Favorable outcomes in sexual functioning are much more strongly associated with having a partner and emotional satisfaction with the relationship than the most prominent hormone values. Other highly important factors included increasing age of the woman, poor health status, smoking behavior, and body size.

## Depressed Mood

Throughout the life span, women are two times more likely than men to suffer from depression. A number of factors, including hormones, reproductive factors, genetics, biology, and societal or cultural norms may increase the propensity for depressed mood in women. The menopause transition may represent a period of heightened risk for the development of clinically significant depressive symptoms based on the increasingly variable and declining estradiol concentrations. The risk is reportedly greater for women regardless of preexisting symptoms. Further, while estrogen therapy was thought to promote improvement in depressive symptoms, the controversial findings from the Women's Health Initiative (WHI) have led to additional questions about the hypothesis that sex steroids and their changes during the menopause are an explanatory factor in depression and mood disorders.

The report from the NIH State-of-the-Science Conference concluded there is limited evidence about mood symptoms in the menopause transition. In studies where hormone concentrations have been related to measures of depressed symptomology, change in FSH and LH levels are the more consistent predictors, whereas change in estradiol and testosterone levels have been substantially less predictive. Further, in general, stages of the menopause transition have not been predictive of mood changes. The gonadotropins, FSH, and LH have not been studied for their direct role in affect and mood, but are considered indirect markers of gonadal function;

however, their more consistent association with mood argues for expanding the view to incorporate other aspects of neuroendocrine signaling.

While the natural menopause may or may not be associated with depressed mood, other attributes associated with the menopause (vasomotor symptoms, insomnia, and other sleep disorders) appear to have a greater impact on presentation with depressed mood. Additionally, other factors including BMI, smoking behavior, stress, and relationship problems, which can change during the menopause transition period, are important factors in depressed mood.

## Cognition and Memory

Memory complaints are common in the menopausal transition, but the implications of these complaints for subsequent cognitive decline and dementia are yet to be defined. In SWAN, approximately 30% of 12 000 women aged 40 to 55 years reported perceived forgetfulness in the previous 2-week period. Sixty-two percent of responses by 230 women, aged 40 to 60 years, to a series of open-ended questions in the Seattle Midlife Women's Health Study (SMWHS) indicated memory changes over a median 24-month period. A cross-sectional study of 1270 Chinese midlife women (58% premenopausal, 27% perimenopausal, and 15% postmenopausal) noted that the Trail Making Test, a test of motor speed and visual acuity, significantly declined with the progression of menopausal status. In contrast, the MWMHP evaluated episodic verbal memory (a word list recall task) cross-sectionally in 326 women aged 52 to 63 years (majority postmenopausal) and concluded that memory was similar across the menopausal transition phases. Both SMWHS and the MWMHP have identified an association between memory problems and depressed mood, suggesting that depressed mood might confound the associations of cognition and menopause-related biological and sociological changes.

Longitudinal data about cognitive changes during the menopausal transition have come from a SWAN substudy in which a subgroup of 868 premenopausal and early perimenopausal women, aged 42 to 52 years, were assessed annually for an average of three years in working memory (Digit Span Backwards) and perceptual speed (Symbol Digit Modalities Test). In the test for perceptual speed (the ability to quickly and accurately compare objects and patterns), there was a significant decrease over time in postmenopausal women and slight increases among perimenopausal women (Table 46-3).

**TABLE 46-3**

**Adjusted Estimated Rate of Change per Year in Cognitive Score by Menopausal Status, Study of Women's Health Across the Nation, 1996–2001**

COGNITIVE TEST	MENOPAUSAL STATUS	ADJUSTED ESTIMATED RATE OF CHANGE PER YEAR	
			95% CI
Digit Span Backwards	Premenopausal	0.17	0.03, 0.30
	Early perimenopausal	0.19	0.09, 0.28
	Late perimenopausal	0.20	-0.14, 0.54
	Postmenopausal	0.03	-0.26, 0.33
Symbol Digit Modality Test	Perimenopausal	0.52	0.05, 0.98
	Early perimenopausal	0.34	0.01, 0.67
	Late perimenopausal	1.51	0.35, 2.66
	Postmenopausal	-1.13	-2.11, -0.15

Adapted from Table 4 in Peyer PM, Powell LH, Wilson RS, Everson-Rose SA, et al. A population-based longitudinal study of cognitive functioning in the menopausal transition. *Neurology*. 61:801–806, 2003.

Whether HT can enhance cognitive performance is controversial. The benefits of HT have been identified in some studies on measures of perceptual speed, fluency, spatial, and articulatory/motor functioning. However, other studies have failed to identify a relationship between postmenopausal estrogen use and cognition. Further, the Women's Health Initiative Memory Study (WHIMS), a substudy of the Women's Health Initiative (WHI) trial, found a slight decline, not improvement, in cognitive function among late postmenopausal women assigned to HT compared to placebo.

### Cardiovascular Disease Risk

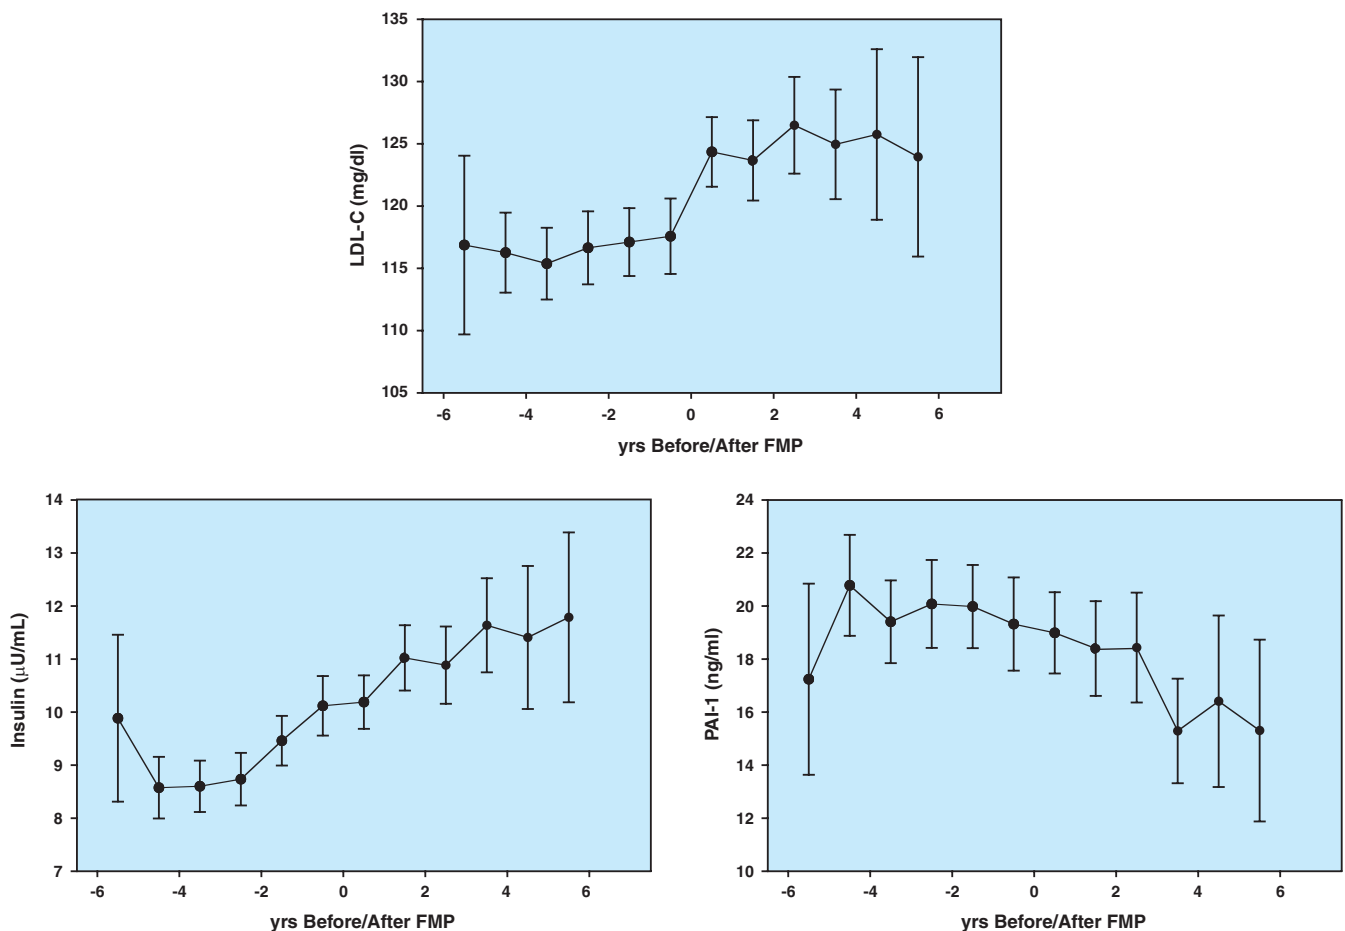

It has been hypothesized that loss of estradiol with the menopause transition is associated with a greater risk for CVD in women following menopause. This hypothesis evolved and was supported by studies comparing age-specific heart disease rates of men and women, observational studies of women with early age at natural menopause or surgical menopause, and studies of women using HT. While one study suggested that for each year of delay in menopause, there was a 2% decrease in CVD mortality risk, other studies have failed to identify a statistically significant association of menopausal age to CVD risk. Thus, studies of menopause and CVD risk have yielded inconsistent results, particularly those focused on natural menopause and the age at menopause. The findings from the WHI trial, in which the use of hormone preparations was associated with greater risk of heart disease events, further calls into question whether estrogen

status is too simplistic a physiological explanation for the variation in heart disease risk in women compared to men.

Atherosclerosis in the abdominal aorta is more likely to occur among women who have a bilateral oophorectomy or experience early natural menopause than among premenopausal women. Heightened risk for CVD among women with bilateral salpingo oophorectomy has been observed, especially when it occurs relatively early and without HT. An early natural menopause is also associated with heightened risk for CVD; however, statistical adjustments for other cardiovascular risk factors such as age and smoking status can eliminate the association of age at natural menopause and CVD.

SWAN has considered the contribution of the menopause transition to four axes associated with CVD (lipids, blood pressure hemodynamics, carbohydrate metabolism, and hemostatic/inflammatory factors). Representative intermediate markers of three of these axes are shown in Figure 46-3. LDL-C and insulin levels appear to increase across the menopause, while PAI-1 levels tend to fall.

Because both menopause and lipid levels are highly correlated with age, it remains uncertain whether lipid changes at the time of menopause are independent of age effects. Observational studies have been limited in their ability to accurately adjust for the effects of age independent of menopause, since few have followed women throughout the entire menopause transition. Some studies have suggested an independent effect of menopause while others have concluded that elevations in LDL-C and decreases in HDL-C are related to aging rather than menopause per se. However,

**FIGURE 46-3.** Change in mean LDL-C (top), mean systolic blood pressure (top right), mean insulin (bottom left), and mean PAI-1 (bottom right)—measures of three axes of cardiovascular disease risk—across the menopause transition, Study of Women's Health Across the Nation. Data represent measures taken approximately 6 yrs before through 6 yrs after the final menstrual period (FMP) for a total of 2336 observations in 722 women.

in SWAN, a longitudinal study across the menopause transition, menopause status-related changes were greater than aging-related changes for total cholesterol and LDL-C, whereas the magnitude of change for HDL and triglycerides were apparently less sensitive to the menopause-related changes. Increases in total cholesterol and LDL-C during menopause are gradual and occur late in the transition. In the MWMHP and SWAN, for reasons yet unknown, HDL increases slightly in the year prior to menopause, a trend that is then offset by a similar decrease in the year following the FMP. The Pittsburgh Healthy Women Study compared the magnitude of change in risk factors from premenopause to 5 years postmenopause and correlated those changes with carotid disease measured 5 to 8 years after the menopause. Increases in LDL-C and triglycerides and declines in HDL-C were greater during the perimenopause; that is, changes were more pronounced between the premenopausal and first year of postmenopausal evaluations than between the first and fifth years of postmenopausal evaluations. These findings reinforce the idea that understanding the lipid changes during the perimenopause defines a potential time frame for both early prevention and intervention activities that could affect the health of the aging woman.

Limited studies of hemostatic factors (i.e., plasminogen activator inhibitor-1 (PAI-1), tissue plasminogen activator (tPA), C-reactive protein (CRP), Factor VII or fibrinogen) have reported little or no effect of stages of the menopausal transition, defined by irregularity in menstrual bleeding. Androgens or sex hormone binding globulin (SHBG) are more likely to be associated with measures of hemostatic factors than the estrogens. Additionally, higher FSH concentrations were associated with higher Factor VII-c and t(PA) and negatively associated with hemostatic CRP (hsCRP) and fibrinogen concentrations. Clearly, the role of the menopause in relation to CVD-related risks remains to be more clearly elaborated.

## Diabetes Risk

While there is a marked increase in diabetes prevalence during the time of the menopause transition, there is limited evidence that this is a direct consequence of the changes during the menopause transition (although there may be an indirect association). In SWAN, the incidence of diabetes was 2% to 3% per year, with substantial variation within the race/ethnic groups. There are two factors that may be important contributors to diabetes incidence during the menopause transition. First, obesity, particularly central obesity, increased markedly during the transition period (see “Obesity and Body Composition”), and central or visceral obesity is associated

with an increased risk of diabetes. A second element that is altered with the menopause transition is the relative amount of androgen in relation to estrogen. With the relatively stable production of adrenal androgens and the diminished production of ovarian estrogen, there is a shift in the androgen:estrogen ratio. Whether this shift is actually associated with an increased risk of diabetes, and the degree of altered ratio that might be required to generate the increased risk, is an area of active investigation.

## Obesity and Body Composition

The role and impact of obesity and body composition (lean, fat mass, and skeletal muscle mass) during the menopause are poorly documented. Longitudinal changes of body composition during the menopausal transition from one study are shown in Table 46-4. Among the 543 pre- or perimenopausal women at study entry, there was a 0.6% (~0.5 kg) annual increase in weight, which was a relative 6-year increase of 3.4%. There was an annual increase of 0.7% in BMI (~0.2 kg/m<sup>2</sup>) and a relative 6-year increase of 4%. There was a 1.6% (~0.57 kg) increase in fat mass for a relative 6-year increase of 10%. There was a 1% (~0.9 cm) annual increase in waist circumference, representing a 6-year increase of 6%. Annual measurements of lean mass did not change across the 6-year time period.

This longitudinal study also found that increasing levels of FSH were associated with increasing fat mass and waist circumference, before and after adjusting for baseline age, baseline fat mass, or baseline waist circumference. Increasing FSH was associated with increasing fat mass, and decreasing lean mass and skeletal muscle mass across the 6-year timeframe. While waist circumference continued to increase during the transition, approximately 1 year after FMP, the rate of increase slowed. Women continued to gain fat mass, and no point was identified at which the rate of change increased or decreased. These body size changes take on new relevance as current research increasingly identifies that adipose tissue functions as an endocrine organ, secreting a variety of cytokines including leptin, adiponectin, resistin, PAI-1, tumor necrosis factor (TNF)- $\alpha$ , and interleukin (IL)-6 with immunological, vascular, and metabolic actions.

## Bone Loss

It is common wisdom that the immediate postmenopause is a time of accelerated bone loss; in a sample of white women followed prospectively for 16 years, radial bone loss in the perimenopause to 5 years

**TABLE 46-4**

**Estimates of Body Composition Changes with Time from Statistical Models with Body Composition Measures as the Dependent Variables and Time as the Linear or Curvilinear Independent Variable(s)**

BODY SIZE/COMPOSITION MEASURES	ANNUAL CHANGE	RELATIVE 6-YEAR CHANGE	ABSOLUTE CUMULATIVE 6-YEAR CHANGE
Weight (kg)	0.6% (~0.5 kg)	3.4%	2.9 kg
Height (cm)	-0.064 cm	0.24%	-0.38 cm
BMI (kg/m <sup>2</sup> )	0.7% (~0.2 kg/m <sup>2</sup> )	4%	1.2 kg/m <sup>2</sup>
Waist (cm)	1% (~0.9 cm)	6.2%	5.7 cm
Fat mass (kg)	1.6% (~0.57 kg)	10.1%	3.4 kg
Skeletal muscle mass (kg)	-0.18% (~0.04 kg)	-1.06%	-0.23 kg

Sowers M, Zheng H, Tomey K, et al. Changes in body composition in women over six years at mid-life: ovarian and chronological aging. *J Clin Endocrin Metab.* 2007;92:895-901. Copyright 2007, The Endocrine Society.

postmenopause was reportedly 2.4% to 2.6% per year compared to 0.4% to 1.9% per year in the 5 to 11 years postmenopause. However, few studies have examined bone mineral density (BMD) change prospectively during the menopausal transition, incorporating information about hormone patterns and bleeding patterns. Several studies, including SWAN, the Michigan Bone Health and Metabolism Study, and the MWMHP now indicate that bone loss commences prior to the menopause and that the acceleration in remodeling deficit is related to rise in FSH in the perimenopause. Initial cross-sectional reports from the MWMHP showed that FSH levels were incrementally higher among Caucasian women classified as pre-, peri-, and postmenopausal, and that BMD levels were progressively lower for each of the three groups. In SWAN, BMD levels were 2.5% lower in those pre- and early perimenopausal women with FSH levels greater than 26 mIU/mL; these same women had greater n-telopeptide levels, indicating increasing bone resorption. Moreover, SWAN studies indicated that information about baseline FSH values and subsequent FSH values were predictive of the amount of BMD change over a corresponding 4-year period (Figure 46-4). Estradiol concentrations were not predictive of rate of bone loss although women with estradiol levels less than 35 pg/mL had significantly lower BMD. In another study of 231 women, aged 32 to 77 years, with multiple measures of sex steroids and BMD, bone loss was associated with lower estrogen and SHBG, but FSH change was not evaluated.

Postmenopausal bone loss has been attributed to a state of relative estradiol deficiency, so it may appear incongruous that FSH concentrations were more predictive of bone loss during the transition than were estradiol values. There is limited reason to believe that FSH is acting directly on bone through receptors or by nongenomic means. Since FSH serves as a proxy measure of ovarian dynamics involving estradiol, FSH values may better characterize ovarian status and its changes than would estradiol values.

**FIGURE 46-4.** Adjusted least square means of lumbar spine bone mineral density (BMD) by varying levels of FSH (top) and Estradiol (bottom), Study of Women's Health Across the Nation. Measures were adjusted for ethnicity, study site, BMI, and physical activity.

Thus, there is growing evidence from longitudinal studies that bone loss begins earlier than thought, accelerates in the late perimenopausal period, and continues into the early postmenopausal period. The rate of loss appears to decelerate approximately 10 years after the FMP. There are marked individual differences in the rate of bone loss, and risk factors contributing to this wide variation are yet to be fully characterized. More research is needed to evaluate the predictive value of measures of bone microarchitecture to consider the predictive values of biochemical markers of bone turnover in relation to perimenopausal bone loss and to address rates of bone loss in determining subsequent fracture risk.

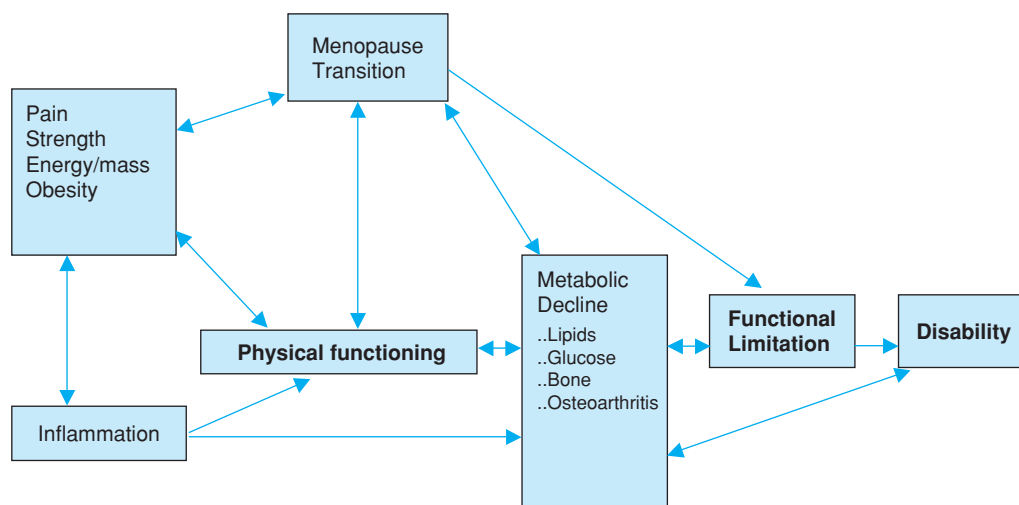

## Physical Function

Geriatricians are familiar with the role of physical function assessment in elderly people, but increasing information suggests that 12% to 25% of newly menopausal women already have substantial functional limitations. The long-term implications for physical limitations for women in the fifth through the seventh decades have not been evaluated. Women are more likely than men to report a physical limitation, for reasons that are poorly understood, although there is evidence that these are probably true reflections of increasing disability. It has been hypothesized that the period of the menopause transition could represent the time of initiation and exacerbation of functional limitations because of the increasing prevalence of diabetes, less favorable lipid profile, decline in sensory function including hearing and vision, and greater propensity to obesity (Figure 46-5).

A 10-item physical function measure (MOS SF-36) provided evidence of a relatively high prevalence of physical limitations in 16 063 women, aged 40 to 55 years, at the seven nationwide SWAN sites. Nine percent of the more than 16 000 interviewees reported substantial functional limitation (difficulty in climbing one flight of stairs, walking one block, or bathing/dressing one's self) while 11% of the interviewees reporting some degree of functional limitation. As shown in Table 46-5, menopausal status was associated with greater risk of physical limitation among postmenopausal women or HT users, compared to premenopausal women, after statistical adjustment for age, difficulty in paying for basics, and being obese.

Two other studies, including women of menopausal transition age, have identified that female participants are more likely to have functional limitations than men, have a greater rate of decline in physical function than men, and are less likely to recover from disability than men. While there is an increased risk of functional limitations with changes during the menopause transition, these risks are dwarfed by those observed in women who report difficulty in paying for basics such as food, housing, and medical care.

Two longitudinal studies of performance-based measures of functioning suggest that two groups are vulnerable to decrements in physical function. In Michigan SWAN and the Michigan Bone Health and Metabolism Study, those women who had transitioned to the postmenopause, as well as women with surgical menopause (both without HT), took a longer time to walk short distances, ascend and descend stairs, and had less reach in comparison to pre- and perimenopausal women, after statistical adjustment for age, time in study, smoking status, and BMI. Gait studies indicated a slower walking velocity in these menopausal women (both natural and surgical).

**FIGURE 46-5.** Conceptualization of the development of functional limitations at midlife in women. (Adapted from Figure 1 of Sowers M, Pope S, Welch G et al. *The Association of Menopause and Physical Functioning in Women at Midlife.* *J Am Geriatr Soc.* 49:1485–1492, 2001.)

## Osteoarthritis

Between the ages of 40 and 55 years, the incidence of x-ray-defined osteoarthritis of the knee (OAK) increases 2% to 3% per year. There has been a long-term debate as to whether estrogen interacts favorably to sustain the collagen associated with cartilage in women. As identified in the section below on skin, collagen loses its flexibility as fibrillar cross-links develop. Limited studies have compared prevalence of OAK in those with and without HT use. However, there are well-known differences in women prescribed hormones, such as smoking behavior and body size, which are risk factors for the development and progression of osteoarthritis.

One study has found that women at the midlife who developed x-ray-defined OAK had greater odds of having lower baseline endogenous estradiol levels during the early follicular phase, even following adjustment for age, BMI, and physical activity. In addition, women who developed OAK had greater odds of having low levels of the estrone metabolite, 2-hydroxyestrone. Since viable interventions for OAK are restricted to joint replacement, the menopause may be a time in which there should be substantial focus on preventive strategies.

## Skin and Collagen

During the menopause transition, notable changes occur in skin that not only include the esthetic associations with increasing wrinkling, sagging, and thinness, but also health-related associations such as

change in collagen, elastin, and water content, atrophy, and change in wound-healing responsiveness.

Sebum production decreases with the menopause transition, diminishing the barrier to insensible water loss and leading to an increased frequency of dry skin. Additionally, there are declines in collagen, particularly type III, and elastin levels that make skin less resilient and 10% to 20% thinner. Notably, skins that are richly colored with melanin are intrinsically protected from the impact of photoaging. This may explain the lower prevalence of atrophy, dry skin, and wrinkling observed in women of African descent.

Atrophy of the skin is associated with a prolonged time required for wound contraction and wound healing as well as impaired formation of granulation tissue. Because this more fragile skin is associated with the menopause transition, careful suturing is required to prevent skin tears.

Hormone replacement, including topical application of estradiol cream, has been used therapeutically to treat conditions of the aging skin. Additionally, transdermal estrogen delivery systems have been used to avoid the first-pass hepatic metabolism of oral exogenous estrogen replacements. While effective, these methods may have their own adverse effects including allergic/inflammatory reactions.

## CONCLUSIONS

The endocrine, sociological, and physiological changes that accompany menopause occur over 8 to 10 years, although the actual

**TABLE 46-5**

**Level of Physical Functioning Limitation or Substantial Limitation in Reference to No Physical Limitation in 16 063 of the SWAN Cross-Sectional Study in Women Aged 40–55 Yrs**

MENOPAUSE STATUS	SOME LIMITATION		SUBSTANTIAL LIMITATION	
Premenopausal	1.00	Reference	1.00	Reference
Perimenopausal	1.10	(0.95, 1.28)	1.73	(1.46, 2.06)
Natural postmenopause	0.95	(0.77, 1.16)	2.67	(2.21, 3.24)

HT use	1.57	(1.31, 1.88)	2.33	(1.90, 2.87)

Modified from Table 4 of Sowers M, Pope S, Welch G, et al. *The Association of Menopause and Physical Functioning in Women at Midlife.* *J Am Geriatr Soc.* 49:1485–1492, 2001.

duration of the menopausal transition period may be highly variable among individual women. At least in some women, there may be a period of time spanning 2 to 4 years around the FMP in which changes are more pronounced as indicated by variation in levels of FSH, amount of bone loss, and changes in lipid levels. There is substantial between-woman variability during the transition period and greater understanding of that variation is an area of active research.

Vasomotor symptoms are a hallmark of the perimenopausal transition, experienced by more than two-thirds of women. Emerging studies suggest that possible risk factors include greater body size and smoking behavior. Studies from community samples suggest that vasomotor symptoms have a substantial effect on the quality of life of approximately 10% of women. Further, the impact of the vasomotor symptoms may not be restricted to the actual events; their contribution to other conditions, such as disrupted sleep or exacerbation of mood disorders, may have substantial effect on the quality of life.

Ovarian aging appears to be associated with alterations in lipids, bone, and body composition. Thus, the midlife is a time of small but significant changes in a number of systems, including glucose, insulin, lipids, sleep patterns, bone, and joints. Weight gain in midlife is small on an annual basis, but cumulative changes over midlife can be quite substantial and have important effects on other systems. Collectively, these changes are associated with decrements in physical functioning in both natural and surgical menopause.

It is likely that the coming generations will have higher expectations about quality of life, including those that ensue from the menopausal transition, because they are better educated, more often in the labor force, and have smaller families relative to previous generations. Midlife is an optimal time to consider a reorientation to disease prevention and health promotion by the geriatric health care team.

# Sexuality, Sexual Function, and the Aging Woman

*Stacy Tessler Lindau*

## INTRODUCTION

Until recently, little has been known about women's sexuality in later life. Negative societal attitudes about aging, sexuality among older people, and women's sexuality in particular, present a significant barrier to scientific inquiry and medical attention to older women's health concerns. Proven interventions for promoting female sexual well-being or treating women's sexual problems are not widely available. Public health attention to older women's sexuality is virtually nonexistent.

The 2005–2006 National Social Life, Health and Aging Project (NSHAP), funded by the National Institutes of Health, provides the first population-representative, baseline data on sexuality among older women and men in the United States and informs many of the insights presented in this chapter. The study enrolled a national probability sample of 3005 community-residing men and women aged 57 to 85 years (75.5% weighted response rate), with oversampling of African-American, Hispanic, and men in the 75- to 85-year-old age group. About half the respondents were male, half were female, and they were divided approximately equally across three age strata: 57 to 64, 65 to 74, and 75 to 85 years. Respondents participated in a face-to-face questionnaire covering social, psychological, and health domains, including detailed information on sexual relationships and functioning. It is the first comprehensive, population-based study of older women's sexuality.

This chapter first locates older women's sexuality in a sociodemographic context, describes sexual activity, behaviors and problems experienced by women in later life, reviews physiological changes that affect sexual functioning as women age, and recommends a clinical approach to evaluation, prevention, and treatment of sexual problems common among older women. Older women, and their sexual relationships, are very heterogeneous. Generalizations made in this chapter, based on population data from the NSHAP study and findings from other sources, are rooted in statistical norms but should

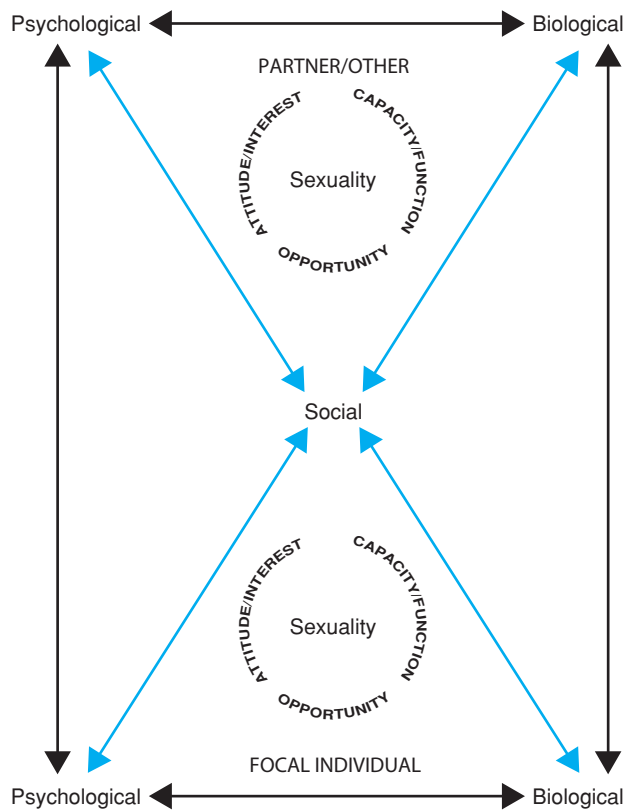

not be interpreted as a normative prescription for older women's sexuality.

## Interactive Biopsychosocial Model

The interactive biopsychosocial model (IBM) provides a conceptual framework for understanding the relationship between sexuality and health throughout the life course (Figure 47-1). To the degree that medicine attends to matters of sexuality, the orientation is largely negative. The medical model approach to understanding sexuality focuses on sexual dysfunction as a problematic consequence of aging, disease, or treatment. Occasionally, medical texts suggest that older patients' complaints about sexual problems, particularly male erectile difficulties, may herald serious underlying disease and ought not be ignored. While clinically valid, this narrow conceptualization of sexuality defies its multidimensional nature and limits understanding of the meaning of sexuality for health.

A broader framework, as defined by the IBM, conceptualizes a bidirectional relationship between sexuality and health. Sexual behavior can result in health problems, such as sexually transmitted infection, victimization, and, in younger women, unwanted pregnancy. Aging, physical and mental health problems, surgeries, and medications can cause sexual dysfunction. The IBM acknowledges this reciprocal relationship between sexuality and health but incorporates the possibilities that sexuality may also be health-promoting and that aging, or even illness, may confer advantages for sexual life.

In this model, health comprises biological, psychological, and social components and is conceptualized as jointly produced by a woman in conjunction with her spouse or other intimate partner. Joint production of health means that both partners of the couple contribute assets (or liabilities) to the "health endowment," and these assets and liabilities impact the health of the other. The hourglass shape symbolizes the dynamic nature of both health and intimate relationships over time. Clinically, this model can be used as a

**FIGURE 47-1.** The Interactive Biopsychosocial Model. (Adapted from Lindau ST, Laumann EO, et al. *Synthesis of scientific disciplines in pursuit of health: the Interactive Biopsychosocial Model. Perspect. Biology Med.* 46(3 Suppl):S74–S86, 2003.)

mnemonic for the broad domains of inquiry pertinent to assessing a patient's sexual history and reminds the clinician of the importance of ascertaining the presence, and health, of the patient's intimate partner.

## SOCIODEMOGRAPHIC CONTEXT OF OLDER WOMEN'S SEXUALITY

Sexuality in later life for most, but not all, people occurs in the context of a long-term marital relationship. For men, aging is largely a partnered experience. Men are significantly more likely than women to have a spouse or other romantic partner in later life and to be engaging in a satisfying sexual relationship, even despite a high prevalence of erectile difficulties. As a result of greater longevity, women, in contrast, are much more likely to experience aging, illness, and death without their life partner (Figure 47-2).

Still, many older women regard sexuality as important for health and relationships and, among those with a spousal or other intimate relationship, many engage in regular sexual activity. Women tend to be less satisfied with sex in later life than their male counterparts and also report a high frequency of sexual problems including low desire, vaginal dryness, and difficulty experiencing orgasm. An older married woman is often healthier and more vital than her spouse and commonly assumes a caregiver role, which can interfere with the romantic dynamic of the relationship. Physical health problems, medications, and medical treatments affect the sexual lives of older

couples; older heterosexual adults with a spouse or other intimate partner who are not sexually active most commonly attribute this to the male partner's health problems.

Sexuality is widely valued by older adults, even those without a partner, as an important aspect of health and life. In his 2001 report, the U.S. Surgeon General, David Satcher, acknowledged that "Sexuality is an integral part of human life. . . Sexual health is inextricably bound to physical and mental health. . . (it) is not limited to the absence of disease or dysfunction, nor is its importance confined to just the reproductive years. . ." Although some aspects of aging are regarded as detrimental to sexual life, older women also identify ways in which aging is beneficial for sexuality (Table 47-1).

Lack of formal sexuality education combined with widely restrictive social, religious, and cultural practices around female sexuality during much of the twentieth century have influenced the current generation of older women's sexual expectations throughout their life. As a result, many report that they have never discussed nor would they initiate discussion of sexual matters with anyone, including their spouse. Most older women report that they have never spoken of sexual matters with a physician, yet feel that sexuality is an appropriate issue for physicians to address and that the physician, rather than the patient, should initiate the discussion (Table 47-2). Gender and age differences between women and their physicians can also present barriers to communication about sexual matters. In addition, older women perceive physicians to be poorly trained to deal with patients' sexual concerns and that physicians presume older women to be asexual or disinterested (Table 47-2).

Aging of the baby boomers, the generation of the sexual revolution, is expected to increase demand for medical attention to sexual matters over the next several decades. Although male longevity is expected to increase, older women will continue to outnumber older men through 2050; this presents a significant gender disparity in the opportunity for formation of new sexual relationships in later life and, in some cases, results in multiple women sharing a single male partner. Little is known about the implications and consequences of nonmonogamy in later life, but health assessment of older women, as discussed in detail below, should include questions to ascertain sexual activity, number of current sexual partners, and partner monogamy as this information may be relevant to risk for sexually transmitted disease (STD) and/or psychological well-being.

## Sexuality in Long-Term Care Institutions

Although older women's sexuality has largely been a taboo subject, residential institutions for elderly people have long recognized that sexual expression and desire continue even among individuals affected by dementia, frailty, and other life-threatening illness. Dementia, mental illness, and some medications, including dopaminergic medications such as those used to treat Parkinson's disease, can result in sexual disinhibition or hypersexuality, sometimes directed at nursing home staff. The U.S. federal and many state governments declare a right to privacy for residents of nursing homes or elder care institutions; protection of privacy for sexual expression by institutionalized elders is not explicitly guaranteed by the government and therefore relies on individual institutions and providers to respect privacy and maintain individuals' sexual dignity.

Some responsive institutions have addressed this problem by providing private rooms for residents and by training staff to understand and accept elder sexuality in a respectful manner. Sometimes,

**FIGURE 47-2.** Prevalence of relationships and sexual activity by age and health status. Panel A shows the percentage of survey respondents who were in a spousal or other intimate relationship. Panel B shows the percentage of respondents who were sexually active in the previous year among those with a spousal or other intimate relationship. Blue symbols denote men, red symbols women, plus signs respondents who reported being in excellent or very good health, triangles respondents who reported being in good health, and circles respondents who reported being in fair or poor health. (Adapted from Lindau ST, et al. *A study of sexuality and health among older adults in the United States.* *N Engl J Med.* 2007;357(8):762-774.)

**TABLE 47-1**

### Older Women's Views on Sexuality and Aging

Effects of aging on sexuality	Beneficial	Partners know each other better; decreased sexual inhibition; more time; fewer distractions; know own body
	Detrimental	Less intense physical sexual response; increased inhibition because of poor body image; societal prejudice; need for secrecy
Effects of sexuality on aging	Beneficial	Better circulation; form of exercise; feeling of youthfulness or completeness; security of not being alone; pride in body; optimistic outlook on life; indicative of good general health; happiness/endorphins; physical release; physical outlet; alleviates arthritic pain
	Detrimental	Worry about transmitting or contracting infection; lost status as respected elder if sexually active

Based, in part, on qualitative work by S. T. Lindau funded by the John A. Hartford Foundation, 1993.

sexual relationships form among older residents with dementia who have, but may not remember, a community-residing spouse. Likewise, community-residing spouses may initiate new intimate relationships while maintaining involvement with and commitment to their institutionalized spouse. The implications of these relationships for health and integrity in later life are a growing reality, but poorly understood and often a cause of distress for families. Sexual exploitation and abuse of older women living in residential facilities (and in the community) is poorly documented, but vulnerability is heightened by cognitive impairment, which can interfere with a woman's ability to consent to sexual relations.

## SEXUAL ACTIVITY, BEHAVIOR, AND PROBLEMS

### Sexual Partnership

The NSHAP study provides the first comprehensive population-representative data on sexual activity, behavior, and problems experienced by community-residing women (and men) aged 57 to 85 years in the United States. For older women, sexual activity is largely determined by availability of a sexual partner. Among women aged

**TABLE 47-2****Older Women's Perceptions about Barriers to Discussing Sex with a Physician**

## Why patients don't discuss sex

- Patients "don't know what they don't know"
- Patients feel intimidated
- Feel that it might be disrespectful to physician
- Feel uncomfortable discussing sex with male physician
- Feel uncomfortable discussing sex with younger physician
- Worry that difference in sexual orientation between patient and physician will threaten relationship
- Think physicians not capable of or interested in discussing sex, so no value in raising the issue

## Why physicians don't discuss sex

- Physicians assume older people are not interested in talking about sex or having sex
- Physicians "look upon us as their parents"
- Physicians don't know enough to feel qualified to talk about sex
- Physicians assume someone else is dealing with these issues
- Physicians are focused on treating older people for illness rather than maintaining health and quality of life
- They don't have time
- Physicians have their own hang-ups about sex
- Physicians are embarrassed to talk about sex with older female patients
- Physicians' religious beliefs interfere

Based, in part, on qualitative work by S. T. Lindau funded by the John A. Hartford Foundation, 1993.

57 to 64 years, about 85% have a current spouse or other romantic or intimate partner. Nearly all of these relationships are reported as heterosexual, monogamous, and involve sexual activity. However, the proportion of women with a partner declines with age, because of earlier male mortality, and by age 85 years, only about 40% of women have a partner, and fewer than 20% engage in sexual relations.

As compared with younger women, those 57 years and older report fewer total sexual partners over the lifetime. In the NSHAP study, 5% of women reported ever having a female sexual partner and only 5 women (0.3%) reported currently being in a relationship with another woman. Although data on lesbian relationships at older ages are very limited, estimates from the younger population suggest that women in this study may have underreported same-sex relationships. Additionally, qualitative research and clinical experience reveals cases of older women choosing or demonstrating receptivity to female partners for the first time in later life. Some women explain this as a choice caused by the scarcity of men and others are fulfilling a lifelong interest. Most sexually active older women report that their relationships are monogamous. However, women with nonmarriage partners are significantly more likely to report that their partner has had other sexual partners during the relationship. In the NSHAP study, nearly 1 in 10 married women and twice as many nonmarried women with a sexual partner believed that their current partner had other sexual partners during the relationship.

## Sexual Activity

Among those who are sexually active (defined in the NSHAP study as engaging in "any mutually voluntary activity with another person

that involves sexual contact, whether or not intercourse or orgasm occurs" during the prior 12 months), the kinds and frequency of sexual activity in which women engage are not substantially different from that observed among younger women. Most commonly, sexual activity involves vaginal intercourse, hugging, kissing, or other forms of sexual touching, and about 45% of sexually active women engage in oral sex. On average, the frequency of sexual activity for those with a sexual partner ranges between monthly and two to three times per month. Again, this is similar to that observed among younger sexually active adults. About a quarter of women aged 57 to 85 years report masturbating in the previous year. Interestingly, the prevalence of masturbation among women without a partner is the same as it is among women with a partner. This is also true for older men (50% report masturbating) and suggests that older adults maintain an individual desire for sexual pleasure and/or release, even in the absence of a sexual partner.

## Sexual Problems

Among sexually active women, approximately half report having one bothersome sexual problem; almost one-third report having two. In contrast to older men whose sexual problems are heavily concentrated around erectile difficulties, older women are more likely to have sexual problems in multiple domains. The most common sexual problems experienced by older women are summarized in [Table 47-3](#). Lack of interest in sex, pain with intercourse, unpleasurable sex, and inability to experience orgasm are much more common among older women as compared with their male counterpart. Of course, some proportion of sexually inactive women discontinued sexual activity as a result of bothersome sexual problems and, therefore, the NSHAP study underestimates the prevalence of problems in the whole population. On the other hand, many older women engage in sex despite bothersome problems. The explanation for this is unknown: the rewards or gains of sexual engagement may outweigh these negative experiences, some women may obligatorily participate in sex, others may lack the ability to refuse.

**TABLE 47-3****Most Common Sexual Problems Experienced by Older Women\***

	PERCENTAGE BY AGE GROUP <sup>†</sup>		
	57-64	65-74	75-85
Lacked interest in sex ( <i>n</i> = 504)	44	38	49
Difficulty lubricating ( <i>n</i> = 495)	36	43	44
Unable to climax ( <i>n</i> = 479)	34	33	38
Pain during intercourse ( <i>n</i> = 506)	18	19	12
Sex not pleasurable ( <i>n</i> = 498)	24	22	25
Anxious about performance ( <i>n</i> = 500)	10	12	10
Avoided sex because of problems ( <i>n</i> = 357)	34	30	23

\*Among those of 1550 women surveyed in the National Social Life, Health and Aging Project who reported having sex in the last 12 months, as indicated by the number of respondents in each row.

<sup>†</sup>Estimates (means) are weighted to account for differential probabilities of selection and differential non-response. Asked only of those who reported at least one sexual problem.

Problems related to sexuality in later life, including female sexual dysfunction, can result from sexually transmitted infection, trauma, and sexual violence or abuse. These topics are discussed below. Sexual dysfunction, including clinical diagnosis and treatment, is discussed in more detail later in this chapter.

### Sexually Transmitted Infection

Data from the National Health and Nutrition Examination Survey (NHANES) and NSHAP provide the only U.S. population prevalence of sexually transmitted infections among older women. Overall, prevalence of most infections in the general population is very low, although it may be higher in some elder residential communities or geographic regions with high concentrations of sexually active older adults (e.g., Florida and Hawaii in the United States), or in other subpopulations. STD prevalence among older adults is likely underestimated because of lack of uniform tracking systems and underidentification in the clinical setting. One study showed that physicians are more likely to counsel older African-American and married women about human immunodeficiency virus (HIV) and other STDs, but the majority of older women report that a physician has never initiated such discussion.

Viral infections, including genital herpes simplex virus (HSV) and human papillomavirus (HPV), are among the more prevalent STDs found in older women. HSV-2 seroprevalence among men and women 70 years and older based on NHANES III data (1988–94) was 28%, but women had a higher overall prevalence than men and rates were much higher among blacks (74%) and Mexican Americans (45%). High-risk, or oncogenic, HPV (HR-HPV) prevalence among women aged 57 to 85 years, based on 2005–2006 NSHAP data was 6% and did not vary significantly across age or racial/ethnic groups. The prevalence of this sexually transmitted infection is similar to that documented by NHANES for women aged 50 to 59 years and calls into question age-based eligibility criteria for screening and prevention strategies, including implementation of HPV vaccination.

While there is evidence for new infection in later life as a result of sexual transmission, and infection of sexual partners by infected older women occurs, the majority of incident infections occur earlier in life and either persist or are latently expressed. HR-HPV is an important factor in cervical dysplasia and cancer, a leading cause of female cancer death in the world. In the United States, about 20% of cervical cancer cases, but more than a third of cervical cancer deaths, occur in women aged 65 years and older. Most screening and prevention strategies, including HPV vaccine, use age-based eligibility criteria that largely exclude older women.

Although data are very limited and likely underestimate prevalence (as explained above), population incidence estimates of other STDs among older women are lower than 1% for *Chlamydia trachomatis*, *Neisseria gonorrhoea*, and Syphilis. U.S. population data on *Trichomonas vaginalis* among older women are not available; late twentieth century data from Danish and Chinese epidemiological studies indicate that very few cases occur among women older than 60 years. Changes in the cervical epithelium caused by loss of estrogen in older women may account for reduced susceptibility to some infections such as HPV and Chlamydia.

The vast majority of cases of HIV/AIDS in the United States and the world occur among people younger than age 50 years. However, the rate of new HIV infection among older women in the United

States, particularly those of minority racial and ethnic groups, has been increasing over the last several years, due mostly to transmission by heterosexual sex. Prolonged survival of individuals infected with HIV in their fourth and fifth decades primarily accounts for increasing prevalence of HIV and AIDS in the United States among older adults. Of all prevalent HIV infections in the United States, 10% to 13% are estimated to occur among people aged 50 years and older. In 2002, 25% of Americans diagnosed with HIV/AIDS after the age of 55 years were women. Public health messages regarding HIV/AIDS prevention and detection have not targeted older women, and physicians rarely offer HIV counseling or testing to this group.

STD prevention strategies have not been well-tested for older adults. Few older women, including those in nonmarital sexual relationships, report using condoms. Condom use by older couples to prevent STDs may be compromised by similar knowledge, communication, behavioral, and cultural barriers experienced by younger couples and by changes in male and female physiology that occur with age. A condom is best applied when the penis is fully erect, but for some older men, full erection may not occur until after coitus is initiated. For women, increased susceptibility to condom-induced vaginal irritation or abrasion may result from vaginal dryness and/or atrophy caused by estrogen depletion.

Counseling women with new or multiple sexual partners warrants attention to prevention of STDs including discussion of barrier methods such as male and female condom and the dental dam (for oral sex) (Figure 47-3). Couples receptive to using condoms should be taught proper application, encouraged to use foreplay to encourage full penile erection and maximal female arousal before penetration, and consider water-based lubricants (oil-based lubricants or vaginal medications can reduce condom effectiveness) to reduce vaginal and vulvar friction. Condoms with spermicide are not necessary for postreproductive age women and should be avoided because they have a shorter shelf-life and have been associated with urinary tract infection in younger women. Male and female condoms and dental dams are for one-time use only.

### Sexual Trauma, Violence, and Abuse

Early life events, including sexual trauma in the form of abuse, exploitation, genital injury, and rape, can have lasting effects on sexuality and health that persist into later life. Estimates of lifetime intimate partner violence among older women indicate that 20% to 26% of women are victims; nearly 40% in one study reported that this was severe, including forced sex or sexual contact. In the NSHAP study, 9% of women aged 57 to 85 years reported a lifetime history of forced sex (which may or may not have been with an intimate partner); of these, nearly 40% reported that the most recent event occurred at or younger than age 19 years and 16% reported that the most recent event occurred after age 40 years. Sexual dysfunction, particularly conditions such as vaginismus, dyspareunia, inability to experience orgasm, lack of pleasure with sex, and disturbing fantasies are more common among women with a history of sexual trauma, violence, or abuse. In conjunction with medical treatment and/or physical therapy, psychotherapy including cognitive-behavioral techniques and strategies used for treatment of posttraumatic stress can be effective in helping women at any age cope with sexual violence and experience positive sexual relationships.

**FIGURE 47-3.** Dental dam, female condom, and male condom. (A) Latex dental dam. (B) Latex female condom. (C) Latex male condom.

Elder mistreatment, or abuse, discussed in Chapter 60, can also involve sexual abuse but is not limited to an intimate partner. In fact, lack of a spouse or other partner, cognitive impairment, and institutionalization are risk factors for female sexual abuse and rape in later life. Very little is known about how commonly older women experience sexual violence or abuse, but few older women report that a physician has ever asked questions to ascertain sexual victimization. Screening questions for identifying intimate partner violence in the clinical setting are summarized in [Table 47-4](#) and should be part of routine assessment of the older woman.

Consideration of intimate partner violence and sexual abuse in the acute or emergency care settings should be given, particularly when a woman presents with physical injury, vague symptoms (especially recurrent visits), acute mental status changes, and/or is accompanied by a partner or other individual who interferes with the patient's interaction with health care providers.

## FEMALE SEXUAL RESPONSE CYCLE

The female sexual response cycle provides one simplified framework for understanding and remembering domains of sexual problems experienced by women. The Masters and Johnson model of the female sexual response cycle, based on physiologic research initiated in the 1960s with a convenience sample of local sex workers, other volunteers, and patients presenting for treatment of sexual problems or contraception, remains the most widely represented model in medical textbooks and the foundation for the Diagnostic and Statistical Manual definitions for sexual dysfunction. This traditional, linear model describes four phases of human sexual response: excitement, plateau, orgasm, and resolution (sex therapist Helen Singer-Kaplan modified this in 1979 to include orgasm, excitement, and desire)

and illustrates notable differences in female as compared with male sexual physiology ([Figure 47-4A](#)).

According to Masters' and Johnson's work, the female sexual response is more variable than that of males and orgasm maybe single and peak-like, as in men, more gradual or undulating, and/or repetitive during a single sexual encounter. The typical male sexual response is described as much more uniform, peaking in a single orgasm, and includes a latency period during which a subsequent orgasm cannot occur. Arousal for women tends to require tactile stimulation, otherwise known as foreplay; for younger men, visual stimulation plays an important role in arousal but this can abate with age. Many women require direct clitoral or periclitoral stimulation before, during, and/or following intercourse (which may involve penile–vaginal, penile–anal, oral, or manual penetration) in order to experience orgasm. This maybe particularly important for older women engaging in vaginal intercourse with male sex partners because of reduction in the firmness and fullness of the male erection in later life. A longer duration to orgasm in older men maybe realized by some couples as better synchrony of the arousal phase and more frequent experience of simultaneous orgasm.

The pattern of female sexual response may vary across time within a single relationship or with different sexual partners, although little is known empirically about the physiology of the female sexual response cycle in later life or in the context of very long-term (several decades or more) relationships. Psychoemotional changes, and changes in physical appearance with age, including appearance of the vulva and breasts, can negatively or positively affect an older woman's feeling of attractiveness, and can influence her interest in sex. Some women indicate less psychological inhibition about physical appearance with age, or improvement with age, both of which can be sexually liberating.

TABLE 47-4

## Measurement Tools to Assess Intimate Partner Violence

MEASURE	CHARACTERISTICS	CONTENT
Women's Experience with Battering (WEB) Scale	10 items 1 = (strongly disagree) to 6 = (strongly agree)*	<ul style="list-style-type: none"> <li>• My partner made me feel unsafe even in my own home</li> <li>• I felt ashamed of the things my partner did to me</li> <li>• I tried not to rock the boat because I was afraid of what my partner might do</li> <li>• I felt like my partner kept me a prisoner</li> <li>• My partner could scare me without laying a hand on me</li> <li>• I hid the truth from others because I was afraid not to</li> <li>• I felt owned and controlled by my partner</li> <li>• My partner made me feel like I had no control over my life</li> <li>• My partner had a look that went straight through me and terrified me</li> </ul>
Behavioral Risk Factor Surveillance Survey (BRFSS)	5 items yes/no response scale†	<p><i>Sexual</i></p> <ul style="list-style-type: none"> <li>• Now I want to ask you about forced sex involving vaginal, oral, or anal penetration. Has an intimate partner ever forced you to participate in a sex act against your will?</li> <li>• Has an intimate partner ever threatened, coerced, or physically forced you into any sexual contact that did not result in intercourse or penetration?</li> </ul> <p><i>Physical</i></p> <ul style="list-style-type: none"> <li>• Has an intimate partner ever hit, slapped, shoved, choked, kicked, shaken, or otherwise physically hurt you?</li> </ul> <p><i>Psychological</i></p> <ul style="list-style-type: none"> <li>• Have you ever been frightened for your safety, or that of your family or friends because of the anger or threats of an intimate partner?</li> <li>• Has an intimate partner ever put you down, or called you names repeatedly, or controlled your behavior?</li> </ul>

\*WEB scores equal to or higher than 20 (range 10–60) is an indicator of exposure to abuse.

† Any woman who answered “yes” to any of the BRFSS questions for their most recent partner is classified as having “any abuse.”

Adapted from Bonomi AE, Thompson RS, Anderson M, et al. Ascertainment of intimate partner violence using two abuse measurement frameworks. *Injury Prevention*. 12(2):121–124, 2006.

Changes in men's sexual response that occur with age can affect female partners both physically and psychologically. As men age, the sexual response becomes more similar to that of women (a phenomenon some refer to as “feminization of the male sexual response cycle”). Tactile stimulation and foreplay are increasingly important for older male arousal, duration to erection and orgasm is longer, and latency (or the refractory period) between orgasms is increased. Because few older men or women are aware of this phenomenon, these changes are often perceived as abnormal, cause unnecessary anxiety and shame, and can strain both members of a couple. Some couples cease sexual activity as a consequence and most do not seek medical help.

Building on the pioneering work of Masters and Johnson, Basson proposed a widely referenced intimacy-based, cyclical model of the female sexual response that incorporates the quality and duration of the relationship as well as the psychoemotional component of female sexuality (Figure 47-4B). In older and younger women, sexual desire may occur before or following sexual arousal. This model emphasizes the role of intimacy in generating female sexual desire and suggests that lack of intimacy and unsatisfying sexual encounters can raise the threshold for interest and arousal in a subsequent sexual encounter. Rather than linear and discrete, the phases of the female sexual response are described by Basson as variably overlapping in a way that “blends mind and body.”

Early experimental work suggests that each of these models applies to some women. A survey of nurses (published in 2007) with a response rate of 23% found that the Basson model may resonate most for women with sexual problems. Further empirical characteri-

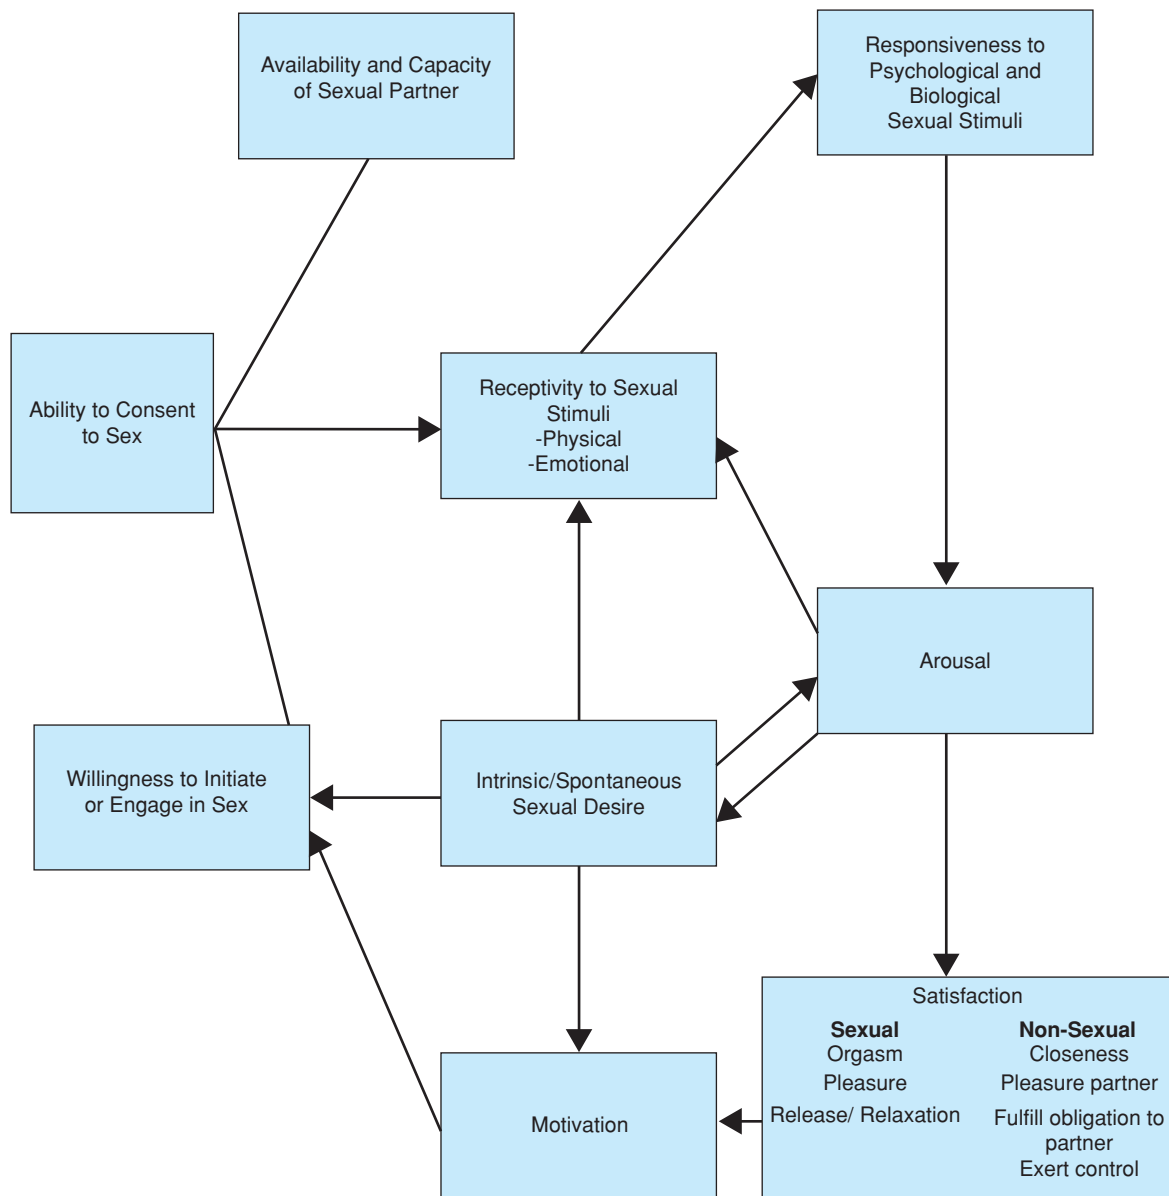

zation of the physiology and psychosocial aspects of the female sexual response cycle in later life, including how it might fluctuate within relationships over long durations of time, across relationships, and with aging, is needed both to inform women's expectations and the clinical approach to older women's sexuality.

## FEMALE SEXUAL PHYSIOLOGY IN LATER LIFE

Effects of senescence on the endocrine, neurovascular, musculoskeletal, genitourinary, and gastrointestinal systems are particularly salient to sexual function in later life. More global changes in physical appearance, sensory function (hearing, vision, olfaction, taste, and tactile sensation), cognitive function and memory, and body aromas such as scent, breath, and genital odor can also affect sexual engagement and enjoyment. The female sexual response involves a complex and highly interconnected series of physiologic events connecting mind and body. Disruptions or changes in any of these physiologic systems caused by age-related changes, physical or mental illness, or medication use can alter the sexual response and the ability of a woman to derive pleasure and satisfaction from her sexual encounters.

### Endocrine System

Loss of estrogen as a result of menopause is a dominant physiologic event that can affect many aspects of older women's sexual

**FIGURE 47-4.** Models of female sexual response cycle. Female sexual response cycle a, b, c refer to three different sexual response patterns found in females. Model of the partnered female sexual response highlighting features pertinent to older women. (Data from Basson R. *The female sexual response: a different model.* *J Sex Marital Ther.* 26(1):51–65, 2000.)

function. Despite extension of the human life span, the age of menopause has not changed. Women can live a third or more of life in menopause: the median age of natural menopause in the United States is about 51.3 years and average female life span is 80.4 years. Surgical menopause occurs when a woman undergoes bilateral oophorectomy (or loses ovarian function as a result of other interventions such as chemotherapy or radiation) prior to natural menopause. In the NSHAP study, about 1 in 5 U.S. women aged 57 to 85 years report a history of surgical menopause. Women who have undergone bilateral oophorectomy, pre- or postmenopause, also experience an abrupt and irreversible loss of androgen production.

Estrogen is important for maintaining skin, subcutaneous, mucosal (vaginal, bladder, and rectal) and musculoskeletal integrity, the

vaginal microenvironment (pH balance and microflora), vascular flow to the vagina and clitoris via regulation of nitric oxide synthase expression, and sensory perception. Over time, in the genital tract, low estrogen results in vaginal dryness, loss of epithelial cell glycogen, shortening of the vagina, narrowing of the introitus, thinning of the labia, and diminution of the fat pad underlying the mons pubis (Table 47-5). Loss of vaginal acidity results from glycogen depletion and can increase propensity for vaginitis. Urinary and fecal incontinence can be exacerbated by estrogen depletion and inhibit social and sexual relationships as well as sexual function. Maintenance of sexual activity in later life appears to offset some of these local genital changes, in part by maintaining flexibility of the vulvovaginal tissues, pelvic floor musculature, and pelvic joints. Additionally, sexual activity and other forms of physical contact may mitigate estrogen-related

**TABLE 47-5****Age-associated Anatomical and Physiological Changes in the Vagina.**

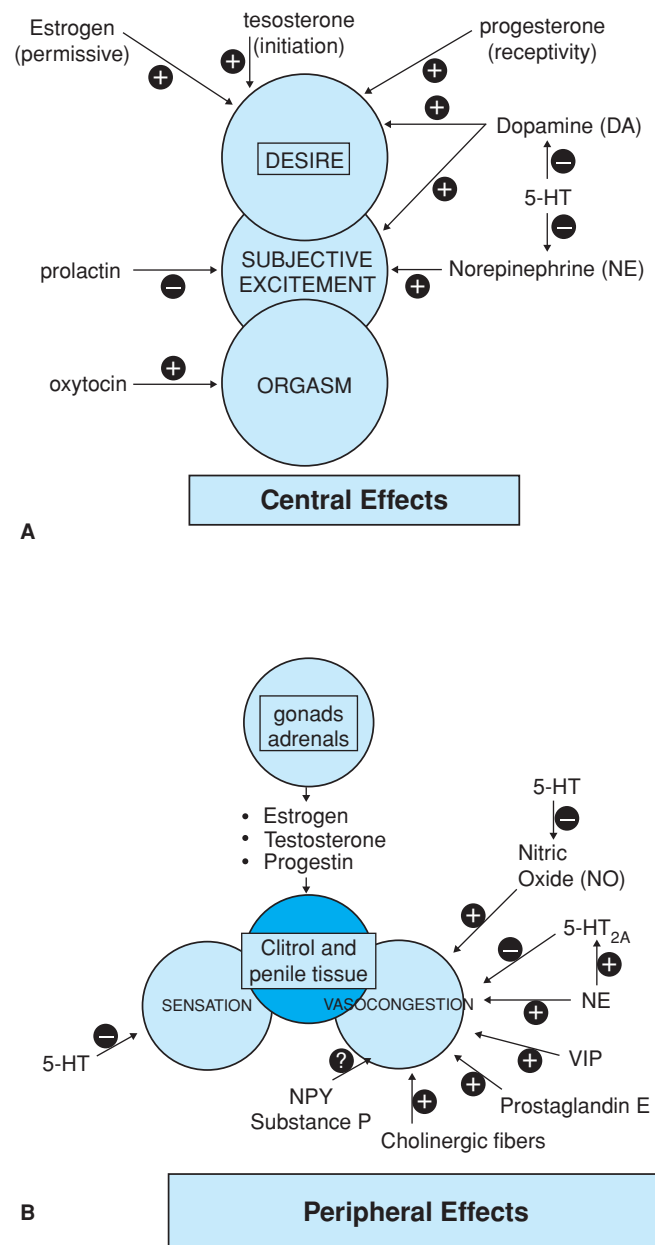

Narrowing of vaginal barrel
Epithelium loses glycogen content and normal bacterial flora
Pathogenic bacteria often replace lactobacillus, resulting in atrophic vaginitis
Decreased lubrication results in dryness
Reduced vaginal blood flow
Vaginal pH increases from 4.5–5.5 to 7.0–7.4
Atrophy of vaginal mucosa
Pale color
Loss of vaginal folds

decline in sensory perception and function with age and may play a role in female attractiveness. Largely owing to highly publicized findings from the randomized, controlled hormone therapy trials of the U.S. Women's Health Initiative Study (comparing use of combination equine estrogen alone or in combination with progesterone to placebo among postmenopausal women aged 50 to 79 years at baseline), a minority of women currently use prolonged estrogen therapy for treatment of menopausal symptoms or preservation of sexual function.

Testosterone, along with dehydroepiandrosterone (DHEA), plays an important role in female libido, arousal, genital sensation, and orgasm. Loss of testosterone can exacerbate vaginal mucosal atrophy, thinning of pubic hair, and may compromise an older woman's sense of general well-being. Although female androgen insufficiency as a treatable condition or syndrome is controversial, testosterone therapy for low libido has been shown to be effective in clinical trials involving women with bilateral oophorectomy or total loss of ovarian function as well as postmenopausal women on estrogen therapy (estrogen reduces bioavailable testosterone by increasing sex hormone binding globulin production). However, the U.S. Food and Drug Administration (FDA) has not approved a testosterone patch for this indication. Use of testosterone or DHEA to treat female sexual dysfunction is currently off-label in the United States and most countries and requires close monitoring for side effects. Although rare, irreversible deepening of the voice and growth of facial hair may occur with testosterone use.

Figure 47-5 summarizes central and peripheral hormonal mediators of sexual function (also see Chapter 107). Understanding centrally mediated neuroendocrine changes that occur with senescence is an active area of discovery, focused heavily on understanding cognitive pathophysiology. In women and female animal studies, interest in the cascade of neuroendocrine events resulting in menopause has been similarly driven by an effort to understand the role of sex hormones and hormone therapy in neuroplasticity and degeneration, as well as by efforts to treat female infertility. Application of this knowledge to female sexual function in later life, particularly sex differences in endocrine regulation of the sexual response cycle is nascent.

Aside from its peripheral effects, described above, estrogen plays an important central role both via direct membrane receptor activity and modulation of neurotransmitters. Estrogen appears to exert

**FIGURE 47-5.** Central and peripheral effects on sexual function. + indicates a positive effect. – indicates a negative effect. VIP, vasoactive intestinal polypeptide; 5-HT, serotonin (5-hydroxytryptamine); NPY, neuropeptide Y; NE, norepinephrine. (Clayton AH. *Sexual function and dysfunction in women*. *Psychiatr Clin North Am*. 26(3):673–82, 2003.)

neurotrophic and neuroprotective activity in the brain that mitigate against hypothalamic damage that occurs with age. Estrogen also interacts with serotonin and norepinephrine metabolism, which may explain the role of estrogen depletion in sleep, mood, memory and, through these and no doubt other mechanisms, the female sexual response cycle in later life.

The hypothalamic-pituitary-adrenal (HPA) axis mediates the human physiologic stress response and, of course, is the pathway or pacemaker through which sex hormonal regulation occurs. The loss of temporality and pulsatility in HPA neural signaling is a key event in menopause; the dynamics of HPA function over the portion of

the life span following menopause, and the implications for female sexual functioning in later life are much less well-defined. Vasoactive intestinal peptide (VIP), now recognized to play a role in female sexual arousal via vasocongestion of the clitoral tissue, also signals time of day information for central GnRH regulation. Rhythmic synthesis of VIP in the brain appears to disappear by middle age in women and maybe an important triggering event in the loss of hypothalamic-pituitary-ovarian axis coordination required for ovulation and menstruation. The peripheral effects of changes in central VIP metabolism for later life sexual arousal in women are unknown.

### Neurovascular System

Neurovascular physiology, mediated by the sympathetic and parasympathetic nervous systems and a growing list of nonadrenergic/noncholinergic neurotransmitters (e.g., nitric oxide, VIP, nonadrenergic noncholinergic (NANC) is particularly important for the arousal and orgasm phases of the female sexual response cycle. Arousal involves vascular engorgement of the genitopelvic organs, including the labia, vagina, and clitoris, lengthening, dilation and lubrication of the vagina, retraction of the clitoral hood, and tumescence of the clitoris. Microvascular integrity is important for genital sensation and orgasm. Clitoral sensation, in particular, can be compromised by microvascular disease as seen in chronic smokers and women with hypercholesterolemia or diabetes.

Cardiovascular disease caused by atherosclerosis can impair women's sexual function in later life both through psychological and physiological mechanisms. Men are significantly more likely than women to be diagnosed with cardiovascular disease (although it is the leading cause of death for women) and to be counseled about the sexual implications of this condition. Attention to older women's sexual concerns in the setting of cardiovascular disease such as recovery after acute myocardial infarction (MI) or pacemaker/defibrillator placement involves reassurance about the safety and timing of resuming sexual activity (including intercourse, masturbation, and orgasm) and the possible sexual side effects of medications or devices used to treat these conditions. Phosphodiesterase inhibitors are used in men to treat neurovascular causes of erectile dysfunction; similar effectiveness has not been found in women. The only U.S. FDA-approved device for treatment of female sexual dysfunction, the Eros Therapy<sup>TM</sup> (UroMetrics) clitoral pump, may assist some women with microvascular disease in experiencing improved clitoral sensation, vaginal lubrication, and orgasm.

### Musculoskeletal System

Parity, childbirth-related injury, pelvic or lower extremity trauma, obesity, and sedentariness can compromise the integrity of the vulvar, pelvic floor, and lower extremity musculature. Effective contraction and relaxation of the peri-introital, perineal, and pelvic floor muscles is important for penetration, arousal, orgasm, and the relaxation phase following orgasm. Loss of flexibility of hip muscles and compromised stability and mobility of hip joints commonly experienced by women with arthritis or hip fracture can interfere with sexual functioning in later life. Skeletal changes in the hips and vertebrae

caused by loss of bone density, osteoporosis, vertebral compression and fracture, and arthritis can make vaginal penetration, particularly using "missionary" (female supine with hips and knees flexed) position difficult and maybe accommodated by use of alternative sexual positioning such as side-lying or sex without vaginal penetration. Prevention and treatment of these conditions with attention to maximizing musculoskeletal strength and flexibility can improve overall physical functioning and help preserve sexual capacity for aging women. Endorphin release associated with pleasurable sexual activity may help alleviate musculoskeletal pain.

### Genitourinary System

Changes in the genitourinary system are heavily influenced by postmenopausal loss of estrogen. The urethral orifice can become everted and sensitive to friction, which may cause pain during penetration. Laxity in the pelvic tissues can result in prolapse of the uterus and vaginal walls (i.e., cystocele, rectocele, enterocele). Cervical contact with sexual penetration can cause an "electric shock" or otherwise painful sensation during vaginal intercourse and limits the depth and force of penetration; cervical prolapse that is visible at the introitus or procidentia (prolapse through the vagina) can make vaginal intercourse very difficult physically and psychologically. Urinary incontinence is common, and commonly goes untreated, for older women and loss of urine during intercourse, particularly with orgasm, can also cause physical and psychological discomfort with sex and avoidance of sex. Pessaries maybe used to reduce prolapse and treat urinary incontinence; some, such as ring pessaries, are designed for compatibility with intercourse but should be removed and cleaned following intercourse. Procedures to treat pelvic organ prolapse and urinary incontinence may improve sexual functioning for some women, but colpocleisis (partial or total surgical closure of the vagina to treat prolapse) is largely prohibitive for penetrative vaginal sex.

### Gastrointestinal System

Gastrointestinal changes with aging that are most relevant to female sexual function include incontinence of stool and flatus, hemorrhoids, and borborygmy. Anal incontinence typically results in cessation of sexual activity and can be very socially isolating. Hemorrhoids can be exacerbated by sexual activity, particularly anal intercourse, and may result in bleeding during or following sex. Borborygmy can be controlled to some degree by timing of meals in relation to symptoms. Older women who have ceased and/or who wish to resume sexual activity after a hiatus should be screened and evaluated for both urinary and anal incontinence and treated in order to prevent embarrassing or painful sexual experiences that can be very detrimental to her sexual self-image and function.

## FEMALE SEXUAL DYSFUNCTION

Use of terms like "dysfunction," "normal," and even "healthy," in relation to human sexuality requires caution and has been criticized, particularly in the feminist and recent psychology literatures. For example, what is a normal level of sexual desire for older women? Is

celibacy unhealthy? Few older women report same-sex partners, so is lesbianism abnormal? Is a distressing sexual difficulty a “dysfunction” or a “normal” response to unhappy circumstances in a relationship? Critiques are rooted in a painful history of sexual discrimination, particularly in the United States, and partially in medical history; as recent as the early 1990s, female sexual dysfunction could be diagnosed as a sexual problem experienced by a woman even if it was only troublesome to her partner. In addition, skeptics of the “medicalization” of female sexuality question how “normal” or “functional” sexuality can be defined as the absence of problems, given the high prevalence of sexual problems in the population.

### Diagnostic Classification of Female Sexual Dysfunction

The current Diagnostic and Statistical Manual IV–TR classification of female sexual dysfunction stipulates that the problem is persistent or recurrent and causes marked personal distress or interpersonal difficulty. The 2nd International Consensus of Sexual Medicine (2003) adopts a similar classification approach for clinical diagnosis of sexual dysfunction (Table 47-6). Although many validated tools, such as the Female Sexual Function Index and the Sexual Function Questionnaire, can be used to assist clinical diagnosis of female sexual dysfunction (these are generally more relevant for younger women), parallel tools have not been widely validated for use in population studies, particularly of older women. Consequently, population estimates of sexual dysfunction from the NSHAP study (illustrated in Figure 47-6) and others are useful for quantifying the baseline prevalence of sexual problems in later life, or even bothersome sexual problems, but should not be expected to translate into population rates of female sexual dysfunction, clinically defined.

### Causes of Female Sexual Dysfunction

Causes of female sexual dysfunction in later life can be primary, such as hypoactive sexual desire disorder, or secondary. Secondary causes can be related to the IBM model referred to previously and include (1) interpersonal and personal psychological factors including depression and substance use, (2) biological factors including a wide spectrum of illnesses, injuries, physical disabilities, and their medical and surgical treatments (note that earlier life illnesses such as cancer and cancer treatment have been shown to have long-lasting effects on sexual function in survivors), and (3) social factors. The patient’s psychosexual history and her current partner’s physical and mental health, medication, and substance use and sexual function must also be investigated in order to gain a full picture of the patient’s sexual functioning and to appropriately tailor therapeutic interventions. Common medications affecting older women’s sexual function are summarized in Table 47-7.

### Sexual History—Talking and Communication about Sexual Problems

The NSHAP study and several other surveys including older women, even those who are not sexually active, indicate that patients are widely receptive to physician initiation of discussion about sexual problems. If appropriately addressed, patients are not offended; to the contrary, inquiring about this aspect of a woman’s history

and health can signal that the physician respects her as a vital and whole person. Table 47-8 lists several questions that can be incorporated into a routine geriatrics encounter and should be tailored to the individual’s needs. Questions to assess sexual dysfunction when identified are ideally addressed to the individual and the couple and are summarized in Table 47-9. Identification of the level of personal distress caused by each problem can be assessed informally by asking “How much does this problem bother you?” and can be noted as a lot, somewhat, or not at all (a validated instrument, the Derogatis Female Sexual Distress Scale (2002) is useful, particularly for research purposes). The clinician should also document whether the problem is lifelong or acquired and situational or generalized, as these features are important for diagnosis and treatment.

### Clinical Management of Female Sexual Dysfunction

A growing, but nascent, evidence base for treatment of female sexual problems (few studies include women older than 65 years) limits the strength of recommendations for management. Treatment of most sexual problems seems to benefit from an interdisciplinary approach, involving psychology, medical evaluation and consideration of medical or surgical treatment, and in some cases, physical therapy. Unfortunately, cost can be prohibitive, particularly for mental health services, which are generally poorly covered by Medicare and private insurance plans. The summary presented here draws heavily on recommendations by Basson (2005) from the international committee convened by the Foundation of Urological Disease (2002–03) and accepted with revisions by the Second International Consensus of Sexual Medicine (2003). It aims to give primary care providers initial treatment options. Where available and affordable, referral to a specialist with experience in treatment of female sexual dysfunction maybe optimal. The International Society for the Study of Women’s Sexual Health (<http://isswsh.org>) and the Society for Sex Therapy and Research (<http://www.sstarnet.org/>) are useful online resources. Psychotherapy, including couples’ and sex therapy, cognitive-behavioral approaches, and sensate focus techniques have long been implemented for treatment of female sexual dysfunction and can be adapted to the needs of older women and couples.

### Dyspareunia

Dyspareunia, or pain with intercourse, is a common problem for older women, and many cease sexual activity as a consequence. Thinning of the vaginal mucosa, prolapse of the pelvic organs, and shortening of the vagina caused by loss of estrogen or surgery (by age 60 years, approximately one in three of U.S. women have undergone hysterectomy) in addition to deconditioning resulting from infrequent or prolonged abstinence from sex, can contribute to this problem in older women. Skeletal pain caused by arthritis, vulvar skin conditions, and neurogenic pain can also cause dyspareunia. Management involves treatment of the underlying condition and may include cognitive-behavioral therapy. Vaginal estrogen therapy to address atrophy and pelvic physical therapy including transvaginal pelvic floor massage show clinical benefit in many cases.

TABLE 47-6

## Female Sexual Dysfunction Definitions

SEXUAL DYSFUNCTION	DSM-IV-TR	BASSON (2005)
<i>Sexual desire/interest disorder</i>	<p>"<i>Sexual aversion disorder</i>"—Persistent or recurrent extreme aversion to, and avoidance of, all (or almost all) genital sexual contact with a sexual partner.</p> <p>"<i>Hypoactive sexual desire disorder</i>"—Persistently or recurrently deficient (or absent) sexual fantasies and desire for sexual activity. The judgment of deficiency or absence is made by the clinician, taking into account factors that affect sexual functioning, such as age and the context of the person's life.</p>	Feelings of sexual interest or desire, sexual thoughts or fantasies, and responsive desire are absent (or diminished). Motivating reasons or incentive for attempting to become sexually aroused are scarce or absent. The lack of interest is beyond the normative lessening that may occur with life cycle and relationship duration.
<i>Sexual arousal disorder</i>	Persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate lubrication-swelling response of sexual excitement.	<p>"<i>Subjective sexual arousal disorder</i>"—Absent or markedly reduced subjective sexual arousal (feelings of excitement, pleasure) from any type of stimulation. Vaginal lubrication and other signs of physical response still occur.</p> <p>"<i>Genital arousal disorder</i>"—Absent or impaired genital sexual arousal: minimal vulval swelling or vaginal lubrication from any type of sexual stimulation, and reduced sexual sensation from caress of the genitalia. Subjective sexual excitement still occurs from nongenital sexual stimuli.</p> <p>"<i>Combined Sexual Arousal Disorder</i>"—Absent or markedly reduced subjective sexual arousal (feelings of excitement, pleasure) from any type of stimulation, and absent or impaired genital sexual arousal (vulvar swelling, lubrication).</p> <p>"<i>Persistent sexual arousal disorder</i>"—Spontaneous, intrusive and unwanted genital arousal (tingling, throbbing) when sexual interest or desire is absent. Any awareness of subjective arousal is typically but not invariably unpleasant. The arousal is unrelieved by orgasm(s), and the feelings persist for hours or days.</p>
<i>Orgasmic disorder</i>	Persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase. Women exhibit wide variability in the type or intensity of stimulation that triggers orgasm. The diagnosis of Female Orgasmic Disorder should be based on the clinician's judgment that the woman's orgasmic capacity is less than would be reasonable for her age, sexual experience, and the adequacy of sexual stimulation she receives.	Despite self-report of high sexual arousal, orgasm from any kind of stimulation is lacking, markedly diminished in intensity or considerably delayed.
<i>Vaginismus</i>	Recurrent or persistent involuntary spasm of the musculature of the outer third of the vagina that interferes with sexual intercourse.	<p>Persistent or recurrent difficulties in allowing vaginal entry of a penis, finger or any object, despite the woman's expressed wish to do so. There is often (phobic) avoidance; anticipation, fear or experience of pain; and variable involuntary contraction of pelvic muscles.</p> <p>Structural or other physical abnormalities must be ruled out or addressed.</p>
<i>Dyspareunia</i>	Recurrent or persistent genital pain associated with sexual intercourse in either a male or a female.	Persistent or recurrent pain with attempted or complete vaginal entry or penile-vaginal intercourse

Adapted from Basson R. *Women's sexual dysfunction: revised and expanded definitions*. CMAJ. 172(10):1327–1333. 2005.

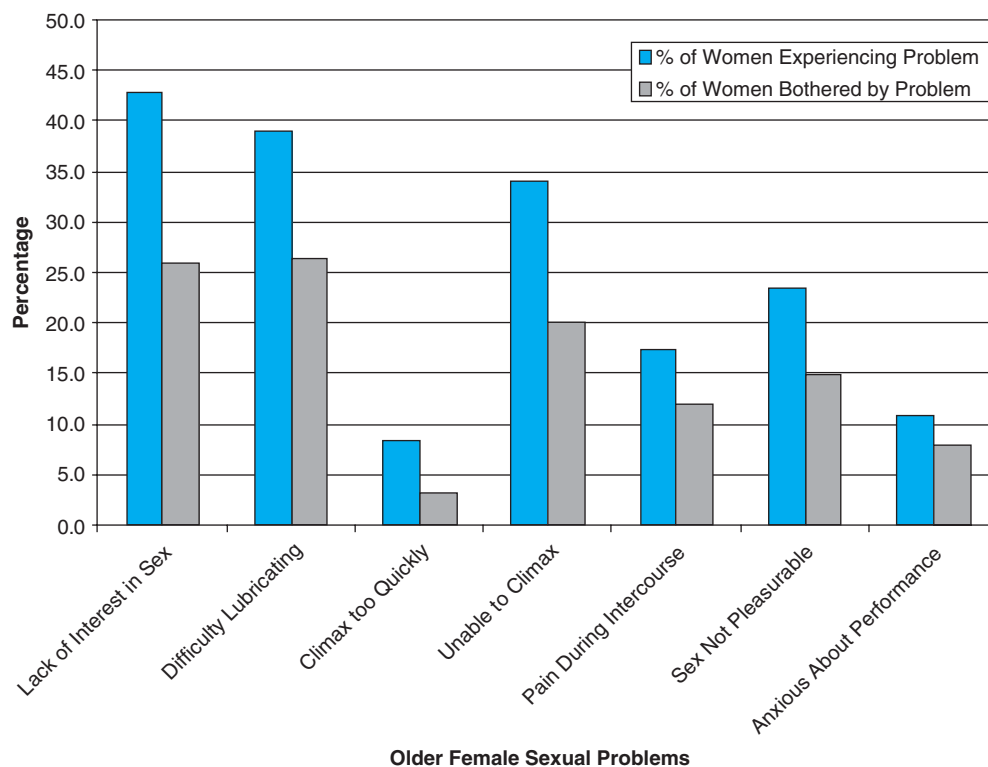

American Psychiatric Association 2000. (DSM-IV-TR) *Diagnostic and Statistical Manual of Mental Disorders, 4th ed*. Washington, DC: American Psychiatric Press, Inc.

## Vaginismus

Treatment of vaginismus, another condition that can occur in women who have been abstinent for prolonged periods, is best accomplished in conjunction with behavioral therapy that allows a woman to gain comfort and control with penetration. A period of nonsexual genital and peri-introital self-touch followed by gradu-

ated vaginal dilator or insertion therapy that can involve the patient and her partner can easily be instructed. Under appropriate circumstances in the office setting, including a chaperone if necessary, guided practice by the patient with the dilators and a handheld mirror can also be accomplished.

Dilators can be used with water-based vaginal lubricant or vegetable oil to facilitate passage and should be used with caution in

**FIGURE 47-6.** Sexual Problems among Older Women<sup>a,b,c</sup>

<sup>a</sup>Estimates are weighted to account for differential probabilities of selection and differential non-response.

<sup>b</sup>Among those of 1550 women surveyed in the National Social Life, Health and Aging Project who reported having sex in the last 12 months.

<sup>c</sup>Asked only of those who reported at least one sexual problem.

women with recent hysterectomy so as not to perforate the vaginal cuff. Vaginal estrogen therapy prior to or in conjunction with dilation maybe appropriate in women with severe atrophy. Dilator kits can be purchased from a medical supplier or directly by patients via the Internet and typically cost between US \$40 to \$150. Use over a several-week period, on a daily basis for 15 to 30 minutes, in a reclining position under relaxed conditions, followed by washing of the dilator with a gentle soap and warm water should be instructed.

Periodic assessment by the clinician should occur to ensure safe and hygienic use and to promote progress. Women who use pessaries for treatment of urinary incontinence or pelvic organ prolapse and those who have undergone vaginal, vulvar, bladder, or colorectal surgery or anogenital radiation, may benefit from consultation with a gynecologist or urologist prior to initiating dilator therapy.

### Orgasmic Disorder

Management depends heavily on whether the disorder is lifelong or acquired and situational or generalized. Because many older women, particularly 75 years and older do not masturbate (and may never have), ability to assess orgasmic ability maybe limited. Encouragement to self-stimulate either manually or with a vibrator, a technique sometimes used with younger women, must take into account the older woman's experience and attitudes about masturbation. Psychotherapy to assess psychological issues and attitudes regarding orgasm and to complement physical interventions maybe necessary. Education about vulvar anatomy, the role of the clitoris in orgasm, and variations in female orgasm maybe therapeutic for some women. Women with arousal disorders also typically do not experience orgasm so evaluation of arousal should be included in women with this complaint.

### Persistent Sexual Arousal Disorder

This rare condition can disproportionately affect older women and may relate to a new onset seizure disorder. Consideration of brain imaging and referral may be necessary. Management strategies are uncertain, but physician awareness of the condition, if communicated to the patient, can itself be reassuring particularly for older women who may feel extremely embarrassed and stigmatized.

**TABLE 47-7**

#### Medications Associated with Sexual Problems in Older Women

##### Cardiovascular and Antihypertensive Medications

- Beta adrenergic blockers
- Clonidine
- Digoxin
- Spirolactone

##### Psychoactive Medications

- Amphetamines and related anorexic drugs
- Antipsychotics
- Barbiturates
- Benzodiazepines
- Lithium
- Selective serotonin reuptake inhibitors
- Tricyclic antidepressants

##### Histamine H2 – receptor blockers

- Narcotic analgesics

##### Gonadotropin releasing hormone agonist

- Ketoconazole
- Phenytoin sodium

**TABLE 47-8****Sexual History-Taking and Sexual Education in the Routine Geriatrics Encounter****Context:**

Ensure privacy

Communicate comfort and matter-of-fact attitude

Educate patient about how typical changes in sexuality that can occur with age and specific health conditions/treatments; educate about safety in sexual relationships

If proxy required or requested, educate and engage that person

**Transition:<sup>a</sup>**

*"To round out my understanding of your health (or your health concerns) today, may I ask you a couple of questions about your sexual life?"*

**Questions:**

*"Do you currently have a spouse or other romantic, intimate, or sexual partner?"*

*"How many partners have you had in the last year?" "Does your partner have other sexual partners?"*

*"Is your partner male or female?" "Have your partners been male, female or have you had both male and female partners?"* This is an opportunity to communicate non-judgmentalism about same-sex relationships and openness to the possibility of non monogamy.

*"When is the last time you had sex?"* If no longer having sex, ask: *"What are the reasons you stopped having sex?"*

*"Are you satisfied with your sexual life?"*

*"Do you have any worries or difficulties with regard to your sexual life?"<sup>b</sup>*

*"How's your partner's health?" "Is your partner having any sexual problems?"*

*"Has anyone ever forced you to have sex or sexual contact?"<sup>c</sup>*

If new partner, or concern about risk factors:

*"Have you and your partner been tested for sexually transmitted infections, including HIV/AIDS?"*

Educate about testing, inform about confidential versus anonymous testing and meaning of test results. Plan follow-up visit to provide post-test counseling.

*"Do you use condoms to prevent sexually transmitted infection?"* Educate about barrier methods for STD prevention.

**Conclusion:**

If no problems identified or patient not sexually active: *"I want to encourage you to feel comfortable talking with me about any sexual concerns should they arise."*

If problem(s) identified: *"I'm concerned about the problem you're having. Would you and your partner be willing to return (or be referred) to discuss this further?"*

<sup>a</sup> Not always necessary, but can be useful if no other obvious transition. The screening sexual history can easily flow out of questions to ascertain the home setting, such as "Who lives at home with you?" and "Are you safe in your home?"

<sup>b</sup> If the patient responds yes, the clinician could then pursue the line of questions summarized in Table 8 or defer to a subsequent visit (see Conclusion).

<sup>c</sup> If yes or risk factors, pursue questions summarized in Table 4.

**TABLE 47-9****Questions to Assess Sexual Dysfunction in Primary Care Setting**

WHO	QUESTIONS
<i>Individual Partner (alone) –interview patient and partner alone, if permission from patient to interview partner</i>	<ol style="list-style-type: none"> <li>1. Clarify this partner's view of the problem(s) and how this partner thinks they are coping.</li> <li>2. Review this partner's sexual response to self-stimulation.</li> <li>3. Ask about the interviewee's past partnered sexual experiences and their positive and negative aspects.</li> <li>4. Determine a developmental history: any losses or traumas, and how he or she coped.</li> <li>5. Inquire if the partner ever experienced sexual, emotional or physical abuse, whether as a child or as an adult.</li> </ol>
<i>Couple</i>	<ol style="list-style-type: none"> <li>1. Ask the couple to explain their sexual problem(s) in their own words.</li> <li>2. Establish duration of problems; generalized or situational</li> <li>3. Determine the context of the sexual problems including relationship quality.</li> <li>4. How is the erotic context? What frequency of sex is expected or attempted? Are there concerns about safety from STDs or privacy? Adequacy of partner's sexual skills? Is there mutual communication about sexual needs?</li> <li>5. Determine the rest of the sexual response for each partner.</li> <li>6. Inquire how each partner has reacted to the problem(s).</li> <li>7. Note any previous treatment(s), their compliance and benefit. Clarify why the couple is seeking help now, and assess their motivation to make changes.</li> </ol>

## Medical Therapy for Sexual Desire/Arousal Disorders and Dyspareunia

Although there are currently no FDA-approved medical treatments for female sexual dysfunction, androgen therapy is being used off-label in some cases for treatment of sexual desire/interest disorder in a subset of women with bilateral oophorectomy or those taking oral estrogen (which can reduce bioavailable testosterone by increasing sex hormone binding globulin levels). Treatment of depression can improve sexual desire and interest, but some antidepressants, particularly selective serotonin reuptake inhibitors (SSRIs), can inhibit sexual interest. Bupropion has been used in combination with SSRIs to offset this side effect and appears to be effective for some women.

Off-label use of phosphodiesterase inhibitors has also been implemented for women with genital arousal disorder (a very small subset of women with sexual dysfunction). Tricyclic antidepressants and anticonvulsants are being used by some practitioners for treatment of vulvovestibulitis (a cause of dyspareunia), but these should be used with caution because of central nervous system side effects that maybe exaggerated in older women, particularly those taking other medications. Funding for intervention research in the area of female sexual dysfunction comes primarily from pharmaceutical sources supporting clinical trials of small numbers of young, healthy subjects followed for brief periods. Building an evidence base is a necessary step to offering safe and effective medical, psychological, and other treatments for female sexual dysfunction in later life. More than a dozen drugs for treatment of female sexual dysfunction, particularly sexual desire/interest disorder, are currently in preclinical and clinical trials.

## CONCLUSION

Older women comprise more than half the population of older adults in the United States and will outnumber older men until 2050. Despite this, many aspects of older women's health are neglected by researchers and clinicians, including sexuality. Sexual and intimate relationships in later life can promote health and well-being and sustain a basic human need. Many older women engage in sexual relationships despite sexual problems and pain, others discontinue sex caused by problems that could be treated. Physicians caring for older women can positively impact their patient's sexual functioning and overall well-being by initiating and fostering an open and ongoing dialogue about sexual matters in the context of healthy aging or in relation to medical conditions and their treatments. Research

is needed to establish trajectories of older women's sexuality with aging and to provide an evidence base for diagnosis and treatment of female sexual dysfunction in later life.

# Gynecological Disorders

*Karen L. Miller* ■ *Tomas L. Griebing*

In the United States, women comprise 60% of the older population, so that geriatricians need a working knowledge of gynecologic care, including cancer screening, symptom evaluation, and assessment of incidental findings. After first presenting suggestions for a gynecological history and physical examination in an older woman, this chapter addresses findings and issues in the order they would be approached on a physical examination. Following this, evaluation and management of some common gynecological issues are presented. Management of incontinence with pessaries is included in this chapter, but other incontinence issues are dealt with in Chapter 59. Gynecological care encompasses management of benign breast disease, which is also included in this chapter. Hormone replacement therapy (HRT) is discussed primarily in Chapters 46 and 47, but discontinuation and topical therapies are addressed here.

## GYNECOLOGICAL HISTORY

A gynecologic history (Table 48-1) should include age of menarche and menopause, use of hormone replacement (indication, type, route, dose, timing of onset in regards to menopause, duration), current sexual activity, new sexual partners, past gynecological or urogynecologic procedures and their indications, number of pregnancies carried beyond 20 weeks, exposure to diethylstilbestrol (DES), Papanicolaou (pap) smear frequency and results in the past 10 years, mammographic screening in the past 5 years, breast cancer, gynecologic cancers, and history of pelvic irradiation. If urogynecological procedures were performed, note whether the symptoms were resolved, and whether they recurred. Important family history includes gynecological and other malignancies.

DES was first synthesized in 1938, and until as late as 1971 was employed to reduce pregnancy complications. Women ranging in age from 50 to over 100 years could have received DES during pregnancy. These women have an increased risk of breast cancer, but

not of other gynecological malignancies. DES exposure in utero increases the risk of adenocarcinoma of the cervix and vagina mainly in adolescence and the third decade. These women are just beginning to enter geriatric age. The older ones in this cohort (age 40 years and above) have shown an increased incidence of breast cancer compared to women not exposed in utero, so continued surveillance is warranted. Current recommendations are to follow age-appropriate screening guidelines.

Additional information that is sometimes relevant includes total parity (spontaneous or induced abortions, preterm deliveries, term deliveries), route of deliveries (vaginal or cesarean), obstetrical trauma, and past contraception used (especially hormonal). The older a cohort of women, the less the association of current urogynecologic disorders with obstetrical history. Therefore exact knowledge of parity, route of delivery, highest birth weight, or use of forceps have little bearing on understanding etiologies and planning nonsurgical management in advanced age.

The gynecological review of symptoms should include breast pain or lump, nipple discharge; pelvic pain; vaginal bulge, pressure, discomfort, discharge, or bleeding; vulvar irritation, lumps, or rashes; irritative voiding symptoms (frequency, urgency, dysuria), urinary and fecal incontinence or urgency; difficulty voiding or defecating; sexual activity; and sexual abuse.

## PHYSICAL EXAMINATION

Breast examination should be performed annually (see Table 48-1). Pelvic examination recommendations for older women vary. Specific utility or cost-effectiveness of the pelvic examination apart from cervical cancer screening in older women has not been studied. Oftentimes despite a negative review of systems, problems are remembered by the patient during the pelvic examination. It may be that the more frail or cognitively impaired the patient, the more important the examination because of a lack of reporting ability. The American

**TABLE 48-1****Gynecological Periodic Examination**

	<b>COGNITIVELY INTACT</b>	<b>COGNITIVELY IMPAIRED*</b>
Preventive services	Mammography annually (or biennially) until reduced life expectancy Cervical cytology annually if risk factors, triennially if no risk factors (Upper age limit disputed, no limit per ACOG, age 70 per ACS)	Mammogram more useful than pap smear. (Shorter lead time for breast cancer.)
History	Hormones: menarche, menopause, past and current hormone use Breast complaints: pain, lump, nipple discharge Vulvovaginal irritation, bulge, bleeding, discharge Urinary issues: incontinence, frequency, urgency, hesitancy, nocturia Defecation issues: Constipation, incontinence (gas, liquid, solid) Sexual practices, contacts, satisfaction, abuse	Current hormone use Staining of brassiere or clothing Apparent discomfort in perineal area Toileting practices, pad use Defecation frequency, stool consistency Sexual behavior
Physical examination	Breast examination annually Pelvic examination every 1 to 3 yrs External genitalia/perineum: architecture, integument Urethra: meatus visibility, condition Bladder: tenderness, fullness Vagina: integument, discharge Cervix: lesions, growths Uterus: size Adnexa: palpability, mass	Breast examination annually if tolerated Annual inspection of external genitalia is potentially useful. Initial internal examination is worthwhile, but subsequent examinations may have lower benefit except for fecal impaction.

ACOG, American College of Obstetricians and Gynecologists; ACS, American Cancer Society.

\*Considerations in the cognitively impaired (moderately to severe impairment) are suggestions from clinical experience (Level D evidence).

College of Obstetricians and Gynecologists (ACOG) recommends an annual pelvic examination in asymptomatic patients. Some chronic conditions have a medical indication for annual reexamination, such as lichen sclerosus. Because of Medicare regulations excluding payment for preventive care, patients with lichen sclerosus, pelvic organ prolapse, and other chronic conditions should be educated that they need the pelvic examination annually because of their condition, not for a “routine pap smear.”

Breast examination includes axillary, supraclavicular, and infraclavicular lymph nodes. During the abdominal examination, the inguinal lymph nodes should be assessed. Performance of the pelvic examination in older women requires more patience, ingenuity, leg positioning, and speculum variety than in younger women. Use of additional assistants or a central foot rest may allow the patient to be examined in the dorsal lithotomy position. Both genital inspection and internal bimanual examination can also be performed in the lateral decubitus position, albeit with less certainty about the bimanual palpation of internal organs and assessment of pelvic organ prolapse. Examination in the standing position may be necessary to demonstrate the extent of prolapse. If the examination needs to be performed in a bed, the patient's hips can be elevated on an upside-down bed pan covered with a folded towel or on a stack of towels to allow speculum insertion.

Typical age-related changes of the external genitalia include decreased fat content of the mons pubis and labia majora and diminished pubic hair. Vulvar structures include a right and left labium majus, a right and left labium minus, and the clitoris. The labia minora meet anteriorly to form the clitoral hood at the distal end of the clitoris. Each of these structures should be noted upon examination. The clitoris may be prominent because of a predominance of androgen relative to estrogen, or it may be obscured by labial fusion. The urethra may not be easily visualized if it has receded into the vaginal canal from atrophy or is obscured by fused labia. Lifting the

labia anteriorly without lateral stretching will usually allow meatus visualization without undue pain. “Perineum” refers to the entire vulva, perineal body, and anus, that is, the approximate boundary of the pelvic outlet, through which the urogenital ducts and rectum pass. However, it is also used to indicate the area between the anus and posterior part of the external genitalia, especially in lay publications and Medicare documents. These areas should be inspected and their neurological status examined. Sensation to light touch in the labia majora and perianal regions correspond to the lower lumbar (L4–L5) and sacral (S2–S4) dermatomes. Altered sensation, including asymmetry, may be associated with voiding, defecatory, or sexual dysfunction.

Speculum examination is facilitated by having an adequate variety of specula, including very narrow with normal length. Pediatric specula are appropriately narrow but usually too short to reach the cervix or vaginal apex. Lubrication with water or water-soluble lubricating jelly applied to the introitus or sides of the speculum eases insertion. If the patient is tender, 2% lidocaine jelly applied to the introitus, especially the posterior fourchette, will reduce sensation within 2 to 3 minutes. This is particularly useful for cognitively impaired women. If a pap smear is to be obtained, the jelly can be wiped away with a cotton swab. The vaginal walls should be inspected as the speculum is withdrawn whenever possible.

Bimanual examination is usually performed first with two fingers in the vagina, then with one in the vagina and one in the rectum. More information is obtained with the vaginal hand than the abdominal hand. Assess the size, orientation, and mobility of the cervix and uterus (if present), support of the vaginal apex, presence of any pelvic organ prolapse, and identification of any mass lesions. Rectal sphincter tone should be assessed, and the bulbocavernosus reflex can be tested if neurologic impairments are a consideration. Any palpable mass warrants additional evaluation. The presence and characteristics of stool in the rectal vault should be noted as this may be a

clinical sign of constipation or other significant defecation disorder. A stool occult blood test may also be obtained. This requires changing gloves before the rectal examination if any bleeding occurred with speculum insertion or pap smear.

## ISSUES AND CONDITIONS BY ANATOMICAL APPROACH

### Benign Breast Disease

The breast is a complex structure subject to many pathological conditions, including ones affecting skin, muscle, nerves, ligaments, vasculature, and mammary ducts and alveoli. While numerous studies address the epidemiology of breast cancer and cancer precursors, little is known about the epidemiology of benign breast disease, especially in older women. Whereas fibrocystic changes in breast tissue are present asymptotically in over half of older women, the prevalence of symptoms constituting “benign breast disease” is unknown. These usually present as a lump, pain, nipple discharge, or inflammation.

### Breast Lump

Physical examination of the breast should not be completely supplanted by mammography, which can be negative in the setting of palpable tumors. Evaluation of a lump includes not only a description of the size, position, and character of the lump, but also documentation of pertinent negatives, such as lymph nodes, skin changes, and nipple discharge. All lumps should be evaluated by a surgeon or breast specialist, and a diagnostic mammogram should be obtained. Whether the mammogram is done before or after the surgeon sees the patient depends on the physicians and systems involved. If the patient complains of a lump not palpated by the physician, additional consultation is in order. If both the patient and physician agree that now there is no palpable abnormality, the patient should be asked to return in 2 months for reassessment.

### Breast Pain

Breast pain is common and rarely indicative of dangerous pathology. It may be unilateral or bilateral, intermittent or persistent, and may or may not be associated with exogenous hormone therapy. Only half of women with significant breast pain seek medical attention. An important aspect of the history is the impact of the pain, such as inability to hug grandchildren, or awakening at night. Causes of pain originating in breast structures include fibrocystic disease, duct ectasia, trauma, sclerosing adenosis, and stretching of Cooper’s ligaments. Cancer uncommonly presents with breast pain, and mastalgia is not an indication for a diagnostic mammogram. However, surgical consultation is occasionally in order for focal persistent pain. Many conditions can be perceived as breast pain, such as costochondritis (Tietze’s syndrome), cervical radiculopathy, intercostal neuralgia, thrombophlebitis of the thoracepigastric vein (Mondor’s disease), herpes zoster, angina, cholecystitis, and hiatal hernia. Physical examination maneuvers to differentiate breast from chest wall pain include palpating the breast between both hands rather than putting pressure on the chest wall, and examination in

the lateral recumbent position. If history and physical examination are benign, and mammographic screening for cancer is current, the patient can be offered reassurance and/or analgesics.

### Nipple Discharge

Breasts always have the potential to secrete fluid, particularly if a woman has lactated previously. History and physical examination of nipple discharge should determine whether it is spontaneous or expressed, unilateral or bilateral, and involves single or multiple ducts. The color of the discharge and the presence of any mass should also be noted. Whereas unilateral, single-duct, spontaneous, bloody discharge holds the most concern, bilateral expressed discharge from multiple ducts does not indicate breast cancer. Many times the situation is between these two clear-cut extremes. A thick grumous or purulent discharge may indicate duct ectasia (dilated lactiferous ducts with inspissated secretions) or subareolar abscess. Duct ectasia is also the most common cause of blood-stained discharge from multiple ducts. If the discharge is white, an evaluation for hyperprolactinemia is in order, although this is rare in older women. Eczematous and other skin conditions may imitate nipple discharge. Most cases of spontaneous discharge necessitate referral.

### Breast Inflammation

Inflammatory conditions intrinsic to the breast include duct ectasia, fat necrosis, foreign body, Mondor’s disease, radiation, and inflammatory carcinoma. Extrinsic conditions that may present with breast inflammation include metastatic lung cancer, Wegener’s granulomatosis, sarcoidosis, and other skin diseases. Evaluation and referral will depend on the specific presentation.

### Vulva

#### Examination of the Vulva

Age and estrogen deficiency may lead to loss of vulvar architecture, especially of the labia minora. Bartholin’s glands are located in the inferior (dorsal) aspect of each labium majus. Any mass, cystic or solid, in the area of the Bartholin’s gland should be referred to a specialist for additional evaluation. Usually these are excised to rule out carcinoma. Cherry angiomas and epithelial inclusion cysts on the labia are common and not concerning. Asymmetrical pigmented lesions should be noted and considered for either biopsy or follow-up examination.

#### Benign Conditions of the Vulva

Literally hundreds of disorders involve the vulva, generally falling into categories of infections, neoplasia, and dermatoses, which may reflect systemic disorders. Establishing clinically useful and pathologically appropriate nomenclature of vulvar disorders is challenging, and classification changes are not infrequent. The most recent classification of dermatoses by the International Society for the Study of Vulvovaginal Disease relies primarily on histologic morphology (Table 48-2). The vulva is more sensitive to allergens and irritants than other skin sites. Estrogen deficiency rarely causes symptoms, but may increase vulvar susceptibility to trauma, irritation, and secondary infection. A patient with “atrophic vaginitis” unresponsive to estrogen usually has a vulvar dermatologic condition. A very

important part of the history is exactly what preparations, cleansing agents or routines a woman has employed to treat symptoms. Atopic, allergic contact, and irritant contact dermatitis may be caused by soaps, feminine hygiene products, or urine. A minor irritation can potentially be exacerbated into a severe irritant vulvitis with almost any topical preparation. Secondary infections with yeast and bacteria frequently occur whenever there is epithelial compromise, and must be treated along with the underlying condition. Ointments have fewer additives than creams and often cause less irritation.

### Inflammatory Dermatoses of the Vulva

Benign inflammatory disorders of the vulva may be difficult to recognize, even by dermatologists, because the warm, moist, frictional environment alters the otherwise typical appearance of these entities. The lichenoid pattern dermatoses, lichen sclerosus and lichen planus, involve inflammation and disruption of basal epidermis.

Lichen sclerosus areas are typically white, bilateral, and relatively symmetrical with sharply demarcated borders, but may assume any configuration. White with a parchment-like surface is the most common appearance, but areas may be pink or red. With more advanced cases, vulvar architecture is lost. Labia minora may not be identifiable. The labia may be agglutinated anteriorly. A biopsy to confirm the diagnosis is helpful. The malignant potential of lichen sclerosus is debated, but may be as high as 4% to 5%. Areas should be inspected at least annually. Treatment is necessary only to control symptoms,

most commonly pruritus. Regimens vary, generally involving aggressive topical steroids for a few weeks with each symptomatic flare, then steroid tapering, then a nonsteroid maintenance regimen. One option is to use clobetasol propionate 0.05% ointment daily or bid for 1 to 2 months, then reduce the schedule over the next 1 to 3 months. Women often erroneously believe less medication is better, and should be encouraged to continue the steroids as prescribed until the itching is completely under control. Maintenance therapy probably reduces the frequency of symptomatic flares. Petroleum jelly, solid vegetable shortening, or other bland barrier ointment should be applied daily. When symptoms recur, steroids are reinitiated. Vaginal stenosis may occur in severe lichen sclerosus cases. Steroids, estrogen cream, dilators, and occasionally surgery may be useful to treat dyspareunia and sexual dysfunction.

New-onset autoimmune disorders of the vulva are uncommon in older women, but should be considered in the differential diagnosis of vulvar ulcers or rashes. Lichen planus may be associated with localized or generalized inflammation, which can be severe enough to cause introital stenosis. Other considerations include Zoon's disorder (plasma cell vulvitis), Behçet's disease, Crohn's disease, aphthous ulcers, and Hailey-Hailey disorder (fragile and inflamed vulvar and axillary skin). Thickened epithelium is no longer called squamous hyperplasia, but is divided into psoriatic and lichen simplex chronicus categories. Psoriatic lesions of the genitalia do not exhibit the silver appearance seen elsewhere on the body, and are more often simply erythematous. There is usually a personal or family history of psoriasis. Lichen simplex chronicus may be primary or superimposed on other dermatoses. Medium to high-potency steroids are administered until symptoms are controlled, then maintenance therapy may be instituted.

### Ulcerations and Infections of the Vulva

The differential diagnosis of genital ulceration includes a wide variety of sexually transmitted diseases, the most common of which in the United States is herpes simplex virus (HSV). A primary infection is usually associated with lymphadenopathy, vaginal discharge, urinary frequency, and painful ulcers on the labia and cervix. The incubation period is 2 to 12 days. Lesions clear in 2 to 3 weeks. Symptoms improve more quickly with the use of antiviral agents (e.g., acyclovir, famciclovir, valacyclovir). Frequent recurrences may require suppressive therapy. Immune suppression, including very advanced age, is a risk factor for HSV infection in the absence of sexual contact and for herpes zoster. Zoster of the S3 dermatome may inhibit detrusor function, and inability to void may be the presenting complaint. Condyloma acuminata may occur at any age, usually in association with human papillomavirus (HPV) from a new sexual contact. Biopsy of any raised lesion is appropriate if the diagnosis is in doubt.

### Cancer of the Vulva

Vulvar cancer is the fourth most common malignancy of the female genital tract, accounting for 3% of all cases. The incidence of invasive vulvar cancer rises steadily with age, reaching 12 per 100 000 per year over age 80 years. Pruritus, pain, and a palpable lesion are typical presenting complaints, but particularly frail older women may not be aware of even a large lesion. Many women delay evaluation, leading to a worse prognosis (Table 48-3). Any focal, raised, irregular, or pigmented lesion warrants biopsy, which may be performed

TABLE 48-3

## Estimated 5-Year Gynecological Cancer Survival by Disease Stage

CANCER TYPE	STAGE I	STAGE II	STAGE III	STAGE IV
Endometrial*	54–88%	40–76%	22–57%	12–18%
Ovarian	80–90%	65–70%	30–59%	17%
Cervical	80–95%	74–77%	46–52%	20–29%
Vulvar	85%	69%	40%	22%
Vaginal	74%	50%	32%	0–18%

\*Includes clinical and surgical staging.

Data summarized from FIGO Annual Report. *J Epid Biostat.* 6:1, 2001.

by the primary care physician without fear of causing spread. The most common vulvar malignancies are squamous cell carcinoma and malignant melanoma.

The incidence of vulvar carcinoma in situ increased 400% from 1973 to 2000, predominantly in women younger than 65 years. This parallels the increase in exposure to HPV. By contrast, the incidence of invasive vulvar cancer increased only 20% during this time. While HPV is the most common cause of vulvar carcinoma in situ and invasive vulvar cancer in younger women, only about half of invasive cancers are caused by HPV in women aged older than 65 years. The remainder may be associated with poor Langerhans cell function alone.

Vulvar intraepithelial neoplasia (VIN) is used to describe histologic findings of squamous dysplasia and squamous cell carcinoma in situ. This is usually considered a premalignant lesion, although there is some controversy about this. Identified risk factors include cigarette smoking and HPV exposure. The most common presenting symptom is generalized pruritus of the vulva. Multifocal lesions are common, and treatment is often performed with carbon dioxide laser ablation of the lesions. Multiple treatments may be needed and close clinical follow-up is indicated to evaluate for recurrence. The presence of high-grade VIN near invasive vulvar carcinomas is usually associated with a poor overall prognosis.

Malignant melanoma of the vulva is rare. However, melanoma should be considered as a possible diagnosis in any patient with pigmented vulvar lesions. This is particularly important if the lesion has increased in size or has irregular borders or coloration. Biopsy is indicated for any such lesion.

Wide local excision may suffice for some early cancers and may be used palliatively in frail women. Radical vulvectomy with inguinal lymphadenectomy, radiation, and chemotherapy may be employed depending on cancer stage and the patient's overall health status.

## Urethra

A urethral caruncle typically appears as a protuberant red area at the urethral meatus in the six o'clock position. This represents a prolapse of the urethral mucosa that may be associated with loss of support of the periurethral fascia. Most caruncles are asymptomatic and do not require any evaluation or treatment. Caruncles are caused by estrogen deficiency, and symptoms of bleeding or pain can be relieved by topical estrogen. If symptoms persist, excision or cauterization may be performed.

## Vagina

### Vaginal Atrophy

Vaginal atrophy secondary to hypoestrogenism includes thinning of the epithelium, loss of rugae, elasticity and distensibility, increase in subepithelial connective tissue and vaginal pH (>4.5), and reduction in vaginal secretions. Lactobacilli are fewer and potential pathogens greater in number, predisposing to urinary tract infections and vaginitides. Atrophic "vaginitis" is poorly defined apart from simple atrophy, but should be diagnosed if there are bothersome symptoms (dyspareunia, irritative voiding symptoms) or signs (telangiectasias, petechiae, inflammation, discharge). A maturation index would reveal 60% to 100% parabasal cells, but is not necessary for the diagnosis.

The preferred treatment remains low dose intravaginal topical estrogen, which can be administered via ring (Estring<sup>®</sup>), tablet (Vagifem<sup>®</sup>), or cream (Premarin<sup>®</sup>, Estrace<sup>®</sup>). The ring lasts 3 months and releases 6 to 9 mcg estradiol daily, of which roughly 10% may be absorbed. Tablets are given nightly for 2 weeks, then twice a week. Serum estradiol rises initially, then remains within the postmenopausal range. Each gram of estrogen cream contains the equivalent of one standard oral or transdermal daily dose. Premarin has 0.625 mg of conjugated equine estrogens per gram, and Estrace has 100 mcg of estradiol per gram. The amounts needed to treat atrophic vaginitis are much smaller than the lowest doses measurable on the applicator, but unless a woman has an extremely strict reason to avoid estrogen, using one-quarter to one-half gram twice weekly approximates an appropriate dose. With all these low doses, progestins to prevent endometrial hyperplasia are not usually needed, and the standard of care is to not prescribe them. However, it should be kept in mind that the amount of systemic estrogen absorbed from vaginal preparations varies considerably between individuals, and endometrial growth from these low-dose preparations could occur. Any brown or red discharge necessitates endometrial evaluation. Breast cancer patients who take aromatase inhibitors may achieve higher serum estradiol levels, and any estrogen preparation should be given only after consultation with an oncologist.

Nonestrogen therapies are far less effective in reducing dyspareunia and irritative voiding symptoms, but may provide significant benefit. Vaginal moisturizers, such as Replens<sup>®</sup>, should be used daily to maintain epithelial moisture and vaginal pH. In addition, vaginal lubricants may be used for intercourse. Frequent sexual activity helps maintain supple tissues.

### Vaginitis, Vaginosis, Vaginal Discharge

Vaginitis, vaginosis, and vaginal discharge may be separate from or associated with vulvar disorders. Inquiry should be made as to color, odor, pruritus, staining of underwear, use of pads, hygienic products and practices employed, and recent sexual contacts. Microscopy with both saline and potassium hydroxide is preferable, but empiric therapy is initiated in some cases. With saline microscopy epithelial cells (e.g., copious, mature, parabasal, clue cells), polymorphonuclear leukocytes, motile flagellates, and yeasts (blastospheres or mycelium) should be noted. Addition of potassium hydroxide lyses cell membranes and better reveals hyphae, as well as releases amine odor in the case of bacterial vaginosis. Measurement of pH

is less helpful in postmenopausal women not taking estrogen since atrophy causes a rise in pH, but a low pH (<4.5) may help identify a yeast infection.

Asymptomatic white discharge with copious epithelial cells but few leukocytes may be simply desquamation, typically in association with either estrogen therapy or recent replacement of externalized vaginal prolapse. Microscopy shows copious epithelial cells and few polymorphonuclear cells. If the patient is not bothered, no further evaluation is necessary. If the discharge is thick, copious, malodorous, pruritic, irritating, or otherwise symptomatic, its etiology must be sought.

Thick, clumpy white discharge with inflammation of the vaginal mucosa is typical of a vaginal yeast infection, usually accompanied by vulvar pruritus. These are less common in postmenopausal than premenopausal women, but occur commonly with estrogen or antibiotic therapy, diabetes mellitus, and immune suppression. Yeasts are normal vaginal flora for up to 50% of women. Symptomatic infections occur as a result of complex host inflammatory response, pathogen virulence, and/or epithelial integrity reasons. *Candida albicans* accounts for 80% to 90% of cases. Microscopy reveals budding yeast and hyphae in roughly half the cases. If yeast infection cannot be confirmed, a culture should be sent. Opinions vary as to whether empiric treatment should be given. Occasional (fewer than four per year) infections in uncomplicated patients can be treated with any of the wide variety of oral and topical antimycotic agents available. Because of polypharmacy issues, topical (intravaginal) therapy is preferred. Oral medication may be better for women with very sensitive skin, and if vaginal treatment is uncomfortable or impractical. Recurrent infections may require 2 to 4 weeks of therapy. Prolonged therapeutic regimens have not been sufficiently studied, and are given according to practitioner preference and experience, such as a topical azole for 7 to 14 days, or fluconazole 150 mg orally every 3 days for three doses. Some women improve after weekly maintenance therapy for 6 months.

Thin, malodorous discharge without pruritus may indicate bacterial vaginosis, a polymicrobial overgrowth of anaerobic bacteria. This is a bacterial colonization (vaginosis) rather than an inflammatory condition (vaginitis). It is more common in postmenopausal women not using estrogen than those on hormone replacement. Diagnosis is established with three of the following findings: thin, grayish-white discharge, pH >4.5, release of odor with the addition of potassium hydroxide (positive whiff test), and more than 20% clue cells on wet mount. Usual treatment for symptomatic patients is either metronidazole gel 0.75% or clindamycin cream 2%. Asymptomatic patients do not require treatment in the absence of planned vaginal surgery. However, if odor is noted on examination, patients often admit to having wondered about it. Recurrence rates are high, even when oral metronidazole is used.

Purulent vaginal discharge without evidence of a pathogen may be associated with vulvovaginal lichen planus or desquamative inflammatory vaginitis. Desquamative inflammatory vaginitis is a poorly understood entity associated with inflammation, high epithelial turnover (many parabasal cells), and Gram-positive cocci. Affected patients have usually tried several unsuccessful antimicrobial therapies. Both of these disorders can be difficult to treat, and generally warrant referral to a gynecologic specialist. The inflammation may cause extreme vulvar tenderness and vaginal stenosis. Topical steroids are given intravaginally, usually achieving substantial relief, but ongoing management will be needed.

If purulent malodorous discharge is persistent, the vagina should be thoroughly examined for evidence of an enterovaginal fistula. Endometritis also causes a thick malodorous discharge, which is often bloody. Even without blood, such discharge can be a sign of endometrial cancer and necessitates an office biopsy.

*Trichomonas vaginalis* is an uncommon finding in older women, but should be considered in the presence of vaginal discharge plus pruritus. If trichomoniasis is present, the patient and her partner(s) should be screened for all other sexually transmitted diseases. *Neisseria gonorrhoea* and *Chlamydia trachomatis* can be detected with nucleic acid amplification testing of a urine sample. Current recommendations for detection and treatment of sexually transmitted diseases are maintained on the Web site of the Centers for Disease Control and Prevention ([www.cdc.gov/std/default.htm](http://www.cdc.gov/std/default.htm)).

## Cancer of the Vagina

Vaginal cancer accounts for only 1% or less of female genital tract cancers. Metastatic disease of the vagina is more common than primary vaginal cancer, notably from cancers of the endometrium, cervix, vulva, ovary, breast, rectum, and kidney. The most common primary vaginal cancer is squamous cell carcinoma, but adenocarcinoma, sarcomas, melanomas, and others do occur. Vaginal squamous cell carcinoma is often preceded by cellular changes and development of vaginal intraepithelial neoplasia, which is associated with concomitant cervical or vulvar neoplasia in about 50% of cases.

Risk factors for primary vaginal cancer are the same as those for cervical cancer (see below). The incidence is higher in women who have had prior gynecologic cancer, particularly cervical, and those who have undergone radiation therapy. In women who are not sexually active, these cancers may grow asymptotically for an extended period, but eventually present with bleeding, discharge, pain, or symptoms involving extension to urinary or rectal structures. As many as 20% of vaginal cancers are detected as a result of screening for cervical cancer. Only half are in the upper one-third of the vagina. Inspection of vaginal walls during speculum withdrawal as well as attentive vaginal palpation during the bimanual examination is important. Surgery is the primary treatment for small localized tumors, but radiation is the mainstay of treatment for most vaginal cancers. Chemotherapy is advocated in some situations.

## Cervix

### Examination of the Cervix

The border between squamous and columnar epithelia (squamo-columnar junction) is the most common site of cervical neoplasia. It is usually visible in young but not older women. Cysts near the cervical os are almost invariably Nabothian cysts. These are not true cysts, but are areas where the squamous cells have covered the glandular epithelium, trapping mucus. They do not require biopsy or treatment. Any lesion whose benignity is uncertain should be further investigated with referral or biopsy. A pap smear is not an appropriate screening test if an abnormality is present.

### Cervical Cancer Screening

The most common consideration regarding older women and cervical cancer screening is the age at which to discontinue pap smears. Although screening has dramatically decreased the toll of cervical

cancer, the age-adjusted incidence and death rates among U.S. women aged 65 years or older are higher than among younger women. Higher mortality is caused by later stage at diagnosis, as well as less aggressive therapy. Among white women, the incidence of cervical cancer women peaks at age 35 to 45 years (15 per 100 000), remains relatively flat through age 65 years, and then declines. Among African-American and other minority women, the incidence continues to rise with age, reaching 30 per 100 000 at age 85 years and above. Thus, although cervical cancer is relatively uncommon in older women, the risk should not be minimized, especially in minority women.

Most major health care organizations with the exception of ACOG recommend discontinuation of routine pap smears after age 65 or 70 years if the woman has been appropriately screened in the previous 10 years. Discontinuation presupposes that the physician keeps an accurate history of risk factors for cervical cancer, although the relevance of many of these factors to older women is uncertain. A higher risk for cervical cancer is potentially present in women having had an abnormal pap smear (especially within the past 3 years), a history of cervical or vaginal cancer, a history of moderate to severe intraepithelial neoplasia, a weakened immune system, a history of sexually transmitted disease (including HPV), onset of intercourse when younger than 16 years, more than five lifetime sexual partners, and exposure to DES *in utero*. While “multiple” sexual partners is frequently listed as a risk factor, exposure to one new sexual partner in advanced age is not addressed. Because of a less active “transformation zone” of the cervix, older women may be less susceptible to acquiring HPV, but this is unknown. It must be assumed that any older women with a new partner may be at risk and should reinstitute pap smear screening. Women in whom screening information is not available should also be screened. The use of HPV DNA testing in older women has not been evaluated. Its utility for primary screening, evaluating an atypical pap smear, or triage is unknown. Although most guidelines recommend three annual pap smears for previously unscreened women, in older women the chance of a significant abnormality in the 2 years following one normal pap smear is low. Prior to discontinuation of screening, a patient should ideally have three normal pap smears within 10 years.

Cytologic screening of women who have undergone a total hysterectomy (*corpus et cervix uteri*) is not recommended unless the hysterectomy was performed for cancer or the woman was exposed to DES *in utero*. However, some older women are not aware their hysterectomy was subtotal (*corpus uteri* only). Furthermore, cancers of the vaginal “cuff” (apex) do occur. Therefore, while not recommended, intermittent vaginal cuff pap smears potentially benefit the individual patient. Women with a history of vulvar cancer, vaginal cancer, cervical or uterine cancer, or DES exposure *in utero* should continue regular cytological screening. If a hysterectomy was performed, it may be appropriate to discontinue screening after three negative pap smears within 10 years.

### Cancer of the Cervix

Cervical cancer is the third most common gynecological malignancy diagnosed in the United States. Although it can occur in any age group, the disease is most commonly diagnosed in patients in the fifth and sixth decades of life. The overall incidence of cervical cancer does not differ between women who have undergone prior supracervical hysterectomy (cervix left *in situ*) and those with an intact uterus.

Three-fourths of cervical cancers are squamous cell carcinoma. Adenocarcinoma, adenosquamous, and clear cell carcinoma comprise most of the rest. Exposure to HPV, particularly HPV subtypes 16 and 18, is associated with an increased risk of cervical cancer. While HPV is the etiologic agent in most if not all cervical cancers in younger women, an unknown number of cancers in older women are not HPV-related. Nonsquamous cell cancers have higher mortality rates. Having had one normal pap smear reduces the risk of squamous cell more than adenocarcinoma. Studies differ on whether age is associated with worse survival after adjusting for confounders.

Symptoms of cervical cancer are variable and depend on tumor stage. Vaginal bleeding, postcoital bleeding, and pain are common presenting symptoms. Early tumors are usually silent and may be diagnosed only by physical examination and pap smear screening.

Radial hysterectomy is the primary treatment for patients with cervical cancer in its early stages. In general, surgery is well-tolerated, even in older women, and age has not been identified as a significant risk factor for perioperative complications. Radiation therapy is the primary treatment of locally advanced disease and adjunctive treatment for many surgically managed cases. Radiation and chemotherapy are also used for palliation in women with metastatic disease, although the overall prognosis is poor.

## Uterus

### Benign Conditions of the Uterus

The postmenopausal uterus shrinks in size. Leiomyomata also shrink postmenopausally. If the uterus is enlarged and it is unknown whether this is stable, pelvic ultrasound and gynecologic consultation should be considered. The endometrium is usually a sterile environment, protected from vaginal flora by cervical mucus. Endometritis is uncommon, but may occur even in the absence of uterine manipulation or exposure to known pathogens. It is usually associated with a purulent discharge, but bleeding may be the predominant symptom. An endometrial biopsy can establish the diagnosis, as well as rule out cancer.

### Cancer of the Uterus

Uterine tumors can begin in either the endometrium or the myometrium. Endometrial cancers are relatively common, but most myometrial tumors are benign.

### Endometrial Neoplasia

Endometrial cancer is the most commonly diagnosed malignancy of the female genital tract. Approximately 36 000 new cases are diagnosed annually in the United States, and it represents the fourth leading cancer among American women. Several risk factors for endometrial cancer have been identified including nulliparity, prolonged exposure to unopposed estrogens, and obesity. These risk factors apply primarily to adenocarcinoma, associated with prolonged unopposed estrogen. The less common serous carcinomas usually arise from atrophic endometrium and tend to be aggressive.

The most common presenting symptom for endometrial cancer is postmenopausal vaginal bleeding. Any patient who presents with abnormal vaginal bleeding should be evaluated as discussed below. Only 35% to 50% of patients with endometrial cancer will have abnormal findings in pap smear alone. Office endometrial biopsy

should be performed. Initial screening pelvic ultrasonography instead of biopsy is acceptable, but the few cases of endometrial cancer arising in a thin endometrium and missed on sonography are usually of the more aggressive serous type. Therefore obtaining a tissue sample is preferable. No guidelines have been established to govern the evaluation of severely impaired women, such as those residing in long-term care. Because limited radiation therapy may palliate symptoms while not causing undue treatment burden, it is wise in most cases to obtain a tissue diagnosis via office biopsy, even if sedation is required.

The primary treatment for endometrial cancer is hysterectomy and bilateral salpingo-oophorectomy, usually with tumor debulking. Radiation therapy and/or chemotherapy are often indicated as adjunctive therapy or in women who are too frail to undergo surgery. The role of laparoscopic surgical techniques is still evolving. It is possible that laparoscopic and robotic technology may eventually lessen the impact of surgical therapy. Prognosis depends on the stage of disease and grade of tumor, with overall 5-year survival estimated at 65%. Age is associated with a worse prognosis, in many cases because of comorbidity, late diagnosis, and lack of aggressive treatment.

### Myometrial Neoplasia

The most common myometrial tumor is the benign uterine fibroid. These can be single or multiple, and can range in size from very small lesions, which do not cause significant symptoms, to large bulky tumors, which can cause abdominal and pelvic pain. Hysterectomy remains the primary form of therapy, but many other techniques are evolving, most notably uterine artery embolization. However, in the absence of hormone therapy, a leiomyoma should not grow and become symptomatic, so any such enlargement is suspicious for cancer.

Malignant lesions of the myometrium include leiomyosarcoma and other sarcomatoid tumors. These do not typically cause bleeding in early stages, and may only be detected by the presence of an enlarging uterus or pelvic mass. They are typically aggressive tumors with high metastatic potential. Surgery is usually indicated and adjuvant chemotherapy and radiation may be utilized. Extension of tumor beyond the confines of the uterus is associated with a very poor prognosis.

## Adnexa

### Evaluation of the Adnexa

Postmenopausal ovaries normally become atrophic and almond-sized. Any adnexal mass palpated in an older woman raises suspicion for a tumor and requires further investigation, usually starting with imaging. Each imaging modality offers advantages and disadvantages, and it should be kept in mind that each occasionally gives misleading information. Transvaginal sonography is the preferred initial technique to evaluate the uterus and adnexa, sometimes with Doppler sonography. Computed tomography (CT) describes ovarian masses less well, but offers a comprehensive evaluation of the pelvis, such as differentiating adnexal structures from bowel and uterus, ruling out abscesses, and detecting lymphadenopathy. Magnetic resonance imaging (MRI) visualizes reproductive organs well, and better defines uterine pathology in many cases. If an adnexal mass is found incidentally on a CT scan, a pelvic ultrasound usually

provides additional useful information. However, if found on MRI, sonographic imaging may be unnecessary.

### Adnexal Cysts

Ultrasonography can differentiate solid and cystic masses. Simple cystic ovarian lesions are common, and are most often benign. CA 125 is elevated with any peritoneal irritation and usually in women with epithelial ovarian causes and should be checked if a mass is found. A simple, unilocular ovarian cyst less than 5 cm in diameter with a negative CA 125 has a very low chance of being malignant. In some cases, such a cyst may be followed with sonography and CA 125 levels every 3 to 6 months. A complex cystic lesion (multilocular or having solid components on ultrasound) indicates an ovarian neoplasm, which may be benign or malignant. Any mass greater than 5 cm in diameter or with any complexity should be referred immediately for surgical consultation.

### Cancer of the Ovary

Ovarian cancer is the second most common malignancy of the genital tract in the elderly women. Its peak incidence occurs between the ages of 50 and 70 years. Specific risk factors include nulliparity, prolonged exposure to estrogen, and mutation of the BRCA-I and BRCA-II genes. Ovarian neoplasms may grow to a considerable size asymptotically. Because ovarian cancer begins silently, the diagnosis is most commonly made at stage III or stage IV disease. The 5-year survival rate for stage IV disease is less than 20% (see [Table 48-3](#)). Initial symptoms are often vague and may include abdominal pain, bloating, gastrointestinal complaints, or a palpable mass, and are usually associated with advanced disease. In retrospect, most ovarian cancer patients have had symptoms for several months before their cancer is diagnosed. Therefore, ordering a pelvic ultrasound to investigate vague lower abdominal complaints is reasonable. Current screening tests of asymptomatic women, pelvic ultrasonography and serum tumor markers, have a low overall yield and are of limited value except in high-risk patients.

Surgical therapy with tumor debulking is the primary treatment for ovarian cancer. Adjuvant chemotherapy may be administered either systemically as an intravenous infusion, or via direct intraperitoneal administration. Intraperitoneal administration may be helpful to deliver higher doses of medication to the affected areas, but both forms of therapy can be associated with significant chemotherapy-related morbidity. Immunotherapy and biologic response modifiers such as interferon and the interleukins may be helpful in some patients.

### Cancer of the Fallopian Tube

Primary cancers of the fallopian tube are rare. The two most common histologic types include serous and endometrioid tumors. Other types of mullerian carcinomas are less common. Mutations of the BRCA-I and BRCA-II genes may be associated with an increased risk for fallopian tube malignancies. Infections including nontuberculous salpingitis may mimic symptoms of fallopian tube malignancy. The symptoms are similar to those seen with ovarian cancers and include abdominal pain and distension. Diagnosis can be difficult and is often delayed because symptoms may be vague and often do not

present until the disease has progressed outside the fallopian tube. These are often aggressive tumors with a poor overall prognosis.

## COMMON CLINICAL ISSUES

### Gynecological Malignancies

Multiple studies have shown that older women have worse cancer survival primarily owing to late detection and nonaggressive therapy. Older women do well with surgery, radiation therapy, and chemotherapy. Treatment paradigms are changing rapidly with advances in medications, surgical techniques, and epidemiological knowledge. For instance, many tumors formerly treated with only surgery and/or radiation now respond to chemotherapeutic agents. Indications for tumor debulking have expanded. For optimal outcomes, it is critical that the correct initial surgery be performed, rather than having the patient undergo an initial diagnostic or partially therapeutic surgery and then later be referred to a cancer center. Therefore, gynecological cancer treatment is usually best when a gynecologic oncologist is consulted early in the course of care.

### Vaginal Bleeding

#### Initial Approach to Vaginal Bleeding

Abnormal vaginal bleeding may occur in as many as 20% of women aged 65 years or older. History should include any sources of estrogen and other hormones. Most bleeding is uterine, predominantly from endometrial atrophy. Even if a likely cause is found, other sources must always be ruled out, including hematuria, hematochezia, vulvovaginal pathology, and trauma (Table 48-4). Examination of the patient who presents with vaginal bleeding generally begins with the breast and abdomen, including axillary, supra- and infraclavicular, and inguinal lymph nodes. External genitalia, vagina, and cervix should be carefully inspected and a pap smear obtained. Bimanual examination should evaluate uterine size, adnexal masses, and mobility of gynecological organs. Rectal examination should evaluate for neoplasms, hemorrhoids, and induration or nodularity in the posterior cul-de-sac (pouch of Douglas).

#### Endometrial Evaluation for Vaginal Bleeding

Uterine bleeding is associated with hyperplasia or neoplasia in 22% of postmenopausal women. Office biopsy is the standard endometrial evaluation. A pelvic ultrasound offers additional and separate information, but is not requisite if the biopsy is negative. An ultrasound should be obtained before or several days after the biopsy to avoid artifact. A thin (<5 mm) endometrium on ultrasound usually rules out endometrial neoplasia, but the false-negative rate is up to 4%. Outpatient hysteroscopy, sonohysterography, and MRI are other potential screening modalities.

#### Genital Prolapse and Incontinence

Genital organ prolapse can be a very bothersome condition for many older women. This may include prolapse of organs from

**TABLE 48-4**

### Differential Diagnosis of Vaginal Bleeding in Older Women

Uterus ( <i>corpus uteri</i> )	Endometrial atrophy Endometritis Endometrial polyp Endometrial hyperplasia Endometrial cancer Endometrial proliferation from estrogen-secreting ovarian tumor Myometrial cancer
Cervix ( <i>cervix uteri</i> )	Polyp Cervicitis Cancer
Vagina	Vaginal atrophy Vaginal infection Vaginal cancer Vaginal trauma Foreign body
Vulva	Ulcerations, excoriations Cancer
Urinary tract	Urethral caruncle Urethral mucosal prolapse Hematuria
Gastrointestinal tract	Rectal polyp Hemorrhoids Hematochezia
Other	Metastatic spread from non-gynecologic primary tumors Oviduct cancer Endometriosis
Systemic illness	Coagulation disorder Hepatic cirrhosis
Iatrogenic	Anticoagulation Estrogen therapy

the vagina (cystocele, rectocele, enterocele) or prolapse of the rectum. Evaluation and treatment of prolapse depends on the involved anatomy and the degree of symptoms experienced by the patient (Table 48-5).

#### Evaluation of Genital Prolapse

The presence of prolapse is only important if it is causing symptoms of bulge, pressure, discomfort, or the patient is experiencing bladder or rectal symptoms. Rarely ulcerations will be detected by examination of an asymptomatic patient, but usually the patient will have mentioned discomfort, bleeding, or discharge. Pelvic organ prolapse has been graded by many different systems over the past century. “POP-Q” is the current standard. Knowing an exact extent of the prolapse, the grade or stage, is useful for planning surgical therapy and following a patient over time for progression. The exact nature (anatomic abnormality) may also be important if urinary or intestinal symptoms are present. Otherwise, exact descriptions are unnecessary, and it is adequate to note whether the vaginal wall(s) extend above (within the vagina), a little below, or far below the introitus. The usual reference point for “introitus” is the hymeneal ring, but any such description will suffice.

**TABLE 48-5****Evaluation and Management of Genital Tract Prolapse**

History	
Bulge, pressure or pain	
Bleeding or discharge	
Urinary frequency or incontinence	
Difficulty initiating or completing voiding	
Constipation	
Need to elevate or support for micturition or defecation	
Physical examination	
Ulcerations or abrasions	
Above or below hymen/introitus with maximal Valsalva	
Anterior vaginal wall, posterior wall, apex	
Urethral support/mobility	
Postvoid residual	
Management	
Estrogen cream for ulcerations	
Barrier cream/ointment to protect mucosa	
Truss (strong elastic support)	
Pessary	
Surgery	
Major vaginal reconstruction	
Vaginal obliterative procedure (colpocleisis)	

Any external prolapse should be inspected for epithelial abrasions. These are often painful, and may bleed if extensive or deep. Topical estrogen is used initially to promote healing. Barrier ointments can be helpful in treating local irritation and abrasions. Reduction of the prolapse is also important to help prevent and treat abrasions.

If there is uncertainty about the type of prolapse, anterior vaginal wall (typically a cystocele) can be differentiated from posterior vaginal wall (rectocele or enterocele) prolapse with a single-blade speculum. The speculum is inserted to first depress the posterior vaginal wall, then removed, then reinserted to elevate the anterior vaginal wall, and having the patient Valsalva or cough. Many older women cannot generate adequate pressure with Valsalva or even with cough, and the only way to determine the extent of prolapse is to examine them in the standing position.

A cystocele is a weakness of the anterior vaginal wall fascia such that the bladder descends toward or outside the vaginal opening. Cystoceles may or may not be associated with stress urinary incontinence. A large cystocele may be associated with a large postvoid residual (PVR), which implies a weak detrusor muscle. An elevated PVR does not imply potential renal damage in women as it may in men, because there is usually no significant outlet obstruction and urine storage and voiding occurs as a low-pressure system, even in the presence of a cystocele. However, a truly obstructed outlet may occur after incontinence surgery, and this history should be sought. Some women may need to manually reduce (elevate) the cystocele in order to initiate or complete micturition.

A rectocele is a protrusion of the rectum through the posterior vaginal wall caused by weakness of the perirectal fascia. Patients may experience difficulty with defecation including the need to strain and the need to “splint” (press on or support) the rectovaginal wall. An enterocele is a herniation of small bowel and peritoneum through the apical vagina or between the uterosacral ligaments and the rectovaginal space. It is the only true hernia among the various forms of prolapse. Enterocele is more common in women who have un-

dergone hysterectomy, but may be present in any posterior vaginal wall prolapse, and rarely in anterior vaginal wall prolapse.

Uterine prolapse may result from defects in support from the cardinal or uterosacral ligaments. The vagina may be entirely everted, which is typically called procidentia (*procidentia uteri*) if the uterus is present, and complete vaginal vault eversion if there is no uterus. An uncommon complication of this condition is hydronephrosis and hydroureter caused by ureteral kinking at insertion into the bladder. This is more likely if the uterus is present. If no therapy is planned, screening with serum creatinine or a renal ultrasound may be indicated to exclude obstructive uropathy.

Rectal prolapse may be associated with significant pain, bleeding, or problems with defecation. A history of both constipation and fecal incontinence is common. Examination reveals an extrusion of rectal tissue outside of the anus. Careful examination should be performed to determine if the prolapse can be reduced. Rectal prolapse that cannot be manually reduced has an increased risk of incarceration with subsequent tissue necrosis. Patients with rectal prolapse should be referred to a colorectal surgeon or gastroenterologist for additional evaluation and management.

### Management of Genital Prolapse

Management of prolapse disorders may be surgical or nonsurgical. The main conditions necessitating definitive treatment or referral to a specialist are nonhealing ulcerations, bleeding, elevated PVRs causing recurrent urinary tract infections, and hydronephrosis. If the patient is not significantly bothered and there are none of the above complications, she can be reassured and managed conservatively. Application of estrogen cream once or twice weekly is advisable for preventive care. On nonestrogen days, application of a topical barrier cream such as solid vegetable oil may be helpful. Large ulcerations require more intensive therapy initially. Some patients find comfort using a supporting elastic panty.

Pessary insertion is straightforward, but good management requires a variety of sizes and types for fitting, appropriate follow-up, and good patient education. Most patients can learn to remove and reinsert their own pessaries. Many women benefit from surgical correction. Patients with burdensome problems who are frail or “afraid of surgery” should still be referred to a specialist (gynecologist, urogynecologist, female urologist) because some surgical options are far less extensive than others.

Procedures generally fall into “reconstructive” and “obliterative” categories. Colpocleisis, a procedure that essentially closes off the vagina, is simple and effective with a very low prolapse recurrence rate of but is only appropriate for women who do not and will not have vaginal intercourse. Rectal prolapse is usually treated surgically with either reduction and fixation of the rectum or excision of the prolapsed portion of the rectum. Treatments to prevent chronic constipation are indicated to help prevent recurrence.

### Pessaries for Genital Prolapse

Pessaries are intravaginal devices that are designed to reduce pelvic organ prolapse. This concept has been used for thousands of years, and there are references to pessary-like devices in the Egyptian hieroglyphs. Pessaries are particularly useful in women who may not be candidates for surgical prolapse repair. They can also be used to determine the response to prolapse reduction, which can help identify patients who might benefit from surgical repair.

Pessaries come in a wide variety of shapes and sizes. Selection is based on patient anatomy and the experience and preference of the health care provider who is fitting the pessary. If a pessary is correctly fit, the patient generally will not feel the device when it is in place. A pessary that is too large may cause pain and may be difficult to insert or remove. A pessary that is too small may not stay in position and will have a tendency to fall out with ambulation or strenuous activity. Topical estrogen and antibiotic creams are often used with the pessary to help prevent infection and tissue erosion. The pessary should be removed periodically and physical examination performed to look for signs of tissue irritation or erosion. If the patient is unable to remove the pessary herself, she must be seen by a nurse or practitioner every 1 to 3 months, depending on the epithelial integrity and amount of vaginal discharge. Neglected pessaries may cause odor, discharge, vaginal wall erosion, and fistula formation. They may also be asymptomatic for many years, such that a cognitively impaired woman will have forgotten that she has a pessary. This is an additional reason that pelvic examination may benefit those with cognitive impairment.

### Pessaries for Urinary Incontinence

Pessaries may also be used to treat stress urinary incontinence. There are pessaries designed specifically for this purpose. These typically have a small “button” or increased width under the urethra designed to provide additional support. This increases the urethral resistance to elevated abdominal pressure. Rarely women may need to remove the pessary in order to void, but usually voiding is not obstructed. Incontinence pessaries may inform those who wish to test whether surgical therapy to increase urethral outlet resistance might be successful. A variety of urethral plugs and caps have also been designed for this purpose. Although many of these other devices have shown good efficacy in clinical trials, patients often find them difficult to use, and compliance is generally low.

### Pelvic Pain and Dyspareunia

While some practitioners consider “pelvic pain” to refer only to disorders associated with viscera, disorders associated with the lumbosacral back, buttocks, hip, perineum, or abdomen are commonly considered in the differential diagnosis and management of pelvic pain. Pain is considered chronic if symptoms have persisted for more than 3 months. History should include not only the usual location, quality, duration, etc., but also symptoms related to bladder and rectum. After the initial visit, it is useful to repeat a careful physical examination at subsequent appointments. It is typical for physical findings to change somewhat, and reexamination helps clarify the source(s) of pain.

### Abdominal and Myofascial Pain

Evaluation of pelvic pain begins with abdominal and musculoskeletal examination, including the lower back, sacroiliac joints, hips, and abdominal wall musculature. A common but often-overlooked cause of pain is myofascial “trigger points.” The history associated with myofascial pain may be vague and inconsistent. The pain may be sharp, burning or dull, exacerbated with exercise or not, and inconsistent in its diurnal pattern. Examination reveals point tenderness that persists or increases when the patient raises her shoulders off the examination table (Carnett’s test). This tensing of abdominal

muscles guards intra-abdominal structures, but not the abdominal wall itself.

### Vulvar Pain, Vaginal Pain, and Dyspareunia

Vulvar pain may be secondary to a specific disorder (inflammation, infection, neoplasm, or neurological disease), or may be present in the absence of any clinically identifiable disorder, which is called vulvodynia. It may be unilateral or bilateral and constant or sporadic. The term “vestibulitis” is often inaccurate, and is not currently used by the International Society for the Study of Vulvovaginal Disease. Rather, pain with touch limited to the vulvar vestibule is termed vestibulodynia. Vulvodynia may be referred pain from pelvic myalgia or spine or hip abnormalities. Herpes zoster and postherpetic neuralgia should be considered in unilateral cases.

Careful single-digit or cotton swab palpation superficially and deeply on the labia, perineum, and around the vaginal vestibule will allow localization of the pain, and may distinguish allodynia (an exaggerated sensitivity to light touch) from hyperalgesia (increased response to a painful stimulus). Areas of erythema should be noted. If vulvodynia is present, referral to gynecological specialist may be useful. A bland barrier ointment such as petroleum jelly or solid vegetable oil applied daily or twice daily may improve symptoms. This works best as long-term preventive therapy. Topical estrogen cream may also be of long-term benefit.

Unlike the vulva, the vagina is rarely a source of pain unless the patient is sexually active. Vaginal pain may be associated with the epithelium, the muscles and supporting tissues, or intraperitoneal pathology. Examination should proceed slowly and sequentially, inspecting then palpating the side, anterior, and posterior vaginal walls before reaching the vaginal apex. For atrophic vaginitis, the best treatment is topical estrogen (see above). Small doses are given more frequently in the first 2 to 4 weeks, after which very low maintenance doses usually suffice. Symptoms improve within the first month, but mucosal remodeling continues for over a year. If, however, the patient is already taking standard estrogen placement, topical estrogen is of unlikely benefit and consultation may be needed. Sexual function and dysfunction are addressed in Chapter 42.

### Pain Associated with Reproductive Organs

If abdominal tenderness is present, only the vaginal hand should initially examine the internal pelvic organs. The uterus and adnexa should be moved with only the vaginal hand before the abdomen is palpated. The uterus and adnexa uncommonly cause pain in older women. Tenderness in these structures should be further evaluated. Endometriosis, hemorrhagic ovarian cysts, and ovarian torsion are rarely issues in older women. Diverticulitis should always be considered.

### Interstitial Cystitis

A history of pain associated with urgency, frequency, and/or nocturia should prompt further evaluation for painful bladder syndrome or interstitial cystitis (IC), especially in association with a tender anterior vaginal wall. The exact etiology of IC is unknown. Theoretical causes include an autoimmune response, direct chemical irritants or inflammatory mediators in the urine, and defects in the epithelial barrier layer of the bladder. IC is typically a diagnosis of exclusion.

Other conditions that should be considered include bladder cancer or carcinoma in situ, bladder stones, and urinary tract infection. The presence of significant symptoms of urinary urgency, frequency, and pain in the absence of these other conditions should prompt consideration of IC as a potential diagnosis.

Cystoscopy with hydrodistension of the bladder under anesthesia is usually used to confirm the diagnosis of IC. Patients typically have a reduced bladder capacity and mucosal lesions including petechial hemorrhages and ulcerations that are visible after hydrodistension. Patients may be treated for painful bladder syndrome without cystoscopic confirmation of IC, but in older persons, it is wise to rule out other pathology. Bladder wash cytology and biopsies are used to help exclude a malignancy as the cause of symptoms.

Treatment for IC includes dietary modification with avoidance of bladder irritants such as caffeine, carbonated beverages, spicy foods, and alcohol. Medical therapies include antihistamines, antispasmodics, and anticholinergic medications. Low-dose tricyclic antidepressant medications are often used for this purpose, although they must be used with caution in elderly patients because of the significant risk of side effects. Pentosan polysulfate is a low molecular weight heparin derivative that is administered orally. It is excreted in the urine and is thought to help rebuild the glycosaminoglycan layer of the bladder. Intravesical therapies may also be used with direct administration of medications into the bladder. Surgical therapy is generally avoided because symptoms may recur even after removal of the bladder.

## Hormone Replacement Therapy

The use of HRT after menopause is controversial and fraught with a potential for more complications than benefits in geriatric-aged women. At this time, no useful and clear outcomes other than vasomotor symptoms, atrophic vaginitis, and osteoporosis prevention and treatment guide our administration. Nonetheless, estrogen has neurotrophic and neuroprotective effects, and HRT investigations in the elderly should continue. Any use of HRT in the elderly will probably evolve toward lower doses. Women require lower estrogen doses to achieve the same biological effects as they age.

In women aged 65 years or older, HRT should not be initiated, and the issue in this age group is often how to discontinue therapy without suffering menopausal symptoms. Many older women can simply discontinue long-term HRT abruptly with minimal symptomatology. If vasomotor symptoms, insomnia, irritability, short-term memory loss, or excess fatigue occur, estrogen can be tapered as slowly as necessary. Potential tapering schedules are innumerable, typically reducing the dose 25% to 50% every 3 to 12 months. If complete discontinuation is then a problem, omitting one dose per week (of oral medication) every 1 to 2 months may be more tolerable. Transdermal estradiol is available in extremely low doses, including 14 mcg patches, which can facilitate the final tapering. If a woman needs to suddenly discontinue estrogen but not progestin, such as with venous thrombosis, progestins effectively eliminate hot flashes. Medroxyprogesterone acetate 30 mg/day or megestrol acetate 20 to 40 mg/day may be required. After several months, this can be discontinued with fewer symptoms.

If an older patient has new vasomotor symptoms without recent estrogen discontinuation, the symptoms are not “menopausal” as the patient may believe. History should include onset, timing during

the day, associated factors, all medications and supplements used, and her symptoms at the time of menopause. Estradiol levels can occasionally be beneficial in interpreting symptoms or enhancing patient comprehension.

## SUMMARY

Numerous gynecological issues occur in older women. Because of a usual reluctance to discuss these matters, physicians should specifically ask about any problems (see [Table 48-1](#)). Pelvic examination may detect unanticipated problems in their early stages, or detect significant current problems in the cognitively impaired. Early diagnosis and treatment of gynecological disorders can improve quality of life and longevity for many older women.

# Sexuality, Sexual Function, Androgen Therapy, and the Aging Male

*J. Lisa Tenover*

Sexuality is a basic human need that exists throughout life in one form or another and is a significant component to quality of life of many older individuals. Although 70% of adult patients in a large sample study considered sexual matters to be an appropriate topic for a general clinician or geriatrician to discuss, sexual problems are noted in less than 2% of primary care physicians' notes. It is not easy to find physicians and other health care providers who are knowledgeable about sexuality in general and sexuality among the aging population in particular. Sexuality and sexual function in the aging female is addressed in Chapter 47. Sexuality, sexual function, and dysfunction in the aging male will be addressed in the first part of this chapter, with the second part being devoted to androgen replacement therapy in the older man.

## SEXUALITY AND SEXUAL FUNCTION IN OLDER MEN

### Sexual Behaviors

Idealized societal concepts of older people do not include sex or the facility for sexual function. A poll conducted by the National Council on Aging, regarding attributes of people aged 65 years or older, reported that older persons were frequently thought of as being “warm and friendly” (74% of respondents) or “wise from experience” (70% of respondents), but being “sexually active” was only attributed to older persons by 5% of the survey respondents. Yet epidemiologic studies of sexuality and aging, such as the Duke Longitudinal Studies, the Massachusetts Male Aging Study, and, most recently, the University of Chicago study, report many older adults are sexually active. Sexual expression can encompass many forms, including sexual intercourse, oral sex, masturbation, intimacy, physical appearance, erotic stimuli (reading, movies) and fantasies (daydreams), but most study data involve the first three components.

Figure 49-1 depicts the prevalence of male sexual activity with a partner based on a probability sampling of 3000 U.S. adults aged 57 to 85 years. The likelihood of sexual activity with a partner declined with age, but nearly 39% of men aged 75 to 85 years reported sexual activity with a partner within the previous 12 months, with 54% of these sexually active 75- to 85-year-old men reporting sex at least two to three times a month.

In addition to partner availability, there are other factors that affect sexual activity in older adults. Health status has a strong influence. Diseases such as arthritis, especially when it involves the hips and pelvis, can affect sexual positions, endurance, and comfort. Urinary incontinence, with or without the need of urinary catheters, or the presence of ostomies can affect body image and may raise physical barriers to sexual activity. Chronic diseases, such as diabetes, stroke, or cardiovascular disease also will have significant impact, especially with regard to erectile function in the aging male, as will be discussed later. The effect of self-reported health status on the prevalence of sexual activity is shown in Figure 49-1. Older men across all age ranges who reported excellent or good health were more likely to be sexually active than men with fair or poor health. Medications also may have an impact on the level of sexual activity and function, particularly for men, as many medications can impact erectile function; this will be discussed in detail later in the chapter.

### Changes in Male Sexual Physiology with Age

Overall there is a gradual slowing of sexual physical response time as men age. It takes more time to achieve sexual arousal, complete the sexual act, and become rearoused for further sexual activity. Table 49-1 lists the specific changes in the male sexual response cycle with age. Some of the changes have been shown to be impacted, at least in part, by low testosterone levels, while others are unaffected by hormone levels. The aging male may need reassurance that slowing of the sexual response is normal and predictable in order to avoid the fear and anxiety that may ensue without such information. Lengthening

**FIGURE 49-1.** Prevalence of male sexual activity with a partner in previous 12 months as obtained from a survey of a probability sample of 3000 U.S. adults aged 57 to 85 yrs. Data are presented by age group and self reported health status. *Data from Lindau ST, Schumm LP, Laumann EO, et al. A study of sexuality and health among older adults in the United States. N Engl J Med 357:762, 2007.*

of the period of foreplay is one approach to adapting to these normal aging changes.

### The Aging Male Homosexual

In the United States, there are about 3.5 million gay people aged 60 yrs and older. Older homosexual men have similar sexual problems as older heterosexual men, but may suffer additional problems of stress while trying to find a partner, especially if their living situation changes and they move into assisted living facilities or nursing homes. Specific organizations that address issues of aging gay and bisexual persons have formed across the country. Examples include Senior Action in the Gay Environment (SAGE) in the New York City area or Gay and Lesbians Older and Wiser (GLOW) in Ann Arbor, Michigan.

Unprotected sex occurs in approximately 10% of older homosexuals. Compared to younger homosexual men, older homosexual men get tested less often for sexually transmitted diseases, including testing for acquired immunodeficiency syndrome (AIDS). The incidence of AIDS is increasing in older men. Education about safe sex practices is important in the older population. Older males with a history of anal sex need to be regularly examined for anal cancer, as the prevalence increases in such persons.

**TABLE 49-1**

#### Changes in the Male Sexual Response Cycle with Age

Lengthening of the excitement phase (plateau)
Decreased penile rigidity*
Longer interval to ejaculation phase (plateau)
Fewer and less forceful contractions of the urethra
Lower ejaculatory volume
Less well defined sense of impending orgasm*
Shortening of the ejaculatory event and orgasmic phase*
Increased occurrence of resolution without ejaculation*
More rapid detumescence
Lengthening of the refractory period

\*Aspects which may be affected by testosterone levels.

Older male homosexuals should be encouraged to get advanced directives for health and to specifically designate their Durable Power of Attorney for Healthcare. This should facilitate the ability of their partners to make their health decisions.

### Sex in Long-Term Care

Persons who live in nursing homes frequently have no opportunity for a private, social, or sexual life. Federal regulations issued in 1978 provide some right to privacy, but it is limited to married couples and to nursing homes that participate in federal Medicare and Medicaid programs. Specifically, the regulations state that (1) the nursing home residents have the right to share a room with their spouse when married residents live in one facility and both spouses consent and (2) the residents have the right to privacy during a visit with their spouse. These regulations are not uniformly enforced, however, and the majority of long-term care staff possess minimal understanding about how to deal with the sexuality of their nursing home residents. Education programs for nursing staff are important.

Additional barriers to sexual expression in long-term care include lack of a partner and physical or mental illness. Issues surrounding romantic liaisons between two unmarried residents in a nursing home can be especially problematic. Deciding about the competency of a cognitively impaired individual to consent to sexual interactions and the objection of adult children to a parent's romantic liaison are just two examples of issues that can arise.

### Sex and Dementia

Issues of sexuality are especially complex for those individuals who have cognitive impairment, as the diagnosis of dementia does not in itself determine in which domains a person is capable of making decisions. Some men with dementia become impotent, but others remain quite interested and capable, and a few older men with dementia become hypersexual. Physicians of demented male patients need to ask the spouse about sexual issues, as the wife may be embarrassed to reveal sexual difficulties. If the problems are placed in the context of dementia, it can assist with discussion of coping strategies.

**TABLE 49-2****Major Categories of Sexual Dysfunction in Older Men**

#1	Erectile dysfunction (ED)
#2	Low desire (libido)
#3	Performance anxiety and other psychological problems
#4	Inability to climax

Nonsexual ways of expressing intimacy, such as touching, holding hands, and massages, might be suggested.

**SEXUAL DYSFUNCTION IN THE AGING MALE****Categories of Male Sexual Dysfunction**

Table 49-2 lists the major categories of sexual dysfunction in older men. Erectile dysfunction (ED) is the most prevalent of these categories. Erectile dysfunction (also called impotence) is defined as the inability to obtain and sustain a penile erection adequate for intercourse. Erectile dysfunction is not a result of aging per se, in that healthy older men do not lose the capacity for erections and ejaculation. However, it is a common problem for the aging man. Severe erectile dysfunction is estimated to be present in 20 million men in the United States. In the Massachusetts Male Aging Study, a community-based study of middle aged and older men, the reported incidence of any erectile dysfunction was 55% for men at age 60 years, and 65% for men at 70 years; the prevalence of total erectile dysfunction at age 70 years was 15%. In the University of Chicago study, about 45% of men aged 65 to 74 years reported having some erectile dysfunction.

Libido, the enthusiasm for sex, or sexual desire, is dependent on learned responses, general health-related quality of life, and, to some extent, serum testosterone levels. As will be discussed later in this chapter, testosterone levels decline in men with normal aging and some men may reach levels that are low enough to affect libido. However, testosterone replacement studies in hypogonadal men suggest that the level of testosterone needed to maintain libido is likely below the serum “normal” range for most men.

Performance anxiety is common in older men and often a result of equating masculinity with speed and magnitude of sexual activity. A man may become so preoccupied by his performance that his confidence and sexual capacity lessen, leading to erectile dysfunction. Depression and psychosocial stresses also are prevalent in older men and contribute to sexual problems. “Widower’s syndrome,” a condition in which a man fails to achieve erection after the death of spouse, is a reported entity.

Inability to reach climax or to resolve without ejaculation can occur. In the University of Chicago study, this occurred in about 16% in the 57- to 64-year age range, but increased to 33% in men aged 75 years and older.

**Erectile Dysfunction****Physiology**

To better understand how diseases and medications impact erectile function, it is important to have at least a cursory understanding

of the physiology of penile erection. An erection of the penis is obtained in three ways: through local sensory stimulation of the penile shaft and glans penis, through visual or auditory stimuli, and spontaneously during rapid eye movement (REM) sleep. As men age, erection becomes more dependent on physical stimulation of the penis and less responsive to visual and other nongenital stimulation.

When the penis is flaccid, there is alpha-adrenergic-mediated vasoconstriction of arterioles and sinusoidal spaces of the corpora cavernosa. During erection, parasympathetic input results in vasodilatation, which leads to an increase in arterial blood flow and pressure in the cavernosal sinusoids, resulting in occlusion of the venous outflow system and penile erection. A number of neurotransmitters play a role in this process. Nitric oxide is released by penile endothelial cells and cavernous sinus nerves during sexual stimulation. This release of nitric oxide, along with other agents such as prostaglandins E1 and E2 and vasoactive intestinal peptide (VIP), results in smooth muscle relaxation within the corpora, which leads to an erection.

**Etiologies**

Table 49-3 lists the major etiologies of erectile dysfunction. The prevalence of the specific etiology depends on the type of reporting center (primary care, urology, endocrinology). Vascular disease, which includes both atherosclerotic arterial occlusive disease and corpora cavernosa venous leak, is the most common cause of erectile dysfunction across referral centers. The likely mechanism is that penile hypoxia leads to replacement of corpora smooth muscle by connective tissue, which results in impaired cavernosal expandability and inability to compress subtunical venules. Risk factors for vascular erectile dysfunction include the presence of diseases and habits associated with atherosclerosis, such as diabetes mellitus, hypertension, hyperlipidemia, and smoking. Trauma and Peyronnie’s disease can exacerbate the potential for corpora venous leakage. The penis is a high blood flow system during erectile function, so erectile

**TABLE 49-3****Major Etiologies of Erectile Dysfunction**

Vascular disease	Atherosclerotic arterial occlusive disease, corpora venous leak
Neurologic disease	Neuropathy, cord injury, stroke, multiple sclerosis, temporal lobe epilepsy, Parkinson’s disease
Diabetes mellitus	Both vascular and neurologic effects
Other systemic diseases	Renal failure, COPD
Hormonal	Hyper- and hypothyroidism, hypercortisolemia, severe hypogonadism
Urologic	Lower urinary tract systems (LUTS) caused by BPH
Surgery/trauma	Prostate cancer surgery, Peyronnie’s disease
Lifestyle	Obesity, smoking, heavy alcohol use
Medications	
Psychogenic	Depression, anxiety

dysfunction maybe an early sign of vascular inadequacy on the basis of atherosclerosis. Men who present with erectile dysfunction of vascular etiology are at very high risk of developing other vascular diseases, such as angina, myocardial infarction, or stroke, within 2 years of their diagnosis of erectile dysfunction. This risk remains even when controlled for current smoking or family history of myocardial infarction. Therefore, men with erectile dysfunction of suspected vascular etiology should be provided with appropriate screening and treatment for cardiovascular disease. Men with uncontrolled hypertension can develop erectile dysfunction as well, and erectile dysfunction can improve when the blood pressure normalizes. Men with mild to moderate hypertension need not restrict themselves sexually, but because systolic blood pressure can increase significantly with sexual activity, those with uncontrolled or severe hypertension should postpone sexual activity until blood pressure is controlled.

Neurological diseases, such as peripheral neuropathy, spinal cord injury, stroke, multiple sclerosis, temporal lobe epilepsy, and Parkinson's disease all can cause erectile dysfunction. In men who develop multiple sclerosis, about half of them present initially with erectile dysfunction. In these men, erectile dysfunction maybe present for some amount of time, then disappear, and reappear at the next exacerbation. Men with stroke-related erectile dysfunction also tend to have ejaculatory problems.

Diabetes mellitus is the most common single disease to cause erectile dysfunction. The pathophysiology involves neuropathic, angiopathic, and general vascular changes. Although the severity of hyperglycemia has been suggested as a predictor of erectile dysfunction, there is little relation to the likelihood of erectile dysfunction in older men treated with oral agents or those needing insulin. Age, duration of diabetes, and other diabetic complications appear to be better predictors of erectile dysfunction than degree of hyperglycemia. Sometimes erectile dysfunction is the first symptom of diabetes mellitus, so all men who present with newly diagnosed erectile dysfunction should be evaluated for undiagnosed diabetes.

Significant other systemic diseases that can cause erectile dysfunction are renal failure and chronic obstructive pulmonary disease (COPD). Chronic renal failure impacts erectile function through effects on the vascular system and via the development of autonomic neuropathy. In addition, many men with end-stage renal disease are severely hypogonadal. Neither hemodialysis nor testosterone replacement in men with renal failure have been shown to improve erectile dysfunction. Men with COPD and low PaO<sub>2</sub> have decreased cavernosal nitric oxide. Oxygen therapy may improve erectile function in some men with COPD.

Both hypercortisolemia and hyper- and hypothyroidism have been associated with hypoactive sexual desire and erectile dysfunction. Hypothyroidism also is associated with delayed ejaculation, with a prevalence of up to 64%; normalization of thyroid function frequently leads to improvement. Hyperthyroidism is associated with a 50% prevalence of premature ejaculation, which also improves with normalization of thyroid function.

Many studies have shown a clear association of erectile dysfunction with aging, but there have been no consistent correlations of erectile dysfunction in older men with low serum testosterone levels. In the Massachusetts Male Aging Study, where serum testosterone levels were measured throughout the study duration, of the men with no erectile dysfunction at baseline who were then followed up 8 years later, 16% developed erectile problems. Of the men who

developed erectile dysfunction, 22% were in lowest tertile for serum testosterone levels, but 12% were in highest tertile. Other studies in healthy older men have shown that testosterone levels may correlate with sexual desire, but not with erectile function or coitus frequency.

Erectile dysfunction and lower urinary tract symptoms (LUTS), occurring as the result of benign prostatic hyperplasia (BPH), have significant effects on each other. Treatment of one can often improve the other. Both LUTS and erectile dysfunction are prevalent in the older male and frequently coassociate, contributing to diminished quality of life. Epidemiologic studies have shown strong associations between LUTS and erectile dysfunction, with a temporal relationship in onset and cessation and a dose response. A study in older men who had both erectile dysfunction and LUTS and were treated with the phosphodiesterase-5 (PDE-5) inhibitor, sildenafil, for 12 weeks, reported that both erectile function and LUTS symptoms improved with the sildenafil treatment.

While transurethral resection of the prostate (TURP) for BPH seldom results in erectile dysfunction, surgery for prostate cancer is more extensive and results in some degree of erectile dysfunction in about 60% of men. Nerve sparing surgery offers a greater chance of preserving sexual potency. In addition, penile rehabilitation with PDE-5 inhibitors immediately after surgery helps prevent complete erectile dysfunction. Peyronnie's disease, in which fibrosis of the corpora occurs, also can lead to erectile problems.

A number of lifestyle factors have been associated with the development of erectile dysfunction. Obesity alone is associated with a 20% increased risk of developing erectile problems. Although men with obesity often have low serum total testosterone levels, their free testosterone levels usually are normal, making hypogonadism an unlikely cause for obesity-associated erectile dysfunction. Often, however, obese men have elevated serum estrogen levels owing to the conversion of androgens to estrogens in adipose tissue. Improving obesity can improve erectile function. Smoking also can cause erectile dysfunction, both from direct effects of nicotine on penile smooth muscle and from longer term effects on accelerating atherosclerosis. High levels of alcohol consumption are associated with erectile dysfunction, but moderate to low alcohol use has been associated with a lowering of the risk of erectile dysfunction. Physical activity alone, regardless of weight, can improve or delay development of erectile dysfunction.

A large number of medications have produced adverse drug events reports involving male sexual dysfunction, usually erectile dysfunction. These medications are listed in [Table 49-4](#). By and large, the effects on sexual function are medication class effects based on mechanisms of action. It is unlikely that medications would precipitate symptomatic erectile dysfunction in a man who had absolutely no erectile problems prior to initiating the medication, but for men with mild preexisting erectile dysfunction, these medications may precipitate clinically significant erectile problems. Sometimes, when relying on adverse drug event reports in the absence of large randomized trials, conclusions regarding the potential of a medication to impact sexual function maybe exaggerated or incorrect. For example, although the 5- $\alpha$  reductase inhibitor, finasteride, has been reported to cause erectile dysfunction, analysis of the prospective quality of life data from the large Prostate Cancer Prevention Trial showed finasteride had no significant effect on sexual function.

A few comments about some of the medications listed in [Table 49-4](#) are warranted. Among the diuretic antihypertensives, hydrochlorothiazide has frequently been reported to be associated with

**TABLE 49-4****Medications Associated with Male Sexual Dysfunction**

Antihypertensives
Central acting agents (reserpine, clonidine, alpha-methyl dopa)
Diuretics (thiazides; spironolactone)
Beta-blockers (especially propranolol)

Digoxin
Many cancer chemotherapeutics
Phenytoin
Ketoconazole
Clofibrate
Metoclopramide
5-alpha reductase inhibitors
St. John's Wort

erectile problems, yet analysis of the large NHANES database for evaluation of the effect of medication exposure on erectile dysfunction using multivariate analysis showed that the use of thiazides was not associated with erectile dysfunction. Among the beta-blockers, propranolol is the one most associated with erectile dysfunction, and erectile problems are more often seen with the higher beta-blocker dosages. Among the antidepressants, both tricyclic antidepressants and serotonin reuptake inhibitors are associated with erectile dysfunction. Mirtazapine, bupropion, and citalopram have been reported to cause somewhat fewer negative sexual side effects. Many benzodiazepines, including those used to counteract insomnia, are associated with exacerbation of erectile dysfunction, but sleep deprivation alone can induce sexual dysfunction.

### Evaluation of Sexual Dysfunction

The first step in evaluation of sexual dysfunction is often the most difficult: eliciting the information that the patient has sexual dysfunction. Screening for sexual dysfunction can be done by asking a brief question or two about sexual activity in all patients and can legitimize the topic for conversation. Examples of possible screening questions include: "Are you satisfied with your sexual activity?"; "How has your illness affected your sex life?"; if the patient has a chronic illness; or "Many of my male patients your age have noticed some change in their sexual function; how about you?"

If sexual dysfunction is discovered during screening, then a more extensive sexual and health history and physical examination are

warranted. A careful history from the man's sexual partner can be helpful as well. If psychological or couples' problems exist, or if the patient is depressed, these should be treated before pursuing the direct management of other problems, such as erectile dysfunction. As noted earlier, an evaluation for general vascular disease and for diabetes, as well as a medication evaluation, should be done.

### Treatments for Erectile Dysfunction

The initial step in the treatment approach to erectile dysfunction is to identify reversible causes and then to change them if possible. This includes making alterations in a medication regimen, facilitating smoking cessation and weight loss, and encouraging physical exercise. If there is evidence for a significant psychological component to the erectile dysfunction, couples counseling or treatment for depression, if appropriate, are warranted.

Table 49-5 lists the current medical treatments for erectile dysfunction. Vacuum erection devices consist of a vacuum cylinder connected to a pump to create controlled negative pressure, and one or more constriction rings that go at the base of the penis after vacuum-induced engorgement has occurred. Intercourse occurs with rings in place, but the ring should not be left on for more than 30 minutes. Erection satisfactory for intercourse occurs in 75% to 90% of the users. Overall satisfaction rate is 65% to 70% if the method is chosen and used, but only about 12% of men select the vacuum device as an initial choice of therapy. Side effects or reasons for dissatisfaction include pain, inconvenience, and premature loss of rigidity. There are few contraindications to its use, but if on anticoagulants, these devices should be used with care.

Penile prosthetic implants are either semirigid/noninflatable or inflatable. Designs have improved over the last decade, and the 5-year failure rates for the inflatable prosthesis are now about 5%. Infection is the most significant complication and varies from <1% to 16%.

Erection predominantly requires arterial dilation and venous sinusoidal relaxation, facilitated by alpha adrenergic blockade and smooth muscle relaxation via mechanisms involving nitric oxide, prostaglandin E1 (PGE1), acetylcholine, or VIP. Nitric oxide activates guanylate cyclase in smooth muscle cells, leading to a rise in cGMP, which leads to muscle relaxation. cGMP is degraded in the

**TABLE 49-5****Current Medical Treatment Options for Erectile Dysfunction**

PDE-5 inhibitors
Sildenafil, vardenafil, tadalafil
Testosterone

penis predominantly by PDE-5. Major medications approved for use in the United States for treating erectile dysfunction are PGE1, PDE-5 inhibitors, or alpha adrenergic blockers. Delivery methods for these medications are by intracavernous injections, transurethral, or oral.

Intracavernous injections with PGE1 or a PDE inhibitor, with or without an alpha adrenergic blocker have efficacy of 65% to 90%. Side effects include mild local pain (10% to 15%), penile fibrosis, prolonged erections, and rhinitis. PGE1 can also be delivered via urethral insertion, followed by vigorous penile massage to assist with medication delivery. Reported efficacy is between 45% and 65% and side effects include mild pain, minor urethral bleeding, dizziness, and lowered blood pressure.

The main oral therapies for erectile dysfunction are the PDE-5 inhibitors, sildenafil, vardenafil, and tadalafil. Reported efficacy is variable, ranging from 45% to 90%. There are no good data to support one PDE-5 inhibitor as more efficacious than another. None of these medications are totally specific for the PDE-5 enzyme, but vardenafil is a little more specific than the other two, so there is a lower incidence of visual “blue haze” with this agent. Tadalafil has the longest half-life of the three medications. Side effects of these agents are primarily related to their effects on lowering blood pressure, which can lead to events such as myocardial infarction and stroke in susceptible patients. Oral alpha adrenergic blockers, such as yohimbine or phentolamine, have been used to treat erectile dysfunction, but with low efficacy (10% to 20%).

### Testosterone and Male Sexual Dysfunction

The human male requires at least a minimal amount of testosterone for normal sexual behavior. Profoundly hypogonadal young and middle-aged adult men need testosterone to restore both libido and normal erectile function, but serum levels of testosterone that need to be achieved in order to restore full sexual function are low and often below the normal serum testosterone range. There are, however, men with very low serum testosterone levels and no overt sexual dysfunction and men with complete erectile dysfunction who have high serum testosterone. Decreased libido is considered the most prominent symptom of low testosterone and can impact erectile function. Using low libido as a screening for low testosterone, however, is not very sensitive. In the Massachusetts Male Aging Study, assessment of the association of low testosterone with low libido demonstrated that the two were significantly associated when evaluated on a population level, but decreased libido was not a strong predictor of testosterone level in an individual man. If a man had low libido, the positive predictive value that he also would have a low serum testosterone level (<300 ng/dL) was only about 23%.

Testosterone works in the brain to affect sexual interest, but it also has effects in the penis. Testosterone can increase the level of penile nitric oxide synthetase, leading to an increase in nitric oxide and the vasodilatory cascade. It also may have direct effects on other penile neurotransmitters. A meta-analysis of studies of erectile dysfunction and testosterone treatment in nonelderly adult men demonstrated that the prevalence of low testosterone as a reversible cause of erectile dysfunction was only 1% to 35%, and studies that showed an improvement in libido with testosterone treatment often did not show an improvement in erectile dysfunction. There have been several placebo-controlled studies in which men with erectile dysfunction and low testosterone levels, who initially did not respond therapeu-

tically to a PDE-5 inhibitor, when given testosterone in addition to the PDE-5 inhibitor then did show improved erectile function. This suggests that testosterone’s direct effects in the penis may synergize with PDE-5 inhibitors to improve erectile function in some men.

There have been only a few trials of testosterone replacement in older men in whom sexual function was assessed, in most cases as secondary or tertiary study outcomes. In seven of the most recent studies of testosterone replacement in which aspects of sexual function were measured and at least some men were 65 years and older, three studies reported improvement in libido or morning erections with testosterone therapy, while four studies reported no changes in any aspects of sexual function with testosterone therapy.

In summary, testosterone replacement therapy is not the primary treatment for the majority of older men with erectile dysfunction, but maybe beneficial in some older men in whom decreased libido is a significant complaint or serum testosterone levels are very low. In addition, testosterone therapy can be used as adjunctive therapy for hypogonadal men who have failed PDE-5 inhibitor therapy alone.

## ANDROGEN REPLACEMENT THERAPY IN OLDER MEN

When an older man presents with decreased libido and/or erectile dysfunction, androgen deficiency is considered a potential cause. However, androgens have effects on a broader range of organs and physiologic functions than those involved with sexual function. Testosterone levels decline with normal aging, a decline that may parallel changes in muscle, bone, and other androgen-responsive tissues. This has led to the concept that replacing androgens, mainly testosterone, in testosterone-deficient older men might prevent, stabilize, or even reverse some of the detrimental target-organ changes seen with aging.

### Androgen Physiology and Changes with Aging

A further discussion of this topic appears in Chapter 107. Nearly all testosterone, which is the most plentiful androgen in the human male, circulates in blood bound to two proteins, albumin and sex hormone-binding globulin (SHBG); only about 1% to 2% of testosterone circulates totally free in plasma. Testosterone is tightly bound to SHBG, whereas its affinity for albumin is weak. Because of the strong affinity of testosterone for SHBG, the portion of plasma testosterone not bound to SHBG is often called *bioavailable* testosterone. Bioavailable testosterone best correlates with parameters such as bone mineral density and sexual function in older men, and is predictive for the development of frailty in inner-city African-American males. It is not known, however, if non-SHBG (*bioavailable*) testosterone is the component of testosterone that is truly bioavailable to every androgen target organ; for example, testosterone bound to SHBG maybe available to the prostate.

Not all target organ effects of testosterone are the result of the steroid directly, but maybe the result of one of its metabolites. Testosterone can be converted to 17 beta-estradiol through the action of an aromatase enzyme. In men, the majority of estrogen is felt to come from the action of an aromatase enzyme in adipose tissue rather than from direct production by the testis. Testosterone also

can be converted, via a 5- $\alpha$ -reductase, to dihydrotestosterone (DHT), which is the predominant androgen in some organs, such as the prostate. Although some DHT is found in serum, most of the effects of DHT at the target-organ level are felt to be caused by its local formation from testosterone. Both testosterone and DHT affect target organs through their interaction with the same intracellular androgen receptor.

Figure 107-4 and Table 107-9 in Chapter 107 summarize age-related changes in the hypothalamic-pituitary-testicular axis. Serum levels of total testosterone, free testosterone, and bioavailable testosterone, but not DHT, decline with aging in many normal men. Both cross-sectional and longitudinal studies demonstrate these age-related changes. Most data on testosterone levels and age are from studies where the men were predominantly Caucasian of western European descent. Some smaller cross-sectional evaluations of men of African-American or Asian descent, however, suggest that these ethnic groups also may demonstrate age-related testosterone decline. Figure 49-2 demonstrates the longitudinal effects of aging on total testosterone and free testosterone index (total testosterone/SHBG) as determined from 890 men in the Baltimore Longitudinal Study of Aging (BLSA). There is an average testosterone decline of 1.24 nmol/L/decade of age beginning at about 30 years of age.

While age alone has a strong predictive value for lower plasma testosterone levels, concomitant disease such as diabetes mellitus, liver disease, or hemochromatosis can contribute. Certain medications also have been associated with lower testosterone levels, including ketoconazole, cimetidine, and glucocorticoids. Only some men

will develop testosterone levels as they age that are low enough to cause obvious hypogonadism. The prevalence of “late onset” hypogonadism in the older male population is uncertain, largely because there is no agreement on how to define testosterone deficiency in this age group. There is no target-organ change, physiologic finding, or symptom that readily assists with this definition, and in general, serum LH levels are not helpful. Unlike the thyroid hormone axis, where an elevated serum thyroid-stimulating hormone level can establish the diagnosis of hypothyroidism, serum LH levels in most older men, even those men with quite low testosterone levels, are usually within the “normal” range for young adult men. It is possible that a single cutpoint for serum level of testosterone cannot define hypogonadism for all older men; the desired level of testosterone that maximizes target-organ effects may vary by the androgen target organ of interest, as well as being different among individuals.

### Defining Hypogonadism in Older Men

In 2004, the Institute of Medicine (IOM) published a report on the current state of knowledge about the potential risks and benefits of testosterone therapy in older men and made recommendations about the need for additional clinical studies. This IOM report recognized that there were a limited number of studies, especially placebo-controlled randomized trials, of testosterone therapy in older men and that the assessments of risk and benefits have been limited, making for uncertainties as to the value of such therapy. The IOM concluded that clinical studies further evaluating the risks and benefits of testosterone replacement therapy in older men could ethically be conducted, and that studies targeting efficacy of such therapy for specific clinical endpoints were needed. The IOM targeted for this research those areas in which there are not currently safe and effective treatment options: weakness and frailty, sexual dysfunction, cognitive dysfunction, and well being and quality of life.

The American Academy of Clinical Endocrinology, the Endocrine Society, the American Society of Andrology, and the International Society of Andrology have all now published clinical guidelines for diagnosis and treatment of testosterone deficiency in adult men. Within these guidelines are included some recommendations related to late onset hypogonadism. All the societies have agreed that late onset hypogonadism should not be just a biochemical diagnosis, but must include age-related pathology or symptoms that would warrant treatment. All the societies, as well as the IOM, also have agreed that total testosterone levels are the appropriate initial test for hormonal evaluation. In these guidelines, cut-off values for serum total testosterone levels, above which older men are not likely to have testosterone deficiency, vary from 200 ng/dL (6.9 nmol/L) up to 346 ng/dL (12 nmol/L). A number of the clinical trials of testosterone therapy in older men have enrolled men with serum total testosterone levels higher than these current recommendations.

The signs and symptoms that might be related to low serum testosterone levels in older men are listed in Table 49-6. These are based on extrapolation from the clinical syndrome of androgen deficiency in young men. All the listed signs and symptoms are nonspecific and could be indicators of many other diseases that are common in an aging male, making the diagnosis of late onset hypogonadism less than straightforward.

**FIGURE 49-2.** Longitudinal effects of age on plasma total testosterone levels and free testosterone index in men from the Baltimore Longitudinal Study of Aging. Each linear segment represents the data from a cohort, designated by age in decades, who were studied longitudinally (minimum of 4 yrs). For each cohort, the slope of the line equals the mean of the individual slopes, with the numbers in parentheses representing the number of men in that cohort. Longitudinal effects of aging on serum total and free testosterone levels in healthy men. *J Clin Endocrinol Metab.* 86(2):724, 2001. Copyright © The Endocrine Society.

**TABLE 49-6****Signs and Symptoms Possibly Related to Testosterone Deficiency in Older Men**

Reduced muscle mass
Increased visceral fat
Low bone mineral density
Loss of libido
Fatigue; diminished physical or work performance
Decreased energy, motivation, aggressiveness
Depression, dysphoria, or irritability
Vasomotor symptoms
Poor concentration and memory
Sleep disturbance

**Testosterone Therapy Effects on Specific Target Organs****Bone**

The IOM report did not recommend pursuing additional studies of testosterone therapy for treatment or prevention of male osteoporosis, largely because they felt that other efficacious therapies are available. Nonetheless, long standing testosterone deficiency is a known risk factor for male osteoporosis, and testosterone is known to be anabolic for bone. The studies of androgen replacement therapy in older men, which have evaluated an effect on bone have all utilized testosterone as the treatment androgen. This may be important, since testosterone is converted to estradiol *in vivo*, and older men receiving testosterone often show a substantial increase in plasma estradiol levels. Since bioavailable estradiol has been shown to be a better predictor of bone mineral density in older men than any component of testosterone, it is possible that the effects of testosterone replacement on bone in older men could be mediated through its conversion to estradiol.

The published studies of testosterone replacement in older men, which have evaluated bone related outcomes have lasted from 3 to

36 months, with the shorter studies measuring biochemical parameters of bone turnover and the longer studies evaluating bone mineral density. Some, but not all, of the studies enrolled older men who were osteoporotic at baseline. In general, the studies showed that the rate of bone degradation is slowed by testosterone replacement and bone mineral density increases. Whether positive effects on bone density can be maintained over longer periods of time than have been studied and what might be the optimal level of testosterone replacement to achieve the maximal benefit for bone are both currently unknown. There are as yet no data on the effect of testosterone replacement therapy on fracture rates in older men.

**Body Composition and Strength**

Sarcopenia, the loss of muscle mass with age, leads to decreased muscle strength and a decline in physical function. Testosterone is known to have anabolic effects on muscle, through alterations in intramuscular gene expression. Testosterone therapy can lead to an increase in muscle mass. Whether increases in muscle mass will then translate to improvement in muscle strength and improvement in physical function are key to its therapeutic potential in the older individual. There have been at least 15 clinical studies in older men in which fat mass and/or muscle mass have been evaluated in older men during androgen therapy. Table 49-7 summarizes the body composition changes that have been observed in these clinical trials. Changes in body composition with testosterone therapy have occurred consistently: a decline in body fat, an increase in lean body mass (predominantly muscle mass), or both. The magnitude of the changes in both muscle mass and fat mass in older men appear similar in magnitude to that seen with testosterone replacement in young hypogonadal men.

The effects of testosterone replacement therapy on strength and physical function in older men have not been as consistent as have been the changes in muscle mass (Table 49-8). Androgen therapy in older men appears to lead to variable increases in muscle strength. The magnitude of changes in physical performance with testosterone therapy was far less than that would be seen in response to physical

exercise. Studies are now underway to evaluate whether testosterone therapy and exercise training maybe synergistic in improving muscle strength and physical function in older men.

The clinical significance of the fat mass changes with testosterone therapy remains to be delineated. Fat mass loss with testosterone therapy is primarily subcutaneous fat, not visceral fat. Quantitative data on effects of testosterone therapy on insulin sensitivity are lacking, and fasting insulin, glucose, C peptide, or HBA1C are not changed with testosterone therapy in older men. Therefore, whether testosterone replacement therapy will have any impact on metabolic syndrome in older men remains uncertain.

### Mood

Young men with profound testosterone deficiency have symptoms of dysphoria, fatigue, and irritability, all of which improve with normalization of testosterone levels. There is also some epidemiologic support for a relationship between low androgen serum levels and dysphoria or depression in older men. Studies of middle-aged men with depression and low serum testosterone levels have shown no improvement in depression scales with testosterone treatment alone, but for those men treated with an antidepressant and testosterone, depressive symptoms were better than with just antidepressant treatment alone.

There have been no studies of the efficacy of testosterone replacement therapy in depressed elderly men. In older men who were not depressed, there have been at least seven blinded controlled clinical trials, which have evaluated effect on mood; only one of these studies reported any change with testosterone replacement. Another five blinded controlled studies of testosterone therapy in older men evaluated aspects of quality of life by various scales, and none of these reported a change with testosterone therapy.

### Cognition

Cross-sectional studies of older men have found an association of higher serum total testosterone levels with higher scores on some

cognitive tests. In the BLSA, a higher baseline free testosterone index correlated with better scores on visual and verbal memory at baseline and a slower decline of visual memory after 10 years of follow-up. A higher baseline free testosterone index, after adjustment for a number of risk factors, also was correlated with 26% reduction in risk for development of Alzheimer's dementia at 10 years.

To date, there have been eight randomized controlled clinical trials evaluating cognitive function with testosterone replacement therapy in older men without significant cognitive deficits at baseline. Four of these studies involved men with low or low-normal baseline total testosterone and the other four enrolled men with normal baseline total testosterone levels. Half of the studies in each category showed some improvement on aspects of cognition such as visuospatial memory, total memory, or verbal memory, and half of the studies reported no detectable effect of testosterone on cognitive test scores. No consistent effect of testosterone replacement has been observed in older men with dementia, but only small numbers of patients have been studied thus far.

### Cardiovascular System

Compared with premenopausal women, men have a higher incidence of cardiovascular disease and mortality. Whether this sexual dichotomy is because of a protective effect of estrogens in premenopausal women or whether androgens have a detrimental impact on the cardiovascular system in men is not yet known. Epidemiologic studies have demonstrated that low, rather than high, serum testosterone levels are associated with an increased risk of cardiovascular disease in older men. Therefore, testosterone replacement in older men could be beneficial, detrimental, or neutral with regard to the cardiovascular system. Factors associated with risk for cardiovascular disease that might be affected by sex steroids include serum lipoprotein levels, vascular tone, platelet and red-blood-cell clotting parameters, and direct atherogenesis. There are currently no data on the effects of testosterone therapy in older men on many of these parameters. Testosterone therapy may decrease platelet aggregation or positively affect vasomotor tone, but more data are needed.

**TABLE 49-9****Potential or Reported Adverse Effects of Testosterone Replacement Therapy in Older Men**

Liver toxicity (oral androgens only)
Fluid retention
Peripheral edema
Exacerbation of hypertension
Worsening of congestive heart failure
Breast tenderness or gynecomastia
Exacerbation of sleep apnea
Development of polycythemia
Exacerbation of benign or malignant prostate disease
Increased risk of cardiovascular disease
Effects on clotting
Effects on vasomotor tone
Effects on rate of atherogenesis

The effects of testosterone therapy on serum lipoprotein levels in older men have been more extensively investigated. In general, parenteral testosterone therapy has led to a decrease in total and low-density lipoprotein cholesterol levels, a decrease in lipoprotein(a) levels, and no change or a small decrease in high-density lipoprotein cholesterol levels. These changes in serum cholesterol levels with testosterone therapy were generally modest, and the ultimate impact on cardiovascular disease is unknown.

### Adverse Effects of Testosterone

Table 49-9 lists potential or reported adverse effects of testosterone therapy in older men. Liver toxicity, although known to occur with oral methylated agents, has not been seen with parenteral forms of therapy. Fluid retention is possible, especially during the first few months of therapy, but is not as dramatic as in the case of oral anabolic steroids. Testosterone replacement therapy in older men does not appear to cause peripheral edema or exacerbation of hypertension, but there was one reported case of exacerbation of congestive heart failure in a study in which very high doses of testosterone were used. Nearly all the studies of testosterone replacement therapy in older men have enrolled relatively healthy men. In chronically ill, frail, elderly men, fluid retention might pose more of a concern. Tender breasts or gynecomastia occurs in a small number of older men receiving testosterone therapy, perhaps because of the relatively greater increase in serum estradiol levels (as compared with serum testosterone levels) that occurs with the therapy. Testosterone supplementation has been reported to exacerbate sleep apnea, but this adverse effect has not been found uniformly.

Testosterone replacement therapy in older men often increases red blood cell mass and hemoglobin levels. In a meta-analysis of testosterone replacement trials in older men, there was a nearly four-fold relative risk of developing a hematocrit level over 50%. The increases in hemoglobin and hematocrit seen in older men with testosterone therapy are much larger than those usually observed when young hypogonadal men are given testosterone replacement. In some cases in which polycythemia has developed in older men, it has been necessary to either terminate therapy or decrease the dose of testosterone used. While the coexistence of sleep apnea and ele-

vated body mass index seems to contribute to the development of polycythemia in certain older men, this has not been the case for many of the men studied. Methods of testosterone replacement that give a more uniform level of testosterone within the physiologic range throughout the dosing period appear to have less of an effect on red blood cell mass.

Androgens have a role in promoting both BPH and prostate cancer. Androgen deprivation therapy has been used in the treatment of both these disorders, but the exact mechanism by which testosterone supplementation may promote prostate disease in older men is not known. Both the Massachusetts Male Aging Study and the BLSA have reported no relationship between serum testosterone levels and subsequent development of symptomatic BPH. The BLSA did report that a higher free testosterone at baseline increased the risk of detectable prostate cancer during an average 18.5-year follow-up, with relative risk of 2.59 (CI 1.28–5.25).

A number of testosterone replacement studies in older men have evaluated serum levels of prostate-specific antigen (PSA), prostate size, or functional prostate parameters. The large majority of these studies have reported no significant change in PSA serum levels or other prostate parameters. A meta-analysis of adverse events from 19 double-blind, placebo-controlled testosterone replacement trials in middle-aged and older men has been published. These studies represented a total of 651 men who received testosterone, and at least seven of these studies had treatment duration of 1 year or more. Rates of prostate cancer, the number of prostate biopsies performed, and a rise in PSA to greater than 4 ng/mL or a PSA increase of more than 1.5 ng/mL over baseline were numerically higher in men on testosterone compared to placebo, but none of the individual prostate parameters were significantly different between the testosterone and placebo treatment groups. However, the rate of all prostate events combined was higher in the testosterone therapy groups compared to placebo, with those men receiving testosterone having a 1.8-fold higher likelihood of having some “prostate event.”

Since both prostate cancer and BPH are diseases with long natural histories, and the observation time for testosterone therapy in older men is limited to less than 2200 man-years, the long-term effects of testosterone supplementation on the prostates of older men is still of concern. Screening for prostate cancer prior to initiation of testosterone therapy, especially in older men, is mandatory, and periodic monitoring of PSA levels and digital rectal examinations of the prostate should be done while men are on testosterone therapy.

### Testosterone Preparations for Replacement Therapy

The testosterone delivery systems that are currently available in the United States for use in replacement therapy are: long-acting injectable testosterone esters, such as testosterone enanthate or cypionate; transdermal patches; transdermally applied gels; or buccal patch (Table 49-10). The 17-alkylated testosterone oral preparations, although available, are not recommended for male hormone replacement because of hepatotoxicity and unfavorable alterations in serum lipoprotein profiles that occur with their use. All preparations of testosterone should be efficacious for replacement therapy if adequate serum testosterone levels are achieved, so selecting the specific preparation will depend on patient preference with regard to acceptability, dosing regimen, and cost, as well as possible adverse effects related to the specific preparation (Table 49-10).

TABLE 49-10

## Testosterone Delivery Preparations Available in North America: Recommended Dosing in Older Men and Potential Specific Advantages and Disadvantages

PREPARATION	RECOMMENDED INITIAL REGIMEN	ADVANTAGES	DISADVANTAGES
<i>Oral</i>			
17-alkylated testosterone	Not recommended*		
<i>Injectable esters</i>			
Testosterone enanthate or cypionate (100–200 mg/cc)	75 mg IM/wk or 150 mg IM/2 wks	Reliable delivery Good dosing flexibility Low cost	Widely variable serum T levels over dosing period Mood swings Significant increase in hemoglobin Increase in serum estradiol levels Pain at injection site
<i>Implantable pellets</i>	225 mg/4–6 mo	May last up to 6 months Steady serum T levels	Local site infection Extrusion of pellet Significant increase in hemoglobin Poor dosing flexibility
<i>Transdermal patch</i>			
(2.5 or 5 mg)	5 mg patch/d	Easy self application Steady serum T levels	Dermatitis at application site Limited dosing adjustment Poor absorption in some patients
<i>Transdermal gel</i>			
(2.5- or 5-g packets, or pump; 5-g gel delivers 5 mg/day)	5 mg/day	Good dosing flexibility Easy self application Steady serum T levels Invisible	Occasional skin irritation Poor absorption in some patients Mildly elevated serum DHT levels
<i>Buccal</i>			
(30 mg adherent tab)	30 mg q 12 h	Easy self application Not transdermal	Gingival irritation Poor adhesion No dosing flexibility

\*Not recommended because of increased incidence of hepatotoxicity and unfavorable alteration in lipoprotein profiles.

The injectable esters deliver reliable testosterone serum levels, offer a wide range of dosing, and are relatively low in cost, especially if the patient or a family member can give the intramuscular injections. The disadvantages of injectable esters include the necessity for intramuscular injection, with possible discomfort at the injection site, and the large variation in serum testosterone levels over a single dosing period. Especially with the 2- and 3-week dosing regimens, supraphysiologic testosterone levels occur within the first few days after injection, and levels then fall below the normal range just prior to the next dose. This may result in mood swings and significant increases in hemoglobin and estradiol levels, and this is the reason why an every 3-week dosing regimen is not recommended. Since testosterone metabolism slows with aging, the recommended initial dose of injectable testosterone for older men is lower than that used in younger adults.

The pellet formulation delivers relatively stable serum testosterone levels for periods up to 6 months. However, it requires a skin incision and trocar to implant, site infection or extrusion of the pellet are possible, and there is no significant dosing flexibility.

The transdermal patch is easy to apply and provides physiologic levels of serum testosterone throughout most of the 24-hour dosing period. The disadvantages of transdermal patch include possible local skin irritation and limited dosing adjustment (the patch comes in two sizes and can not be cut). The testosterone gels are also easy to apply, deliver physiologic serum testosterone levels, and offer more

dosing flexibility than the patch, because less than a full packet (or pump dose) can be applied. Disadvantages of the gel include its cost, production of mildly elevated serum DHT levels, and some occasional skin irritation. It is important to note that a small percentage of men are unable to achieve normal serum testosterone levels with *any* transdermal preparation. In that case, the injectable esters, the pellet, or the buccal formulation must be used. The disadvantages of the buccal preparation include gingival irritation and loss of the patch as a result of poor adhesion.

# Benign Prostate Disorders

*Catherine E. DuBeau*

## DEFINITIONS

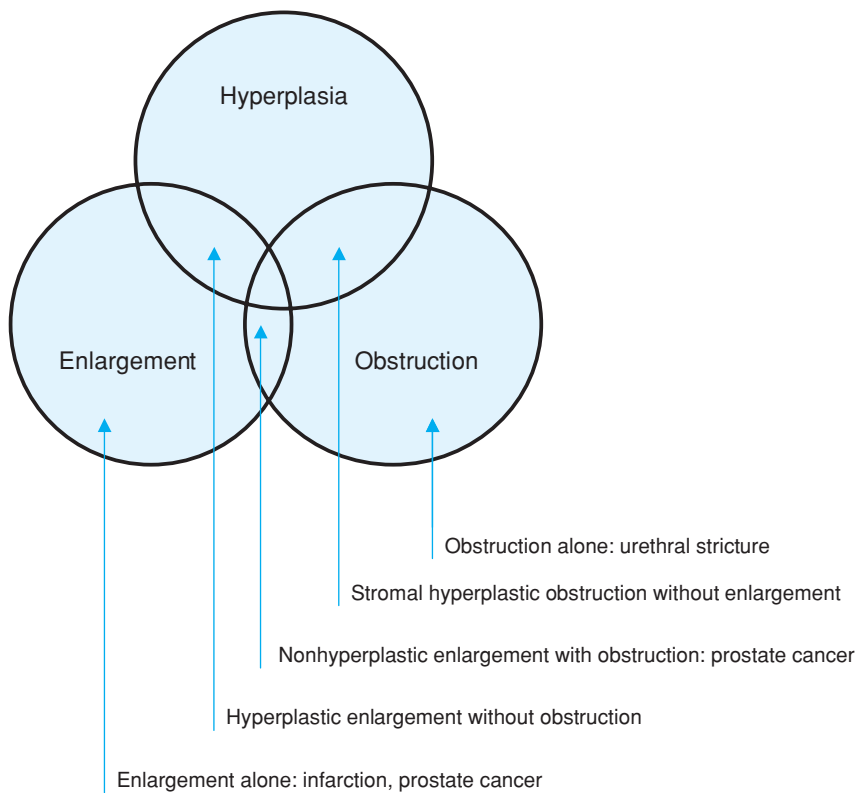

Many terms are used to describe benign prostate disease, and often interchangeably. Precision is important, however, because the conditions overlap only partially (Figure 50-1). Benign prostatic hyperplasia (BPH) is a histological condition characterized by benign proliferation of stromal and/or epithelial prostate tissue. Benign prostate enlargement (BPE) occurs in about half of men with BPH, and is quantified by milliliters of prostate tissue. Bladder outlet obstruction (BOO) occurs in only a subset of men with BPE. Older men often have voiding symptoms (urgency, frequency, nocturia, slow stream, hesitancy, incomplete emptying, postvoiding dribbling, and incontinence), which maybe related to BPH, BPE, BOO, age-related physiologic changes in the lower urinary tract, or comorbid conditions and medications. Therefore, voiding symptoms are best described by the nonspecific term lower urinary tract symptoms (LUTS).

## EPIDEMIOLOGY AND NATURAL HISTORY

Early autopsy and epidemiological studies demonstrated a marked rise in prevalence of BPH and BPE with age, especially during the sixth and seventh decades, and a similar relationship between age and “clinical BPH” (LUTS and BPE on examination) (Figure 50-2). Overall, 28% to 35% of older men without previous prostate surgery have moderate to severe LUTS. More recent data from longitudinal epidemiological studies and placebo arms of treatment trials confirm that the incidence of benign prostate disease gradually and variably increases with age until the ninth decade (Figure 50-3). Only weak correlations exist between BPE, BOO, and LUTS, suggesting that their relationships are nonlinear and complex.

Some data suggest that African-American men have a higher risk of benign prostate disease urinary retention, and BPE/BOO surgery, possibly because they have higher levels of 5 $\alpha$ -reductase and larger prostate transitional zone volume (see section “Pathophysiology”). The very limited available data suggest that Hispanic men have similar risk of BPH and characteristics of BPE as non-Hispanic white men. Asian men generally have lower rates of benign and malignant prostate disease, although this may differ by country of origin.

Progression of benign prostate disease is defined as worsening LUTS, acute urinary retention (AUR), and/or the need for surgical treatment. LUTS can vary significantly over time, and abate as well as progress. In a prospective cohort of men with moderate LUTS, by 1-year symptoms had improved in 16% and worsened in only 24%, and at 4 years, symptoms were only mild in 13%, unchanged in 46%, and worse in 41% (Figure 50-4). The incidence of AUR in men with LUTS and benign prostate disease is low: in a meta-analysis including 6100 moderately symptomatic men, the incidence of AUR was 13.7 per 1000 patient-years in all men and considerably higher in men aged  $\geq 70$  years or taking anticholinergic agents (34.7 per 1000 patient-years). Higher baseline prostate-specific antigen (PSA) levels are associated with greater risk of AUR and surgery; 7.8% of men with PSA levels up to 1.3 ng/mL develop AUR and/or require surgery by 4 years, compared with 12.6% of men with PSA levels 1.4 to 3.2 ng/mL, and 19.9% with PSA levels 3.3 to 12 ng/mL. Change in PSA over time (PSA velocity), however, is not associated with AUR or surgery. As PSA is strongly correlated with prostate volume, it is not surprising that higher volumes ( $>30$  to 40 mL by ultrasound) are associated with worsening LUTS and AUR. Other factors that increase AUR risk include previous episode(s) of retention, baseline postvoiding residual volume (PVR) greater than 100 mL, worsening LUTS, and failure to respond to alpha-blocker treatment.

**FIGURE 50-1.** Examples of incomplete concordance between benign prostatic hyperplasia, benign prostatic enlargement, and bladder outlet obstruction.

## PATHOPHYSIOLOGY

### Hyperplasia

Prostate hyperplasia occurs when prostate cell proliferation exceeds programmed cell death (apoptosis) as a result of stimulated cell

**FIGURE 50-2.** Autopsy evidence of prostate hyperplasia (percent of prostates, solid line with ■), mean weight (ml) of all prostates (dashed line with ◆), mean weight of prostates with hyperplasia (dashed line with ▲), and percent of men with lower urinary tract symptoms (solid line with ○). Data from Berry SJ, Coffey DS, Walsh PC, Ewing LL. The development of human benign prostatic hyperplasia with age. *J Urol.* 132:474-479, 1984; Guess HA, Arrighi HM, Metter EJ, Fozard JK. Cumulative prevalence of prostatism matches the autopsy prevalence of benign prostatic hyperplasia. *Prostate.* 17:214-216, 1990.

growth, inhibition of apoptosis, or both. BPH occurs predominantly in the prostatic periurethral transitional zone, unlike prostate cancer, which tends to occur in more peripheral areas. BPH and prostate cancer are genetically distinct, and one is not a risk factor for the other.

The development of stromal and epithelial hyperplasia in BPH is androgen- and aging-dependent, and involves numerous paracrine and autocrine factors. The trophic androgen for prostate growth is dihydrotestosterone, produced from testosterone within the prostate by the enzyme  $5\alpha$ -reductase (thus the utility of  $5\alpha$ -reductase inhibitors for treatment). In the absence of  $5\alpha$ -reductase, even high serum levels of testosterone will not cause BPH. Additional factors supporting prostate cell growth include inflammatory cytokines (e.g., interleukin-8), autocrine cytokine growth factors, and neuroendocrine cell products. Stromal-epithelial interactions regulating proliferation also involve interactions between androgens, estrogens, and stimulatory and inhibitory peptide growth factors (e.g., fibroblast growth factor-2, transforming growth factor- $\beta$ ). Other regulatory factors include nitric oxide (nitric oxide synthetase levels are low in BPH), vitamin D, and local autonomic innervation and activity. Thus the development of BPH is the end result of numerous pathways involved in regulating sympathetic activity, androgen-estrogen balance, and smooth-muscle proliferation.

The divergence in prevalence between BPH, BPE, BOO, and LUTS results from many lower urinary tract factors (Table 50-1). In addition, numerous medical conditions, medications, and functional impairment may cause or worsen LUTS independent of prostate disease (see Chapter 59).

### Risk Factors

Factors associated with the development of benign prostate disease include age, physical inactivity, high meat and fat intake (especially

**FIGURE 50-3.** Incidence per 1000 man-years of BPH, as defined by LUTS plus a clinical diagnosis of BPH, medical therapy for BPH, or surgical treatment for BPH during follow-up. Data from: Verhamme KMC, Dieleman JP, Bleumink GS, et al. Triumph Pan European Expert Panel. **TABLE 50-1**

**Lower Urinary Tract Factors Underlying the Divergence in Prevalence Between BPH, BPE, BOO, and LUTS**

FACTOR	IMPACT
Ratio of stromal to epithelial hyperplasia (stromal proliferation predominates in 50%, glandular in 25%, and mixed in 25%)	Stromal glands tend to be smaller, more symptomatic, and have worse symptomatic outcomes to prostatectomy
Location of BPH nodules	Adenomas which occurring predominantly in central transitional and periurethral zones of the prostate, predispose to prostatic urethra compression. Adenomas in the median lobes may compress the bladder base without causing BOO.
Fibroelastic properties of prostate capsule	Altered compliance may increase urethral compression in the absence of mechanical BOO.
$\alpha$ -Adrenergic innervation of prostate	Increased number of $\alpha$ -adrenergic receptors promotes smooth-muscle contraction.
Variability in detrusor muscle structure and function	Detrusor contractility can be affected by BPE/BOO-associated increased connective tissue infiltration; smooth-muscle hypertrophy and disintegration; decreased autonomic neuronal number; and conversion from predominantly $\beta$ -adrenergic (inhibitory) to $\alpha$ -adrenergic (stimulatory) responsiveness.
Detrusor overactivity	Detrusor overactivity (DO) is found in about two-thirds of men with BOO. Causality unclear as DO occurs in normal asymptomatic older men and women. DO resolves in up to two-thirds of men after TURP, yet tends to persist in the very elderly.
Atherosclerotic disease	May cause detrusor ischemia leading to impaired contractility, and acute BOO from prostate infarction.

BPH, benign prostatic hyperplasia; BPE, benign prostatic enlargement; BOO, bladder outlet obstruction; LUTS, lower urinary tract symptoms; TURP, transurethral resection of the prostate.

polyunsaturated fats), diabetes, high insulin levels, obesity, low high-density lipoprotein levels, and arteriovascular disease. Vasectomy is not a risk factor and the data on smoking are inconclusive.

## NOCTURIA

Nocturia is defined as voiding at least once during the normal hours of sleep. As many as 80% of older men have nocturia, which is the most bothersome of all of the LUTS associated with benign prostate disease. The three main causes of nocturia are LUT pathophysiology, nocturnal polyuria, and sleep disturbance (Table 50-2). The latter two causes are especially important in older men because of the many age-related changes, comorbid conditions, and medications that can cause them.

Nocturnal polyuria is defined as the excretion of one-third or greater of the daily (24-hour) urine output during normal sleeping hours. Older persons are prone to nocturnal polyuria, possibly

caused by higher nocturnal atrial natriuretic peptide levels and/or altered secretion of vasopressin. Some older person may excrete 50% or more of their 24-hour urine output during the night. For this reason, one episode of nocturia is considered normal in older persons and even the best treatment may not be able to completely eliminate nocturia. Another cause of nocturnal polyuria is peripheral edema (Table 50-2); edema fluid mobilizes when the patient reclines, leading to increased urine output. Sleep apnea is an underappreciated cause of nocturnal polyuria; apnea should be suspected when the patient or his partner report loud snoring, apneic periods, excessive daytime sleepiness, and morning headaches, and in men who are obese and/or have hypertension.

When aroused owing to primary sleep disorders, patients may sense their bladder volume (which tends to be higher at night) and get up and void, and report these episodes as “nocturia.” Common causes of sleep disturbance in older persons include age-related changes in sleep architecture (see Chapter 55); pain (e.g., from arthritis), depression, restless leg syndrome, gastric reflux, pulmonary and cardiac diseases, dementia, and the effects of many medications.

**TABLE 50-2**

### Causes of Nocturia

1. Nocturnal polyuria
  - a. Age-related delay in urine excretion
  - b. Fluid intake
    - i. Late afternoon and evening intake
    - ii. Caffeine
    - iii. Alcohol
  - c. Peripheral edema
    - i. Venous insufficiency
    - ii. Congestive heart failure
    - iii. Medications
      1. Gabapentin
      2. Pregabalin
      3. Thiazolidinediones
      4. Nonsteroidal anti-inflammatory agents
      5. Pyridine calcium blockers (e.g., nifedipine)
  - d. Medical conditions
    - i. Obstructive sleep apnea
    - ii. Uncontrolled diabetes mellitus
2. Sleep disturbance
  - a. Insomnia
  - b. Depression
  - c. Congestive heart failure
  - d. Obstructive sleep apnea
  - e. Pain (e.g., arthritis)
  - f. Restless leg syndrome
  - g. Medications
    - i. Stimulants
    - ii. Beta-blockers
    - iii. Steroids
    - iv. Thyroxine
    - v. Selective serotonin reuptake inhibitors antidepressants
    - vi. Withdrawal from alcohol, narcotics, benzodiazepines
3. Lower urinary tract dysfunction
  - a. Decreased functional bladder capacity
    - i. Detrusor overactivity
    - ii. Increased postvoiding residual volume
      1. Impaired contractility
      2. Outlet obstruction

## EVALUATION

Benign prostate disease maybe asymptomatic, but most commonly presents with LUTS; other symptoms include urinary retention, recurrent urinary tract infections, or hematuria (from prostatic varices). Table 50-3 lists the recommended evaluation in men

**TABLE 50-3**

### 2006 American Urological Association Guideline on the Management of Benign Prostatic Hyperplasia

#### *Recommended Evaluation of LUTS Suggestive of BPH*

1. Medical history should be done to identify other causes of voiding dysfunction or comorbidities that may complicate treatment.
2. A physical examination, including both digital rectal examination and a focused neurological examination, should be performed.
3. Urinalysis should be performed by dipstick or microscopic examination of the sediment to screen for hematuria and infection.
4. Measurement of prostatic specific antigen should be offered to patients (1) with at least a 10-year life expectancy and for whom a diagnosis of prostate cancer would change management, or (2) for whom the PSA measurement may change the management of their voiding symptoms.
5. The AUA Symptom Index should be used for the initial assessment of each patient.

#### *Optional Components*

1. Other validated measures of the frequency or severity of LUTS, symptom bother, interference with daily activities, urinary continence, sexual function, or general or disease-specific measures of quality of life.
2. Urine cytology may be considered in men with a predominance of urgency, frequency and nocturia, especially with a history of smoking or other risk factors for bladder carcinoma in situ and bladder cancer.
3. Following the initial evaluation, measurement of postvoiding residual (PVR) and urine flow rate maybe appropriate. They are usually not necessary in men managed with watchful waiting or medical therapy. However, they may be helpful in patient with a complex medical history or prior failure of BPH therapy, and in those desiring invasive therapy.

*Adapted from AUA Guideline on the Management of Benign Prostatic Hyperplasia, 2006 Update. Chapter 1: diagnosis and treatment recommendations. Available at: <http://www.auanet.org/guidelines/bph.cfm> Accessed June 27, 2007.*

TABLE 50-4

## American Urological Association Symptom Index

<b>1. Incomplete emptying:</b> Over the past month, how often have you had the sensation of not emptying your bladder completely after you finished urination?						
Not at all	Less than 1 time in 5	Less than half of the time	About half of the time	More than half of the time	Almost always	Your score
0	1	2	3	4	5	
<b>2. Frequency:</b> Over the past month, how often have you had to urinate again less than 2 hours after you finished urinating?						
Not at all	Less than 1 time in 5	Less than half of the time	About half of the time	More than half of the time	Almost always	Your score
0	1	2	3	4	5	
<b>3. Intermittency:</b> Over the past month, how often have you found that you stopped and started again several times when you urinated?						
Not at all	Less than 1 time in 5	Less than half of the time	About half of the time	More than half of the time	Almost always	Your score
0	1	2	3	4	5	
<b>4. Urgency:</b> Over the past month, how often have you found it difficult to postpone urination?						
Not at all	Less than 1 time in 5	Less than half of the time	About half of the time	More than half of the time	Almost always	Your score
0	1	2	3	4	5	
<b>5. Weak stream:</b> Over the past month, how often have you had a weak stream?						
Not at all	Less than 1 time in 5	Less than half of the time	About half of the time	More than half of the time	Almost always	Your score
0	1	2	3	4	5	
<b>6. Straining:</b> Over the past month, how often have you had to push or strain to begin urination?						
Not at all	Less than 1 time in 5	Less than half of the time	About half of the time	More than half of the time	Almost always	Your score
0	1	2	3	4	5	
<b>7. Nocturia:</b> Over the past month or so how many times did you get up to urinate from the time you went to bed until the time you got up in the morning?						
None	1 time	2 times	3 times	4 times	5 times	Your score
0	1	2	3	4	5	

## ADD UP THE SCORES FOR THE TOTAL AUA SCORE =

**Quality of Life Due to Urinary Symptoms:** If you were to spend the rest of your life with your urinary condition just the way it is now, how would you feel about that? (circle)

Delighted      Pleased      Mostly Satisfied      Mixed      Mostly Dissatisfied      Unhappy      Terrible

Adapted from Barry MJ, et al. The American Urological Association symptom index for benign prostatic hyperplasia. *J Urol.* 148:1549–1557, 1992.

presenting with LUTS suggestive of benign prostate disease from the American Urological Association (AUA) 2006 Guideline on the Management of Benign Prostatic Hyperplasia. The sections below highlight aspects of the evaluation especially relevant to older men.

## History

The evaluation of older men with LUTS closely parallels that of older persons with urinary incontinence (UI; see Chapter 59). The history should include the onset, progression, and associated factors for the common LUTS (slow stream, urgency, nocturia, etc.), and quantification of LUTS using the AUA Symptom Index (see below). Distinguishing between “irritative” and “obstructive” LUTS is not useful, because the terms are poorly specific and does not correlate with symptom bother, severity, or physiologic measures. Older men always should be evaluated for causes of LUTS other than prostate disease. The history and review of systems should question patients about hematuria, dysuria, and pelvic pain (rare in benign prostate disease, more suggestive of infection, bladder stone, prostate or bladder cancers); episodes of urinary retention; cardiac symptoms (regarding possible congestive heart failure in patients with nocturia); bowel and sexual function; type and amount of fluid intake (in relationship to frequency and nocturia symptoms); and sleep disturbance. All medications (including nonprescription drugs) must be reviewed, with a focus on drugs that can decrease detrusor contractility (anticholinergics, calcium channel-blockers), diuretics,

drugs that can cause pedal edema (see Table 50-2), and  $\alpha$ -adrenergic agents.

## American Urological Association Symptom Index

The American Urological Association Symptom Index (AUASI) quantifies the severity of BPH-associated LUTS on a scale 0 to 35; scores of 0 to 7 indicate mild symptoms, 8 to 19 moderate, and 20 to 35 severe (Table 50-4). An additional question, not tallied in the total score, assesses disease-specific quality of life impact. The similar International Prostate Symptom Score (IPSS) is widely translated and identically scored. A change in AUASI of  $\pm 5$  points has an 80% probability of indicating a true clinical change. The threshold for clinical change varies with symptoms severity (minimum perceptible difference is 2 points for AUASI <20 and 6 points for AUASI  $\geq 20$ ). Any magnitude of change, however, may be caused by interval changes in comorbidity and medications and not prostate disease.

## Other Measures of LUTS and Quality of Life

There are a variety of other measures of LUTS and their impact. Some of the more widely used are the International Consultation on Incontinence Questionnaire (ICIQ) male module (ICIQ-MLUTS) and the BPH Impact Index. To assess sexual function, the Derogatis Interview for Sexual Functioning-Self Report and the International Index of Erectile Function can be used. Depending on the patient's symptoms, other potentially useful scales are the Incontinence

Impact Questionnaire and ICIQ Urinary Incontinence Short Form; and UI-specific and general quality of life measures e.g., ICIQ-LUTSqol, Urogenital Distress Inventory, Urge Impact Scale, SF-12.

The impact of LUTS on quality of life is critical to evaluate because it is the primary determinant of treatment. Quality-of-life impact may include interference with daily activities, work, sleep, and sexual function; worry, embarrassment, and impaired self-esteem; and physical discomfort. Patients' perception of bother may be independent of LUTS severity, and bother from an individual symptom may be more important than from all symptoms. Determining a patient's most bothersome symptom can help target evaluation and treatment; for example, nocturia is often extremely bothersome, yet many prostate-specific treatments are not very effective for it.

### Physical Examination

Given the many medical causes of LUTS in older men a complete physical examination is required and should include evaluation of cognition, function, and mobility. The neurological examination should include the bulbocavernosus reflex, anal wink, and perineal sensation to assess sacral nerve integrity. Digital rectal examination (DRE) should be done to assess prostate nodularity, rectal tone, masses, and stool impaction. DRE is not accurate for assessing prostate volume, even when performed by specialists, because BPH adenomas can occur in the anterior and median lobes that are inaccessible to rectal palpation. Prostate volume is not associated with BOO, and is important only for decisions regarding surgical approach for prostatectomy. Although higher volume is associated with disease progression, it should not be routinely assessed for this purpose because accurate measurement requires ultrasound.

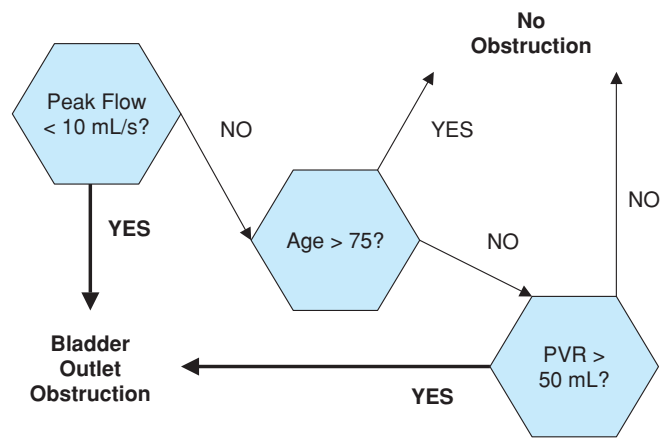

### Laboratory Tests

Only urinalysis is needed in routine assessment. As noted in the AUA guideline, PSA should be offered *only* to men with at least a 10-year life expectancy, or for whom PSA measurement and/or a diagnosis of prostate cancer would change management (see Chapter 96). Serum creatinine is not required because of the extremely low prevalence of renal insufficiency in men with LUTS. Vitamin B-12 level may be considered in men with a high PVR because of the association of vitamin B-12 deficiency with peripheral neuropathy and detrusor underactivity.

### Postvoiding Residual and Urine Flow Rate

PVR is not needed in the initial evaluation, especially in men with mild-moderate LUTS who can be managed with watchful waiting or medical therapy. PVR is small in randomly selected community men (75th percentile, 35 mL). In a large trial of men with moderate LUTS, the baseline mean PVR was  $110 \pm 74$  mL. PVR correlates modestly with prostate volume, but is not significantly associated with age, AUASI, quality-of-life indices, BOO, or the need for invasive therapy.

PVR should be considered in men with coexistent neurological disease, impaired renal function, bladder-suppressant medications (anticholinergics, opiates, calcium channel-blockers), or who have failed empiric therapy. Inability to pass a urethral catheter for PVR measurement is more likely a result of sphincter spasm than BOO;

**FIGURE 50-5.** Algorithm for the clinical diagnosis of bladder outlet obstruction in older men with LUTS. PVR, postvoiding residual volume. Adapted from DuBeau CE, Yalla SV, Resnick NM. Improving the utility of urine flow rate to exclude outlet obstruction in men with voiding symptoms. *J Am Geriatr Soc.* 46:1118–1124, 1998.

this can be overcome using intraurethral lidocaine jelly and patient relaxation. Older men tend to have a larger PVR in the morning, which can increase within-patient PVR variability.

Urine peak flow rate measurement is commonly used in urologic practice, but is not routinely required. Low urine flow rates result from either impaired detrusor contractility, BOO, and/or a low bladder volume. Peak flow rate is very sensitive for BOO (peak flow  $> 12$  mL/s with voids  $\geq 150$  mL excludes BOO), but low flow rates are nonspecific. PVR, peak flow rate, and age can be combined in an algorithm to diagnose BOO with a sensitivity of 90% (vs. 55% for flow rate alone) and specificity of 43% (63% in men aged  $> 75$  years) (Figure 50-5).

### Bladder Diaries (Frequency–Volume Charts)

Although not specified by the AUA guideline, bladder diaries can be very helpful to determine if polyuria contributes to frequency and/or nocturia symptoms (Table 50-5). To complete the diary, the patient records the time and volume of all voids (continent and incontinent). Several studies (albeit primarily in women) confirm that bladder diaries are reliable and valid, especially when done for 3 days.

### Specialized Testing

#### Urodynamic Studies

Urodynamic studies are not needed in the initial evaluation of men with LUTS, especially for those manageable with watchful waiting or medical therapy. Even for men considered for surgery, the AUA guideline considers urodynamics, cystoscopy, and prostate ultrasound optional. Urodynamics should be considered: (1) for frail older men (especially those with Parkinson's disease or spinal cord injury) who desire surgical treatment, in order to exclude conditions such as detrusor hyperactivity with impaired contractility; and (2) for men who have failed empiric therapy and further management is desired. The urodynamic tests to evaluate LUTS are cystometry and pressure-flow study. Cystometry measures bladder pressure during

TABLE 50-5

## Use of a Bladder Diary in the Evaluation of LUTS and Nocturia

DATE	TIME	VOLUME VOIDED (mL)	ARE YOU WET OR DRY?	AMOUNT OF LEAKAGE	COMMENTS
4/5	3:05 pm	240	Dry		
	6:10 pm	210	Dry		Beer with dinner
	8:15 pm	150	Dry		
	10:20 pm	150	Dry		
	10:30 pm	45	Dry		Went to bed
4/6	3:15 am	270	Wet	Tablespoons	
	5:50 am	300	Dry		
	7:40 am	120	Dry		Coffee
	9:50 am	60	Dry		
	11:20 am	90	Dry		
	12:50 pm	120	Dry		
	1:40 pm	120	Dry		
	3:35 pm	90	Dry		
	6:00 pm	90	Dry		
	8:40 pm	215	Dry		
10:25 pm	180	Dry		Went to bed	
4/7	1:00 am	240	Dry		
	3:50 am	400	Dry		Almost didn't make it
	5:20 am	200	Dry		
	8:00 am	180	Dry		Coffee
	11:15 am	90	Dry		
	4:00 pm	120	Dry		

Bladder diary of 75-year-old man with LUTS and bothersome nocturia. Shaded portions are the nighttime urine output (from time of sleep up to and including first morning void). The diary demonstrates nocturnal polyuria ranging from 720 to 1200 mL. On 4/6, nocturnal polyuria constituted 60% of the 24-hour urine output (1200/[1200 + 785]). The diary also demonstrates the common finding of lower voided volumes during the day compared tonight (60–240 mL vs. 45–400 mL). Even with the higher functional bladder volume at night, the volume of polyuria insures that he would have to awaken to void at least three times (1200 mL/400 mL = 3 voids). Thus, the evaluation of this patient should first focus on possible non-LUT causes of nocturnal polyuria.

Adapted from DuBeau CE, Resnick NM. Evaluation of the causes and severity of geriatric incontinence: a critical appraisal. *Urol Clin N Amer*, 18:243–256, 1991.

filling to determine detrusor stability (vs. overactivity), contractility, and compliance. The standard for diagnosing BOO is pressure-flow study, which simultaneously measures flow rate versus bladder pressure during voiding.

### Other Tests

Cystoscopy is needed only in men with hematuria (especially those with risk factors for bladder carcinoma such as smoking), positive cytology, or pelvic pain; it should not be used to diagnose BOO. Renal ultrasound may be considered in men with new renal impairment, yet even in this group, hydronephrosis is usually only found in men with PVR >150 mL.

## MANAGEMENT

### Making Treatment Decisions

Treatment decisions must be patient-centered because benign prostate disease has variable impact on patients and only a small absolute risk of morbidity. No treatment prolongs life or guarantees durable cure, and watchful waiting and lifestyle changes provide relief with little risk for many men. Only the small minority of men with hematuria, significant renal impairment, hydronephrosis, re-

current urinary tract infections, retention, and large PVR (e.g., over 200 mL) require immediate referral to a urologist. Issues to discuss in making management decisions include symptom severity and quality of life impact; their risk for disease progression; preferences for immediate versus delayed symptom improvement; likely treatment outcomes and adverse effects; short- and long-term costs; and ability to comply with long-term monitoring. Providers should offer guidance in tailoring treatment so that men are supported in—and not burdened by—decision making. There are video and print decision aids to help both patients and providers weigh treatment risks and benefits. Men with nocturia should be offered prostate-specific medical and invasive therapy *only* after treatment of any contributing polyuria and/or sleep disturbance.

Multiple medical problems, frailty, and short life expectancy need not preclude treatment of benign prostate disease. The broad range of available therapies permits tailoring to the desired immediacy of symptom relief, avoidance of specific adverse effects, and patient comorbidity. Noninvasive treatment is possible in care settings where adequate clinical monitoring and medication adjustment are possible. Assisted-living residents will require either community or in-patient skilled nursing after surgical interventions. Across settings, surgery may not be desirable for men at high risk for in-hospital functional and cognitive decline.

Treatment decisions of course include the efficacy, durability, and associated adverse effects of therapy. Table 50-6 summarizes outcomes for the major therapies based on meta-analyses and

systematic reviews. Figure 50-6 shows the suggested treatment algorithm.

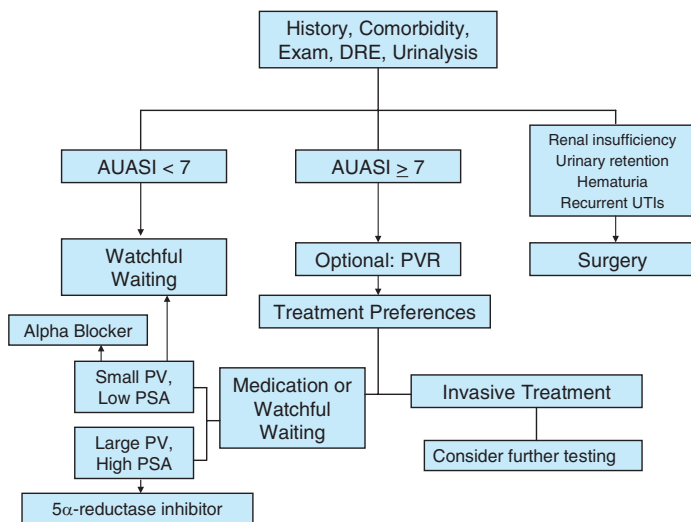

## Nonpharmacological Management

### Watchful Waiting

The natural history of benign prostate disease and the large placebo effects seen in randomized controlled treatment trials support the use of watchful waiting as a specific intervention. Men most appropriate for watchful waiting have mild to moderate LUTS, are comfortable with this approach, and can be reliably followed. Clinicians should be “watchful” and not passive in following these patients, with regular follow-up, instruction in voiding hygiene, and behavioral approaches to decrease LUTS (see Chapter 59), counseling to avoid medications that can cause retention (e.g., over-the-counter “cold” tablets containing  $\alpha$ -agonists and antihistamines), and careful monitoring for men on anticholinergics or calcium channel-blockers.

Unhurried voiding without straining may help with bladder emptying. Addition of an afternoon loop diuretic may help reduce nocturia in men with nocturnal polyuria if other approaches have failed. A pilot study of the efficacy of a patient self-management program comprising education and reassurance, lifestyle modifications, and behavioral interventions was encouraging, and results of a randomized trial are forthcoming.

In the largest randomized trial of watchful waiting versus transurethral resection of the prostate (TURP) ( $n = 556$  men with moderate LUTS), TURP had significantly greater symptom improvement at 3 years yet the watchful waiting results were not trivial (mean decrease in symptom score 66% and 38%, respectively). One-third of men on watchful waiting crossed-over to TURP, but absolute failure rates with watchful waiting were low (urinary retention 2.9%, PVR >350 mL 5.8%, worsening LUTS 4.3%). There were no significant differences in sexual function, general well-being, or social activities. The improvement in LUTS was less in men with the least symptom bother, especially after TURP. In the Medical

**FIGURE 50-6.** Algorithm for treatment of symptomatic BPH. PVR, postvoiding residual volume; UTI, urinary tract infection; AUASI, American Urological Association Symptom Index; PV, prostate volume; PSA, prostatic-specific antigen. (Adapted from the American Urological Association Guideline on the Management of benign prostatic hyperplasia [BPH]; Marberger M. *Drug insight: 5 $\alpha$ -reductase inhibitors for the treatment of benign prostatic hyperplasia.* *Nat Clin Pract Urol.* 3:495–503, 2006.)

Therapy of Prostatic Symptoms (MTOPS) trial, only 17% of men in the placebo (watchful waiting) arm had “clinical progression” at 4 years, and 80% of these cases were considered “progression” because of AUASI increase of  $\geq 4$  points.

## Medications

### Alpha-Adrenergic Blockers

Alpha<sub>1</sub>-selective adrenergic blockers reduce BPH-related LUTS by several proposed mechanisms: decreased contractility of prostatic tissue, capsule, and urethra; increased apoptosis caused by higher levels of tumor growth factor- $\beta$ ; and improved vascular flow to the detrusor. Currently available agents are prazosin (1 to 2 mg twice daily), terazosin (2 to 10 mg daily), doxazosin (4 to 8 mg daily), tamsulosin (0.4 to 0.8 mg daily), and alfuzosin (10 mg daily). Time to onset of action is 2 to 4 weeks. Randomized controlled trials show no significant differences in LUTS reduction between these agents. Efficacy is greater in men with more severe LUTS, and appears durable, although most long-term data are from open label trials. Alpha-blockers do not prevent urinary retention and are not very effective in reducing nocturia.

Side effects most commonly include asthenia, headache, dizziness, and more significantly orthostatic hypotension; all are more prevalent with higher doses. For all of the agents, withdrawal rates in published trials are 10% to 15%, and may be higher in clinical practice. Tamsulosin is the only agent selective for the  $\alpha_{1A}$ -receptor and the only one associated with retrograde ejaculation and a high risk of intraoperative floppy iris syndrome during cataract surgery. To prevent the latter complication, special surgical approaches are necessary and men taking tamsulosin should alert their ophthalmologist. The impact of stopping tamsulosin preoperatively is unclear, as some cases occurred months after discontinuation. Tamsulosin also has the lowest risk of orthostatic hypotension. Alfuzosin should be taken within 1 hour of a meal to maximize bioavailability. Terazosin

and doxazosin have significantly higher rates of dizziness, orthostasis, and treatment withdrawal than tamsulosin. Orthostatic hypotension is more likely in men with hypertension, regardless of any hypertension treatment. Slow titration from minimal starting doses and nighttime dosing help mitigate first-dose hypotension. Alpha blockers should *not* be used as first-line antihypertensive agents in men with LUTS and hypertension. Men with diastolic dysfunction or taking other antihypertensives need to be carefully monitored, and men treated with doxazosin especially should be monitored for congestive heart failure. Concomitant use of phosphodiesterase type 5 inhibitors for erectile dysfunction can cause potentially dangerous hypotension with all alpha blockers except tamsulosin.

### 5- $\alpha$ Reductase Inhibitors

The 5- $\alpha$  reductase inhibitors (5- $\alpha$ RI) finasteride and dutasteride decrease prostate size by blocking the 5- $\alpha$  reduction of testosterone to dihydrotestosterone, the active androgen for prostate growth. 5- $\alpha$ RI decrease prostate volume over 6 months by a maximum of 30%. 5- $\alpha$ RI have a slow onset of action, with no significant decrease in LUTS until 6 to 10 months; they should not be used when men want rapid symptom improvement or life expectancy is short. Lifetime use is necessary to prevent recurrent BPE and LUTS, raising the potential for higher lifetime treatment costs. In one study, finasteride was more cost-effective for men with moderate LUTS than watchful waiting (up to 3 years) and TURP (up to 14 years), but cost-effectiveness decreased over time.

The PLESS trial (Proscar<sup>®</sup> Long-term Efficacy and Safety Study) established the disease-modifying effects of 5- $\alpha$ RI in men with moderate to severe LUTS and BPE. Finasteride decreased the incidence of AUR (absolute risk reduction [ARR] 5% [95% CI 10–5%], number needed to treat [NNT] 26–49), and prostatectomy (ARR 4% [95% CI 7–3%], NNT 18–31). Risk reduction was apparent by 1 year and was greatest in men with large glands (prostate volume > 58 mL and/or PSA  $\geq 1.4$  ng/mL). Sexual dysfunction with finasteride was 8% greater than placebo (absolute difference).

Although 5- $\alpha$ RI maintain or even increase serum testosterone levels, they can cause adverse sexual effects including decreased libido (6%) and impotence (8%). A subanalysis of PLESS found no effect of finasteride on bone density over 4 years. Finasteride decreases PSA levels by 40% to 60% in the first year. When prostate cancer screening is appropriate for men given 5- $\alpha$ RI, PSA should be monitored and if it remains stable or rises, biopsy is necessary. In the Prostate Cancer Prevention Trial, finasteride lowered prostate cancer rates (25% relative reduction, 20% absolute), but high-grade tumors more common (37% vs. 22% with placebo). Considerable debate continues about the implications of this finding for long-term 5- $\alpha$ RI treatment, but results from a forthcoming similar trial with dutasteride may provide more answers.

### Combination Therapy

Because of their different mechanisms of action, combination treatment with alpha-blockers and 5- $\alpha$ RI have the potential for additive benefit. The pivotal Medical Therapy of Prostate Symptoms (MTOPS) study randomized nearly 3000 men with moderate LUTS to placebo, doxazosin, finasteride, or both with a mean follow-up of 4.5 years. The primary outcome was “clinical progression,” not LUTS reduction. At 1 year, only doxazosin (alone or in combination)

was significantly more effective than placebo, but at 5 years, finasteride was more effective than doxazosin, and combination therapy more effective than either finasteride or doxazosin alone (albeit with high withdrawal rates and adverse effects). Men with baseline prostate volume >40 mL and/or PSA >4 ng/mL benefited the most from combination therapy. Disease progression was associated with rising PSA and prostate volume during the trial in men on placebo or doxazosin, but not finasteride or combination therapy. The Symptom Management After Reducing Therapy (SMART) trial evaluated whether the efficacy of short-term combination therapy could be maintained with a 5- $\alpha$ RI alone. After 24 weeks of dutasteride  $\pm$  tamsulosin, stopping tamsulosin caused increased symptoms only for men with severe baseline LUTS. Additional data will come from the CombAT trial (Combination of Advodart<sup>®</sup> and Tamsulosin), which will follow men at high risk for progression over 4 years.

Another approach combines alpha blockers with antimuscarinic bladder relaxants for men with more severe frequency, urgency, and/or urge UI. In a 12-week trial of tamsulosin and extended-release tolterodine, ( $n = 979$ , 25% aged  $\geq 70$  years) 80% of men on combined therapy had subjective improvement, versus 71% with tamsulosin alone, 65% with tolterodine, and 62% with placebo. AUR occurred in only 3 men on placebo, 2 on tolterodine, and 2 on combination therapy. Other studies have demonstrated the safety of using antimuscarinic agents in men with LUTS.

### Phytotherapy

Plant-derived compounds that have been used to treat BPH-related LUTS, especially outside of the United States, include saw palmetto,  $\beta$ -sitosterols, and cernilton. Most phytotherapy trials suffer from short-term treatment (typically 4 to 24 weeks) and lack of standardized preparations. Although a Cochrane systematic review concluded that saw palmetto significantly improved LUTS and decreased nocturia, in a recent 1-year trial saw palmetto had the same AUASI and quality of life outcomes as placebo among men with moderate to severe LUTS. Cochrane meta-analyses also have concluded that  $\beta$ -sitosterols and cernilton significantly reduce LUTS, but the source trials were heterogeneous and small. Phytotherapeutic agents have few reported side effects, but long-term data are lacking.

### Emerging Therapies

Several agents that act on neurotransmitters and trophic factors other than alpha adrenergic systems and androgens are under active investigation. In early trials, phosphodiesterase type 5 inhibitors decreased LUTS but did not affect flow rate, and intraprostatic injection of botulinum toxin-A decreased prostate size. There are no data yet on effect size and duration, impact on other outcomes and disease progression, and adverse effects. A randomized trial of the calcitriol analog BXL-353 is underway.

## SURGERY

### Transurethral Resection of Prostate

TURP remains the standard surgical treatment for benign prostate disease because it has the best evidence for robust and durable symptom improvement. The advent of new surgical and minimally in-

vasive procedures has not diminished its central role. The absolute indications for TURP are high grade BOO, urinary retention (medical causes excluded), recurrent urinary infections, hydronephrosis, recurrent hematuria, and renal impairment. These indications account for nearly one-third of all TURPs, and for 50% to 60% of operations in men older than age 80 years.

TURP is superior to watchful waiting in preventing worsening LUTS, elevated PVR, and AUR over 5 years (10% vs. 21%, NNT 9). Men with urodynamically demonstrated BOO have the best symptomatic outcomes, but quality of life improves only in men with severe LUTS. Efficacy declines over time, from 87% decrease in LUTS at 3 months to 75% at 7 years, and reoperation rates average 1% per year. Symptom reduction tends to be lower in older men (<80%). It has been difficult to demonstrate the cost-effectiveness of TURP in the United States because of the marked geographic variability in operation rates, charges, and length of stay. Whether TURP prevents late detrusor decompensation from BOO is unclear, and the true proportion of men at risk is unknown.

Adverse effects of TURP include retrograde ejaculation (74%); erectile dysfunction (14%, and increases with age); immediate surgical complications (12%); UI (5%); bleeding requiring transfusion (2%); failure to void; and infection. In one trial, there was no difference in erectile dysfunction and UI rates between TURP and watchful waiting. Men over age 80 years have higher rates of complications (early 30% to 40%, late 13% to 22%), reoperation (4% per year), and perioperative mortality (2% to 3% vs. 0.4%); but no change in long-term survival. Many of the studies in elderly men, however, did not adjust for increased comorbidity.

### Laser Prostatectomy

Laser surgery has the advantage of being an outpatient procedure, with outcomes similar to TURP. In one randomized controlled trial, TURP was superior to noncontact lasers in improving LUTS and quality of life at 7 months, but outcomes were equivalent at 1 year. The sole 5-year study found higher reoperation rates with laser (38%) despite a TURP reoperation rate (16%) higher than nearly any other study. Laser procedures require longer postoperative catheterization and cause more infections and urethral irritation than TURP. Side effects vary by technique, and can include impotence, retrograde ejaculation, increased urgency and frequency, UI, and bladder neck stricture.

Several laser systems are available, and some have already been abandoned for lack of efficacy. Holmium laser enucleation of the prostate (HoLEP) is mainly used for men with AUR with significant BPE. It provides results similar to TURP with less bleeding and shorter recovery time, but the technique can be more difficult to learn. Initial studies suggest that HoLEP may produce more durable results than other laser surgeries. Photoselective vaporization of the prostate also has similar efficacy as TURP, with less bleeding and a shorter recovery; it appears to work better for smaller prostates. Transurethral evaporation of the prostate is used less frequently. Because of poor efficacy and high adverse events, Ng:YAG lasers (used in visual laser ablation of the prostate, contact laser ablation, and interstitial coagulation systems) are seldom used today.

### Open Prostatectomy

Men with very large prostate volume (>60 mL) require open prostatectomy (via an abdominal or perineal approach) because the

operative time needed for TURP in these cases significantly increases perioperative complications. Open procedures account for  $\leq 5\%$  of prostatectomies, and some surgeons prefer to perform an “incomplete” TURP to avoid the morbidity of abdominal or perineal surgery. In retrospective studies, open prostatectomy has lower reoperation rate and mortality than TURP, but these analyses did not adequately control for the higher age and comorbidity in TURP patients or the secular trend of decreasing TURP mortality.

## Minimally Invasive Procedures

### Prostate Incision

Transurethral incision of the prostate (TUIP) is a technically simpler procedure used in men with small glands ( $< 30$  mL). TUIP is done local anesthesia with shorter operation time and less bleeding than TURP. TUIP has similar symptomatic efficacy to TURP at 1 year. In a select case series, at two years only 8% of TUIP patients had required a subsequent TURP. TUIP has the potential to be a safe and effective alternative for obstructed older men with smaller prostates who have high operative risk and have failed noninvasive treatment.

### Thermotherapy

Transurethral needle ablation (TUNA) employs transurethrally placed radiofrequency needles to heat prostate tissue, causing coagulation necrosis and a tissue defect. Symptomatic efficacy is smaller and less durable than with TURP, and no studies compare TUNA to other procedures, medical therapy, or watchful waiting. Transurethral microwave thermotherapy is a related outpatient procedure that requires repeated treatments. Symptomatic improvement is typically modest, and in short-term trials is inferior to TURP, sham procedures, and terazosin. The future of these procedures is uncertain.

### Stents

Urethral stents to facilitate voiding should be reserved for high risk patients with recurrent AUR who are unfit for surgery or for whom long-term indwelling catheterization is undesirable. Permanent absorbable stents are complicated by encrustation, pain, and infection, and failure rates run 20% to 30%. Nonabsorbable temporary stents are complicated by migration, UTI, stricture, and encrustation.

## PREVENTION

Data on risk and protective factors suggest that increased physical activity, a diet low in meat and fat and high in vegetables and

micronutrients, and moderate alcohol consumption may prevent or slow the progression of benign prostate disease. Weight loss for obese men, glycemic control in diabetes, and treatment of high cholesterol also may be important. However, there are no intervention trials to support these suggestions.

# Aging and Homeostatic Regulation

George A. Kuchel

*“Besides more or less obvious physical changes in old age, physiological investigation may reveal increasing limitation of the effectiveness of homeostatic devices which keep the bodily conditions stable.”*

Walter Bradford Cannon (1871–1945)

## BACKGROUND

Elderly patients present the clinician with many unique challenges. Many of these issues are fully discussed in chapters that address care of older adults in the context of individual organ systems and diseases (Chapters 61 to 130). However, some of the most common, debilitating and costly clinical problems seen in geriatrics are extremely challenging because they defy conventional medical wisdom by crossing traditional organ- and discipline-based boundaries. Termed “geriatric syndromes,” conditions such as frailty (Chapter 52), delirium (Chapter 53), falls (Chapter 54), sleep disorders (Chapter 55), dizziness (Chapter 56), syncope (Chapter 57), pressure ulcers (Chapter 58), incontinence (Chapter 59), and elder mistreatment (Chapter 60) are discussed individually. Nevertheless, given the central importance of these diverse conditions to the practice and science of geriatric medicine, it is also important to address their common features.

In addition to being highly prevalent in the frail elderly, geriatric syndromes also exert a substantial impact on quality of life and disability. Moreover, these are complex multifactorial conditions in which large numbers of underlying and provocative risk factors involving different organ systems interact in influencing ultimate clinical presentation, course, and outcome. These unusual features present important challenges for the clinician since the patient’s chief complaint may point away from, rather than toward, the specific pathologic condition, which actually underlies the change in health status. At times, the two processes may involve distinct and distant organs with a disconnect between the site of the underlying insult and the site highlighted by the resulting clinical symptom. For

example, when an infection involving the urinary tract precipitates delirium, it is the altered neural function in the form of cognitive and behavioral changes, which permits the diagnosis of delirium and which determines many functional outcomes.

Grouping distinct conditions together as geriatric syndromes also highlights those common features that may help in the development of innovative clinical and research strategies. One of the primary goals of geriatric medicine has been to maintain functional independence in frail older adults, addressing the common paradox of an older patient who is able to maintain usual function under basal conditions, yet decompensates when exposed to seemingly minor challenges. In fact, the clinical dilemma of a frail older adult who is at significant risk of delirium, falls, or incontinence can be restated within a homeostatic framework. Viewed in this manner, function is determined by a complex balance between underlying physiology and health; the nature, number, and intensity of the challenges being experienced, as well as overall physiological plasticity expressed as the effectiveness of relevant homeostatic mechanisms. This approach has several advantages, above all, permitting a collaborative dialogue between investigators conducting more descriptive research and those interested in the study of mechanisms.

## HOMEOSTASIS IN A HISTORICAL CONTEXT

The term homeostasis was first coined by Claude Bernard in the mid-nineteenth century and is now extensively used in the medical literature. Unfortunately, it is often forgotten that homeostasis has always referred to the body’s attempts at maintaining an internal constancy, which is required for optimal function. Far from reflecting physiologic “stasis,” effective homeostasis actually requires that all relevant compensatory mechanisms remain suitably vibrant, responsive, and well-calibrated. During the twentieth century, it became increasingly clear that overall health status, as well as many individual disease processes may impair an individual’s ability to appropriately

respond to common homeostatic challenges. The recognition that aging can also exert a measurable impact on homeostatic mechanisms came later, but is not recent, as illustrated by the 1932 quote preceding this chapter from the great physiologist Walter Cannon. Finally, in the modern era, several events have greatly impacted upon our understanding of homeostasis. In an extension of the concept of homeostasis, Yates has introduced the term homeodynamics to emphasize the concept that the resiliency of living organisms requires a dynamic interplay of multiple regulatory mechanisms rather than a constancy of the internal environment. Advances in basic research have also permitted investigators to explore homeostatic principles at the level of subcellular processes ranging from gene expression to protein turnover. Most recently, some of the limitations inherent in purely reductionist studies have led to a trend toward systems biology, emphasizing an integration of relevant homeostatic processes from the level of individual cells to tissues and organisms. Moreover, it is now possible to begin defining mechanisms in a manner which reflects the multifactorial and systemic nature of typical geriatric conditions or syndromes.

## HOMEOSTATIC REGULATION IN OLD AGE

### General Considerations

Physiological systems responsible for maintaining homeostatic regulation may control variables as divergent as body temperature, blood pressure, intracellular calcium, or serum cortisol. At the same time, even among distinct systems, it is possible to observe shared common physiological principles by which they all exert homeostatic control (Table 51-1). With these considerations in mind, a number of investigators have sought to identify unifying and preferably specific “fingerprints” by which aging affects homeostatic control within different physiologic systems.

### Systemic Patterns of Change

Homeostenosis of old age has been viewed as a diminished capacity to respond to various homeostatic challenges. Even healthy older adults may exhibit homeostenosis when exposed to a cold or hot environment, on rapidly assuming the upright posture, and while responding to an acute fluid challenge or hypovolemia. Traditionally, these deficits were attributed to a loss of physiologic reserve, an appealing, yet somewhat ill-defined concept emphasizing static (e.g., losses in neuronal numbers, declines in glomerular filtration rate) rather than dynamic explanations. In an effort to better define physiological factors responsible for the dynamic nature of stability in old age, disease, and frailty, Lipsitz has instead focused on categories of relevant complexity that decline with aging. For example, study of aged bone and brain demonstrates evidence of declining complexity in terms of trabecular or neuronal architecture. Other examples of declining complexity involve physiological processes such as narrowing of auditory frequency responsiveness, decreased long-range correlations in time series data such as blood pressure measurements, as well as increased randomness or stochastic activity in terms of cardiac intervals. It has been proposed that such alterations in dynamics of physiologic systems contribute to functional decline and frailty.

**TABLE 51-1**

### Common Features of Homeostatic Dysregulation in Old Age

CONCEPT	EXAMPLES
Homeostenosis	Diminished capacity to respond to varied homeostatic challenges such as changes in ambient temperature, orthostasis, fluid load or dehydration
Diminished physiological reserve	Increased homeostatic vulnerability as a result of a critical loss in numbers of neurons or a decline in glomerular filtration rate
Loss of complexity	Declines in bone or neuronal architecture; narrowing of hearing frequency responses or loss of long-range correlations in blood pressure readings
Enhanced variability	Greater inter- and intraindividual variability in sympathetic activity or blood pressure readings
Higher basal activity	Basal sympathetic activity is elevated in older adults
Excessive response to stressors	Sympathetic responses to common challenges are excessively large and prolonged
Diminished end-organ responsiveness	Ability of peripheral catecholamines to increase heart rate via $\beta$ -adrenergic receptors or to mediate arterial vasoconstriction via $\alpha$ -adrenergic receptors is decreased.
Loss of negative feedback	Ability of corticosteroids to downregulate activity of the hypothalamic-pituitary-adrenal system via negative feedback is diminished
Allostatic load	Increased biological burden in terms of estimates of cumulative exposure exacted by attempts to adapt to life's demands predicts future mortality, as well as declines in cognitive and physical function

However, changes in complexity should not be confused with those involving variability. These are two distinct concepts, with aging often having distinct and at times directly opposite, effects on complexity and variability. For example, aging *increases* interindividual and intraindividual variability in blood pressure measurements, while long-range correlations involving the complexity of these readings *decrease* with aging. Finally, proponents of the concept of allostatic load have used population-derived measurements (e.g., blood pressure, waist-hip ratio, cholesterol, glycosylated hemoglobin, cortisol, catecholamines, and DHEA-S) as an estimate of cumulative physiologic burden exacted on the body through attempts to adapt to life's demands.

### Alterations in Specific Homeostatic Mechanisms

In addition to systemic perspectives of homeostasis, there has also been a growing interest in uncovering specific homeostatic mechanisms that are impaired in old age. For example, markers of sympathetic activity such as peripheral norepinephrine (NE) levels are elevated in older adults under basal conditions. At the same time, a variety of different stimuli (see below) result in an elevation in

peripheral NE levels, which is both enhanced and prolonged in older adults. Another common feature is a decline in end-organ responsiveness of many, but not all, receptors to their relevant ligand in the form of a neurotransmitter or hormone. Finally, decreased tissue responsiveness translates in many cases to lessened effectiveness of negative feedback mechanisms as shown for a number of hormones, including corticosteroids.

## Reconciling Different Views of Homeostatic Dysregulation

Many different aspects of homeostatic dysregulation in old age have been emphasized in published studies, often in support of a specific concept or theory. Nevertheless, common unifying principles can sometimes be identified. For example, research conducted using simple gene circuits has shown that negative feedback loops enhance the complexity and stability of such systems, permitting more precise and rapid responses to homeostatic challenges. Thus, declines in negative feedback demonstrated for many mammalian homeostatic systems could also contribute to some of the other commonly described features of homeostatic dysregulation in old age and frailty. Moreover, a marker of “allostatic load” such as peripheral cortisol, is not only a predictor of future cognitive and functional impair-

ment, but can also contribute to neuronal cell death involving hippocampal cells involved in cognition, while also contributing to a decline in the ability of cortisol to downregulate its own synthesis and release.

## SPECIFIC HOMEOSTATIC CHALLENGES

### General Considerations

As discussed earlier, under normal basal conditions, many older adults are able to maintain their usual level of function even in the presence of a large number of health problems. However, once exposed to additional challenges, the same individuals may experience rapid and at times even catastrophic declines in their health status and functional independence. A growing understanding of normal homeostatic mechanisms has led many investigators to conduct studies evaluating the impact of aging on such responses. Table 51-2 provides an overview of our current understanding of the impact of aging on the ability to effectively respond to specific homeostatic challenges in terms of the most relevant biomarkers or physiological measurements. However, it must also be noted that aging

**TABLE 51-2**

**Impact of Aging on Physiological Responses to Specific Homeostatic Challenges**

HOMEOSTATIC CHALLENGE	SELECTED BIOMARKERS UNDER BASAL CONDITIONS	IMPACT OF AGING ON RESPONSE TO SPECIFIC CHALLENGE	CHAPTERS
“Fight or flight” challenge or mental stress	—Norepinephrine ↑ —Epinephrine N.C. —Sympathetic neural recordings ↑ —Cortisol levels N.C.	Enhanced and prolonged ↑ in norepinephrine levels, sympathetic neural activity and cortisol levels	7, 70, 107
Decreased ambient temperature	—Temperature N.C. —Metabolic rate ↓	—Sensation of cold ↓ —Shivering intensity ↓ —Thermogenesis ↓ —Vasoconstriction ↓	
Elevated ambient temperature	—Temperature N.C.	—Sweating responses ↓ —Vasodilatation ↓ —Ability to raise cardiac output ↓	
Orthostasis, meals, and hypovolemia	—Blood pressure N.C.	—Hypotension risk ↑ with frailty, comorbidity and concurrent challenges	57, 74, 88
Hyperglycemia and hypoglycemia	—Fasting glucose N.C. or small ↑	—Glucose clearance ↓ —Response to hypoglycemia N.C. or small ↓	107, 109
Fluid challenge and dehydration	—Serum sodium N.C. —Osmolarity N.C. —Osmolality N.C.	—Ability to retain Na <sup>+</sup> in salt depletion ↓ —Ability to excrete Na <sup>+</sup> in salt loading ↓	88
Bladder outlet obstruction	—Detrusor contractility mildly ↓	—Ability to raise detrusor pressure ↓ —Likelihood of detrusor decompensation with muscle degeneration and fibrosis ↑	55
Major burns and trauma		—With comorbidity favorable outcome ↓	37, 68
Altered physical activity		—Extent and speed of deconditioning ↑ —Extent and speed of gains in muscle mass and strength ↓	29, 37, 114, 115
Anticholinergic medications		—Xerostomia, cognitive problems, constipation, urinary retention ↑	8, 53, 55, 63
Antidopaminergic medications		—Rigidity, poverty of movement ↑	63, 66
Neuronal degeneration		—Compensatory neuronal plasticity ↓	61

may influence some of these measurements under basal conditions. Moreover, since some of these topics are discussed in far greater detail elsewhere in this book, relevant chapter numbers are also provided. Finally, when evaluating the large body of literature that supports the information provided in Table 51-1, several overarching principles must be kept in mind. First, while animal studies largely support results of human research, occasional discrepancies have been noted. Thus, all summary findings in Table 51-1 are based on human research. Second, clinicians deal with older adults who represent the full spectrum of health, comorbidity, disability, and frailty. Nevertheless, in order to attribute a specific physiological change to aging, it is important to make a distinction between changes that are caused by confounding illness from those associated with usual or successful aging. With these considerations in mind, most of the changes reported in Table 51-1 can be attributed to normal aging, with common geriatric illnesses often enhancing such vulnerability. In many cases, it remains unknown whether individuals who age particularly well or successfully also exhibit these changes.

### “Fight or Flight Response”

When confronted with a stressful situation, animals and humans respond in a fairly predictable fashion involving a series of predetermined responses collectively referred to as the fight or flight response. Although thought to have evolved as a response to the risk of attack by a predator, in the context of our patients, such responses are more commonly activated during mental stress for any reason (Chapter 7, Psychosocial Disorders; Chapter 70, Mood Disorders), while caring for an ill or disabled spouse (Chapter 7, Psychosocial Disorders; Chapter 65, Dementia) or during bereavement (Chapter 7, Psychosocial Disorders; Chapter 31, Dying Patient). Stress results in the activation of hypothalamic and brainstem neurons, leading to increased stimulation of sympathetic preganglionic neurons, which regulate cardiac and adrenal medullary function. Stress also promotes the release of corticotropin-releasing factor, which in turn increases ACTH release. All of these events result in both local and systemic release of corticosteroids and catecholamines, which are ultimately responsible for mediating most of the clinical features of the response to stress (Chapter 107, Aging of the Endocrine System and Selected Endocrine Disorders). The above sequence of reactions can ultimately influence a broad range of systemic functions ranging from cardiac performance, energy metabolism, as well as immune and inflammatory responses. Under basal conditions, the overall sympathetic nervous system (SNS) activity appears to increase with aging.

This basal activity increase is manifested in the form of increased sympathetic nerve activity on microneural recordings, elevated basal plasma NE, and less consistently epinephrine (E) levels, while basal cortisol levels do not appear to be altered with aging. In contrast, both systems demonstrate somewhat similar patterns of dysregulation in old age with enhanced and prolonged responsiveness following exposure to varied challenges. For example, assuming the upright posture, an oral glucose meal, insulin infusion, isometric exercise, and mental stress all result in enhanced elevation of peripheral NE levels in older subjects, while cortisol responses to surgical stress are also increased. Moreover, demonstrated deficits in terms of decreased negative feedback have been proposed as being major contributors to exaggerated SNS and hypothalamic-pituitary-adrenal (HPA) axis activation with aging. For example, the ability of clonidine or elevated blood pres-

sure to downregulate SNS activity via central nervous system (CNS)  $\alpha_2$ -receptors or baroreceptor activation, respectively, is impaired in old age. This is in addition to well-described declines in the ability of peripheral catecholamines to increase heart rate via  $\beta$ -receptors or to mediate arterial vasoconstriction via  $\alpha$ -adrenergic receptors. Similarly, the ability of circulating corticosteroids to downregulate HPA activity via hypothalamic receptors is also diminished in old age.

## Lowered Ambient Temperature

### Epidemiology

Older adults are less able to adjust to extremes of low temperature. Hypothermia has historically received greatest attention in the United Kingdom, at least in part as a result of a tendency to maintain lower indoor ambient temperatures in the winter than is the custom in the United States. Some of this earlier British literature described hypothermia among 3.6% of individuals 65 years and older admitted to the hospital, with nearly 10% of community-dwelling older adults found to demonstrate evidence of borderline hypothermia. Nevertheless, recent literature has demonstrated a significant prevalence of hypothermia in North America. U.S. CDC statistics point to the fact that hypothermia-related deaths may also occur in sunbelt states and illustrate the importance of advanced age, chronic medical conditions, substance abuse, and homelessness as contributing risk factors. Moreover, a number of individual case series have highlighted the need to remain vigilant to the development of hypothermia among frail and immobile residents of air conditioned long-term care facilities. Concerns have also been raised about the role played by medications, which may enhance the risk of hypothermia.

### Pathophysiology

While basal body temperature remains unaltered with aging, older adults are less able to sense and respond to cold challenges when exposed to lowered ambient temperatures. Relevant mechanisms include a decreased sensation of cold, as well as declines in shivering intensity, thermogenesis, and vasoconstriction. Such changes may be related to both physiologic declines associated with aging or with specific diseases. For clinical purposes, hypothermia is generally defined as a body core temperature of less than 35°C (95°F), obtained using tympanic, rectal, or esophageal probes. Nonetheless, significant clinical consequences may occur outside of the boundaries of these definitions. Moreover, the development of frank hypothermia depends on a balance between the severity and length of the cold exposure and an individual subject's ability to sense and mount an effective response to such a challenge. Ultimately, aging, frailty, comorbidity, and diseases may all contribute to determining an individual's specific vulnerability.

Normal body temperature is regulated by the thermoregulatory center, which controls heat loss and heat generation by regulating sweating, blood vessel tone, as well as shivering and nonshivering (chemical) thermogenesis. Older adults demonstrate evidence of deficits in both afferent and efferent thermoregulatory pathways. For example, a diminished sensitivity to changes in environmental temperature may have both physiologic and behavioral consequences. As a result, already compromised compensatory mechanisms may be overwhelmed by the fact that older individuals may be less likely

to seek suitable shelter or clothing in the cold. Declines in shivering thermogenesis may be particularly catastrophic in older adults, given the importance of these mechanisms in normal responses to the cold. Other contributing physiological risk factors for hypothermia include deficient autonomic mechanisms with a decreased vasoconstrictor response, which is more common among older adults with orthostatic hypotension, as well as decreased ability of  $\beta$ -adrenergic stimuli to effect thermogenesis. Of course, decreases in lean body mass with a lower metabolic rate also enhance the vulnerability of older adults. Absence of fat mass may also provide frail older adults with less insulation against heat loss.

A large number of potentially reversible factors also need to be considered. For example, malnutrition, hypothyroidism, hypoglycemia, as well as immobility and decreased physical activity may all contribute to decreased thermogenesis. Medications, which have been linked to hypothermia, include alcohol, phenothiazines, barbiturates, benzodiazepines, opioids, and general anesthetics, as well as more recent antidepressants and neuroleptics. Central thermoregulatory control may also be affected by hypothalamic neural injury following anoxic, vascular, traumatic, or malignant lesions. Severe sepsis, especially in frail older adults, can occasionally overwhelm host defenses, resulting in a blunted and even paradoxical response to infection with hypothermia. The association of infection with hypothermia is generally viewed as a poor prognostic sign and is felt to reflect altered hypothalamic regulatory function. Finally, a clinician's approach to hypothermia is incomplete without an assessment of the cognitive, social, and economic factors, which may result in self-neglect, poor judgment, or lack of financial resources to provide for adequate heating.

### Clinical Presentation

Early manifestations of hypothermia may be subtle and nonspecific. Moreover, older adults may become hypothermic even without exposure to extremely cold temperatures. Thus, a high index of suspicion is essential, as is a thermometer capable of recording very low temperatures. Early hypothermia (core temperatures of 32°C to 35°C or 90°F to 95°F) can be associated with fatigue, lethargy, apathy, slow gait, slurred speech, confusion, and cool skin. Challenging the diagnosis is the nonspecific nature of these symptoms and signs, combined with the finding that some hypothermic older patients may not complain of feeling cold and may not shiver. With more advanced hypothermia (core temperatures of 28°C to 32°C or 82°F to 90°F), skin becomes cold and cyanotic, while hypopnea and altered consciousness first become apparent. Bradycardia, as well as atrial and ventricular arrhythmias, represent common cardiac abnormalities. These cardiac events, combined with volume contraction resulting from fluid redistribution, as well as cold-induced water and solute diuresis contribute to the risk of hypotension and cardiovascular collapse in these individuals. Altered consciousness may progress to coma with slowing of neurological reflexes and sluggishness of pupillary responses. Finally, with core temperatures below 28°C (82°F), individuals may be mistaken for dead since they may be unresponsive and apneic, with very cold skin, ventricular fibrillation, absent neurologic reflexes, as well as fixed and dilated pupils. Individuals who have survived early cardiovascular complications of severe hypothermia, are at risk for pneumonia, aspiration, pulmonary edema, pancreatitis, gastrointestinal hemorrhage, acute renal failure, and intravascular thrombosis. Abnormal J (Osborne)

waves may follow each QRS on the electrocardiogram (ECG). These relatively specific changes disappear as temperature returns to normal. Much less specific ECG changes include bradycardia, prolongations of P-R interval, QRS complex, and QT segment, as well as atrial fibrillation, premature ventricular contractions, and ventricular fibrillation. ECG changes may mimic those seen with acute myocardial ischemia or infarction. Finally, hypothermic individuals may also suffer from hypothyroidism. Not only do myxedema coma and hypothermia share some clinical features, but hypothyroidism may contribute to the development of hypothermia. On occasion, a history of previous thyroid disease, a surgical scar in the thyroid region, or a delay in the relaxation phase of deep tendon reflexes may provide the only clues.

### Treatment

**Emergency Care** Severe hypothermia represents a medical emergency. If outdoors, such individual need to be immediately moved away from severe cold, wet clothing must be removed and warmed blankets applied. Early cardiac monitoring is essential since even minor stimuli can trigger significant dysrhythmias. Procedures such as chest compression or pacemaker placement should be avoided as long as a heartbeat is detectable and patient is breathing spontaneously. In individuals who are asystolic or in ventricular fibrillation, resuscitation should be pursued. Since a cold heart may be relatively unresponsive to drugs or electrical stimulation, such efforts must be pursued aggressively and need to include warmed intravenous fluids (e.g., 5% dextrose normal saline without potassium).

**General Support** Severe hypothermia is associated with a mortality exceeding 50%. These figures worsen further with advanced age and with associated comorbidity. As a result, such patients require close supportive care in an intensive care unit. Such supportive care must include treatment of contributing conditions such as infection, hypoglycemia, and hypothyroidism. Clinicians need to have a high index of suspicion for infection in hypothermic older adults, administering broad spectrum antibiotics without waiting for results of confirmatory cultures. When administering thyroid hormone for suspected hypothyroidism, corticosteroids may also be required in order to avoid inducing adrenal insufficiency. While ECG monitoring is necessary, central lines should be avoided, given cardiac irritability in these subjects. Pharmacodynamic and pharmacokinetic properties of many commonly used drugs may become dramatically altered in hypothermic patients, creating therapeutic challenges. Such drugs may accumulate as metabolism is delayed and as ever increasing doses are administered because of a lack of response at lower temperatures, causing potential problems as responsiveness to accumulated doses of these medications increases during body warming. Since insulin is ineffective at temperatures below 30°C (86°F), it should not be administered at low temperatures. Volume depletion as well as hypoxemia needs to be corrected. Intubation may be required and blood gases should be monitored. Nevertheless, rewarming strategies may need to be undertaken immediately following stabilization, since cardiac arrhythmias, acidosis, fluid, and electrolyte disorders may be resistant to treatment until body core temperatures are raised.

**Rewarming** For patients who are only mildly hypothermic (core temperatures of 32°C to 35°C or 90°F to 95°F), passive rewarming

techniques using insulating materials and transfer to a warm environment generally suffice. For such individuals, active external rewarming using electric blankets, warm mattresses, hot water bottles, or warm water baths are generally not necessary. Moreover, such treatment can be associated with significant risk as warmth-induced peripheral vasodilatation may precipitate hypovolemic shock in vulnerable individuals.

For individuals in more severe hypothermia (core temperatures under 32°C or 90°F), active core rewarming becomes necessary. A variety of techniques are available, with peritoneal dialysis rewarming representing the most practical solution in most institutions. Mediastinal lavage involves a major surgical procedure, while extracorporeal circulation requires special equipment and carries risks of hypotension and heparin-induced hemorrhage. Gastric lavage using balloons filled with warm fluid is simple, yet rate of warming may be slow and pharyngeal irritation may induce arrhythmias. Peritoneal dialysis with rapid instillation and removal of warm (40°C or 104°F) potassium-free dialysate can provide for safe core warming within six to eight fluid exchanges.

## Raised Ambient Temperature

### Epidemiology

Heat stroke is a major public health problem with nearly 4780 U.S. deaths attributed to extreme heat between 1979 and 2002. Recent heat waves in the United States (e.g., Chicago) and abroad (e.g., France) have graphically illustrated the tremendous vulnerability of older adults to excessively high temperatures. Given a growing awareness of the need to be vigilant for the development of hyperthermia in institutional settings, nursing home cases have fortunately become more rare. Nevertheless, older adults living in the community, especially those who are frail, suffer from disabilities and live alone are at great risk. In addition to the risk of heatstroke, hyperthermia also contributes to excessive cardiac mortality and morbidity. Older women appear to be at a particularly high risk of dying during a heat wave.

### Pathophysiology

As in the case of hypothermia, heatstroke represents an example of homeostatic decompensation in which older adults' deficient or sluggish compensatory mechanisms are unable to maintain normal body temperature in the face of increased environmental temperature. Excess mortality in older adults during heat waves may be attributed to heat-provoked cardiac events or to primary thermoregulatory failure. In recent years, there has been a growing awareness that heatstroke is a form of hyperthermia, which is associated with an excessive systemic inflammatory response contributing to multiorgan dysfunction. Impairments of thermoregulatory systems may occur at a number of different levels and, as in the case of hypothermia, may result from aging or from associated comorbidity and diseases. Sweating responses to thermal, pharmacologic, and chemical stimuli are reduced with aging, representing a significant contributor to homeostatic decompensation by older adults faced with significant heat challenges. Moreover, older adults require higher body core temperatures before compensatory sweating mechanisms are activated. During times of heat stress, younger individuals depend on being able to increase their skin heat loss by shunting blood

flow from core toward peripheral blood vessels. In older individuals, the extent and speed of these important compensatory homeostatic mechanisms is impaired as a result of decreased cardiac output and a diminished vasodilatation of peripheral blood vessels. However, some of the above changes may also be the result of occult cardiac disease or physical deconditioning. For example, maximum oxygen uptake appears to be a much more important predictor of sweat rate and forearm flow during exercise than is chronological age. Moreover, with increased physical activity, older adults are able to improve some of these physiological responses to heat challenge toward those seen in younger individuals. Finally, as for hypothermia, presence of significant comorbidity, medications, as well as social and environmental factors may further place older adults at risk of homeostatic decompensation during heat waves. For example, decreased mobility or impaired judgment caused by dementia or psychiatric illness may keep some older adults from seeking assistance and from taking sensible precautions such as removal of heavy clothing and increasing fluid intake. Moreover, air conditioning may not be an option for individuals living on a fixed income. Common chronic conditions such as congestive heart failure, diabetes mellitus, COPD, and alcoholism further enhance the risk of heatstroke. Anticholinergic agents used for urge incontinence, depression, or behavioral problems may also contribute to hyperthermia by inhibiting normal sweating mechanisms, while diuretics may lead to hypovolemia.

### Clinical Presentation

Earliest warnings of thermoregulatory failure or heat exhaustion may be subtle and nonspecific. In addition to a feeling of warmth, such individuals may also present with a sense of lethargy, weakness, dizziness, anorexia, nausea, vomiting, headache, and dyspnea. Frank heatstroke is defined clinically as a core body temperature above 40°C (105°F) that is accompanied by hot, dry skin, and major central nervous system abnormalities, which may include delirium, convulsions, and coma. Nonneurologic multiorgan dysfunctions are also common and may include congestive heart failure, cardiac arrhythmias, hepatic necrosis, hypokalemia, respiratory alkalosis, metabolic acidosis, and hypovolemic shock. Rhabdomyolysis, disseminated intravascular coagulation, and acute renal failure may occur in older adults, but are more common in exertional heatstroke typically seen in younger athletes.

### Treatment

Heatstroke is a medical emergency, requiring prompt and aggressive therapy. Rapid cooling is essential since its pathophysiology involves thermoregulatory failure rather than a reset thermostat point. Field management must include removal of clothing, cooling the patient's skin with cold water or ice packs, and transfer to cooler setting. Cool intravenous fluids should be considered, but oral hydration may lead to aspiration. Other effective cooling techniques include ice-water baths, cold water gastrointestinal lavage, or the administration of cool water followed by warm air to promote evaporation. Irrespective of the technique chosen, speed is of the essence with careful continuous monitoring in order to prevent hypothermic overshoot. Careful fluid balance management and cardiovascular monitoring are also essential. However, given the high prevalence and mortality associated with heatstroke, preventive measures are extremely important. Above all, vulnerable older adults, as well as their families

and neighbors must be educated as regards both the seriousness of this problem and commonsense strategies, which can help reduce its toll.

### Orthostasis, Meals, and Hypovolemia

An ability to appropriately respond to the challenge of assuming the upright posture is absolutely critical to remaining independent. Under normal conditions, significant or symptomatic orthostatic hypotension is rare among healthy older adults (Chapter 57, Syncope). However, aging does blunt the ability of older individuals to defend against more major hemodynamic challenges, especially among frail individuals, in the presence of significant comorbidity and following exposure to multiple provocative factors (Chapter 88, Disorders of Fluid Balance; Chapter 74, Aging CVS). The presence of hypertension increases the risk of hypotension by decreasing baroreceptor sensitivity and ventricular compliance beyond declines observed in normal aging. Use of hypotensive medications, as well as the presence of diseases such as for example diabetes mellitus, aortic stenosis, and Parkinson's disease, are all important risk factors. Some risk factors can be synergistic as seen with a modest diuretic-induced sodium depletion, which can induce orthostatic hypotension in previously well-compensated healthy old adults. Similarly, while meal ingestion induces only negligible and asymptomatic blood pressure changes in most healthy older adults, frail elderly nursing home residents may develop symptomatic postprandial hypotension, which may even contribute to altered mental status and syncope.

### Hyperglycemia and Hypoglycemia

Aging has been shown to be associated with glucose intolerance. Even in healthy individuals who do not meet criteria for diabetes mellitus or for impaired glucose tolerance, aging is associated with a dramatic slowing in the return of glucose levels back to normal following a glucose ingestion. In contrast, most healthy older adults are able to respond adequately to hyperglycemia. Nevertheless, diabetes, malnutrition, medications, as well as a number of comorbidities may significantly attenuate older adults' ability to recover from a hypoglycemic episode (Chapter 107, Aging Endocrine System; Chapter 109, Diabetes).

### Fluid Challenge and Dehydration

When given a major water challenge, older adults tend to have greater difficulty in appropriately diluting their urine. While less well studied, declines in GFR (glomerular filtration rate) tend to compromise the ability of the aged kidney to deal effectively with a sodium load.

Difficulties with water disposal can predispose older individuals to develop hyponatremia, while decreased capacity to adapt to increased salt load may contribute to dependent edema, nocturia, hypertension, and congestive heart failure. The aged body's capacity to prevent dehydration is also affected. Aging is associated with a decreased sensation of thirst even in the setting of significant dehydration. Moreover, aging is associated with a delay in the time required for the kidney to appropriately concentrate urine in response to sodium restriction. Large numbers of medications, as well as the presence of significant comorbidity, can further enhance the clinical impact of these aging-related changes (Chapter 88, Disorders of Fluid Balance).

### Bladder Outlet Obstruction

Bladder outlet obstruction is a relatively common complication of benign prostatic hyperplasia and older men with this problem are much more likely to develop urinary retention with detrusor decompensation than are their younger counterparts. Normally, during a compensatory phase, bladder emptying is maintained with an increased bladder muscle mass, mostly caused by hypertrophy of individual muscle cells. During a subsequent decompensation phase, the bladder undergoes muscle loss, collagen infiltration, and axonal degeneration. Aging appears to increase the likelihood of detrusor decompensation, with its associated degenerative changes (Chapter 55, Incontinence).

### Major Burns and Trauma

For any given total percentage of body surface burned, advanced age contributes to a measurable decrease in survival. Such systemic vulnerability has been attributed to a combination of progressive reductions in the function of many organs, together with simultaneous reductions in varied homeostatic capabilities and functional impairments associated with specific disease states. In spite of remarkable improvements in the perioperative care of older adults, older individuals have significantly worse outcomes than their younger counterparts following burns, road traffic injuries, and head trauma. While more research is needed, this differential vulnerability may be related to the catastrophic nature of these events, as well as underlying vulnerabilities and presence of significant comorbidity (Chapter 68, Brain Trauma; Chapter 37, Surgery).

### Altered Physical Activity

Older adults are particularly vulnerable to the loss of function and the development of individual adverse events following bed rest. With immobilization, muscle mass can be lost at a rate of up to 5% a week, which together with disruptions in subcellular muscle structure, can result in losses in muscle strength, which may approach 40% by 6 weeks. When unloaded, aged muscle cells are more likely to atrophy or to degenerate via apoptotic mechanisms. Strategies, which can diminish the impact of bed rest, include opting for minimally invasive surgery whenever possible, rapid mobilization following surgery or injury, exercise, nutritional supplementation, as well as efforts to decrease offending medications and to address relevant comorbidity. Increased physical activity represents an extremely attractive option since contrary to conventional wisdom, even frail institutionalized older adults are able to benefit from exercise, experiencing significant benefits in terms of muscle mass, muscle performance, and improvements in relevant homeostatic mechanisms (Chapter 29, Rehabilitation; Chapter 114, Exercise; Chapter 115, Mobility).

### Anticholinergic Medications

While systematic literature is lacking, older adults appear to be highly sensitive to anticholinergic effects of commonly used medications including altered cognitive function, dry mouth, constipation, and urinary retention. Some of this vulnerability can be attributed to the presence of underlying disease or preclinical pathology. For example, subjects with Alzheimer's disease develop new learning deficits at lower scopolamine doses than do age-adjusted normal controls,

while the presence of detrusor underactivity predisposes older adults to develop urinary retention when treated with anticholinergic agents. However, aging in itself contributes to an enhanced anticholinergic vulnerability as shown by the presence of an augmented and prolonged inhibition of stimulated parotid flow rate in healthy older adults following exposure to an intravenous anticholinergic drug (glycopyrrolate). Increased blood–brain permeability in old age and in the setting of specific diseases has been proposed as one mechanism that could mediate an augmented vulnerability to develop cognitive or other CNS problems with anticholinergic medications. Other relevant contributing mechanisms include a decreased homeostatic capacity with declines in both numbers and complexity of relevant cellular elements, as well as an aging-associated loss in the ability of muscarinic receptors to be upregulated when exposed to anticholinergic agents (Chapter 8, Pharmacology; Chapter 53, Delirium; Chapter 55, Incontinence; Chapter 63, Psychoactive Drugs).

### Antidopaminergic Medications

Older adults often develop extrapyramidal side effects when given neuroleptic agents with potent antidopaminergic properties. Interestingly, adverse events such as acute dystonia are relatively rare in old age, while others including rigidity, poverty of movement, and tardive dyskinesia appear to be more common in old age. In many cases, early or preclinical Parkinson's disease may render individuals more vulnerable to pharmacological disruption of relevant CNS dopaminergic circuits. Moreover, aging-associated declines in numbers and function of CNS dopaminergic neurons, as well as a decreased capacity to compensate for additional losses by upregulation of dopaminergic receptors or by neuronal plasticity involving surviving dopaminergic fibers, are also likely to contribute to the loss of such homeostatic mechanisms (Chapter 63, Psychoactive Drugs; Chapter 66, Parkinson's Disease).

### Neuronal Degeneration

Past dogma has held that aging is associated with a significant, progressive, and inevitable decline in all categories of neurons. In recent years, this pessimistic view has been greatly modified with evidence of selective neuronal vulnerability, as well as dramatic demonstrations of the brain's continued plasticity throughout the lifespan. The observation that specific neurons and neural circuits are vulnerable to aging- and disease-associated declines, while others are quite resistant, has raised considerable hope for the development of physiologically sound interventions, which could help maintain normal neural function into old age. First, evidence of selective neural vulnerability raises the possibility of developing interventions designed to specifically target the most vulnerable cellular elements. Second, many decades of research have demonstrated the presence of neuronal plasticity, in particular collateral sprouting, the formation of new nerve terminals by intact nerve cells, which represents a compensatory homeostatic mechanism with the potential of maintaining normal function following declines in neural circuits, which are similar and in near proximity. Collateral sprouting involving peripheral and central nerve cells tends to decline in old age, yet the ability of modifiable factors such as hormonal levels and nerve activity or experience to influence this category of neural plasticity raises hope

for the development of effective interventions (Chapter 61, Aging Brain).

### ACKNOWLEDGMENT

GAK would like to acknowledge the contribution of Dr Itamar Abrass who authored CH. 124, Disorders of Temperature Regulation in the previous edition.

# Frailty

Linda P. Fried ■ Jeremy D. Walston ■ Luigi Ferrucci

## FRAILITY IS AT THE CORE OF GERIATRIC MEDICINE

The cornerstone, even *raison d'être*, of geriatric medicine concerns the identification, evaluation, and treatment of frail older adults and prevention of loss of independence and other outcomes for which they are at risk. The proportion of frail within the older population is high and will increase with the aging of society. A focus on frailty has been a consistent theme in geriatric theory and practice. In 1990, Fretwell stated “frailty in an individual (is) defined as an inherent vulnerability to challenge from the environment.” Because of the high-risk status of frail older adults, geriatric medicine seeks to intervene in frail patients to prevent or minimize illness and dependency. In 1992, a conference on the physiologic basis of frailty agreed that controversy on definition and limited understanding of etiology hindered preventive strategies. In 1993, W. Bortz stated that “A major threat to active life expectancy is the development of frailty. . . . Despite absence of easy categorization, there is no question as to the immense participation of frailty in both individual and composite morbidity and mortality. Recognizing this pervasive impact on well-being, it is strange to note the lack of critical insight that attends it.” Baltes and Smith observed that the oldest old, those in the “fourth age” after 85 years (in developed countries), are particularly biologically vulnerable and frail and have compromised ability to tolerate stressors. As a result, their well-being is increasingly dependent on the use of extrinsic compensations to maintain life and autonomy, because there is such diminished ability to compensate physiologically. These observations frame the conceptual understanding that aging is associated with increased likelihood of frailty, and that older persons have reduced physiological reserve than younger persons and these changes are likely independent of disease. Over the past 15 to 20 years since the statements above, we have attained increasing clarity about the definition and characteristics of frailty and its import and etiology, and a new basis for prevention and interventions. This chapter seeks to synthesize this knowledge.

Geriatric medicine has found the concept of frailty compelling for several reasons (Table 52-1). First, frail individuals are perceived to constitute those older adults at highest risk for a number of adverse health outcomes, including disability, dependency, institutionalization, falls, injuries, acute illness, hospitalizations, slow or incomplete recovery from illness and/or hospitalization, and mortality.

Additionally, they have compromised ability to tolerate hospitalization or invasive procedures and are at high risk of related complications.

Second, frail older adults are thought to be a subset in high need of health care and community and informal support services, as well as long-term care. These special needs were the main basis for the development of comprehensive geriatric assessment and creation of specific geriatric systems for care delivery as optimal clinical approaches to decreasing preventable adverse outcomes for frail older adults. The provision of care for this increasing subgroup of frail individuals is a critical clinical and public health concern. Although some decry the increased costs anticipated as the numbers of frail older adults increase, others, particularly in geriatric medicine, propose that redesign of health care delivery to optimize outcomes in these vulnerable older adults will lead to a health care system specifically tailored to chronic care delivery and, if so, less costly. The ability of the health care system to care effectively for those who are frail, and even to prevent frailty, will depend on our ability to grow a geriatrically expert, adequately sized clinical work force, and to provide appropriate economic incentives, recognizing that caring for frail older people requires exceptional skills and is extremely time-consuming.

Third, the prevalence of frailty is high, with estimates ranging from 10% to 25% of persons aged 65 years and older, with as many as 30% to 45% of those aged 85 years and older identified as frail. Such estimates are based on clinical perceptions of a notable change in vulnerability, health status, and clinical appearance with age in a substantial subset of older adults that is not explained by disease alone. These changes are often reported by family and friends of patients, as well as clinicians, when they describe the patient as

**TABLE 52-1****Frailty is at the Core of Geriatric Medicine**

1. Frail older persons are at risk for multiple adverse health outcomes, including
  - a. Medical instability
  - b. Disability, dependency
  - c. Institutionalization
  - d. Injuries
  - e. Falls
  - f. Acute illness
  - g. Hospitalization
  - h. Health care resources utilization
  - i. Slow or incomplete recovery from illness and/or hospitalization
  - j. High risk of iatrogenesis and side effects from medical interventions
  - k. Mortality
2. The prevalence of frailty increases dramatically with age.
3. Frailty is manifested as an impaired ability to cope with challenges in health and reduced ability to regain a stable health status, possibly related to reduced functional reserve. Severity of frailty spans from subclinical to a clinical stage to impending death.
4. In aging individuals, the variability in health and functional status is explained less and less by the effect of clinically evident or even subclinical diseases. Older age is associated with increased vulnerability to multiple diseases with no evident pathogenetic connections. Such global vulnerability is not explained by changes in recognizable risk factors.
5. Frail older persons require intensive and multidimensional continuous care and have high need of community and informal support services. These care needs necessitate a shift in the deployment of health care resources.
6. Geriatrics is a medical specialty particularly skilled in care of frail older adults.

“appearing” frail. This condition includes a composite image of loss of muscle mass, weakness, slowed pace of movement, decreased activity and engagement, and possibly unexplained weight loss—often in combination. This clinical characterization is supported by an extensive literature summarized by Ferrucci et al. (Table 52-2).

Fourth, it is thought that the increased risk of adverse outcomes associated with frailty is a result of an increased vulnerability to stressors itself caused by a decreased ability to maintain homeostasis when the individual is stressed. Stressors can be intrinsic, such as infection, or extrinsic, such as change in environment. There is some evidence to suggest that, in addition to those who already appear frail clinically, a subset of older individuals have subclinical frailty, i.e., have increased vulnerability to adverse outcomes in the face of stressors but without the clinical stigmata of frailty or any of its outcomes. Further, some clinical reports indicate that there is a subset of older adults with advanced frailty stigmata and significant outcomes, particularly disability or dependency, who have lost reserves and resilience to a point that they have a very high likelihood of dying within 6 to 12 months, and are quite unlikely to respond to therapies, including rehabilitative therapies. These differentiations of vulnerability—with or without the clinical appearance of frailty and its sequelae—are consistent with the idea of a continuum of frailty among older adults as a core component underlying the heterogeneity of health status observed with increasing age (Figure 52-1).

This continuum of frailty incorporates what is thought clinically to be a distinct causal pathway to disability, with frailty being a major etiologic risk factor independent of disease (Figure 52-2).

Note that the causal pathway from frailty to disability has not been considered in the conceptualization of the causal pathway to disability proposed by the World Health Organization and the Institute of Medicine, which map the effect of specific diseases and impairments. In contrast, conceptually, a survey in six U.S. academic centers and one in Great Britain indicated that 98% of geriatricians (both faculty and postdoctoral fellows) thought that frailty and disability were separate, but causally related, conditions; 90% of the

geriatricians interviewed thought that frailty caused disability (of which 40% thought that this was usually or always the case), while 88% thought that disability caused frailty (of which 13% thought that this was usually or always the case) (Table 52-3). These close and bidirectional relationships likely cause frequent co-occurrence of frailty and disability and the conceptual confusion of the two.

Increasingly, frailty is thought distinguishable from disability (as an outcome) and comorbidity, although there are overlapping co-prevalences (Figure 52-3).

A fifth reason that the concept of frailty has had saliency for geriatricians is the mounting evidence that there is a decrease with age in the ability of disease alone to explain the increased variation in health status, outcomes, or response to therapy. Measures of subclinical organ system changes and physical functional and cognitive variables, rather than presence or absence of diseases, are the most powerful predictors of longevity and functional outcomes. For example, in the Cardiovascular Health Study, physiological and functional measures, rather than diseases, were significant predictors of 5-year mortality, with the exception of congestive heart failure. In analyses from the Canadian Study of Health and Aging and the Gothenburg H-70 Cohort Study, Rockwood et al. demonstrated that deficit accumulation, from a list of 40 to 51 symptoms, signs, and disabilities as well as diseases, predicts mortality in a linear fashion in relation to a baseline count of deficits, with all deficits weighted equally. In the InCHIANTI study, slow walking speed (<0.8 m/s) was as strong a predictor of mortality as a diagnosis of malignant cancer. Thus, nosologically defined diseases, alone or in combination, are not sufficient to explain functional outcomes in older persons, suggesting that a disease-independent, age-related alteration accounts for the progressively higher variability in health, impairments, prognosis, and outcomes with aging. This condition, if not equivalent to frailty as defined above, is certainly reminiscent of this condition. Age-related frailty may explain why older age is associated with the increased variability in response to treatments, both in terms of

effectiveness and risk of side effects, not explained fully by disease status. The increased risk of iatrogenesis is likely a product of the altered reserves and associated physiologic vulnerabilities that are components of frailty.

Sixth, with increasing age, there is a concurrent, increased susceptibility to multiple chronic diseases that is not explained by “classic” risk factors. This increased susceptibility with no evident pathogenetic connections in risk between the multiple diseases could be related to the progressive collapse of the regulatory network of biological signals aimed at maintaining the homeostatic equilibrium. For example, there is evidence that old age is associated with a low grade, chronic proinflammatory state, which also appears to be causally related to frailty (see further). Physiologic dysregulation with aging in this and many other systems may lead both to aggregate loss of reserves and vulnerability and to disease-specific manifestations such as atherosclerosis. Such associations could lead to correlation between frailty and disease, which does not indicate a true causal association. In some instances, frailty maybe the terminal stage of selected chronic diseases. Overall, as represented by Figure 52-3 and Table 52-3, frailty, comorbid disease, and disability are overlapping, causally related, but distinct entities.

Seventh, given the discussion above, it would appear that frailty is a condition of impending deterioration in health and functional status that requires immediate attention to prevent disability and other associated outcomes. It requires substantial clinical expertise

to both recognize those who are frail and/or vulnerable, and accurately diagnose and effectively intervene to prevent adverse outcomes or frailty itself. Because of the complexity of presentation, attendant vulnerabilities, and multiple health problems likely to be concurrently present, health care in frail older people needs to be skilled, intensive, and continuous to be effective and, therefore, is intrinsically more expensive. Current U.S. health care models are driven, however, by a unique focus on disease diagnosis and a primary organization for acute, event-driven care, with reimbursement for care heavily driven by specific diagnostic categories. This approach does not permit addressing effectively the complexity of care issues, nor the specialized care required when frailty is also present, or for frailty in the absence of disease. In regards to the former, for example, care for a patient with a hip fracture is erroneously considered the same, regardless of age or frailty status of the individual, with reimbursement the same as well. However, expert geriatric care for a frail older patient with a hip fracture has a greater real cost of caring and likely commensurate benefit. Redesign of care and reimbursement to match the needs of such patients will likely lead to improved care outcomes and potentially decreased overall costs. Overall, postulating the existence of age-related frailty addresses and incorporates all of the issues above, assuming that frailty can be operationalized and recognized in clinical practice.

## WHAT IS FRAILITY?

There is strong consensus among geriatricians and gerontologists that frailty is a clinical state of increased vulnerability and decreased ability to maintain homeostasis that is age-related and centrally characterized by declines in functional reserves across multiple physiologic systems. This vulnerability is age-related and also related to, but distinct from, disability and disease states (see [Table 52-3](#) and

[Figures 52-2 and 52-3](#)). There is general agreement as well that frailty results from underlying physiologic and/or biologic alterations that are age-associated and maybe compounded by single or multiple diseases, or even be an end-stage outcome of severe disease. Key systems thought to be involved in development of frailty include musculoskeletal, hormonal, immune, and inflammatory systems, with likely contributions from the autonomic and central nervous systems. Sarcopenia, or loss of muscle mass with aging, is thought to be a central manifestation of frailty. In fact, a change in body composition with a progressive decline in lean body mass, mostly represented by muscle, is an almost obligatory manifestation of aging and, past a threshold severity, of frailty itself. However, the rate of age-associated decline in muscle strength and muscle mass is profoundly modulated by a number of physiologic factors including inflammation, hormones, neurological integrity, nutritional status and physical activity, along with other contributors. It is noteworthy that the multiple physiologic systems that affect sarcopenia are also thought to contribute to generalized dysfunction that is aging-related, an issue well beyond sarcopenia itself. This is consistent with the theory proposing that it is the aggregate dysregulation of many systems that results in the vulnerability and clinical presentation of frailty more than the dysregulation of any one system.

One way to understand frailty is by comparison with the traditional concept of disease. Traditionally, diseases are defined by symptoms, signs, and pathophysiologic mechanisms. Specific diseases impair selected aspects of the homeostatic equilibrium that is essential for life. A large variety of stressors continuously challenge the homeostatic equilibrium and facilitate the emergence of diseases. Health is characterized by a perfect equilibrium between stressors and homeostatic mechanisms ([Figure 52-4A](#)). Diseases emerge when specific physiological system(s) or anatomical structure(s) are impaired and pose an entropic challenge that cannot be fully counteracted by homeostatic mechanisms. This is typical of young and middle age, where diseases are stochastic, somewhat “rare” events that often target a specific mechanism ([Figure 52-4B](#)). For example, a brain hemorrhage is unlikely to occur in a healthy, young individual unless there is clear cause (malignant hypertension, aneurysms etc). In old age, this can more easily result from a combination of multiple processes that include both strong entropic challenges and thinning of the mechanisms that maintain the homeostatic equilibrium ([Figure 52-4C](#)). Under the assumption that homeostatic mechanisms are general, it is more difficult with aging to recognize a specific pathophysiological mechanism for each disease and clinical presentation maybe atypical. As a result, treatment of specific diseases one by one is less likely to be successful. Understanding the causes of derangement of the homeostatic mechanisms and possibly correcting them is more likely to be beneficial than targeted treatment of a specific system. According to this interpretation, prevention in old age may need to be focused on reinforcing homeostatic mechanisms rather on risk factors for specific diseases. This is compatible with the idea that change in nutrition and exercise are the only interventions that have been shown to prevent disability.

There are several dominant theories as to the underlying causes of physiologic vulnerability and compromised homeostasis of frailty. They include the following:

1. Frailty comes from accumulation of potentially unrelated diseases, subclinical dysfunctions, and disability across organs, parts, and systems of the body. This approach has been posited by Rockwood and colleagues, who have operationalized this theory in

**FIGURE 52-4.** Diseases in young and old age. Homeostatic equilibrium is maintained by robust function and interconnections between multiple physiologic systems (A). When one system is dysregulated or impaired, as in a specific disease, disability can result in the specific areas of function affected by the disease (B). The derangement of general homeostatic mechanisms characteristic of frailty induces a multiple systems impairment which emerges clinically as frailty as well as development of multiple diseases and complex patterns of disability (C).

terms of a summary of all potential deficits present in an individual (symptoms, signs, diseases, geriatric conditions, laboratory abnormalities, disabilities); a simple count of all such deficits assessed has been shown to predict mortality. This approach indicates that a summary measure of deficit accumulation across many different types of health conditions at many levels (functional, clinical, physiological) predicts risk of mortality. Inferentially, frailty is an intermediary, almost latent, construct that is the summary effect of all of these deficits on homeostatic reserves; the number of deficits leads to a dose–response relationship with mortality, presumably through this intermediary mechanism.

- Frailty is a unique pathophysiological process: This theory posits that frailty can be characterized as a primary defect, which involves the diminution of physiologic function and, eventually, breakdown of homeostatic mechanisms. This could result from alterations in a range of basic biological mechanisms, which then lead to dysregulation of multiple physiologic systems. These systems are known to mutually affect each other, providing a rich network of homeostatic regulation and ability to compensate, to a degree, if any one system is impaired. This redundant network, with intact function within and between systems, underlies reserves and resiliency to stressors (Figure 52-5A). Dysregulation of multiple systems with aging, and decreased effectiveness of interconnections (Figure 52-5B) could lead to depletion of reserves and compromised ability to maintain homeostasis in the face of stressors. Ultimately, this could lead to a negative spiral of declining function. Basic biological systems involved may well include those that maintain a stable production, distribution, and utilization of energy, while key physiologic systems include hormones, immune, inflammatory, and neurological processes. Decreased energy available would diffusely affect multiple physiological systems, leading to compromised function both within and between systems. Further, decreased availability of energy

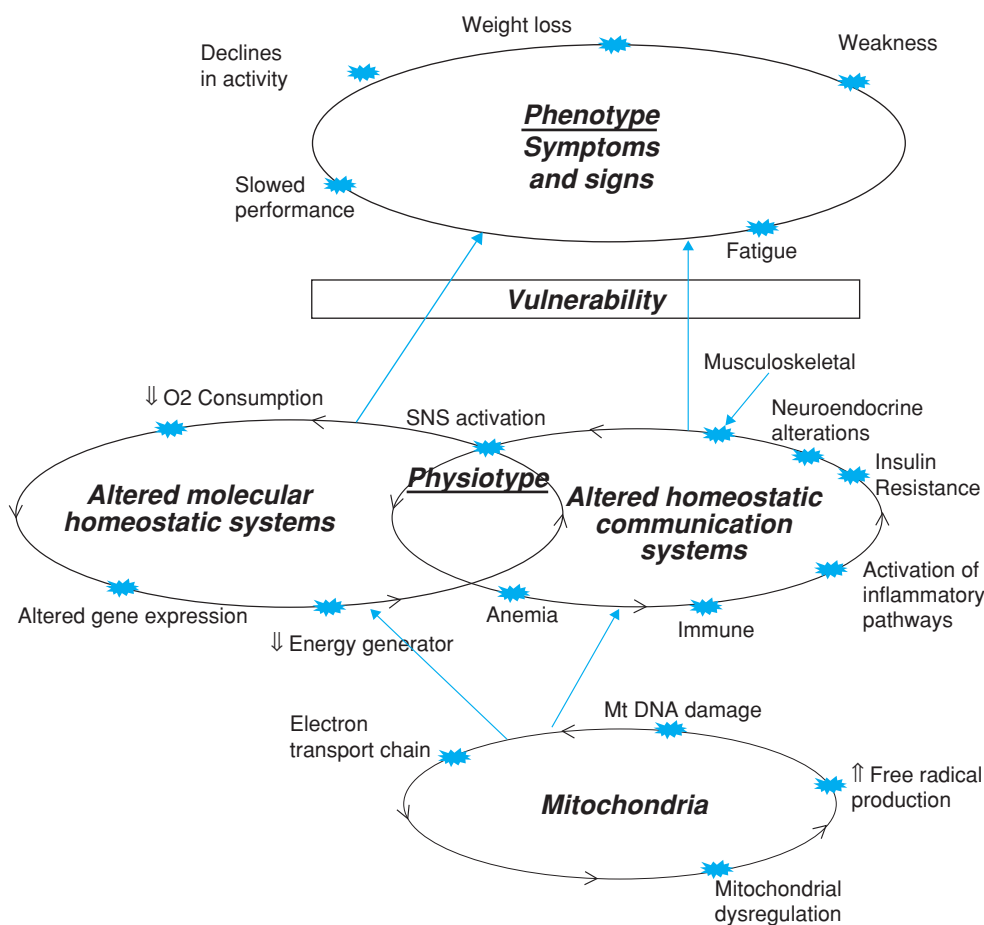

could underlie decline in physical function, especially in tasks requiring endurance (Figure 52-6). A similar scenario could occur as a result of other basic biological alterations with aging, such as shortened telomeres or excessive free radical damage. Alternatively, or additionally, frailty may result from a progressive loss of complexity in the function of individual physiologic systems and in their regulation of homeostatic responses, leading to both chronic over- or underfunction.

The complexity of the homeostatic network in a healthy organism allows rapid and flexible adaptations to different types and intensities of internal and external perturbations. The more specific the response, the more rapid and efficient the adaptation. With aging, the range of adaptive strategies may progressively become limited, up to the point that the normal state of redundancy is lost and any perturbation is addressed with a more limited number of stereotypic

**FIGURE 52-5.** Conceptual summary of interconnections between biologic and physiologic systems that comprise a stable homeostatic system, with rich network that offers redundancy and reserves. (A) Robust interconnections between these systems, as indicated by multiple arrows. (B) Many fewer arrows, signifying decreased function of different systems and weakened interconnections, threatening homeostasis. From Fried LP, Hadley EC, Walston JD, et al. *From bedside to bench: research agenda for frailty*. *Sci Aging Knowledge Environ*. 2005[31]:pe24, 2005.

**FIGURE 52-6.** Hypothesized levels of the syndrome of frailty.

responses. For example, heart rate can decrease or lose the more complex modulations in the frequency domain typically seen in healthy, younger individuals. Similarly, altered energetics could lead to compromised networks and adaptive responses; the former are graphically suggested by the decreased number of arrows linking different physiological and biological systems in [Figure 52-5B](#), compared with [Figure 52-5A](#). Both types of processes could underlie dysfunctions in many physiologic systems, as well as in the communication between systems. Other mechanisms may also be at issue.

Building on a scientific paradigm of frailty previously proposed by Buchner et al. and Fried and Walston, Ferrucci and Ruggiero have further developed the theory regarding the existence of an energetic pathway to frailty. This theory is summarized in [Figure 52-7](#). The box on the left represents the total amount of energy, or ATP molecules, that can be generated in a time unit. Because most of the energetic metabolism is aerobic, the total dimension of the box can be operationally defined as maximum oxygen consumption ( $MVO_2\max$ ). A large amount of this energy is needed simply to maintain the human machine in a homeostatic equilibrium. In a broadly accepted interpretation, this amount of energy is the basal metabolic rate. Recent evidence suggests that factors that influence basal metabolic rate include not only physiological factors but also pathological components. On top of the “minimum requirement for homeostasis,” which is a function of age, sex, body composition, and physical activity, we need to consider, especially in an older person, an extra quota of energy required to balance the unstable homeostasis caused by pathology. We may call this extra energy “homeostatic effort.” Theoretically, in a healthy individual, the “homeostatic effort”

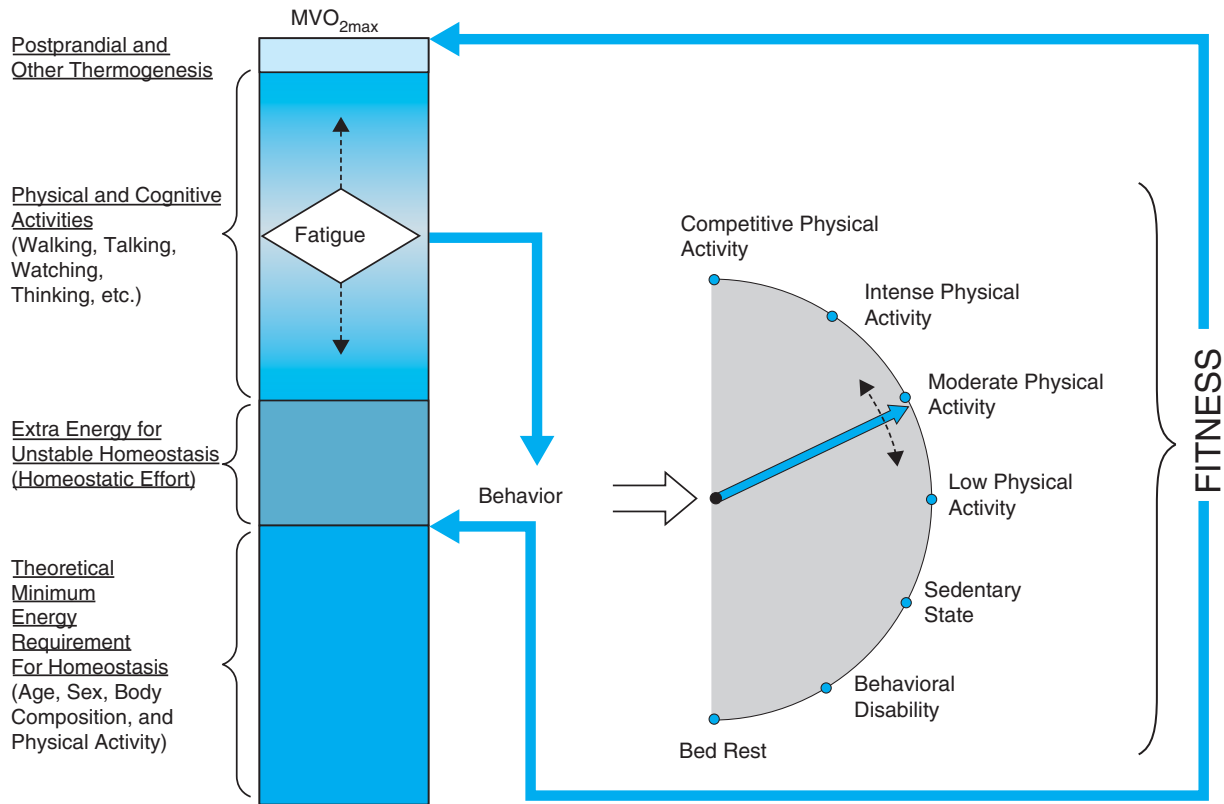

is negligible but increases rapidly with health status deterioration. There is evidence that the “homeostatic effort” is a risk factor for mortality. The remaining energy in the “box” is used for cognitive and physical activities. This maybe highly diminished if the “homeostatic effort” is high.

Within the range of energy that is used for physical activity, with increasing workload the individual starts experiencing fatigue. The threshold at which fatigue develops is influenced by a number of still undefined factors, which certainly include biological (inflammation, oxidative stress, hormones, anabolic metabolism), psychological, and physiological factors. Efficiency of movement (or, analogously, the efficiency of thinking) also affect the amount of workload that the individual can accomplish before feeling fatigue. Whether the threshold is low or high conditions the level of physical activity in daily life. If fatigue develops for small workloads, the individual is likely to be sedentary. On the contrary, if a high level of workload can be handled without much feeling of fatigue, then the individual will be more physically active.

In the long term, a sedentary state reduces the total amount of energy that can be generated (shrinks the box), thereby triggering a vicious cycle that leads to progressive, accelerated decline in physical function ([Figures 52-7 and 52-8](#)). In this model, an active lifestyle is the best preventive strategy to frailty.

A complementary, potentially related theory considers the clinical implications of energy dysregulation in terms of both homeostatic instability and resulting manifestations, including low muscle strength, reduced exercise tolerance, slowed motor speed, further decreased physical activity, increased fatigue, or “exhaustion.” Note

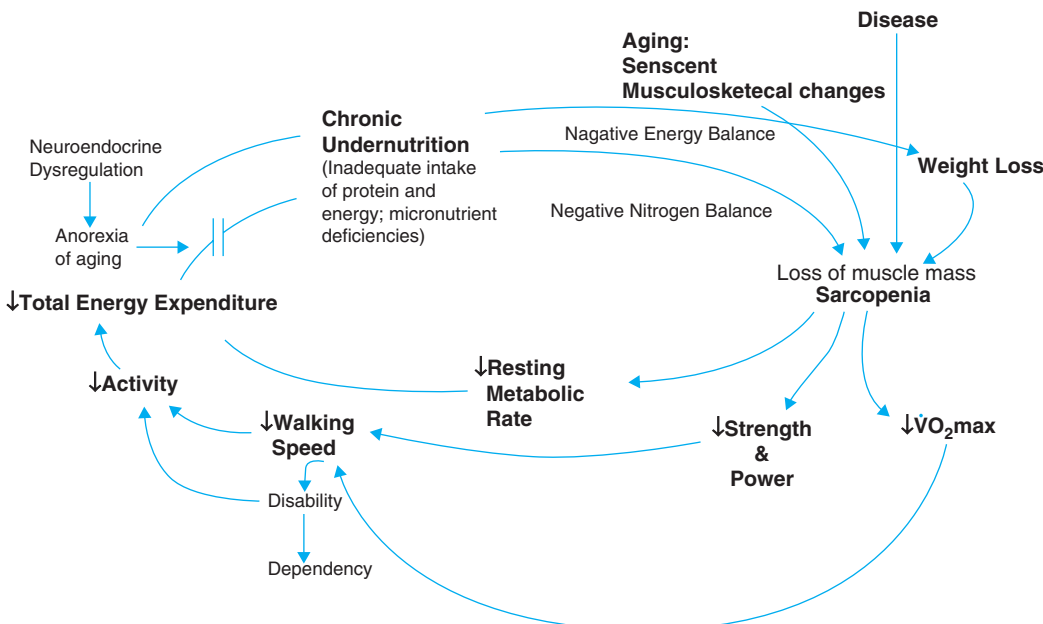

### Vicious Cycle of Energetic Frailty

**FIGURE 52-7.** Vicious cycle of energetic frailty.

that the accelerated loss of muscle can be masked by a parallel increase in fat mass, leading to the condition of sarcopenic obesity. In terms of etiology, note that the proposed dysenergetic origin of frailty is consistent with the fact that many of the genetic diseases associated with mitochondrial DNA mutations emerge with clinical

manifestations concentrated at the level of muscle and the central nervous system. The consequences of decreased energy can be exacerbated in catabolic states and in the common situation of anorexia of aging, both leading to decreased nutritional intake out of proportion to the level of energy expenditure through activity. These

**FIGURE 52-8.** A vicious cycle of frailty, resulting from dysregulated energetics as well as altered physiologic functioning, intra- and intersystem. From Fried LP, Tangen CM., Walston J, et al. Frailty in older adults: evidence for a phenotype. *J Gerontol A Biol Sci Med Sci.* 56;M146–M156, 2001.

scenarios would compound the dysregulation of energetics above, adding further loss of lean body mass and, if severe enough, weight loss to the clinical picture.

Thus, a defined and unique pathogenetic mechanism could explain the clinical presentation of frailty. It has been proposed by Fried and Walston that dysregulated energetics may initiate a vicious cycle involving a clinical presentation of the elements above (see [Figure 52-8](#)), with increasing numbers of manifestations present as the severity of frailty increases, which is driven by dysregulated energetics, as supported by the discussion above. Further, recent evidence from Bandeen-Roche supports frailty being a clinical geriatric syndrome, whereby a critical mass of the central symptoms and signs identify it, not any one, and the clinical presentation is linked to underlying pathophysiology (see [Figures 52-6 and 52-8](#)).

Ultimately, the homeostatic response may become so inefficient that the normal level of homeostatic mechanisms may no longer be possible and other less robust and efficient states of equilibrium are selected instead. Note that, according to this approach, the frailty phenotype, or its underlying physiologic status, or “physiotype,” may represent the best possible state of equilibrium in that specific person at any given level of physiologic function, an attempt to prevent a spiral of deterioration toward death. Since adaptive responses can theoretically be improved, prevention and treatment maybe possible.

The idea that a unique pathophysiologic process is involved in the genesis of both the vulnerability and the clinical presentation of frailty (see [Figure 52-6](#)) is particularly attractive because it implies that diagnosis of frailty as a distinct clinical entity is possible based on a finite number of criteria (signs, symptoms, test results, etc.). In addition, and perhaps more important, if prevention and treatment are possible, then diagnostic criteria can provide a basis for targeting persons who already show clinical manifestations and may lead to the ability to identify those in a subclinical stage. Targeting interventions to those with clinical manifestations could have a goal of reducing consequences of frailty or causing its remission. Targeting those at earlier stages, such as those vulnerable to stressors or with excessive and unopposed oxidative stress as a cause of homeostatic dysregulation, could have the benefits of frailty prevention as well as decreased adverse outcomes and potentially reduced susceptibility to disease.

## HOW CAN FRAILTY BE IDENTIFIED IN CLINICAL PRACTICE?

Given the marked vulnerability to adverse health outcomes of those who are frail, it is critically important to have clinically valid approaches to recognizing frailty. This would provide a basis for incorporating intentional approaches to prevention and treatment of frailty into clinical care. To date, there are no formally agreed-upon diagnostic criteria that identify the biological state of vulnerability underlying frailty, or clinical evident frailty. Recognition of standardized clinical approaches is a critical next step as these to improve screening and targeting of care and implementation of effective interventions to decrease premature or preventable frailty and decrease adverse outcomes associated with frailty. Additionally, it is likely that frail older adults are the subset most vulnerable in terms of patient safety issues. Application of geriatric principles of care for frail older adults to situations that could compromise safety maybe a highly effective approach to prevent adverse events.

Clinical scenarios are illuminating. We present here three clinical case histories that reflect the heterogeneity observed in older adults, and describe some of the clinical differences that may help identify those who are most frail (see [Figure 52-1](#)).

*Case 1:* The first case involves a very robust older man who underwent surgery and did very well. He was 75 years old, had a history of hypertension, mild congestive heart failure, and chronic knee osteoarthritis. He walked daily and lifted some weights, but had experienced increasing knee pain that slowed his activity level. He was admitted for an elective knee replacement and did very well in the postoperative period. He went home after 3 days on anticoagulation and narcotic pain medications, tolerated home physical therapy for 2 weeks, and returned close to his functional baseline within a month.

*Case 2:* In the second case, a man with a similar clinical history exhibited vulnerabilities to adverse outcomes following surgery that differentiated him from the first patient. This man, also 75 years old and with a history of hypertension, mild congestive heart failure, and chronic knee osteoarthritis, walked several times a week for exercise and volunteered at a hospital gift shop. He had to stop these activities because of increasing knee pain and fatigue about 2 months prior to surgery. He underwent elective knee replacement and did well in the immediate postoperative period. However, after being given narcotic pain medications, he became delirious, pulled out his foley catheter, and fell out of bed. He refused all physical therapy interventions and developed incontinence. He was eventually transferred to a subacute rehabilitation facility, where he gradually recovered over 3 weeks. He was then transferred to home and required 3 more weeks of physical therapy. After 3 months, he approached his previous functional baseline, but still described fatigue and inability to do as much as he did before.

*Case 3:* An obviously frail, vulnerable older man without known medical illness had a series of adverse events near the end of life. He was 83 years old and had lived alone since his wife died 5 years earlier. He had a history of hypertension, compensated congestive heart failure, and a fall with fracture of left hip 3 years earlier. He did most of his own activities of daily living, but was not able to get out in the community anymore because of fatigue and fear of falling. He had minimal activity and almost no planned exercise. He was found on the floor by a neighbor when it was noticed that he had not been outdoors to get his morning newspaper. The patient reported that he had simply fallen and was too weak to get up. In the emergency room and subsequent hospitalization, the physicians identified diffuse muscular weakness and elicited a history of a 10 pound weight loss over a year, but found no other laboratory or obvious medical etiology for his decline and weakness. The patient was transferred to subacute rehabilitation and gradually improved to the point where he could ambulate 20 feet with a walker. However, he was not able to care for himself as he did previously, and was therefore transferred to an assisted living facility. He died there, of undefined causes, 3 months later.

These case histories illustrate the continuum of frailty (see [Figure 52-1](#)) and underlying biological differences between older individuals. The first patient was very robust and manifested little vulnerability to complications of surgery. The second patient, while appearing quite similar in history and stamina to the first patient, was clearly more vulnerable to the stressor of the same surgery and took much longer to recover. He did have some subtle differences from the first patient, in that he was fatigued for a period of time before the surgery, in addition to having knee pain. Finally, the third

patient was overtly frail, with diffuse weakness, fatigue, low activity and energy, and weight loss. Verdery and others have proposed that, past a certain point in severity, frailty is a predeath phase that is irremediable (see [Figure 52-1](#)). Consistent with this, the third patient died 3 months after discharge.

These case histories suggest that frailty is, in fact, a continuum, ranging from latent physiological alterations to a clinically apparent syndrome without, and then with, resulting disability. There is now substantial theory that a “physiotype” of underlying alterations in physiological systems occurs (as above), with the consequent development of a clinical presentation, or “phenotype,” past a certain level of severity of global dysfunction (see [Figures 52-6 and 52-8](#)). This latent physiotype may become clinically or phenotypically apparent when vulnerable systems decompensate in the face of stressors.

### STANDARDIZED APPROACHES DEVELOPED TO ASCERTAIN FRAILITY

Several approaches have been developed to identify those who are frail. One, developed by Rockwood and colleagues, described above, creates a summary measure of deficit accumulation across many different types of health conditions at many levels: functional, clinical, and physiological. It was designed to quantify the theorized impact of aggregate disease and illness burden. The investigators have shown that increasing numbers of conditions present are associated with a stepwise increase in mortality risk. Inferentially, they theorize that the aggregate physiological effect of these multiple conditions is “frailty.” This approach has the two main disadvantages: the number of parameters to be collected makes it unsuitable for clinical utilization and, second, it does not offer a unifying theory as to etiology that might guide prevention and treatment.

A second approach posits, consistent with discussion in the prior section, that there is a distinct pathophysiology to frailty with a syndromic clinical presentation. Several groups have proposed related approaches, building on the observation of characteristic signs and symptoms of people who are “frail.” In 1999, Paw et al. posited that inactivity and malnutrition were two major determinants of frailty that jointly provide strong prediction of the adverse outcomes of frailty. In the Zutphen Elderly Study, they found the combination of inactivity (less than 210 mins of physical activity per week, among walking, bicycling, hobbies, gardening, odd jobs, and sports) and weight loss (more than 4 kg over 5 years) identified 6% of this cohort of older men as “frail,” and predicted slow walking speed, and greater disability and mortality. By necessity, these authors used weight loss over 5 years, but identified this as a limitation to sensitivity and suggested use of weight loss over the last year instead. Overall, the authors claim that this approach offers a simple, inexpensive, and effective screening for identifying a frail population.

In 1998, Fried and Walston proposed that there were a few major presenting symptoms and signs of frailty, and that these were interrelated in a vicious cycle, or feed-forward loop, resulting from dysregulated energetics (see [Figure 52-8](#)), with declines in strength, energy, walking speed, physical activity, and weight loss (over 1 year), all interrelated and presenting cardinal manifestations of a clinical syndrome of physical frailty.

This proposal was subsequently operationalized by defining the frail as those with a critical mass of clinical manifestations, i.e., three or more. This definition has been validated (face, criterion, construct, predictive) in more than five population-based studies

as identifying those at high risk of disability, falls, hospitalization, hip fracture, and mortality. Further, this frailty phenotype has been shown to have characteristics of a medical syndrome, in which the multiplicity of signs and symptoms present identifies those who are frail more than any one or two. Risk of adverse outcomes is more strongly associated with the constellation of presentations than with any one or two and no specific cluster of criteria carry distinguishable risk. This approach to characterizing frail older adults is based on the theory of a discrete syndrome with specific definable causes, both biological and environmental. By this definition of frailty, prevalence is 7% overall in community-dwelling men and women aged 65 years and older, and increases with increasing age from 3% in those 65 to 74 years up to 25% in those 85 years and older. There is a twofold higher prevalence in African-American older adults, compared to whites, at each age group 65 years and older. Using this definition, there is now evidence as to the natural history of frailty, indicating it is a dynamic but generally chronic, progressive condition, with 43% transitioning to states of greater frailty over 18 months, while 23% transitioned to states of lesser frailty, and almost no one transitioned from frail to being nonfrail. Further, initial presentations of frailty are most likely to be decreased strength or slow walking speed, which then predict development of additional manifestations, consistent with the hypothesis of a cycle of frailty (Xue et al., personal communication). Those with one or two manifestations are at twofold higher risk of progressing to three, four, or five over 3 years, thus suggesting they are prefrail. There is now strong evidence for the association of this clinical phenotype with dysregulation in number of physiologic systems. Thus, with this approach, frailty can be thought about in terms of a core phenotype manifesting a syndrome, with definable outcomes and recognized etiology. Ongoing research aims to define the physiological alterations and the ultimate biological causes of frailty (see [Figures 52-6 and 52-8](#)).

As stated by Bergman, the underlying assumption of an operational definition of a syndrome, based on symptoms, is that domains used for the diagnosis do not represent all possible manifestations of the syndrome; rather, they constitute the important domains that can be easily and reliably measured and together maximize specificity of the diagnosis. Because many components of the pathological process are associated with each other, it is not necessary to require the presence of all of them to make the diagnosis. Consistent with this, these authors suggest that the phenotype described above, with distinct, standardizable measures and criteria for definition, built on biologic theory, validated with diagnostic criteria that are strongly age-related, lends itself for use in screening, diagnosis, and as a basis for prevention and treatment of frailty; the components are summarized in [Table 52-4](#).

A disadvantage of this particular definition, however, is that assessment requires approximately 10 to 15 minutes: to weigh a patient, measure grip strength and walking speed, and to ask two questions regarding “exhaustion” and a physical activity questionnaire. Studenski and others advocate that measurements of walking speed and possibly strength should be considered geriatric “vital signs” and assessed regularly in clinical settings. If this is implemented generally in clinical practice, then the time-consuming part of this assessment is determining physical activity level; methodological work is needed to develop a more parsimonious approach to screening physical activity than current questionnaires offer.

An alternative approach has been proposed for clinical characterization of patients as frail and using clinical judgment particularly to measure change over time clinically and/or in response to treatment.

TABLE 52-4

## Components of Frailty Phenotype as Initially Operationalized in CHS (Three or More Components Present Indicate Frailty)

GRIP STRENGTH*	WALK TIME	EXHAUSTION	PHYSICAL ACTIVITY (LEISURE)	WEIGHT LOSS
	≥6–7 s to walk 15 ft	“Everything I did was an effort.” or “I could not get going.”	Men (kcal/week): <383 Women (kcal/week): <270	>10 lb in past yr
Cut-Off for Grip Strength (kg) Criterion for Frailty				
<i>Men</i>				
BMI ≤24		<29		
BMI 24.1–26		<30		
BMI 26.1–28		<30		
BMI >28		<32		
<i>Women</i>				
BMI ≤23		<17		
BMI 23.1–26		<17.3		
BMI 26.1–29		<18		
BMI >29		<21		

\*Grip strength, stratified by gender and body mass index (BMI) quartiles.

A clinical global impression of change in physical frailty has been developed by Studenski and colleagues to represent the clinician's perspective on clinically meaningful change resulting from interventions on physical frailty, e.g., exercise, nutrition, medications, and multifactorial approaches. This measure records clinician judgment regarding the domains of intrinsic frailty (strength, balance, nutrition, stamina, physical activity, neuromotor function, and mobility) plus appearance, medical complexity, perceived health, healthcare utilization, and outcomes of frailty (physical disability in basic, instrumental, and advanced functions; emotional status; and social status). Its goal is to create a reference point for defining the magnitude of change in simple objective measures in order to eventually measure effects of interventions to prevent or treat frailty, integrating clinical meaning with traditional measurement properties. Evaluation of the measure indicates content and face validity, feasibility, reliability, and acceptability to clinicians, and classification by severity of frailty. Ability to measure change is not yet determined. This global frailty measure can be completed by the clinician in less than 10 minutes per patient.

### POTENTIAL USES OF AN OPERATIONAL DEFINITION OF FRAILITY

It would appear that enough theoretical and evidenced-based research has been done to establish an operational definition of frailty. We suggest here why having an initial standardized definition of frailty is so important. First, clinically, this would provide a starting point of a standardized, validated approach to identifying geriatric patients at high risk of multiple health-related outcomes, including disability and death. Further, there is evidence that such screening could help identify the patients at high risk of complications after acute illnesses and injuries, and most at risk of delayed or blocked recovery or functional decline after a stressful medical intervention, whether a hospitalization, surgical procedure, or chemotherapeutic agent. With the development of expanded research on this area, screening could also offer a basis for prognostication essential to

therapeutic decision-making and potentially for hospice eligibility for those with advanced frailty.

There is already initial evidence that introducing frailty into prognostic algorithms is more predictive of adverse outcomes than staging criteria established by clinical specialties. For example, assessment of frailty contributes substantially to prediction of mortality in older patients with upper gastrointestinal bleeding and characterizing those at risk of dependency after hospitalization. As frail patients are likely to be highly vulnerable to adverse outcomes of medications, environmental hazards, surgery, or “patient safety”-related issues, screening could help focus clinical attention and target preventive care to this high risk group. Further, use of a standardized definition of frailty in clinical care would provide a basis for developing appropriate levels of reimbursement for clinicians caring for this high-risk group that requires time-intensive care for extended time periods. Such expert geriatric care maybe shown to optimize appropriate resource use and, through this, potentially decrease costs of care for this population. Finally, a standardized measure of frailty would offer a basis for screening and identification of participants in randomized, controlled clinical trials aimed at prevention or treatment of frailty and/or its major consequences.

Frail older individuals who are not yet disabled and those with early disability who are at high risk of progression are most likely to benefit from interventions to prevent disability and therefore, represent ideal candidates for clinical trials that target these outcomes. Ironically, a substantial proportion of older persons with frailty, as well as comorbidity, are often excluded from clinical trials. As a result, the effectiveness of most new treatments for chronic diseases that typically affect older persons, particularly medications, has historically been established in individuals substantially healthier than age-matched persons in the general population. Thus, when these new medications are utilized in older or frail persons, who often have the greatest need for new therapeutic agents, unexpected side effects commonly emerge and the benefits evidenced in the original trials may not occur or be relevant in this population. In these complex patients, it is critical to know if the intervention has improved, or at least slowed, decline in functioning.

Conducting a clinical trial in the frail population is far more complex than doing the same trials in younger and healthier individuals: we suggest eligibility criteria based on a multistage process, and implementation of strategies to improve retention and compliance and monitor their effectiveness. Estimation of cost and sample size should contemplate high dropout rates and interference by competing outcomes. In spite of the difficulty, it should be recognized that research in this subgroup is essential to the advancement of geriatric medicine.

Overall, we propose that the screening criteria already validated could provide a starting point for a standardized definition of frailty. Only by implementation of a standardized definition can ongoing research serve as a basis for refinement and broad improvements of these same criteria.

### EVIDENCE AND THEORY REGARDING THE PATHOGENESIS OF FRAILTY AND IMPLICATIONS FOR TREATMENT

Building on the discussion above and [Figures 52-6 through 52-8](#), there is now evidence of the syndromic nature of frailty, and that there are inputs at multiple levels including (1) biologic, (2) altered physiological functions in homeostatic systems and altered communications systems, and then (3) a clinical presentation that appears to be the outcome of these multiple changes and constitutes a constellation of presentations that are interrelated in themselves and likely involved in a vicious cycle of dysregulated energetics. The aggregate impact of dysfunction at multiple levels is thought to result in compromised ability of the organism to maintain homeostasis and the vulnerability to stressors manifested by frail older adults. This section summarizes evidence to date at each level in [Figure 52-6](#) and discusses the systems biology of frailty as a complex system. It draws primarily from the Women's Health and Aging Studies (WHAS), the Cardiovascular Health Study, and the InCHIANTI Study, which have all utilized the CHS frailty phenotype in [Figure 52-8](#) and [Table 52-4](#). This section then is followed by a section, which discusses the implications of this evidence in terms of potential treatments.

The clinical phenotype of frailty is based on proposed interrelationships of declines in strength, performance, energy, activity, and weight loss (see [Figure 52-8](#)). It is well established that sarcopenia contributes to altered production and utilization of energy. With loss of muscle mass and decreased muscle function, there is a decline in muscle strength and exercise tolerance. The latter can be validly represented by the concept of "fatigue" or "exhaustion." Although it directly relates to the amount of physical work the individual can produce, "fatigue" or "exhaustion" may also directly result from altered cellular production or consumption of energy. Further, there is evidence that declines in strength and exercise tolerance predict both slower walking speed and further decreases in physical activity. In a subset of older adults, who maybe frail (although that is not yet demonstrated), there is a mismatch between inadequately low food intake and inadequately high energy expenditure through physical activity (even at low levels), resulting in further loss of muscle and, in cases extremely severe cases, weight loss. These interconnections support the concept of a "cycle" of frailty. There is now evidence that this cycle has a natural history of chronic progression that often begins with declines in strength and/or walking speed, which

then predicts declines in physical activity. However, when strength, walking speed, and physical activity are all impaired, then the system rapidly progresses toward frailty.

A number of physiologic systems at abnormal levels have been shown to be associated with the frailty phenotype above. These include sarcopenia and higher fat deposits in muscle, low testosterone, insulin, DHEA-S, and IGF-1, higher levels and blunted diurnal variation of cortisol, insulin, elevated proinflammatory markers (i.e., IL-6 and C-reactive protein [CRP]), elevated markers of blood clotting, anemia, low micronutrient levels (especially total carotenoids, beta carotene, and lutein/zeaxanthin), decreased immune function (with decreased T cell proliferation and altered cytokine production), and decreased heart rate variability. Further, the severity of abnormality within each system and, particularly, the number of systems at abnormal levels are associated with the presence and severity of frailty (see [Figures 52-4 to 52-6](#)). Frail older women are more likely to have two or more micronutrient deficiencies and low daily energy intake of 21 kcal/kg or less, along with low intake of protein, vitamins D, E, C, and folate. Thus, circulating antioxidants are low in those who are frail compared to nonfrail. It is beyond the scope of this chapter to review the physiology of each system.

These systems are themselves interrelated, affecting each other as well as the clinical presentation. New evidence indicates that the risk of frailty is highly associated with multiple systems at abnormal levels, significantly more than any one system described above. The multiplicity of systems at abnormal levels is the hallmark of frailty. In spite of overwhelming evidence that age and frailty affect multiple physiological parameters in parallel, most research on biomarkers of aging is based on single measures. As schematically shown in [Figure 52-9](#), it is generally assumed that decline in one parameter can be fully corrected by replacement, restoring the individual to the improved trajectory of "normal aging." This is the rationale for replacement of testosterone or estrogen. Unfortunately, but not completely

**FIGURE 52-9.** Dysregulation of one physiological system, as may be the norm in a specific disease (A) is the exception in frailty, where multiple physiologic systems are dysregulated (B). The implications of this finding for potential therapies is discussed in the text.

unexpectedly, this approach has met with little success. Results of trials of testosterone and estrogen replacement are somewhat disappointing. An alternative hypothesis that may explain the partial failure of this approach, exemplified in Figure 52-9, is that multiple parameters decline together, as the organisms attempts to obtain different states of equilibrium during the aging process. This interpretation implies that only by examining at multiple parameters at the same time will we be able to identify effective interventions. The condition when only one hormonal axis is dysfunctional is probably different from the multihormone dysregulation and may respond to different therapeutic approaches.

One hallmark of frailty is the dysregulation of homeostatic or communications systems, at both the molecular and physiological level (see Figure 52-6). As mentioned previously, declines in hormones important in muscle mass maintenance such as IGF-1 and DHEA-S, and increases in afternoon cortisol levels and in inflammatory and clotting markers, point toward the immune and neuroendocrine systems as likely candidates as the physiological source of this dysregulation (Figures 52-6 and 52-10). Theories of basic aging provide in part a molecular explanation for some of these changes. For example, increased oxidative stress generated in mitochondria is likely to set in motion many processes that can impair physiology. Further, declines in energy production (ATP) can lead to less efficient signal transduction and protein transcription and translation in many cells, which in time leads to alterations in biological systems. In addition, free radicals themselves damage mitochondrial DNA, which in turn will lead to even less efficient energy production and greater increases in oxidative stress. This process may lead to increasing DNA and protein damage, as well as direct transcription of inflammatory mediators, which are strongly associated with frailty. Although much work remains to be done in this area, physiological association studies are providing clues as to where these investigations should focus.

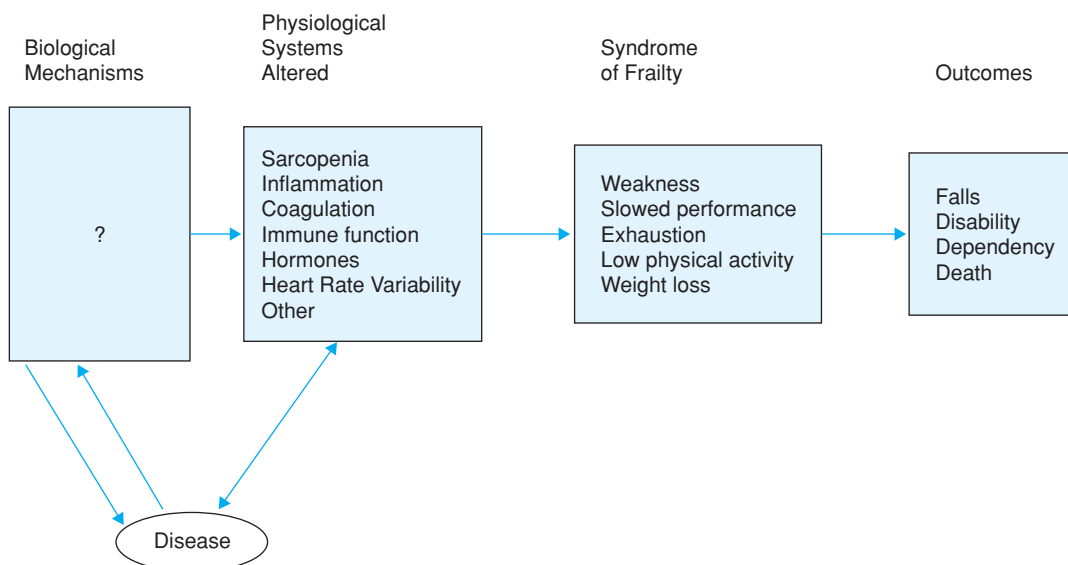

## BIOMARKERS OF FRAILTY AND HOMEOSTATIC DYSREGULATION

An intriguing hypothesis that emerges from recent data in the literature is that the aging process affects multiple physiological systems

in parallel (harmonically, see Figure 52-9) because the signaling network that maintains a stable homeostasis and adequate distribution/utilization of energy becomes progressively less efficient and less able to adapt to stress. Although all elements of this homeostatic network have not been identified, some indications as to the most critical components have begun to surface. The primary elements required for energy generation are provided by nutrition (in this context, oxygen is considered a nutrient) and constitute the input of the system. The output of the network is energy expenditure, which is mostly accounted for by resting metabolic rate and physical/cognitive activity. The production of energy during aerobic metabolism generates reactive oxygen species (ROS; oxidative stress) that are scavenged by antioxidant mechanisms. A dynamic stability of the internal environment is maintained by the combined effects of hormones and the autonomic nervous system. Finally, the integrity of the “self” is maintained by the immune system through inflammatory processes. Although these homeostatic systems are traditionally addressed in medicine as compartmentalized physiological systems, it is becoming clear that they belong to the same signaling network and function in a very integrated way.

Researchers have proposed that accumulated damage in the homeostatic network maybe captured by measuring signaling molecules freely circulating in the bloodstream. We have already mentioned the importance of studying multiple hormone dysregulation in older patients. It has been recently demonstrated that serum levels of single hormones such as testosterone, DHEA-S, and IGF-1 are only weak predictors of metabolic syndrome, frailty, and mortality. Evidence in support of the hypothesis that aging is associated with dysregulation of different components of the homeostatic network is emerging rapidly, especially for biomarkers of inflammation and nutritional status. Through studying the relationship between and among elements of this paradigm, we will better understand the age-related pathway to frailty and progressive disability.

Aging and frailty are associated development of a mild proinflammatory state, indicated by increased levels of proinflammatory markers. It has been demonstrated that, among nondisabled older persons, those in the highest IL-6 tertile are at high risk of developing disability over a 4-year follow-up. Older persons with elevated IL-6 and high CRP had higher mortality and there is some evidence that a short-term increase in IL-6 is a strong, independent predictor

**FIGURE 52-10.** Model pathway of frailty.]

of mortality. Additionally, some studies suggest that the causal link between inflammation and disability is accelerated sarcopenia. In accordance with this hypothesis, there is increasing evidence that inflammation is involved in the pathogenesis of age-related muscle wasting, perhaps by the up-regulation of the NF- $\kappa$ B activation of the ubiquitin proteasome pathway. Adiposity appears to play an important role in the inflammatory process, and, possibly, the onset of sarcopenia. Studies have suggested that inflammatory cytokines produced by adipose tissue, especially visceral fat, accelerate muscle catabolism and may contribute to the vicious cycle that initiates and sustains sarcopenic obesity and may lead to frailty in older persons. There is cogent evidence of a connection between inflammation and frailty, but whether the link between these two conditions is completely explained by the effect of inflammation on sarcopenia is unclear. Inflammatory states also affect energy availability, hematology, and hormonal status.

Emerging data suggest that quantitative and qualitative undernutrition is an important, and perhaps reversible, cause of frailty and disability in older persons. Oxidative stress is a major mechanism implicated in the pathogenesis of sarcopenia; aging muscle shows increased oxidative damage to DNA, protein, and lipids. Carotenoids quench free radicals, reduce damage from ROS, and appear to modulate redox-sensitive transcription factors such as NF- $\kappa$ B that are involved in the upregulation of IL-6 and other proinflammatory cytokines. A recent but robust literature suggests that inadequate intake of antioxidant and anti-inflammatory nutrients (in particular selenium, vitamin E, carotenoids, and polyunsaturated fatty acids (PUFAs)) contribute to sarcopenia and decline in physical function in older persons. In the InCHIANTI baseline evaluation, plasma alpha-tocopherol, but not gamma-tocopherol, was significantly correlated with knee extensor strength and lower extremity performance. Intake of vitamin C and beta-carotene were significantly correlated with knee extensor strength, and vitamin C was significantly associated with lower extremity performance. In addition, low selenium level was independently associated with poor muscle strength and higher mortality. In the WHAS, low selenium level was a risk factor for mortality and future increase in inflammatory markers, and in conjunction with low vitamins B-6 and B-12, was an independent risk factor for mortality. Low alpha-tocopherol was an independent correlate of frailty and poor cognitive function. Both in WHAS and InCHIANTI, low carotenoids was an independent risk factor for accelerated decline of muscle strength and incident disability. Thus, deficient intake of multiple nutrients is an independent correlate of frailty, even after adjusting for total energy intake.

Examining the many overlaps between the different components of the homeostatic network, it is disappointing to realize that most studies to date have somewhat arbitrarily dismantled and deconstructed a perfectly integrated architecture. This approach stems, in part, from following the epidemiological paradigm of studying “risk factors to predict outcomes” or, more generally, “independent and dependent variables.” It is now apparent that the traditional epidemiological approach is inadequate to capture the multiple and often reciprocal interrelationships between events and processes. This methodology was developed in the context of studying cardiovascular disease and cancer, with the basic assumption that “exposure” to one or more risk factors increases the probability of an “event” to occur. This perspective is so ingrained that establishing a temporal relationship between the risk factor and the event is considered a necessary step for determining causality. There are at least two reasons why this model is inadequate for studying the aging process and for

investigating compensation, homeostasis and frailty in particular: (1) For all practical purposes, many of the events and processes we study occur at the same time. For example, inflammation is followed by a modification of iron metabolism, hormone levels, cardiovascular reactivity, oxidative stress, and autonomic activity within seconds. In this context, demonstrating that “baseline inflammation predicts changes in iron metabolism” in the context of a longitudinal study is very unlikely. The system that maintains stable homeostatic and maximal function is redundant and its elements are connected by complex, nonlinear interactions. For example, although increased IL-6 is usually considered a negative event, it may be in reality an unsuccessful attempt to compensate for deteriorating health status. This alternative hypothesis is compatible with most data in the literature, but is seldom discussed. In the end, to completely explicate the complexity of the physiology and pathology of homeostasis, new epidemiologic paradigms and statistical methodology must be developed.

An essential but still unanswered question should be addressed to further understand the mechanisms that lead to frailty in old age. Why is such a high level of complexity required to guarantee a stable homeostasis? Is the level of complexity an indicator of weakness or robustness? Complex physiological dynamics enable an organism to rapidly respond to internal and external perturbations. The complex dynamics underlying healthy physiological control systems probably serve an important purpose: they enable an organism to mount a focused adaptive response in order to perform a specific task or overcome an external stress. Therefore, baseline system complexity should predict one’s ability to mount a response. Because the response is, by definition, singular and directed at overcoming a stress, it should be less complex than the baseline condition. Lipsitz and Goldberger have conducted extensive theoretical and empirical work indicating that aging and disease are associated with a loss of complexity in a variety of fractal-like anatomic structures and dynamics of many integrated physiological processes. Such progressive loss of complexity implies loss of adaptive capacity. In fact, less complex systems respond to stress with less specific, stereotyped responses that are less effective and efficient. Researchers have suggested that such loss of complexity may be reversible with interventions such as exercise that can restore healthy dynamics in multiple physiological systems.

## TREATMENT AND PREVENTION OF FRAILITY

Diagnosis, treatment, and prevention of frailty can be considered in terms of our current understanding of frailty and according to each of the levels described in [Figures 52-6 and 52-10](#) and the sections above. The first premise of evaluation is to identify vulnerable, frail individuals before the adverse outcomes for which they are at risk occur. Such a clinical approach should involve careful identification of secondary frailty resulting from latent, undertreated, or end-stage disease such as congestive heart failure, which could be causing a catabolic state and weight loss or decreased nutritional intake. A number of diseases which cause wasting are responsive to therapy, including congestive heart failure, diabetes, thyroid disease, tuberculosis, and other chronic infections, undiagnosed cancer, and inflammatory conditions such as temporal arteritis. Psychological conditions such as depression, psychosis, and grief—as well as dementia—can also present in this manner.

Whether or not frailty results from underlying disease, focus should be placed on the prevention of related adverse outcomes

(see Table 52-1 and Figure 52-10), including falls, delirium, and disability. Evaluation should also include screening for factors that may exacerbate vulnerability for these outcomes, such as medications, hospitalization, surgery, or other stressors, with intervention as indicated. Outpatient geriatric assessment and intervention, with patient-centered goal-setting, family and/or caregiver involvement, and regular follow-up by a geriatrically expert team would help facilitate the identification of problems that would benefit from intervention. Such longitudinal, continuous care has been demonstrated to slow functional decline and reduce symptoms and adverse outcomes in frail older adults.

If disease has been ruled out as the cause of frailty, and thus frailty appears to be the primary condition, a goal should be to institute supportive interventions early. These include targeting the environmental provocations that can trigger or accelerate manifestations of frailty, especially low activity, inadequate nutrition, and catabolic medications. The goal of this intervention would be prevention of muscle loss and improvement in strength and energy. Much of the focus of future research in this area will likely focus on populations where specific deficiencies or increased requirements are recognized.

Attention to maintaining strength and nutritional intake may include prescription of regular exercise, potentially with additional nutritional supplementation if indicated. Screening of frail individuals should evaluate factors such as depression that may contribute to decreased activity or food intake. There is now good evidence indicating that resistance exercise to increase strength of a frail older adult has potential from both a preventive and a therapeutic point of view. In very frail nursing home patients, aged 72 to 98 years, Fiatarone et al. showed that progressive resistance exercise training over a 10-week period improved strength, gait velocity, stair-climbing power, and spontaneous physical activity. Greatest benefit from this resistance (strengthening) exercise program was seen in those who were initially weak but without severe muscle atrophy, i.e., a group with more recent onset of weakness. These findings indicate benefit from exercise for even the most frail, while suggesting that improvement is greatest if declines in strength are caught earlier rather than later. Note that, in this randomized, controlled trial, nutritional supplementation was only effective if added to exercise training; used by itself, it did not lead to increased muscle mass, strength, or functional improvements.

At the other end of the spectrum, primary prevention of frailty through regular strength training also has good potential. In one study of 40 postmenopausal women aged 50 to 70 years, high-intensity strength training exercise 2 days per week led to increased bone mineral density in the femoral neck and lumbar spine, plus significantly improved muscle mass, muscle strength, and dynamic balance in those receiving training, compared to controls. In addition, as with the nursing home patients engaging in resistance exercise (above), the exercise group increased their energy expenditure 27% in activities outside of the intervention itself, compared with the controls who decreased their energy expenditure by 25%. Thus, resistance training appeared to improve a number of risk factors for frailty, as well as for osteoporotic fractures. Evans has also reported that high-intensity strength training has highly anabolic effects in the elderly population. He reported a 10% to 15% decrease in nitrogen excretion at the initiation of such training, which persisted for 12 weeks. That is, progressive resistance training improved nitrogen balance. As a result, older patients performing resistance training had a lower mean protein intake requirement than did sedentary

subjects. In contrast, aerobic exercise causes an increase in protein requirements. Overall, exercise training appears to improve muscle mass and strength and resulting functional performance. It is notable that increases in strength with high-intensity strength training are substantially greater than those seen to date with growth hormone, while increases with growth hormone do not appear to translate into functional improvements.

Preservation of fat-free mass and prevention of sarcopenia should help prevent the decrease in metabolic rate described in association with frailty. Maintenance of strength should facilitate maintenance of exercise tolerance directly and also because those with improved strength appear to engage spontaneously in more activity. In prevention of frailty, this appears to be a critical stage, both to prevent the downward cycle of frailty and the development of disability. Otherwise, with declining exercise tolerance, activities of daily living start to take up larger proportions of  $VO_2$  max, with highly sedentary older adults requiring as much as 90% of their  $VO_2$  max to carry out basic self-care tasks.

The role of nutritional supplementation is less well defined. In the trial by Fiatarone of resistance exercise and nutritional supplementation in frail nursing home patients, total energy intake did not increase in those exercising (without nutritional supplementation) or in those receiving nutritional supplementation but not exercise, compared to controls. This was the case even though this population had a marginal nutritional intake at baseline. Only with both exercise and nutritional supplementation did energy intake increase; these people gained weight but not fat-free mass, however.

## CONCLUSION

For geriatric medicine, studying frailty and establishing an operational definition that allows its implementation in clinical practice is an opportunity, a need, and a responsibility. To make explicit the value of geriatric medicine, the fundamental difference between using a whole patient-centered approach compared to the disease-centered approach should be demonstrated in terms of health outcomes. Understanding and operationalizing frailty in clinical practice maybe a key to reaching this goal. Frailty is also an opening that allows a view into the complexity of events that cause susceptibility and loss of function in older individuals. Through this opening, it maybe possible to identify new targets for interventions that, in the future, may reduce the burden of morbidity and disability in this vulnerable portion of the older population.

# Delirium

Sharon K. Inouye ■ Michael A. Fearing ■ Edward R. Marcantonio

Delirium, defined as an acute disorder of attention and global cognitive function, is a common, serious, and potentially preventable source of morbidity and mortality for hospitalized older persons. It occurs in 14% to 56% of such persons and represents the most frequent complication of hospitalization for this group. With the aging of the U.S. population, delirium has assumed heightened importance because persons aged 65 years and older presently account for more than 49% of all days of hospital care. Delirium complicates hospital stays for at least 20% of the 12.5 million patients 65 years of age or older who are hospitalized each year and increases hospital costs by \$2500 per patient, so that \$6.9 billion (in 2004 U.S. dollars) of Medicare hospital expenditures are attributable to delirium. Importantly, substantial additional costs linked to delirium accrue after hospital discharge because of the increased need for institutionalization, rehabilitation services, closer medical follow-up, and home health care. Delirium often initiates a cascade of events in older persons, leading to a downward spiral of functional decline, loss of independence, institutionalization, and ultimately, death. These statistics highlight the importance of delirium from both clinical and health policy perspectives. In fact, a recent consensus panel identified delirium as among the top three target conditions for quality-of-care improvement for vulnerable older adults. With its common occurrence, its frequently iatrogenic nature, and its close linkage to the processes of care, incident delirium can serve as a marker for the quality of hospital care and provides an opportunity for quality improvement.

## DEFINITION

The definition of and diagnostic criteria for delirium continue to evolve (Table 53-1). The standardized criteria for delirium that appear in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision* (DSM-IV-TR) remain the current diagnostic standard. Expert consensus was used to develop these criteria, however, and performance

characteristics such as diagnostic sensitivity and specificity have not been reported for DSM-IV criteria. A standardized tool, the Confusion Assessment Method (CAM), provides a brief, validated diagnostic algorithm that is currently in widespread use for identification of delirium. The CAM algorithm relies on the presence of acute onset and fluctuating course, inattention, and either disorganized thinking or altered level of consciousness. The algorithm has a sensitivity of 94% to 100%, specificity of 90% to 95%, and high interrater reliability. Given the uncertainty of diagnostic criteria for delirium, a critical area for future investigation is to establish more definitive criteria, including epidemiologic and phenomenologic evaluations assisted by advances in functional neuroimaging and other potential diagnostic marker tests.

## EPIDEMIOLOGY

Most of the epidemiological studies of delirium involved hospitalized older patients, in whom the highest rates of delirium occur. Reported rates vary based upon the subgroup of patients studied and the setting of care (e.g., hospital, intensive care, surgical). Previous studies estimated the prevalence of delirium (present at the time of hospital admission) at 14% to 24% and the incidence of delirium (new cases arising during hospitalization) at 6% to 56%. The rates of delirium in high-risk hospital venues, such as the intensive care unit and posthip fracture settings, range from 70% to 87% and 15% to 53%, respectively. Delirium occurs in up to 60% of patients in nursing homes or postacute settings, and in up to 83% of all patients at the end of life. The rates of delirium in all older persons presenting to the emergency department in several studies have ranged from 10% to 30%. While less frequent in the community setting, delirium is an important presenting symptom to emergency departments and community physicians, and often heralds serious underlying disease. Delirium is often unrecognized; previous studies have documented that clinicians fail to detect up to 70% of affected

**TABLE 53-1****Diagnostic Criteria for Delirium**

Diagnostic and Statistical Manual (DSM-IV) Diagnostic Criteria

- A. A disturbance of consciousness (i.e., reduced awareness of the external environment) with reduced ability to focus, sustain, or shift attention.
- B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting dementia.
- C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate over the course of a 24-hour period.
- D. Evidence from the history, physical examination, or laboratory findings that the disturbance is caused by an underlying organic condition or is the direct physiologic consequences of a general medical condition or its treatment.

The Confusion Assessment Method (CAM) Diagnostic Algorithm\*

Feature 1. Acute onset and fluctuating course

This feature is usually obtained from a reliable reporter, such as a family member, caregiver, or nurse, and is shown by positive responses to these questions: Is there evidence of an acute change in mental status from the patient's baseline? Did the (abnormal) behavior fluctuate during the day, that is, tend to come and go, or did it increase and decrease in severity?

Feature 2. Inattention

This feature is shown by a positive response to this question: Did the patient have difficulty focusing attention, for example, being easily distractible, or have difficulty keeping track of what was being said?

Feature 3. Disorganized thinking

This feature is shown by a positive response to this question: Was the patient's thinking disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject?

Feature 4. Altered level of consciousness

This feature is shown by any answer other than "alert" to this question: Overall, how would you rate this patient's level of consciousness (alert [normal], vigilant [hyperalert], lethargic [drowsy, easily aroused], stupor [difficult to arouse], or coma [unarousable])?

\*The ratings for the CAM should be completed following brief cognitive assessment of the patient, for example, with the Mini-Mental State Examination. The diagnosis of delirium by CAM requires the presence of features 1 and 2 and of either 3 or 4.

patients across all of these settings. Furthermore, the presence of delirium portends a potentially poor prognosis; hospital mortality rates in patients with delirium range from 22% to 76%, as high as mortality rates associated with acute myocardial infarction or sepsis. Following hospitalization, the one-year mortality rate associated with cases of delirium is 35% to 40%.

## ETIOLOGY

The etiology of delirium is usually multifactorial, like many other common geriatric syndromes, such as falls, incontinence, and pressure sores. Although there may be a single cause of delirium, more commonly, delirium results from the interrelationship between patient vulnerability (i.e., predisposing factors) and the occurrence of noxious insults (i.e., precipitating factors). For example, patients

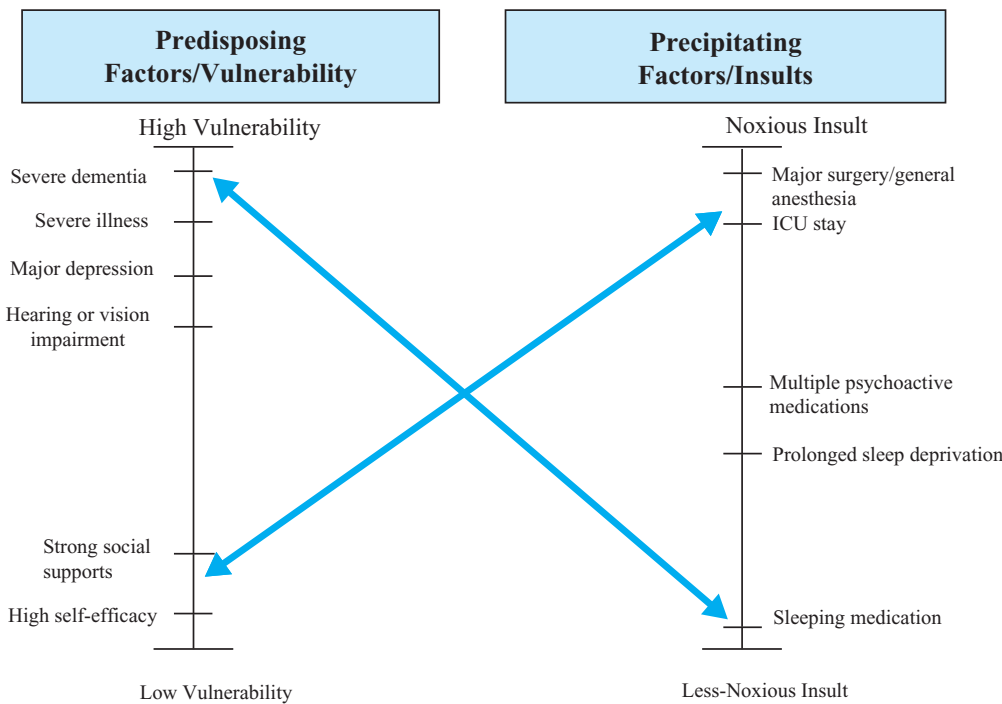

who are highly vulnerable to delirium at baseline (e.g., such as patients with dementia or serious illness) can experience acute delirium after exposure to otherwise mild insults, such as a single dose of a sedative medication for sleep. On the other hand, older patients with few predisposing factors (low baseline vulnerability) would be relatively resistant, with precipitation of delirium only after exposure to multiple potentially detrimental insults, such as general anesthesia, major surgery, multiple psychoactive medications, immobilization, and infection (Figure 53-1). Moreover, based on predictive models of delirium, the effects of multiple risk factors appear to be cumulative. Clinically, the overall importance of the multifactorial nature of delirium is that removal or treatment of one risk factor alone often fails to resolve delirium. Instead, addressing many or all of the predisposing and precipitating factors for delirium is often required before the delirium improves.

## Predisposing Factors

Predisposing factors for delirium include preexisting cognitive impairment or dementia, advanced age, severe underlying illness and comorbidity, functional impairment, male gender, depression, chronic renal insufficiency, dehydration, malnutrition, alcohol abuse, and sensory impairments (vision or hearing) (Table 53-2). Preexisting cognitive impairment, or dementia, is a powerful and consistent risk factor for delirium demonstrated across multiple studies, and patients with dementia have a two- to fivefold increased risk for delirium. Moreover, up to half of delirious patients have an underlying dementia. Nearly any chronic medical condition can predispose to delirium, ranging from diseases involving the central nervous system (e.g. Parkinson's disease, cerebrovascular disease, mass lesions, trauma, infection, collagen vascular disease), to diseases outside the central nervous system, including infectious, metabolic, cardiac, pulmonary, endocrine, or neoplastic etiologies. Independent predisposing risk factors for delirium at the time of hospital admission validated in a predictive model include severe underlying illness, vision impairment, baseline cognitive impairment, and high blood urea nitrogen (BUN):creatinine ratio (used as an index of dehydration). Predictive risk models that identify predisposing factors in populations such as surgical patients, cancer patients, and nursing home residents, have recently been developed and aid in the understanding of baseline patient characteristics contributing to delirium risk.

## Precipitating Factors

Major precipitating factors identified in previous studies include medication use (see section on "Drug Use and Delirium"), immobilization, use of indwelling bladder catheters, use of physical restraints, dehydration, malnutrition, iatrogenic events, medical illnesses, infections, metabolic derangement, alcohol or drug intoxication or withdrawal, environmental influences, and psychosocial factors (see Table 53-2). Decreased mobility is strongly associated with delirium and concomitant functional decline. The use of medical equipment and devices (e.g., indwelling bladder catheters and physical restraints) may further contribute to immobilization. Major iatrogenic events occur in 29% to 38% of older hospitalized adults (three to five times the risk when compared with adults younger than 65 years old). Examples include complications related to diagnostic or therapeutic procedures, allergic reactions, and bleeding caused

**FIGURE 53-1.** Multifactorial model for delirium. The etiology of delirium involves a complex interrelationship between the patient's underlying vulnerability or predisposing factors (*left axis*) and precipitating factors or noxious insults (*right axis*). For example, a patient with high vulnerability, such as with severe dementia, underlying severe illness, hearing or vision impairment, might develop delirium with exposure to only one dose of a sleeping medication. Conversely, a patient with low vulnerability would develop delirium only with exposure to many noxious insults, such as general anesthesia and major surgery, ICU stay, multiple psychoactive medications, and prolonged sleep deprivation. (Adapted from Inouye SK. *Delirium in hospitalized older patients. Clin Geriatr Med.* 475, 1998.)

by over anticoagulation. Many of these events potentially are preventable. Disorders of any major organ system, particularly renal or hepatic failure, can precipitate delirium. Occult respiratory failure has emerged as an increasing problem in elderly patients, who often lack the typical signs and symptoms of dyspnea and tachypnea. In older adults, acute myocardial infarction and congestive heart failure may present with delirium or “failure to thrive” as the cardinal fea-

ture, and minimal or none of the usual symptoms of angina or dyspnea. Occult infection, caused by pneumonia, urinary tract infection, endocarditis, abdominal abscess, or infected joint, is a particularly noteworthy cause of delirium because older patients may not present with leukocytosis or a typical febrile response. Metabolic and endocrinologic disorders, such as hyper- or hyponatremia, hypercalcemia, acid–base disorders, hypo- and hyperglycemia, and thyroid or adrenal disorders, may also contribute to delirium. The precipitating factors for delirium in hospitalized older patients that have been validated in a predictive model include use of physical restraints, malnutrition, more than three medications added during the previous day (more than 70% of these were psychoactive drugs), indwelling bladder catheter, and any iatrogenic event. The presence of these independent factors contributes to delirium risk in a predictable and cumulative manner, yet each risk factor is potentially modifiable.

**TABLE 53-2**

### Predisposing and Precipitating Factors for Delirium

#### Predisposing factors

- Dementia or underlying cognitive impairment
- Severe illness
- Comorbidity
- Depression
- Vision and/or hearing impairment
- Functional impairment, inactivity
- Volume depletion
- Chronic renal insufficiency
- Structural brain abnormality or previous stroke
- History of alcohol abuse
- History of delirium
- History of falls
- Advanced age
- Baseline use of psychoactive drugs
- Male gender
- Malnutrition

#### Precipitating factors

- Psychoactive drugs
- Immobilization
- Indwelling bladder catheters
- Physical restraints
- Dehydration
- Poor nutritional status
- Iatrogenic complications
- Intercurrent medical illnesses
- Major surgical procedure
- Metabolic derangements (electrolytes, glucose, acid–base)
- Infections
- Hypoxia
- Alcohol or drug intoxication or withdrawal
- Sensory deprivation
- Sensory overload
- Pain
- Emotional stress, bereavement
- Prolonged sleep deprivation

### Drug Use and Delirium

In 40% or more of delirium cases, use of one or more specific medication contributes to its development. While medications often incite delirium, they are also the most common remediable cause of delirium. A broad array of medications and their metabolites can lead to delirium; the most common are those with known psychoactive effects, such as sedative hypnotics, anxiolytics, narcotics, H<sub>2</sub>-blockers, and medications with anticholinergic activity (Table 53-3). In previous studies, use of any psychoactive medication was associated with a fourfold increased risk of delirium, while use of two or more psychoactive medications was associated with a fivefold increased risk. Sedative–hypnotic drugs are associated with a 3- to 12-fold increased risk of delirium; narcotics with a threefold risk; and anticholinergic drugs with a 5- to 12-fold risk. The incidence of delirium, similar to other adverse drug events, increases in direct proportion to the number of medications prescribed, because of the effects of the

**TABLE 53-3****Drugs Associated with Delirium**

Sedatives/hypnotics
Benzodiazepines (especially flurazepam, diazepam)
Barbiturates
Sleeping medications (diphenhydramine, chloral hydrate)
Narcotics (especially meperidine)
Anticholinergics
Antihistamines (diphenhydramine, hydroxyzine)
Antispasmodics (belladonna, Lomotil)
Heterocyclic antidepressants (amitriptyline, imipramine, doxepin)
Neuroleptics (chlorpromazine, haloperidol, thioridazine)
Incontinence (oxybutynin, hyoscyamine)
Atropine/scopolamine
Cardiac
Digitalis glycosides
Antiarrhythmics (quinidine, procainamide, lidocaine)
Antihypertensives (beta-blockers, methyldopa)
Gastrointestinal
H <sub>2</sub> -antagonists (cimetidine, ranitidine, famotidine, nizatidine)
Proton pump inhibitors
Metoclopramide (Reglan)
Herbal remedies (valerian root, St. John's Wort, kava kava)

medications themselves, as well as to the increased risk of drug–drug and drug–disease interactions. Recent studies provide compelling evidence that suboptimal medication management, ranging from inappropriate use to overuse of psychoactive medications, occurs commonly in older adults in the hospital and in community settings, and suggests that many cases of delirium and other related adverse drug events may be preventable. As the number of prescription and over-the-counter drugs consumed by the older population increases, review of potentially problematic medications will remain an important step in the search for predisposing factors in the patient with delirium.

### Relationship between Delirium and Dementia

While delirium and dementia are highly interrelated, the nature of their relationship remains poorly examined. The contribution of delirium itself to permanent cognitive impairment or dementia remains controversial; however, previous studies document that at least some patients postdelirium never recover their baseline level of cognitive function. Thus, delirium and dementia may represent two ends along a spectrum of cognitive impairment with “chronic delirium” and “reversible dementia” falling along this continuum. Dementia is the leading risk factor for delirium, and fully two-thirds of cases of delirium occur in patients with dementia. Moreover, studies have shown that delirium and dementia are both associated with decreased cerebral metabolism, cholinergic deficiency, and inflammation, reflecting their overlapping clinical, metabolic, and cellular mechanisms. Delirium can alter the course of an underlying dementia, with dramatic worsening of the trajectory of cognitive decline, resulting in more rapid progression of functional losses and worse long-term outcomes. In follow-up studies, patients with dementia in whom delirium develops have worse outcomes than those with dementia alone, including worsened cognitive function and increased rates of hospitalization, institutionalization, and death.

### PATHOPHYSIOLOGY

The fundamental pathophysiological mechanisms of delirium remain unclear. Delirium is thought to represent a functional rather than structural lesion, with characteristic electroencephalographic (EEG) findings demonstrating global functional derangements and generalized slowing of cortical background (alpha) activity. The leading current hypotheses view delirium as the final common pathway of many different pathogenic mechanisms, resulting from dysfunction of multiple brain regions and neurotransmitter systems. Evidence from EEG, evoked-potential studies, and neuroimaging studies suggest predominantly right-sided abnormalities in delirium localized to the prefrontal cortex, thalamus, basal ganglia, temporoparietal cortex, fusiform, and lingual gyri. Studies using x-ray computed tomography (CT) or magnetic resonance imaging (MRI) have found lesions or structural abnormalities in the brains of patients with delirium. Several studies of cerebral blood flow (CBF) using single photon emission computed tomography (SPECT) found that delirium is mostly associated with decreased blood flow. However, results from previous studies have been highly variable. Associated neurotransmitter abnormalities involve elevated brain dopaminergic function, reduced cholinergic function, or a relative imbalance of these systems. Serotonergic activity may interact to regulate or alter activity of these other two systems, and serotonin levels may be either increased or decreased. Extensive evidence supports the role of cholinergic deficiency. Acetylcholine plays a key role in consciousness and attentional process. Given that delirium is manifested by an acute confusional state often with alterations of consciousness, it is likely to have a cholinergic basis. Anticholinergic drugs can induce delirium in humans and animals, and serum anticholinergic activity is increased in patients with delirium. Physostigmine reverses delirium associated with anticholinergic drugs, and cholinesterase inhibitors appear to have some benefit even in cases of delirium that are not induced by drugs. The stress response associated with severe medical illness or surgery involves sympathetic and immune system activation, including increased activity of the hypothalamic–pituitary–adrenal axis with hypercortisolism, release of cerebral cytokines that alter neurotransmitter systems, alterations in the thyroid axis, and modification of blood–brain barrier permeability. Age-related changes in central neurotransmission, stress management, hormonal regulation, and immune response may contribute to the increased vulnerability of older persons to delirium. The description of delirium as “acute brain failure”—involving multiple neural circuits, neurotransmitters, and brain regions—suggests that understanding delirium may help to elucidate the essential underlying mechanisms of brain functioning.

### PRESENTATION

#### Cardinal Features

Acute onset and inattention are the central features of delirium. Determining the acuity of onset requires accurate knowledge of the patient's prior cognitive status. Pinpointing the origin and time course of changes in mental status often entails obtaining historical information from another close observer, such as a family member,

caregiver, or nurse. Typically with delirium, the mental status changes occur over hours to days, in contrast to the changes that occur with dementia, which present insidiously over weeks to months. Another key feature is the fluctuating course of delirium, with symptoms tending to wax and wane in severity over a 24-hour period. Lucid intervals are characteristic, and the reversibility of symptoms within a short time can deceive even an experienced clinician. Inattention is manifested as difficulty focusing, maintaining, and shifting attention or concentration. With simple cognitive assessment, patients may display difficulty with straightforward repetition tasks, digit spans, or recitation of the months of the year backward. Delirious patients appear easily distracted, experience difficulty with multistep commands, cannot follow the flow of a conversation, and often perseverate with an answer to a previous question. Additional major features include a disorganization of thought and altered level of consciousness. Disorganized thoughts are a manifestation of underlying cognitive or perceptual disturbances, and can be recognized by disjointed and incoherent speech, or an unclear or illogical progression of ideas. Clouding of consciousness is typically manifested by lethargy, with a reduced awareness of the environment that may show diurnal variation. Although not cardinal elements, other frequently associated features include disorientation (more commonly to time and place than to self), cognitive impairments (e.g., memory and problem-solving deficits, dysnomia), psychomotor agitation or retardation, perceptual disturbances (e.g., hallucinations, misperceptions, illusions), paranoid delusions, emotional lability, and sleep–wake cycle disruption.

### Tools for Evaluation of Delirium

Table 53-4 describes the most widely used instruments for identification of delirium, along with their performance characteristics. These include CAM, the Delirium Rating Scale (DRS), the Delirium Symptom Interview (DSI), and the Memorial Delirium Assessment Scale (MDAS). Each instrument has strengths and limitations, and the choice among them depends on the goals for use. Notably, the evaluation for the CAM has been adapted recently as the CAM-ICU for nonverbal or intubated patients. In addition, the DRS–Revised-98 version allows more refined measurements of delirium severity over a broad range of symptoms. An adapted version of the CAM is also being included as the delirium screening tool in the ongoing national test of the new version of the Minimum Data Set (MDS Version 3.0). The Minimum Data Set is a standardized resident assessment that is completed on every person admitted to a Medicare certified nursing home in the United States.

### Forms of Delirium

The clinical presentation of delirium can take two main forms, either hypoactive or hyperactive. The hypoactive form of delirium is characterized by lethargy and reduced psychomotor functioning, and is the more common form in older patients. Hypoactive delirium often goes unrecognized and carries an overall poorer prognosis. The reduced level of patient activity associated with hypoactive delirium, often attributed to low mood or fatigue, may contribute to its misdiagnosis or underrecognition. By contrast, the hyperactive form of delirium presents with symptoms of agitation, increased vigilance, and often concomitant hallucinations; its presentation rarely remains unnoticed by caregivers or clinicians. Importantly, patients can fluctuate

between the hypoactive and hyperactive forms—the mixed type of delirium—presenting a challenge in distinguishing the presentation from other psychotic or mood disorders. Moreover, recent recognition of partial or incomplete forms of delirium has brought attention to the persistence of symptoms among older patients, particularly during the resolution stages of delirium, when manifestation of the full syndrome may not be apparent. Partial forms of delirium also adversely influence long-term clinical outcomes.

### PROGNOSIS

Delirium is an important independent determinant of prolonged length of hospital stay, increased mortality, increased rates of nursing home placement, and functional and cognitive decline—even after controlling for age, gender, dementia, illness severity, and baseline functional status.

Delirium has long been thought to be a reversible, transient condition. Recent research on the duration of delirium symptoms, however, provides evidence that delirium may persist for much longer than previously recognized. In fact, delirium symptoms generally persist for a month or more; as few as 20% of patients attain complete symptom resolution at 6-month follow-up. In addition, those patients with extant cognitive impairment may experience greater deleterious effects than comparable patients without dementia. The chronic detrimental effects are likely related to the duration, severity, and underlying cause(s) of the delirium, in addition to the baseline vulnerability of the patient.

### EVALUATION

The acute evaluation of delirium centers on three main tasks that occur simultaneously: (1) establishing the diagnosis of delirium; (2) determining the potential cause(s) and ruling out life-threatening contributors; and (3) managing the symptoms. Delirium is a clinical diagnosis, relying on astute observation at the bedside, careful cognitive assessment, and history taking from a knowledgeable informant to establish a change from the patient's baseline functioning. Identifying the potentially multifactorial contributors to the delirium is of paramount importance, because many of these factors are treatable, and if left untreated, may result in substantial morbidity and mortality. Because the potential contributors are myriad, the search requires a thorough medical evaluation guided by clinical judgment. The challenge is enhanced by the frequently nonspecific or atypical presentation of the underlying illness in older persons. In fact, delirium is often the *only* sign of life-threatening illness, such as sepsis, pneumonia, or myocardial infarction in older persons. Recently, The Royal College of Physicians has established national guidelines to aid in the prevention, treatment, and management of delirium in older people ([www.rcplondon.ac.uk/pubs/books/pdmd/index.asp](http://www.rcplondon.ac.uk/pubs/books/pdmd/index.asp)). These guidelines highlight both the importance of delirium in the aged, and the need for better recognition and treatment of delirium.

### History and Physical Examination

A thorough history and physical examination constitute the foundation of the medical evaluation of suspected delirium. The first step in evaluation should be to establish the diagnosis of delirium

TABLE 53-4

## Sample Instruments Used to Evaluate Delirium

DESCRIPTION	DOMAINS	VALIDATION	REFERENCE STANDARD	RELIABILITY	FEASIBILITY
<i>Confusion Assessment Method (CAM)</i>					
Nine operationalized delirium criteria scored according to CAM algorithm. Shortened version uses four criteria. Based on observations made during interview with MMSE, by trained lay or clinical interviewer.	<ul style="list-style-type: none"> <li>• Onset/course</li> <li>• Attention</li> <li>• Organization of thought</li> <li>• Level of consciousness</li> <li>• Orientation</li> <li>• Memory</li> <li>• Perceptual problems</li> <li>• Psychomotor behavior</li> <li>• Sleep–wake cycle</li> </ul>	Sensitivity = 0.94–1.0 ( $n = 26$ delirious patients) Specificity = 0.90–0.95 ( $n = 30$ controls without delirium) Convergent agreement with four other cognitive measures Ability to distinguish delirium and dementia verified	Geropsychiatrists' diagnoses based on clinical judgment and DSM-III-R criteria	Interrater: $K = 1.0$ overall	Observer-rated: 10–15 min for cognitive testing and completion of rating
<i>CAM-ICU (CAM adaptation)</i>					
Uses four CAM criteria. Cognitive assessment adapted for use only in nonverbal or ventilated patients.	<ul style="list-style-type: none"> <li>• Onset/course</li> <li>• Attention</li> <li>• Organization of thought</li> <li>• Level of consciousness</li> </ul>	Sensitivity = 0.93–1.0 Specificity = 0.98–1.0 ( $n = 91$ patients)	Delirium expert clinicians' ratings based on DSM-IV criteria	Interrater: $K = 0.96$ overall	Observer-rated: <5 min for cognitive assessment and completion of rating
<i>Delirium Rating Scale (DRS)</i>					
Ten-item rating, with additive score 0 to 32, designed to be completed by a psychiatrist after complete psychiatric assessment. Useful to rate severity.	<ul style="list-style-type: none"> <li>• Onset/course</li> <li>• Cognitive status</li> <li>• Perceptual problems</li> <li>• Delusions</li> <li>• Psychomotor behavior</li> <li>• Emotional lability</li> <li>• Sleep–wake cycle</li> <li>• Physical disorder</li> </ul>	No overlap in scores between delirious group ( $n = 20$ ) and three control groups: demented ( $n = 9$ ), schizophrenic ( $n = 9$ ), and normal ( $n = 9$ ). Convergent agreement with two other cognitive measures. Ability to distinguish delirium and dementia verified	Consult-liaison psychiatrist's diagnosis based on DSM-III criteria	Interrater: intraclass correlation coefficient = 0.97	Observer-rated: based on lengthy interview and detailed assessment (time not specified)
<i>Delirium Symptom Interview (DSI)</i>					
Includes interview with brief cognitive assessment and rating scale for 7 symptom domains of delirium, by trained lay or clinical interviewer.	<ul style="list-style-type: none"> <li>• Course</li> <li>• Organization of thought</li> <li>• Level of consciousness</li> <li>• Orientation</li> <li>• Perceptual problems</li> <li>• Psychomotor behavior</li> <li>• Sleep–wake cycle</li> </ul>	Sensitivity = 0.90 Specificity = 0.80 ( $n = 30$ "cases", 15 noncases, 3 borderline, 2 disagreements by psychiatrist and neurologist). Ability to distinguish delirium and dementia not tested	Psychiatrist's and neurologist's assessments based on presence of any 1 of 3 "critical symptoms" (disorientation, disturbance of consciousness, or perceptual disturbance)	Interrater: $K = 0.90$ overall	Observer-rated part; 15+ min for interview, plus additional time for completion or rating (not specified)
<i>Memorial Delirium Assessment Scale (MDAS)</i>					
Ten-item scale, with additive score 0 to 30 using cognitive testing and behavioral observations, by experienced mental health professionals. Designed to rate delirium severity, not for screening or diagnosis.	<ul style="list-style-type: none"> <li>• Level of consciousness</li> <li>• Orientation</li> <li>• Memory</li> <li>• Digit span</li> <li>• Attention</li> <li>• Organization of thought</li> <li>• Perceptual problems</li> <li>• Delusions</li> <li>• Psychomotor behavior</li> <li>• Sleep–wake cycle</li> </ul>	Sensitivity = 0.82 Specificity = 0.75 (with score = 10; $n = 33$ : 17 delirium, 8 dementia, 8 other psychiatric)	Consult-liaison psychiatrist's diagnosis using DRS, MMSE, and Clinician's Global Rating of delirium severity	Interrater: intraclass correlation coefficient = 0.92 overall	Observer-rated in part; 10+ min for administration

DSM-III, *Diagnostic and Statistical Manual of Mental Disorders*, 3rd ed.; DSM-III-R, *Diagnostic and Statistical Manual of Mental Disorders*, 3rd ed. rev.; DSM-IV, *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed.; MMSE, Mini-Mental State Examination.

through careful cognitive assessment and to determine the acuity of change from the patient's baseline cognitive state. Because cognitive impairment may easily be missed during routine conversation, brief cognitive screening tests, such as the Mini-Mental Status Examination and the CAM, should be used. The degree of attention should be further assessed with simple tests such as a forward digit span (inattention indicated by an inability to repeat five digits forward) or recitation of the months of the year backward. A targeted history, focusing on baseline cognitive status and chronology of recent mental status changes, should be elicited from a reliable informant. In addition, such historical data as intercurrent illnesses, recent adjustments in medication regimen, the possibility of alcohol withdrawal, and pertinent environmental changes may point to potential precipitating factors of delirium.

The physical examination should include a detailed review that focuses on potential etiologic clues to an underlying or inciting disease process. Vital sign assessment is important to identify fever, tachycardia, or decreased oxygen saturation, each of which may point to specific disease processes. Auscultatory examination may suggest pneumonia or pulmonary effusion. A new cardiac murmur or dysrhythmia may suggest ischemia or congestive heart failure. Gastrointestinal examination should focus on evidence of an acute abdominal process, such as occult bleeding, perforated viscus, or infection. Patients with delirium may also demonstrate nonspecific focal findings on neurologic examination, such as asterixis or tremor, although the presence of any new neurologic deficit should raise suspicion of an acute cerebrovascular event or subdural hematoma. As previously mentioned, in many older patients and in those with cognitive impairment, delirium may be the initial manifestation of a serious new disease process. Therefore, attention to early localizing signs on serial physical examinations is important.

A complete medication review, including over-the-counter medications, is critical, and any medications with known psychoactive effects should be discontinued or minimized whenever possible. Because of pharmacodynamic and pharmacokinetic changes in aging adults, these medications may cause deleterious psychoactive effects even when prescribed at customary doses and with serum drug levels that are within the "therapeutic range."

### Laboratory Tests and Imaging

Notwithstanding the growing recognition of geriatric syndromes such as delirium, there is little evidence-based research that assesses the predictive value of laboratory and other diagnostic testing in the evaluation of delirium. Consequently, laboratory evaluation should be guided by clinical judgment, taking into account specific patient characteristics and historical data. An astute history and physical examination, medication review, focused laboratory testing (e.g., complete blood count, chemistries, glucose, renal and liver function tests, urinalysis, oxygen saturation), and search for occult infection should help to identify the majority of potential contributors to the delirium. Obtaining additional laboratory testing such as thyroid function tests, B-12 level, cortisol level, drug levels or toxicology screen, syphilis serologies, and ammonia level should be based on a patient's distinct clinical presentation. Further diagnostic workup with an electrocardiogram, chest radiograph, and/or arterial blood gas determination may be appropriate for patients with pulmonary or cardiac conditions. The indications for cerebrospinal fluid examination, brain imaging, or EEG remain controversial. Their overall

diagnostic yield is low, and these procedures are probably indicated in less than 5% to 10% of delirium cases. Lumbar puncture with cerebrospinal fluid examination is indicated for the febrile delirious patient when meningitis or encephalitis is suspected. Brain imaging (such as CT or MRI) should be reserved for cases with new focal neurologic signs, with history or signs of head trauma, or without another identifiable cause of the delirium. Of note, some neurologic symptoms are associated with delirium, including tremor and asterixis. EEG, which has a false-negative rate of 17% and a false-positive rate of 22% for distinguishing between delirious and nondelirious patients, plays a limited role and is most commonly employed to detect subclinical seizure disorders and to differentiate delirium from nonorganic psychiatric conditions.

### Differential Diagnosis

Distinguishing a long-standing confusional state (dementia) from delirium alone, or from delirium superimposed on dementia, is an important, but often difficult, diagnostic step. These two conditions can be differentiated by the acute onset of symptoms in delirium, with dementia presenting much more insidiously and by the impaired attention and altered level of consciousness associated with delirium.

The differential diagnosis of delirium can be extensive and includes other psychiatric conditions such as depression and nonorganic psychotic disorders (Table 53-5). Although perceptual disturbances, such as illusions and hallucinations, can occur with delirium, recognition of the key features of acute onset, inattention, altered level of consciousness, and global cognitive impairment will enhance the identification of delirium. Differentiating among diagnoses is critical because delirium carries a more serious prognosis without proper evaluation and management, and treatment for certain conditions such as depression or affective disorders may involve use of drugs with anticholinergic activity, for example, which could exacerbate an unrecognized case of delirium. At times, working through the differential diagnosis can be quite challenging, particularly with an uncooperative patient or when an accurate history is unavailable, and the diagnosis of delirium may remain uncertain. Because of the potentially life-threatening nature of delirium, however, it is prudent to manage the patient as having delirium and search for underlying precipitants (e.g., intercurrent illness, metabolic abnormalities, adverse medication effects) until further information can be obtained.

### Algorithm for the Evaluation of Altered Mental Status

Figure 53-2 presents an algorithm for the evaluation of altered mental status in the older patient. The initial steps center on establishing the patient's baseline cognitive functioning and the onset and timing of any cognitive changes. Chronic impairments, representing changes that occur over months to years, are most likely attributable to a dementia, which should be evaluated accordingly (see Chapter 65). Acute alterations, representing abrupt deteriorations in mental status, occur over hours to weeks, although they may be superimposed on an underlying dementia. They should be further evaluated with cognitive testing to establish the presence of delirium. In the absence of notable delirium features (see "Presentation" earlier in this chapter), subsequent evaluation should focus on the possibility of major depression, acute psychotic disorder, or other psychiatric disorders (see Chapters 70 to 72).

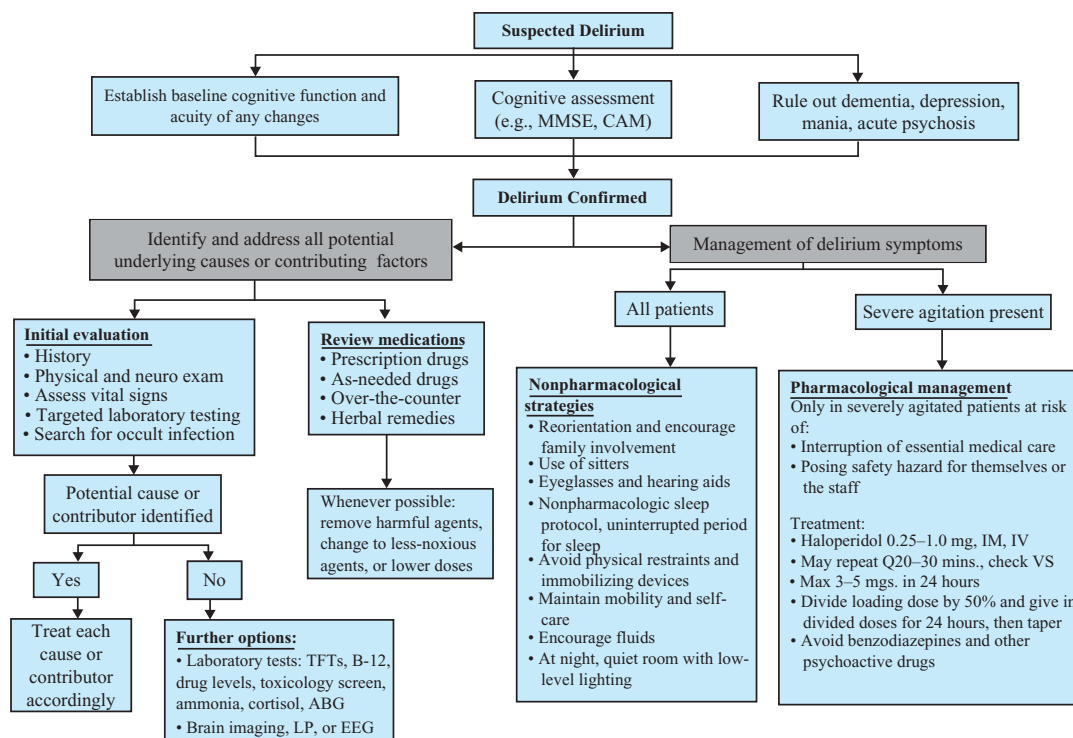

**TABLE 53-5****Differential Diagnosis of Altered Mental Status**

CHARACTERISTIC	DELIRIUM	DEMENTIA	DEPRESSION	ACUTE PSYCHOSIS
Onset	Acute (hours to days)	Progressive, insidious (weeks to months)	Either acute or insidious	Acute
Course over time	Waxing and waning	Unrelenting	Variable	Episodic
Attention	Impaired, a hallmark of delirium	Usually intact, until end-stage disease	Decreased concentration and attention to detail	Variable
Level of consciousness	Altered, from lethargic to hyperalert	Normal, until end-stage disease	Normal	Normal
Memory	Impaired commonly	Prominent short- and/or long-term memory impairment	Normal, some short-term forgetfulness	Usually normal
Orientation	Disoriented	Normal, until end-stage disease	Usually normal	Usually normal
Speech	Disorganized, incoherent, illogical	Notable for parsimony, aphasia, anomia	Normal, but often slowing of speech (psychomotor retardation)	Variable, often disorganized
Delusions	Common	Common	Uncommon	Common, often complex
Hallucinations	Usually visual	Sometimes	Rare	Usually auditory and more complex
Organic etiology	Yes	Yes	No	No

**PREVENTION**

Primary prevention—preventing delirium before it develops—is the most effective strategy for reducing delirium and its associated adverse outcomes, which range from functional disability to longer

lengths of hospital stay, institutionalization, and death. Table 53-6 describes well-documented delirium risk factors and tested preventive interventions to address each risk factor. A controlled clinical trial demonstrated the effectiveness of a delirium prevention strategy targeted toward these risk factors. The selection of risk factors was based upon their clinical relevance and the degree to which they

**FIGURE 53-2.** Flowchart for evaluation of suspected delirium in an older person. ABG, arterial blood gas; B-12, cyanocobalamin for vitamin B-12 level; CAM, Confusion Assessment Method; EEG, electroencephalography; LP, lumbar puncture; MMSE, Mini-Mental State Examination; neuro exam, neurologic examination; TFT, thyroid function tests (e.g., T4, thyroid index, thyroid-stimulating hormone); VS, vital signs. could be modified by employing practical and feasible interventions. Compared with standard care, implementation of these preventive interventions resulted in a 40% risk reduction for delirium in hospitalized older patients.

The Hospital Elder Life Program (HELP; [www.hospitalelderlifeprogram.org](http://www.hospitalelderlifeprogram.org)) represents an innovative strategy of hospital care for older patients, designed to incorporate the tested delirium prevention strategies and to improve overall quality of hospital care. Programs such as HELP underscore the importance of an interdisciplinary team's contributions to the prevention of delirium. For example, trained volunteers and family members can play roles in daily orientation, therapeutic recreation activities, and feeding assistance. Physical rehabilitation experts and nurses can assist with mobilization and the incorporation of daily exercises to prevent functional decline. Dietitians can help to maximize appropriate caloric intake and oral hydration in acutely ill patients. Consultant pharmacists, chaplains, and social workers also may provide specialized expertise to address patient care issues pertinent to individuals at risk for delirium.

Proactive geriatric consultation has been demonstrated to reduce the risk of delirium posthip fracture by 40% in a randomized controlled trial. The targeted multicomponent consultation strategy focused on 10 domains, namely, adequate brain oxygen delivery, fluid/electrolyte balance, pain management, reduction in psychoactive medications, bowel/bladder function, nutrition, early mobilization, prevention of postoperative complications, appropriate environmental stimuli, and treatment of delirium (Table 53-7). The recommendations were carried out with good adherence (77%)

**TABLE 53-7****Preventive Interventions after Hip Fracture**

RISK FACTOR	INTERVENTION
Hypoxia	<ul style="list-style-type: none"> <li>• Supplemental oxygen</li> <li>• Raise systolic blood pressure</li> <li>• Transfusion to Hematocrit &gt; 30%</li> </ul>

and provided a feasible and effective approach to address a leading complication of hip fracture surgery. Although not yet tested, this multicomponent approach is likely to be effective at reducing the risk of delirium in high-risk patients other than those with posthip fracture repair.

At least eight additional recent studies have examined preventive delirium interventions in controlled trials. These studies have applied multifactorial interventions (six studies) or educational strategies targeted toward healthcare staff (two studies), and have demonstrated reductions in delirium rates and/or duration. Multifactorial interventions consisted of staff education strategies combined with the administration of individually tailored treatment and management of patients with delirium. Educational interventions sought to increase awareness and knowledge of delirium among medical staff, in hopes of improving assessment, prevention, and management strategies of patients with delirium. Regarding different care and rehabilitation settings, a recent controlled trial found that home

rehabilitation after acute hospitalization in the elderly was associated with lower risk of delirium, and greater patient satisfaction, when compared with the hospital setting. Taken together, results from controlled trials suggest that 30% to 40% of cases of delirium may actually be preventable and that prevention strategies should begin in the preoperative period.

On a larger scale, preventive efforts for delirium will require system-wide changes and large-scale shifts in local and national policies and approaches to care. Recommended changes include routine cognitive and functional assessment on admission of all older patients; monitoring mental status as a “vital sign”; education of physicians and nurses to improve recognition and heighten awareness of the clinical implications; enhanced geriatric physician and nursing expertise at the bedside; incentives to change practice patterns that lead to delirium (e.g., immobilization, use of sleep medications, bladder catheters, and physical restraints); and creation of systems that enhance high-quality geriatric care (e.g., geriatric expertise, case management, clinical pathways, and quality monitoring for delirium). Implementing these changes will impact not only on delirium, but will result in high-quality hospital care more generally.

## MANAGEMENT

### Pharmacological Management

The recommended management approach for all delirious patients begins with nonpharmacologic strategies (see “Nonpharmacological Management” and “Nonpharmacological Sleep Protocol” later in this chapter), which usually result in successful symptom amelioration. In selected cases, such strategies must be supplemented with a pharmacologic approach, usually reserved for patients in whom delirium symptoms would result in interruption of needed medical therapies (e.g., mechanical ventilation, central lines) or may endanger the safety of the patient or other persons. However, prescribing any drug requires balancing the benefits of delirium management against the potential for adverse medication effects because no drug is ideal for the treatment of delirium symptoms. Sometimes the decision to prescribe may be influenced by other members of the clinical team, the family, or caregivers. All interested parties should understand that the choice of almost any medication may further cloud the patient’s mental status and obscure efforts to monitor the course of the mental status change. Consequently, any drug chosen should be initiated at the lowest starting dose for the shortest time possible.

### Neuroleptics

In general, neuroleptics are the preferred agents of treatment, with haloperidol being the agent in most widespread use, whose effectiveness has been established in a randomized clinical trial. Haloperidol is available in parenteral form and is associated with less postural blood pressure changes and fewer anticholinergic side effects compared with thioridazine; however, high-potency antipsychotics such as haloperidol are associated with a higher rate of extrapyramidal side effects and acute dystonias. The intravenous route can be used when parenteral administration is required, which results in a rapid onset of action and a short duration of effect, whereas oral or intra-

muscular use is associated with a more optimal duration of action. The recommended starting dose is 0.5 to 1.0 mg haloperidol orally or parenterally. The dose may be repeated every 30 minutes after the vital signs have been rechecked and until sedation has been reached. The clinical end point should be an awake but manageable patient, a goal that can be achieved by following the general geriatric prescribing principle, “start low and go slow.” Most older patients naïve to prior treatment with a neuroleptic should require a total loading dose of no more than 3 to 5 mg of haloperidol. A subsequent maintenance dose consisting of one-half of the loading dose should be administered in divided doses over the next 24 hours, with doses tapered over the ensuing several days as the agitation resolves.

### Other Pharmacological Approaches

Benzodiazepines (e.g., lorazepam) are not recommended as first-line agents in the treatment of delirium because of their increased propensity to cause oversedation and to exacerbate acute mental status changes. However, they remain the treatment of choice for delirium caused by seizures and alcohol- and medication-related withdrawal syndromes. While other drugs have been advocated for use in treatment of delirium, their use has been evaluated only in case series or uncontrolled studies and is not recommended. These drugs include the newer atypical antipsychotic agents, procholinergic agents (such as donepezil), and serotonin receptor antagonists (such as trazodone). While the newer antipsychotic drugs (such as risperidone, olanzapine, and quetiapine) have the potential for fewer sedative and extrapyramidal effects, they may be less effective for controlling delirium symptoms and have not yet been evaluated in randomized clinical trials. Moreover, official warnings have been issued regarding the increased mortality associated with use of atypical antipsychotics in dementia patients.

### Nonpharmacological Management

Nonpharmacological approaches are the mainstays of treatment for every delirious patient. These approaches include strategies for reorientation and behavioral intervention, such as ensuring the presence of family members, use of sitters, and transferring a disruptive patient to a private room or closer to the nurse’s station for increased supervision. Orienting influences such as calendars, clocks, and the day’s schedule should be prominently displayed, along with familiar personal objects from the patient’s home environment (e.g., photographs and religious artifacts). Personal contact and communication are critical to reinforce patient awareness and encourage patient participation as much as possible. Communication should incorporate repeated reorientation strategies, clear instructions, and frequent eye contact. Correction of sensory impairments (i.e., vision and hearing) should be maximized as applicable for individual patients by encouraging the use of eyeglasses and hearing aids during the hospital stay. Mobility and independence should be promoted; physical restraints should be avoided because they lead to decreased mobility, increased agitation, and greater risk of injury. Patient involvement in self-care and decision-making should also be encouraged. Other environmental interventions include limiting room and staff changes and providing a quiet patient care setting with low-level lighting at night. An environment with decreased noise allowing for an uninterrupted period for sleep at night is of crucial importance

in the management of delirium. This may require unitwide changes in the coordination and scheduling of nursing and medical procedures, including medication dispensing, vital sign recording, and administration of intravenous medications and other treatments. Hospital-wide changes may be needed to ensure a low level of noise at night, including minimizing hallway noise, overhead paging, and staff conversations.

### Nonpharmacological Sleep Protocol

Nonpharmacological approaches for relaxation and sleep can be effective for management of agitation in delirious patients and for prevention of delirium through minimization of psychoactive medications. The nonpharmacological sleep protocol includes three components: (1) a glass of warm milk or herbal tea, (2) relaxation music or tapes, and (3) back massage. This protocol was demonstrated to be feasible and effective. Use of the protocol reduced the use of sleeping medications from 54% to 31% ( $P < .002$ ) in a hospital environment.

## SPECIAL ISSUES

### Nursing Home Setting

The patient population in nursing homes can be divided into two distinct groups: postacute patients who receive short-term rehabilitative care in nursing homes after an acute hospitalization, and long-term care patients who reside in nursing homes as a result of severe cognitive and functional impairments. Both are high-risk groups for delirium, though the epidemiology differs between the two populations.

For the postacute population, persistent delirium after an acute hospitalization is the major issue. A recent study demonstrated that 16% of new admissions to postacute care met full CAM-criteria for delirium, while another 50% demonstrated signs of subsyndromal (partial) delirium. Patients with delirium on admission to postacute care experience more complications such as falls, have higher rehospitalization rates, and higher mortality. Delirium among postacute patients is also persistent—of those admitted with delirium, over 50% are still delirious 1 month later. Persistence of delirium prevents functional recovery in the postacute setting; only those patients whose delirium cleared within 2 weeks of admission recovered to their prehospitalization functional status. Persistent delirium is also associated with higher mortality.

The long-term care population represents a high-risk group for delirium, with a high prevalence of dementia and functional impairments. In these individuals it is incident, rather than prevalent delirium, which is the primary concern. Large-scale epidemiological studies of delirium in these patients have not been performed, but data from the Minimum Data Set suggest that incident delirium is common in this population, and frequently heralds the onset of an acute illness that results in hospitalization and/or death.

Interventions for delirium in the nursing homes are challenging. First, because of the high prevalence of dementia in both postacute and long-term care populations, case identification can be challenging. This is compounded in the postacute population by a lack of

knowledge of the patient's baseline cognitive state. Poor nursing staffing ratios, high turnover, and competing concerns make attention to delirium challenging in this setting. Nonetheless, these patients represent among the most vulnerable of all elders, and further attention to delirium in this setting is warranted.

### Palliative Care Setting

Management of delirium at the end of life poses particular challenges. Because delirium occurs in more than 80% of patients at the end of life, it is considered nearly inevitable in the terminal stages by most hospice care providers and may serve as a predictor of approaching death. Establishing the goals of care with the patient and family is a crucial step, including discussions about the potential causes of the delirium, intensity of medical evaluations considered appropriate, and the need for titration between alertness and adequate control of pain and agitation. For example, some patients may wish to preserve their ability to communicate as long as possible, while others may focus on comfort perhaps at the expense of alertness. Physicians must be cognizant that even in the terminal phase, many causes of delirium are potentially reversible, and may be amenable to interventions (e.g., medication adjustments, treatment of dehydration, hypoglycemia, or hypoxia) that may improve comfort and quality of life. However, the burdens of evaluation (e.g., invasive testing) or treatment (e.g., reduction in narcotic dose) may not be consistent with the goals for care. In all cases, symptom management should begin immediately, while evaluation is underway. Nonpharmacological approaches should be instituted in all patients, with pharmacological approaches for selected cases. Haloperidol remains the first-line therapy for delirium in terminally ill patients. In end-of-life care, there is a lower threshold for the use of sedative agents. Sedation may be indicated as an additional therapy for management of severe agitated delirium in the terminally ill patient, which can cause considerable distress for the patient and family. Because sedation poses the risks of decreased meaningful interaction with family, increased confusion, and respiratory depression, this choice should be made in conjunction with the family according to the goals for care. If sedation is indicated, an agent that is short-acting and easily titrated to effect is recommended. Lorazepam (starting dose 0.5 to 1.0 mg po, IV, or SQ) is the recommended agent of choice.

### Ethical Issues

In a condition characterized by acute fluctuations in attention and decision-making capacity, delirium presents formidable challenges to the ethical care of afflicted patients (see Chapters 13 and 34). Recent research has highlighted the importance of determining and appropriately documenting cognitive impairment prior to initiating nonemergent treatments. Cognitive assessments in patients with suspected delirium help to ensure that appropriate surrogate decision makers (e.g., family members or caregivers) are involved in representing a patient's wishes, and understanding the risks and benefits of procedures and treatments. Because the patient may exhibit periods of lucidity in delirium, there may be times during which the informed consent process can and should involve the patient. Following resolution of an acute delirium episode, the clinician should be cognizant of ongoing subclinical manifestations of delirium, or partial forms of delirium, which may be important for considerations

of both the long-term management and decision-making capacity of the patient.

# Falls

*Mary B. King*

## DEFINITION

Falls are common in older persons. A fall injury is costly in terms of morbidity, loss of physical function and independence, and mortality, as well as health care utilization. Falls have not always been recognized as a serious health problem. Prior to the 1940s, a fall was considered an unpredictable event that could not be prevented. In the past 20 years, however, research studies have shown the incidence and consequences of falls, revealed their multifactorial etiology, and demonstrated that they can be prevented by treating the factors that increase an older person's risk of falling. Effective treatment requires a multidisciplinary approach. Perhaps because of this, fall prevention is not widely practiced in clinical settings outside of specialized geriatric assessment clinics; thus, falls remain an undertreated public health issue.

This chapter addresses nonsyncopal (Syncope is discussed in Chapter 57) falls—unintentional events in which a person comes to rest on the floor or ground that are not caused by loss of consciousness, stroke, seizure, or overwhelming force. Falls in three different settings—the community, skilled nursing facilities, and hospitals—are discussed; reasons for falling and, therefore, interventions differ by site.

## INCIDENCE AND CONSEQUENCES OF FALLS

### Incidence and Prevalence of Falling

Approximately 35% to 40% of persons age 65 years and over fall in a given year; half of persons who fall do so more than once. The incidence increases steadily after age 60 years; approximately 50% of persons aged 80 years and older fall in a year. Women are more likely to fall than men. More than half of all falls in the community

happen at home. The rates for falls in skilled nursing facilities and hospitals are almost three times that for community-dwelling elders, and are estimated at 1.5 falls per bed per year.

### Fall Injuries

#### Incidence of Fall Injuries

Although young children and athletes also have a high incidence of falls, older persons are at high risk of injury with a fall because of age-related changes such as slow reaction time, impaired protective responses, and comorbid diseases such as osteoporosis. As a result, serious fall injuries, including fractures, lacerations, serious soft-tissue injuries, and head trauma, occur in 5% to 15% of falls in the community. Injury rates are higher, from 10% to 25% of falls, in institutional settings. Approximately 8% of persons aged 65 years and older visit an emergency department because of a fall-related injury each year; almost half of these persons are admitted to the hospital for treatment. In 2003, 1.8 million older persons were treated in an emergency department for nonfatal fall injuries. Fractures, most commonly of the hip, pelvis, femur, vertebrae, humerus, hand, forearm, leg, or ankle, occur in approximately 3% of falls. Conversely, falls account for 87% of all fractures and for more than 95% of hip fractures in this group. Falls are the second leading cause of brain and spinal cord injury in older adults. According to data from 2001 to 2005, the annual rates of nonfatal injuries are about 48% higher for women than men (Figure 54-1).

### Hip Fractures

Hip fractures are probably the most dreaded fall-related injury, as approximately half of older persons who sustain a hip fracture cannot return home or live independently after the fracture, and up to 20% die within a year of the fracture. Between 1993 and 2003, the age-adjusted hospitalization rate for hip fractures initially increased, then

**FIGURE 54-1.** Age-adjusted nonfatal fall injury rates among men and women aged 65 yrs and older, United States. Rates are per 100,000 people, age-adjusted to the 2000 U.S. population. (Redrawn from Centers for Disease Control and Prevention, National Center for Injury Prevention and Control. Web-based Injury Statistics Query and Reporting System [WISQARS], 2005. Available at: [www.cdc.gov/ncipc/wisqars](http://www.cdc.gov/ncipc/wisqars).)

declined, with an overall rate of 775.5 per 100,000 people in 2003. The incidence of hip fracture is higher for women than men, but there was a decline of 20.8% in the hospitalization rate for hip fractures in women between 1993 and 2003, while that for men has remained the same.

### Death

In the United States, unintentional injury is the fifth leading cause of death in persons age 65 years and older; falls are the cause of two-thirds of the deaths resulting from injuries in this age group. In 2003, approximately 13 700 older persons died as the result of a fall. The age-adjusted death rate from falls increased significantly between 1993 and 2003, and men in this age group continue to have a significantly higher fatality rate than women (Figure 54-2).

### Other Consequences of Falling

Falls are costly for older persons, both in terms of health care dollars and in loss of physical function and independence. Fall-related in-

**FIGURE 54-2.** Age-adjusted fatal fall injury rates among men and women aged 65 yrs and older, United States. Rates are per 100,000 people, age-adjusted to the 2000 U.S. population. (Redrawn from Centers for Disease Control and Prevention, National Center for Injury Prevention and Control. Web-based Injury Statistics Query and Reporting System [WISQARS], 2005. Available at: [www.cdc.gov/ncipc/wisqars](http://www.cdc.gov/ncipc/wisqars).)

juries account for approximately 6% of all health care expenses for persons aged 65 years and older in the United States. Falls also take a toll on an older person's independence and quality of life. Falls account for approximately 20% of restricted activity days in older people—more than for any other health condition. In addition to immediate curtailment of activity, older persons who have a fall injury may restrict activity for several months or longer after the injury because of residual physical impairment or because of fear of falling again. Older persons are often unable to get up from the ground or floor after a fall, resulting in long lies with the risk of pneumonia, dehydration, and rhabdomyolysis. Fear of falling occurs in at least 50% of those who fall, and leads to restriction of activities in 10% to 25%. Finally, falls and fall injuries are a major determinant of nursing home placement.

## ETIOLOGY OF FALLS AND FALL INJURIES

A fall occurs when a person's center of gravity moves outside of their base of support and insufficient, ineffective, or no effort is made to restore balance. Classification schemes have been developed to explain how falls occur. One such scheme classified falls according to cause, namely extrinsic, or as a consequence of slips, trips, and other environmental factors that perturbed balance; intrinsic, or as a consequence of deficits in balance, mobility, cognitive or sensory function; nonbipedal falls, such as falling out of bed; or nonclassifiable falls. Falls have also been classified by most likely immediate cause, including environmental factors, balance or gait disorder, drop attack, dizziness, or postural hypotension. However, while observation may suggest that one factor predominates, more often it is the interaction of multiple factors that results in a fall (Figure 54-3). Intrinsic, personal characteristics, in conjunction with pharmacologic and behavioral factors, can alter resting balance or affect an older person's postural responses to challenges posed by the environment, or posed simply by movements such as transfers or walking.

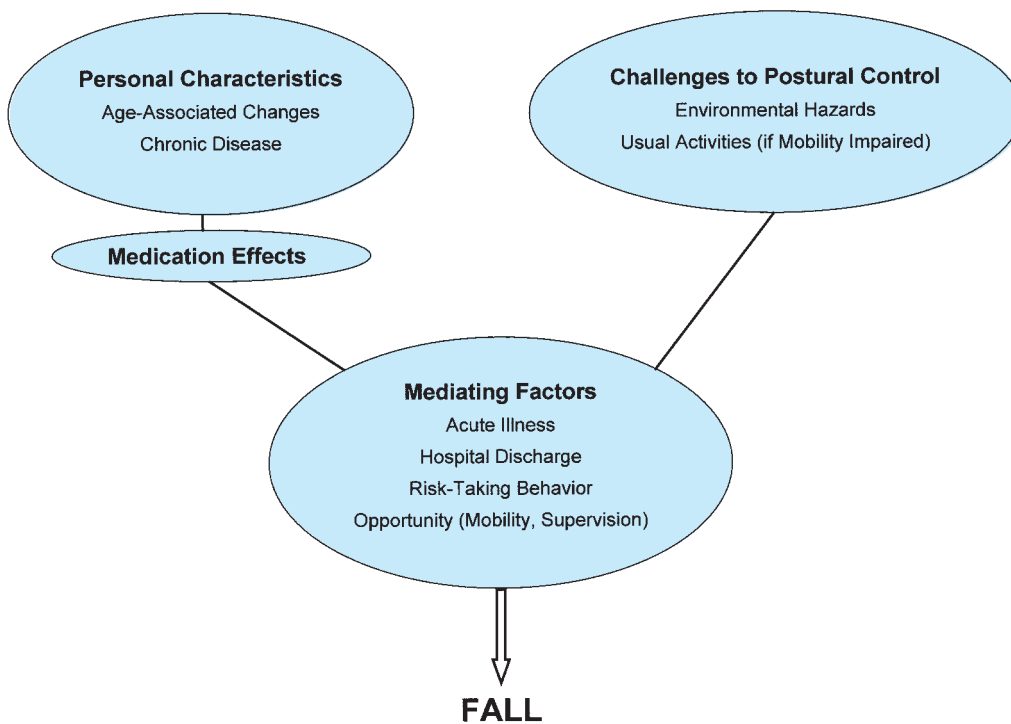

### Risk Factors for Falling

#### Age-Associated Changes and Chronic Diseases

Prospective and retrospective community- and nursing home-based studies in the past 15 years have identified a number of factors that increase an older person's risk of falling. Table 54-1 lists the most commonly identified factors. Studies show that the risk of falling increases with the number of risk factors a person has (Figure 54-4).

Age greater than 80 years, need for assistance with activities of daily living, and previous falls, indicate risk for future falls. While these characteristics cannot be modified, they serve as indicators for clinicians to pay increased attention to the presence of other, treatable risk factors for falls. The most important modifiable intrinsic risk factors for falls are balance, strength, and gait impairments. Impairment in these areas may be caused by a number of sensory, neurological, or musculoskeletal diseases, in addition to deconditioning as a result of lack of activity, age-related changes, and medication effect.

**Postural Control** Balance, or postural control, is dependent upon the integration of visual, vestibular, and proprioceptive input by the central nervous system to effect an appropriate postural response to

**FIGURE 54-3.** Interactions among intrinsic, pharmacologic, environmental, and situational factors that affect risk of falling in older persons. (Modified with permission from King MB, Tinetti ME. Falls in community-dwelling older persons. *J Am Geriatr Soc.* 43:1146, 1995.)

control the movement of the center of mass over the base of support, the feet. With quiet standing, there is little movement of the center of mass. The area over the feet within which a person is able to lean decreases with age. Fall risk has been linked to mediolateral instability; clinically this can be tested by the ability to stand in tandem

stance or on one leg, both of which reduce the mediolateral base of support. The effect of impaired performance of static balance tasks may be manifested in activities such as walking and transferring. Persons who experience difficulty with standing balance tasks may walk more slowly and therefore spend a greater percentage of the gait cycle in more stable double stance with a wider base of support. Maintaining balance during body movements requires a reaction to restore the person's displaced center of mass over the base of support. A loss of balance may be caused by the speed or magnitude of displacement, an inability to quickly detect the displacement because of sensory impairment, slowing of central nervous system integration of sensory information into a motor response, or muscle weakness or joint pain, causing an inadequate or ineffective response. Older persons take compensatory steps at lower levels of balance disturbance than young adults, but may have less effective stepping responses (multiple steps, difficulty controlling lateral stability) with greater challenges to balance. Older persons are slower than young adults in initiating reaching reactions to break a fall or grasp a handrail.

**Sensory Input** Sensory modalities that provide afferent input for balance responses include vision, hearing, proprioception, and vestibular function. Vision is affected by age and disease. While decreased visual acuity may be important, impaired contrast sensitivity (the ability to detect edges) and depth perception have been found to be the most significant visual risk factors for falls. Multifocal lenses, commonly worn by presbyopic older persons, are problematic because the lower, near-vision lenses impair distance depth perception in the lower visual field where tripping hazards would be seen. Cataracts, glaucoma, and macular degeneration affect vision and are common diseases in older persons. There is some evidence that first-cataract surgery can reduce fall risk. Hearing loss is found in more than 50% of older people, and can affect perception of and orientation to the environment. Vestibular function changes with age and with diseases affecting the inner ear. Impaired vestibular function

**TABLE 54-1**

**Results of Univariate Analysis of Most Common Risk Factors for Falls Identified in 16 Studies\* that Examined Risk Factors**

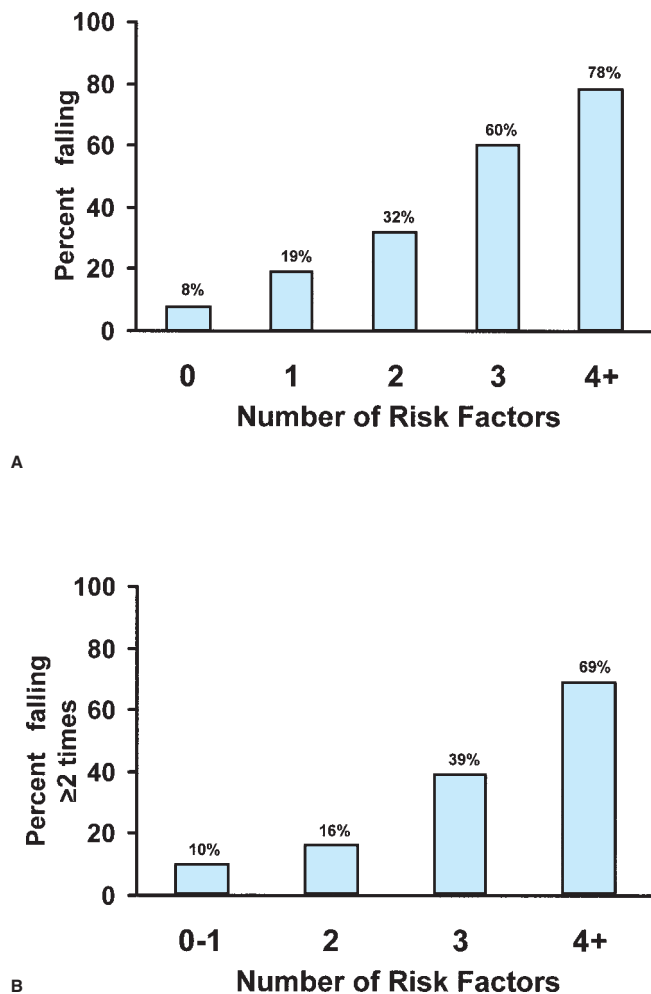

RISK FACTOR	SIGNIFICANT/ TOTAL <sup>†</sup>	MEAN RR-OR <sup>‡</sup>	RANGE
Muscle weakness	10/11	4.4	1.5–10.3
History of falls	12/13	3.0	1.7–7.0
Gait deficit	10/12	2.9	1.3–5.6
Balance deficit	8/11	2.9	1.6–5.4
Use of assistive device	8/8	2.6	1.2–4.6
Visual deficit	6/12	2.5	1.6–3.5
Arthritis	3/7	2.4	1.9–2.9
Activities of daily living (ADL) impairment	8/9	2.3	1.5–3.1
Depression	3/6	2.2	1.7–2.5
Cognitive impairment	4/11	1.8	1.0–2.3
Age >80 yrs	5/8	1.7	1.1–2.5

\*See source for study references.

**FIGURE 54-4.** The risk of falling increases with the number of risk factors present, both for single and recurrent falls. (A) Occurrence of falls, according to the number of risk factors, in a study of 336 persons older than age 75 yrs living in the community. Risk factors included sedative use, cognitive impairment, lower-extremity disability, palmomental reflex, foot problems, and balance/gait abnormalities. (Adapted with permission from Tinetti ME, Speechley M, Ginter SF. Risk factors for falls among elderly persons living in the community. *N Engl J Med.* 319:1701, 1988. Copyright ©1988 Massachusetts Medical Society. All rights reserved). (B) The proportion of subjects who fell more than two times increased with number of risk factors in a study of 325 community-dwelling persons older than age 60 yrs who had fallen in the previous year. Risk factors were difficulty standing up from a chair, difficulty with tandem walk, arthritis, Parkinson's disease, more than three falls or a fall with injury in the previous year, and white race. (Data from Nevitt MC, Cummings SR, Kidd S, et al. Risk factors for recurrent nonsyncopal falls. A prospective study. *JAMA* 261:2663, 1989. Copyright ©1989, American Medical Association. All rights reserved.)

can lead to loss of balance when there is decreased visual input as a consequence of disease, or as a result of environmental factors, such as movement in the dark. Mechanoreceptors in apophyseal joints and peripheral nerves provide proprioceptive input and may be affected by age, degenerative joint disease, cervical disorders such as spondylosis, or peripheral neuropathy. Proprioceptive dysfunction can result in loss of balance on uneven ground or in situations, such as walking in the dark, where there is decreased visual input.

**Central Processing** Central nervous system processing of sensory input to initiate a postural response may be affected by neurolog-

ical diseases such as Parkinson's disease, stroke, or normal pressure hydrocephalus. Cognitive impairment caused by dementia may impair judgment and affect the perception and interpretation of sensory stimuli, resulting in falls even without the presence of a muscle or gait disorder. Depression may increase fall risk because of decreased concentration or awareness of potential environmental hazards.

**Musculoskeletal Impairments** Musculoskeletal impairments increase the risk of falling. Muscle mass and strength decline with age, disease, and inactivity. The older person may no longer be capable of generating the strength and accuracy of response to a balance disturbance (e.g., tripping) that is required. Loss of lower-extremity strength, in particular ankle dorsiflexor strength, has repeatedly been shown to be an important determinant of fall risk. Weakness of hip abductors and adductors may decrease an older person's ability to maintain balance while stepping to avoid a fall. Musculoskeletal diseases such as osteoarthritis can cause pain, deformity, and limited range of motion in joints, particularly in the back, hips, knees, and feet that increase the risk for falls. Upper body arthritis or muscle weakness can affect an older person's ability to break the impact of a fall, increasing the risk of injury such as a fracture. Foot problems, such as calluses, bunions, long nails, or joint deformity, can affect balance by compensatory strategies as a consequence of pain or impaired sensory input.

**Postural Hypotension** Postural hypotension, which may result in instability, occurs in 10% to 30% of community-dwelling older persons aged 65 years and older. A drop in systolic blood pressure of 20 mmHg or more with change in position from lying to standing may be medication-related, caused by dehydration, or a result of age-associated changes or diseases that affect autonomic control of vascular tone. Postprandial hypotension may be suspected in persons complaining of dizziness or who fall after getting up from, or soon after, a meal.

### Medications

Several studies show that the use of four or more prescription and nonprescription medications increases the risk of falling. Older persons often take more than four medications each day because of multiple chronic diseases, multiple prescribing physicians and consultants, accumulation of medications over time, lack of understanding about how to take medications, and demand for medications based on advertising. Medications may cause postural instability by their expected effects on cognitive functioning, fluid and electrolyte balance, or blood pressure, or by adverse effects. Observational data in multiple studies demonstrate an increased risk of falls with anticonvulsants and any psychotropic medication use, including sedative/hypnotics, antidepressants, short- or long-acting benzodiazepines, or neuroleptics. In addition, a meta-analysis of observational studies of cardiac and analgesic drug use showed a weak association between falls and the use of class IA antiarrhythmic medications, digoxin, and diuretics. The risk of an adverse drug event increases with the number of medications taken, such that a person taking nine or more medications has 3.3 times the risk of an adverse event as compared to someone taking four or fewer medications. Fatigue, altered mental status, somnolence, dizziness, and impaired balance, listed as side effects of many medications, are also risk factors for falls.

## Acute Illness and Hospital Discharge

Time-related or situational factors also may result in impaired balance by augmenting already present risk factors for falls. Acute illness, such as pneumonia or exacerbation of congestive heart failure, may present as a fall in a frail older person because of altered mental status, postural hypotension, or weakness. Older persons are also vulnerable after treatment in the emergency department or after hospitalization because of the illness that caused their admission, deconditioning, or medication effects. The risk of a fall in older persons recently discharged from the hospital and receiving home care is about four-fold higher than that for others in the community during the first 2 weeks after discharge.

## Challenges to Postural Control

Extrinsic risk factors for falls include environmental hazards that, in concert with intrinsic factors, increase susceptibility to falls. Because more than half of older persons' falls occur at home, studies have examined the contribution of environmental factors to fall risk. While no particular hazard has been implicated in falls, home safety remains a concern. There are checklists available to use in reviewing home safety; [Table 54-2](#) summarizes areas at home that should be checked. Environmental factors that did not pose a safety risk previ-

ously become hazardous to an older person with declining balance and mobility (e.g., transfers in and out of a bathtub).

## Opportunity to Fall

Additional factors contributing to fall risk are an older person's risk-taking behavior and opportunity for a fall. Older persons with impaired balance or strength may do activities that are beyond their capabilities—such as climbing on a chair or counter to reach high cabinets, hanging curtains, rushing to answer the telephone—because of poor judgment, a desire to maintain independence, or lack of family or friends to help. Persons who are confined to bed or have close supervision are less likely to fall because of lack of opportunity to do so. Fear of falling is frequently seen in older persons, both in those who have fallen and in those with limited mobility who have not yet fallen. Fear may lead to destabilizing compensatory strategies when walking or transferring, such as reaching to hold on to furniture, which increase the risk of falling.

## Risk Factors for Fall Injury

### Osteoporosis

Injury with a fall is dependent upon factors in addition to those for falling. The presence of osteoporosis increases an older person's risk of fracture. A decrease of one standard deviation in femoral neck bone mineral density increases the risk of hip fracture 2.7 times. Low body mass index and low weight increase the force of impact with a fall because of lack of cushioning effect of muscle and subcutaneous tissue (see Chapter 117, Osteoporosis).

### Characteristics of the Fall

The force of a fall and direct impact on a bone increase the likelihood of injury, particularly of fracture. Factors that increase the force of a fall include falling from a greater height, such as on stairs; not attempting to break the fall (e.g., by reaching for furniture); and landing on a hard surface. Falling sideways or directly onto the hip increases the likelihood of hip fracture; falling forward onto an outstretched wrist increases the likelihood of a Colles' fracture.

## FALL PREVENTION IN COMMUNITY-DWELLING OLDER PERSONS

### Trials of Interventions to Prevent Falls

Trials to reduce the incidence of falls have varied in their approach. Investigators have either focused on improving a single factor or multiple factors. Study participants either have been unselected or have been screened for the presence of risk factors. To date, the most successful strategies have been those targeted at older persons at risk or who have fallen, those designed to intervene on multiple risk factors, to be of longer duration or greater intensity, or to be individually tailored to treat risk factors. The involvement of more than one health care discipline in the intervention, including nursing, occupational and physical therapy, and physicians, has also been effective.

**TABLE 54-2**

### Checklist of Measures to Improve Safety in and Around the Home

#### Outside

- Repair uneven pavement, cracked sidewalks
- Install railings for outdoor steps
- Use adequate lighting
- Keep shrubbery trimmed near walks

#### Inside

##### Floors

- Remove throw rugs
- Use nonskid carpet backing; tack down or tape carpet edges
- Avoid wax or use nonskid wax
- Mark high thresholds with reflective tape
- Remove clutter and furniture from traffic areas
- Keep electrical and telephone cords near walls, out of walkways
- Make sure that telephone can be reached from floor, or have emergency call device

##### Lighting

- Adjust to decrease glare
- Have adequate lighting from bedroom to bathroom at night
- Have lights with switches at top and bottom of stairways

##### Stairways

- Install railings on both sides, extending full length of stairs
- Make sure railings are secure
- Ensure stairs have nonskid surfaces and are free of clutter
- Mark top and bottom step with reflective tape

##### Bathroom

- Install grab bars in bath and next to toilet if mobility impaired
- Use rubber mat in bath or shower
- Install raised toilet seat if needed

##### Kitchen

- Keep food, dishes within easy reach
- Do not use cupboards that are too high or too low

### Single Interventions

A number of interventions have been designed to reduce the incidence of falls by improving balance and strength through home or group exercise. The more successful programs generally have been those in which participants were selected for impairments in balance, strength, or mobility; the exercise program was intensive, well-supervised, and sustained over at least 10 weeks; and the program included exercises to improve balance. A meta-analysis of seven of the Frailty and Injuries: Cooperative Studies of Intervention Techniques (FICSIT) trials that studied the effect of exercise on fall risk in older persons showed that, while exercise in general reduced fall risk by 10%, balance exercise reduced the incidence of falls by 17%. In one of the FICSIT studies, practicing Tai Chi C'uan to improve balance significantly reduced the subsequent incidence of falls.

Several studies have examined the effect of modifying the home environment to reduce falls, but there is insufficient evidence that correcting home hazards reduces falls or fall injuries. There was one randomized controlled trial of psychotropic medication withdrawal that was effective in reducing falls. Other trials of single interventions have produced results of questionable effectiveness. Educational programs for older persons about fall risk factor modification have not been effective by themselves in preventing falls.

### Multifactorial Interventions

Several studies employing a multidisciplinary, multifactorial approach to risk factor reduction in community-dwelling older persons have been published, and more are being completed. Effective components of these studies include exercise programs, reduction in the number and dosage of medications, treatment of postural hypotension and other cardiovascular disorders, and treatment of visual impairment. One strategy that has been successful has been a combination of assessment and treatment in the home by a nurse, and/or a physical or occupational therapist, and medical risk factor assessment and treatment in an outpatient office setting. Modification of the home environment to improve home safety as part of a multifactorial intervention has been of equivocal or no efficacy. None of the intervention studies has had enough participants to show a reduction in fall injuries.

### Strategy for Decreasing Falls and Fall Injuries

The most effective fall-prevention programs require coordination of efforts by several health care disciplines to treat the older person who is at risk for falls. The strategy is first to screen for fall risk, and then to perform a thorough assessment and create a treatment plan for those who are likely to fall in the future.

#### Screen for Fall Risk

All older persons seen for routine medical care should be screened for fall risk by asking, at least once a year, if they have fallen. They should be observed getting up from a chair and walking across a room for difficulty with the activity, unsteadiness, or use of an assistive device. Fall risk assessment is included in Center for Medicare and Medicaid's new Patient Quality Reporting Initiative. If there is no history of falls and no problem with balance, mobility, or gait, then no specific fall risk assessment is necessary (Figure 54-5). However, in all healthy older adults, routine vision and hearing screening, regular

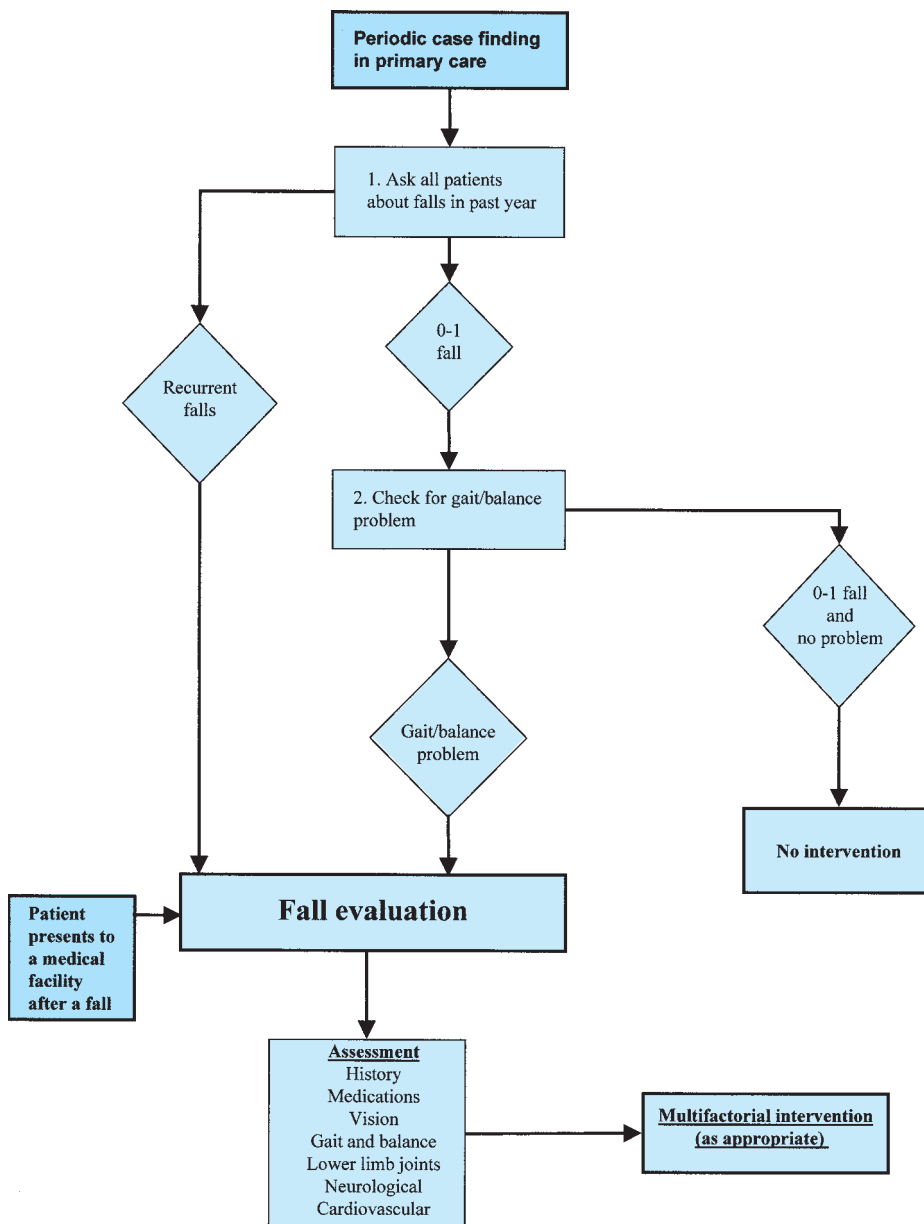

review and reduction, when possible, of medications, screening for and treatment of osteoporosis, exercise prescription, and discussion of home safety, can aid fall prevention.

### Multifactorial Assessment

If there is a history of one or more falls, or if the person has problems with mobility or gait, then a more detailed fall risk assessment is warranted (see Figure 54-5). Other potentially high-risk times are during acute illness, after hospital or emergency department discharge, or after introduction of new medications. Determination of risk factors for falls is within the capability of the primary care provider; it requires a systematic approach and a plan of treatment that often requires coordination among several different specialties and disciplines. Referral to a geriatric specialist with resources to coordinate multidisciplinary care may be the most effective way to accomplish fall risk assessment and treatment. The assessment should include history taking and medication review, physical examination, including physical performance testing, and, when indicated, assessment of the home environment. It is important to look for all possible contributing factors, as the concept of risk reduction is to treat as many factors as possible to lessen the likelihood of a fall.

The medical history should focus on information about physical function, mobility, use of an assistive device such as a cane or walker, performance of activities of daily living, previous falls and fractures, and acute or chronic medical problems. If the person has fallen, details of fall circumstances, including setting and activity at the time of the fall, can help determine specific risk factors for future falls. A list should be made of the dose and frequency of all medications that the older person actually takes, including over-the-counter medications. This can be done by "brown bag" review of medications in the office, or, if the older person is eligible for visiting nurse services, by a nurse in the home.

Aspects of the physical examination that pertain to fall risk are: checking for postural blood pressure changes (lying, then standing after 3 mins); pulse (looking for cardiac arrhythmias and appropriate response to positional change); hearing and visual acuity screening; and examination of joints for range of motion and evidence of arthritis, and of the feet for deformity and painful lesions. A neurologic examination should include mental status testing, cranial and peripheral nerve function, reflexes, muscle strength, and cerebellar and sensory function. Tests of functional gait and balance maneuvers during usual activities are part of a fall risk assessment (Table 54-3). The Timed Up and Go Test can be done in less than 1 minute in an office setting and has high sensitivity and specificity in predicting fall risk. Other measures, such as the Performance-Oriented Mobility Assessment, give more specific information about balance, gait, and mobility impairment, but take longer to perform and are best used for assessment prior to a rehabilitative program. Laboratory testing is determined by the history and physical examination, and may include a complete blood count, fasting blood glucose, electrolytes, blood urea nitrogen (BUN) and creatinine, thyroid-stimulating hormone (TSH), B-12 level, and levels of medications such as digoxin and anticonvulsants. Testing for osteoporosis will determine the need for medication to improve bone density (to reduce risk of fracture). Radiographs, such as cervical spine films, and computed tomography or magnetic resonance imaging of the brain, are only indicated if diseases that would be diagnosed by these tests are suspected.

**FIGURE 54-5.** Algorithm summarizing screening, assessment, and management of falls. (Modified with permission from Anonymous. Guideline for the prevention of falls in older persons. American Geriatrics Society, British Geriatrics Society, and American Academy of Orthopaedic Surgeons Panel on Falls Prevention. *J Am Geriatr Soc.* 49:664, 2001.)

### Multidisciplinary Treatment

Once the older person's risk factors for falls have been determined, an individually tailored, multidisciplinary treatment plan can be put in place. The key components of such a plan include one or more of the following: (1) exercise and training to improve deficits in balance, mobility, and strength; (2) correction of sensory deficits (vision, hearing, vestibular and proprioceptive function); (3) evaluation and treatment of postural hypotension; (4) review and reduction of medications; (5) treatment of foot problems; and (6) environmental modification and use of adaptive equipment, if indicated. Although education is not effective as a single intervention, it is a key component of the treatment plan. The older persons and their caregivers need to understand the importance of falls, the multifactorial nature of fall risk, and the strategies for fall prevention. Table 54-4 summarizes possible interventions for factors that contribute to falling.

Physical therapy, with instruction in exercises to improve balance and mobility, is an important part of the fall prevention strategy. Progressive exercises under the guidance of a physical therapist can

help the older person improve confidence and reduce fear of falling. Older persons can also be taught how to get up from the floor in order to prevent a long lie as a result of a fall.

Other strategies for older persons with limited mobility include wearing an emergency call device in order to summon help or to have a telephone within reach in case of a fall. Treatment of osteoporosis can reduce the likelihood of a fracture with a fall. The use of hip protectors in the community setting has not been shown to be effective in reducing the incidence of falls or hip fractures.

### Falls in Skilled Nursing Facilities

The general approach to fall-risk evaluation and treatment in nursing home residents is the same as with older people living in the community, although the relative importance of individual risk factors for falls in each setting differs. While most community-dwelling elderly persons have as their goal to increase function and maintain independence, nursing home residents and their family members

**TABLE 54-3****Observation of Position Changes, Balance Maneuvers, and Gait Components Used in Daily Activities that Indicate Fall Risk if Not Performed Adequately**

MANEUVER	MEASURE(S) IN WHICH IT IS A COMPONENT	OBSERVATION: ABNORMALITY IN PERFORMANCE THAT INDICATES FALL RISK
<i>Position change or balance maneuver</i>		
Getting up from a chair*	A,B	Does not get up with single movement; pushes up with arms or moves forward in chair first; unsteady on first standing
Sitting down in a chair*	A,B	Plops in chair; does not land in center of chair
Withstanding pull back at waist	A	Moves feet; begins to fall backward; grabs object for support
Side-by-side standing with eyes open	A	Feet not touching side by side; moves feet; begins to lose balance or grabs object for support
Semitandem, tandem standing	C	Cannot maintain stances for 10 s (same as above)
Standing on one leg	A	Cannot maintain stance for 5 s (same as above)
Bending over	A	Unable to bend over to pick up small object (e.g., pen) from floor; grabs object to pull up on; requires multiple attempts to arise
Neck turning	C	Moves feet; grabs object for support; complains of vertigo, dizziness, or unsteadiness
<i>Gait component or maneuver</i>		
Gait initiation	A,B	Hesitates; stumbles; grabs object for support
Step height (raising feet with stepping)	A,B	Does not clear floor consistently (scrapes or shuffles); raises foot too high (more than 2 in.)
Step continuity	A,B	After first few steps, does not consistently begin raising one foot as other foot touches floor
Step symmetry	A,B	Step length not equal (pathologic side usually has longer step length—problem may be in hip, knee, ankle, or surrounding muscles)
Path deviation	A,B	Does not walk in straight line; weaves side-to-side
Turning	A,B	Stops before initiating turn, staggers; sways; grabs object for support
Stepping over obstacles	A	Unable to step over obstacles or loses balance
Gait speed	A B	Unable to increase walking speed without losing balance Takes longer than 10 s to stand up from chair, walk 3 m, turn, walk back to chair and sit

Maneuvers that are components of physical performance tests are indicated as follows: A, Performance-Oriented Mobility Assessment; B, Timed Up and Go Test; C, other maneuvers.

\*Use hard, armless chair.

and caregivers must weigh the risk of decreased safety that may accompany independent mobility, particularly as frailty increases.

The focus of fall risk assessment and treatment in skilled nursing facilities is to find the least-restrictive means by which the resident can move safely. Because it is less likely that personal risk factors as a result of age and chronic disease can be modified sufficiently to prevent falls, and because the opportunity for observation and supervision is greater in the nursing home setting, more emphasis should be placed on improving individual patient safety within the environment.

## Evaluation

A careful assessment of risk factors for falls is important for all residents on admission, at yearly examinations, with a significant change in condition, or after a fall. The history may be difficult to obtain owing to cognitive impairment, and may require input from family members or caregivers. Specific symptoms such as dizziness, foot or joint pain, weakness, or decreased sensation, if elicited, may indicate acute or chronic diseases that contribute to fall risk. As in community-dwelling older adults, the physical examination should include checking for postural changes in blood pressure, screening for cognitive, vision, and hearing impairments, examination of car-

diovascular, musculoskeletal, and neurological systems, and examination of the feet. Tests of balance, transfers, and gait, and observation for proper use of assistive devices are also part of the evaluation. Laboratory testing may be of help in diagnosing or evaluating specific chronic diseases.

Pharmacologic and situational factors play a key role in fall risk in the nursing home. Risk assessment should include regular medication review and reduction, if possible. Medication use, particularly of psychotropic medications, is an important contributor to fall risk in this setting, and this is a factor that potentially can be modified. Because of the prevalence of chronic disease, nursing home residents are likely to be on more than four medications, and may be less able to identify symptoms of adverse reactions to drugs, such as fatigue and dizziness, that increase risk of falling. Early recognition of acute illnesses, such as urinary tract infection or pneumonia, which are likely to begin with symptoms of impaired cognition or mobility, can lead to treatment and preventive measures to keep the older person from falling.

After a fall, there may be greater opportunity to get accurate information about fall circumstances and to evaluate the resident because of closer supervision by health care professionals in this setting as compared to the community. Symptoms of dizziness may suggest postural hypotension or medication effect; symptoms or

**TABLE 54-4****Multidisciplinary Treatment of Factors Contributing to Fall Risk**

FACTOR CONTRIBUTING TO FALL RISK	TREATMENT
<i>Age-Associated or Caused by Chronic Disease</i>	
Impaired balance, gait, mobility Neurologic disease, with impaired strength, sensation, balance, gait, tone, and/or coordination	M: Diagnose and treat specific disease (e.g., Parkinson's disease, stroke, normal pressure hydrocephalus) R: Physical therapy; balance and gait training; correct walking aid E: Home safety assessment; appropriate adaptations (e.g., high, firm chairs, raised toilet seats, grab bars in bathroom)
Dementia, with impaired gait, apraxia	M: Diagnose and treat specific disease; minimize centrally acting medications R: Supervised exercise and walking S: Evaluate home safety; need for supervision
<i>Musculoskeletal disease</i>	
Muscle weakness Arthritides with back/joint deformity causing postural instability Feet: pain, deformity	M: Diagnose and treat specific diseases; referral to podiatry, if indicated, for foot care R: Physical therapy with muscle strengthening exercises, balance, and gait training; correct walking aid; correct footwear E: Home safety assessment; appropriate adaptations
<i>Sensory impairment</i>	
Vision: acuity, accommodation, contrast sensitivity	M: Referral for refraction; cataract extraction R: Balance and gait training E: Home safety assessment with attention to good lighting
Hearing: spatial disorientation, balance impairment, distorted environmental signals caused by decreased auditory input Vestibular dysfunction: spatial disorientation at rest; balance impairment especially with head or body turning	M: Cerumen removal; audiologic evaluation with hearing aid if appropriate M: Avoid vestibulotoxic drugs; surgical ablation R: Habituation exercises E: Good lighting (increased reliance on visual input); home safety assessment
Proprioceptive: cervical disorders; peripheral neuropathy; spatial disorientation during position changes or while walking on uneven surfaces or in dark	M: Diagnose and treat specific disease (e.g., spondylosis, B-12 deficiency, diabetes mellitus) R: Physical therapy; balance and gait training; correct walking aid E: Good lighting (increased reliance on visual input); appropriate footwear; home safety assessment
<i>Impaired perception or concentration</i>	
Dementia: impaired judgment, problem solving Depression: poor concentration or awareness?	See "Dementia" above M: Watch for adverse medication effects E: Home safety assessment
<i>Postural hypotension</i>	
Impaired cerebral blood flow leading to fatigue, weakness, postural instability; syncope if severe	M: Diagnose and treat specific diseases; review medications and reduce/eliminate offending ones; adequate salt and water intake R: Graded pressure stockings; dorsiflexion and hand flexion exercises prior to arising
<i>Total number and dose of medications</i>	
Taking $\geq 4$ medications	M: Regular review and reduction, when possible, of number and dose of medications, including nonprescription medications; consider nonpharmacologic treatments; start medications low and increase slowly
<i>Specific medications</i>	
Sedatives, antidepressants, neuroleptics, diuretics, antihypertensives, antiarrhythmics, anticholinergic medications	
<i>Other</i>	
Change in dose; new medications	
<i>Situational and Environmental Factors</i>	
Onset of acute illness Hospital or emergency department discharge	M: Diagnose and treat specific diseases; close supervision of mobility M: Review medications and doses; look for adverse effects of new medications; evaluate balance, mobility R: Physical therapy if indicated E: Home safety assessment S: Assess need for increased supervision
Risk-taking behavior	S: Assess need for increased supervision or community services R: Recommend avoiding only clearly hazardous and unnecessary activities (e.g., climbing on chairs); balance and gait training E: Home safety assessment
Environmental hazards	E: Home safety assessment

E, environmental; M, medical; R, rehabilitative; S, social services/case management.

signs of acute infection, myocardial infarction, heart failure, or stroke may be elicited. The time and location of the fall may give clues as to the most effective intervention. A fall in the hallway after lunch may indicate postprandial hypotension; a fall in the bathroom near bedtime when nursing staff are helping other residents may indicate the need for scheduled toileting or greater supervision at that time. Examination of footwear and condition of assistive devices may also lead to interventions to prevent future falls.

## Treatment

### Multifactorial Approach

As in community fall prevention and risk reduction, a multifactorial approach is most effective in the nursing home setting; however, the risk factors targeted may be different. Because poor balance and decreased mobility are such important predictors of falls, interventions have been designed specifically to address these impairments. However, while studies have shown that it is possible to improve balance and strength with exercise in nursing home residents, these improvements have not resulted in fewer falls. Multidisciplinary interventions that have been effective included education of patient care staff, ensuring environmental safety, fitting and repair of assistive devices, reduction of psychotropic medications, instruction in safe transfers and walking, exercise classes, and the use of hip protectors. Maintaining a safe environment is of great importance in the nursing home setting, as environmental factors play a larger role in fall risk for patients with impaired mobility and cognition. Attention should be paid to floors, removing clutter, unstable furniture such as rolling tray tables, and lighting. Beds should be low enough so that the resident can sit with knees bent to 90 degrees and feet on the floor. Use of half-rails can improve safety and aid in transfers in and out of bed. Chairs should be firm, with arms. Bathrooms should be equipped with rails and, if appropriate, raised toilet seats.

### Alternatives to Restraints

Since the 1990s, there have been widespread efforts to reduce the use of physical and chemical restraints and to find alternatives to prevent falls in nursing home residents. The use of restraints has not been shown to decrease the incidence of fall injuries. Bed and chair alarms to alert caregivers that residents are getting up are alternatives to restraints for fall prevention. Low beds and mats placed on the floor next to the bed reduce the risk of injury with a fall. Additional alternatives to restraint use to reduce fall risk include structured group activities to increase supervision of at-risk residents, scheduled toileting, particularly before and after meals, and attention to the safe use of assistive devices.

### Hip Protectors

In the setting of a skilled nursing facility, ambulatory older persons at risk for falls also are likely to have osteoporosis. Treatment of risk factors for falls and osteoporosis are not sufficient to prevent all falls and fractures, particularly in residents who have low bone density. One option for treatment is the use of hip protectors, which attenuate the force of a fall on the hip. Those studied most extensively consist of foam or plastic pads placed inside pockets on a stretchy undergarment so that the protectors lie over the greater trochanter of each hip.

The undergarment is designed to be fairly easy to wear without affecting walking or sitting. Initial research indicated that, when worn, hip protectors significantly reduced the incidence of hip fractures. However, as more studies have been done, the evidence supporting the use of hip protectors has become weaker. Their use in the nursing home setting is marginally beneficial in reducing hip fractures. Compliance with hip protectors is problematic because of difficulty pulling the undergarment up or down for toileting, discomfort, poor fit, skin irritation, or lack of perceived risk for hip fracture.

## HOSPITAL FALLS

Research on prevention of falls and fall injuries in the hospital setting has been problematic. Trial design is difficult because of short patient stays, the variation in case mix and staffing in different units in a hospital, and lack of control patients or units. Studies have utilized multifaceted interventions, such that it is difficult to evaluate the effectiveness of individual components. An insufficient number of randomized, controlled trials preclude making evidence-based recommendations concerning the evaluation of fall risk and prevention of falls and fall injuries in the hospital setting, other than that a multifaceted approach appears to reduce the incidence of falls. However, fall prevention is a focus for hospitals as well as hospital regulatory agencies, and best practice nursing guidelines have been published.

Fall prevention requires hospital administrative support and the ongoing attention of staff through multidisciplinary review and revision of patient care. Individual units may vary in their approach because of differences in patient mix and staffing. The components of a fall prevention program should include: (1) risk factor assessment and identification of patients at risk for falls; (2) individualized care plans for fall prevention; (3) evaluation of incident falls; and (4) revision of the care plan after a fall as appropriate to prevent further falls. Communication of falls risk among care providers and to patients and their families is an essential element of a hospital fall prevention program.

### Risk Factor Assessment

Patients at risk for falls in the hospital are those with chronic or acute cognitive impairment; weakness and difficulty with balance, transfers, or gait; need for frequent toileting because of urinary frequency, incontinence, or diarrhea; medication use; history of a previous fall at home or, more significantly, in the hospital; fear of falling; depression; dizziness; functional impairment; environmental factors; and advanced age. Various assessment tools have been created to identify patients at risk for falls; however, risk screening tools may perform better in some hospital unit settings than others. Performing a fall risk screen on a patient at least daily can serve as a reminder of fall risk for nursing personnel caring for the patient.

### Preventive Measures

Once a patient is screened as being at risk for falls, many hospitals use markers in the chart, on the patient's wristband, and/or in the patient's room to designate fall risk and to communicate that risk to caregivers. Standard preventive strategies are used, such as keeping the call bell within reach, the bed in the lowest position, and the room uncluttered. Strategies to address specific risk factors are employed,

such as physical therapy to improve gait and balance; scheduled toileting for those with elimination issues; use of low beds, half-rails on the bed, and nonskid footwear for patients with mobility problems; and increased supervision for patients with cognitive impairment or delirium. The use of physical restraints in acute care settings should be avoided as there is no evidence that restraints prevent falls in these patients, and restraints may increase the risk of injury.

### Evaluation of Falls and Revision of Care Plan

When a patient falls, unit personnel should note the circumstances and outcome of the fall, as well as contributing factors and functional assessment. The physician evaluating the person who falls should note associated symptoms (e.g., dizziness, confusion, incontinence, palpitations, weakness); perform a physical examination, including assessment for postural hypotension, new neurological deficit, and trauma; a medication review to reduce or eliminate possible contributing medications; and appropriate laboratory and radiological studies. This information can be used to revise the nursing plan of care as well as medical treatment.

Communication of fall risk to all hospital personnel taking care of the patient is important; it is also important for patients and their families to be made aware of fall risk in the hospital setting and the plan of care that is in place to decrease that risk. At discharge, fall risk should be communicated to the skilled nursing facility or home care agency that will be providing further care.

### AREAS FOR FUTURE RESEARCH

Although much is now known about falls and their consequences, there are still questions about what the best, most cost-effective interventions are to prevent falls and fall injuries. Within the current U.S. health care system, care is not coordinated among different providers and disciplines and is aimed more at treatment rather than prevention of disease. Given these constraints, studies need to be done of fall prevention in community practice settings. Research studies of interventions that have been successful generally have targeted older persons at risk for falling; yet more needs to be learned about who will benefit most from fall prevention efforts, particularly in nursing home and hospital settings. The most effective treatment of specific impairments, such as visual problems, dementia, and cardiovascular disease, to reduce falls needs further investigation.

### CONCLUSION

Falls are common in older persons, and are costly in terms of injury, loss of function, and health care costs. There is now evidence that multidisciplinary programs aimed at reducing multiple risks for falls are effective in preventing falls in a community research setting. The evidence is less compelling for nursing home and hospital falls. Screening for fall risk, careful assessment of older persons who have fallen or have mobility impairment, and oversight of an individualized, multidisciplinary risk reduction plan are important components of the care of geriatric patients.

# Sleep Disorders

*Mairav Cohen-Zion* ■ *Sonia Ancoli-Israel*

## INTRODUCTION

Over the past several years, much research has focused on normal age-related changes in sleep as a function of aging. However, in addition to these common changes, aging is also associated with an increase in sleep complaints and chronic sleep disturbances, resulting in poorer daytime functioning and increases in health care usage. This chapter reviews sleep and sleep disorders in older adults, including information on presentation, etiology, pathophysiology, evaluation, and management of sleep-related issues.

## CHANGES IN SLEEP WITH AGING

Approximately 50% of community-dwelling elderly persons complain of some form of sleep difficulty. Subjective and objective reports show that when compared to their younger counterparts, older adults take longer to fall asleep, have lower sleep efficiency (defined as the amount of sleep given the amount of time in bed), have more nighttime awakenings, wake up earlier than they would like in the morning, and require more daytime naps (Table 55-1). Polysomnographic (PSG) sleep recordings have confirmed these findings, showing that despite older adults spending more time in bed, they have a harder time getting to sleep, get overall less sleep, and have more nighttime awakenings, resulting in reduced sleep efficiency. It is not surprising then that Multiple Sleep Latency Tests (MSLTs), objective measures assessing daytime sleepiness via PSG-recorded napping opportunities, indicate that older adults are significantly sleepier throughout the day than are younger adults.

One central question raised by researchers in the field is whether these age-related changes represent a decrease in the need for sleep or a decrease in the ability to sleep. Although this question is still being debated and there is no clear consensus on whether there is a reduced need for sleep, there is clearly a reduced ability to sleep

in this population. As discussed in this chapter, sleep difficulties in this population are associated with several factors, including specific sleep disorders, changes in the endogenous circadian clock, medical and psychiatric illness, and medication intake (Table 55-2). Recent developments in sleep research have identified several effective treatments for many of these sleep difficulties. Given the high prevalence of sleep complaints and sleep disorders in this population and the link between insufficient sleep and heightened levels of morbidity and mortality, there is a clear need for increased awareness, assessment, and treatment of these sleep disturbances.

## SLEEP-DISORDERED BREATHING

### Definition

Sleep-disordered breathing (SDB) is characterized by respiratory events, including hypopneas (partial respiration) and/or apneas (complete cessation of respiration), during sleep. These respiratory events occur repeatedly over the course of the night with each respiratory event lasting a minimum of 10 seconds. The number of apneas per hour of sleep is called the apnea index (AI) and the number of apneas and hypopneas per hour of sleep is called the apnea-hypopnea index (AHI; also sometimes called the respiratory disturbance index [RDI]). Clinical diagnosis of SDB is traditionally given when a patient has an AHI of 10 to 15.

The cessations in breathing in SDB lead to repeated arousals from sleep, as well as to reductions in blood oxygen levels over the course of the night, which result in nighttime hypoxemia.

### Epidemiology

SDB is more common in older than younger adults and among nursing home patients, specifically elderly with dementia, when

**TABLE 55-1****Sleep Complaints of Older Adults**

Spend too much time in bed
Spend less time asleep
Increase in number of awakenings
Increase in time to fall asleep
Less satisfied with sleep
Significant increase in daytime sleepiness
Napping more often and longer

compared to those elderly living independently. [Table 55-3](#) summarizes several potential age-dependent risk factors in the development of SDB. The prevalence of SDB varies by severity level or AHI. Approximately 2% to 4% of middle-aged men and women (age 30 to 60 years) have an AHI  $\geq 5$ , compared to 32% to 81% of older adults (age 60+ years). With increasing AHI, these percentages are slightly lower, with 19% to 62% of older adults having an AHI  $\geq 15$  and up to 24% having an AHI  $\geq 20$ . In addition, within the older population, SDB is more common in men than in women and in patients with hypertension, and may be more severe in elderly people in the African-American than in the Caucasian population.

### Pathophysiology

There are three types of apneic events: central, obstructive, and mixed. Central events are a result of a dysfunction of the respiratory neurons. Obstructive events are caused by anatomic obstruction of the upper airways despite respiratory effort. Mixed events are a combination of central and obstructive components.

### Presentation

The cardinal symptoms of SDB are snoring and excessive daytime sleepiness. It is often one or both of these two symptoms that motivate the patient to seek evaluation and treatment of this sleep disorder. Additional symptoms may include insomnia, nocturnal confusion, and cognitive deficits, such as difficulty with concentration and memory.

Approximately 50% of regular snorers suffer from some degree of SDB and snoring may be an early precursor to SDB. Snoring is reflective of the airway collapse and is a component of the breathing cessation during an apneic event. It may be extremely loud, being heard all over the house. Often bed partners have moved into separate bedrooms. While not all snoring is associated with sleep apnea,

**TABLE 55-3****Potential Age-Dependent Risk Factors in Sleep Disordered Breathing**

Increased body mass index (central obesity)
Decreased muscle tension
Changes in airway anatomy
Increased airway collapsibility
Decreased thyroid function
Decreased lung volume

snoring alone is associated with increased risk of ischemic heart disease and stroke.

The excessive daytime sleepiness seen in SDB is associated with sleep fragmentation or repeated nighttime awakenings, which frequently follow the apneic events, and with the nocturnal hypoxia. Daytime sleepiness may manifest as being unable to stay awake or falling asleep at inappropriate times during the day. Patients with excessive daytime sleepiness secondary to untreated SDB may fall asleep while reading, watching television, or at the movies, while in conversation with a group of friends, or while driving. Daytime sleepiness can be a very debilitating symptom, causing social and occupational difficulties, reduced vigilance, and cognitive deficits, including decreased concentration, slowed response time, and memory and attention difficulties. These symptoms may be particularly relevant to older adults who are at an increased risk of developing such symptoms with aging or already suffer from some initial cognitive impairment. SDB may therefore unnecessarily further exacerbate these cognitive deficits.

SDB is often associated with other serious health problems, including hypertension and cardiac and pulmonary disease, which can then lead to increased risk of mortality. Recent research indicates that even those patients with only five events per hour of sleep are at greater risk for developing hypertension. While cause and effect between SDB and cardiovascular disease has not yet been determined, increasing SDB has been associated with increased risk of developing cardiovascular diseases, including hypertension, coronary artery disease, and stroke.

Upon initial evaluation, sleep complaints such as snoring and/or gasping and excessive daytime sleepiness may be suggestive of SDB. The assessment should begin with a thorough sleep history from the patient, including information on daytime behavior. Because the patient is often unaware of (or not disturbed by) the loud snoring or cessations in breathing during the night, it is helpful to have the patient's bed partner present at the assessment interview. The clinician should examine the patient's airway and throat to check for obstruction of the airway. The medical history should include information on history of hypertension and any cardiac or pulmonary problems. The clinician should also collect information on recent weight gain or obesity (excess fatty tissue may contribute to airway obstruction), smoking history (may irritate oropharynx and/or nicotine may affect central nervous system), alcohol intake, and intake of any sedating medications (may result in airway relaxation thus facilitating obstruction). Although patients with SDB are often overweight, it may be less strong a predictor of the presence or absence of SDB in the older population. Thus evaluation of the older patient of normal or even slender weight should not be overlooked.

If the clinician suspects SDB, the patient should be referred for an overnight PSG recording in a sleep disorders clinic, or for

**TABLE 55-2****Factors Contributing to Sleep Disturbances in Older Adults**

Circadian rhythm changes
Primary sleep disturbances (e.g. SDB, PLMS)

Psychiatric illness (e.g., depression, anxiety disorders)
Multiple medications
Dementia
Poor sleep hygiene habits

SDB, sleep disordered breathing; PLMS, periodic leg movements in sleep.

ambulatory monitoring of sleep and respiration in the patient's home. Based on the results of the objective recording, recommendations for treatment can be suggested.

## Management

Pharmacologic treatments for SDB are ineffective; however, there are several effective nonpharmacologic treatments that have become first-line treatment of SDB.

### Positive Airway Pressure

The gold standard for treatment for SDB is positive airway pressure. There are several types of devices that provide positive airway pressure, including continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), and auto-CPAP. CPAP is composed of a nose mask, which is connected via a hose to a machine that provides continuous air pressure. The air pressure acts as a splint to maintain the opening of the upper airway, thereby preventing the obstruction or collapse of the airway. The degree of air pressure (traditionally, 5 to 20 cm H<sub>2</sub>O) is set individually for each patient at the sleep laboratory and is dependent on the patient's AHI or the severity of the patient's SDB. CPAP alleviates all snoring and most of the apneic events, repeated awakenings, and nighttime hypoxemia in these patients. This intervention is also very effective in the reduction of daytime sleepiness and has been shown to improve cognitive performance.

BiPAP was designed to allow for the variation in positive airway pressure during expiration and inspiration. The device looks and acts similarly to CPAP but rather than providing continuous airway pressure, the BiPAP device has reduced expiratory positive airway pressure (EPAP) when compared to the inspiratory positive airway pressure (IPAP). The BiPAP prevents the obstruction of the airway by using lower EPAP levels when compared to CPAP. At this time, there are no data to suggest that BiPAP is more effective than CPAP; however some reports suggest better compliance with BiPAP, possibly because of its more gentle approach, when compared to CPAP.

The auto-CPAP was designed to allow for the overnight variability in airway pressure, which is adjusted automatically depending on the extent of airway obstruction, which may fluctuate with specific sleep stages and body position. In contrast to the constant airway pressure in traditional CPAP, this device adjusts for periods of reduced obstruction by providing lower airway pressure, while providing greater airway pressure with increases in obstruction. To date, no studies suggest increases in compliance with the auto-CPAP when compared to other positive airway pressure devices.

Clinicians should be aware of possible poor patient compliance, however, these devices are recommended for nightly use and are a long-term management approach. The addition of a humidifier to some units reduces the discomfort and possible nasal irritation associated with the use of these devices. Clinicians should not assume that elderly patients cannot tolerate CPAP; one study has shown the extent of dementia, older age, and AHI severity are not associated with compliance, rather only the presence of depression seems to be linked with poor long-term compliance.

### Surgical Interventions

There are several different surgical approaches for the treatment of SDB, including (1) nasal reconstruction, which corrects nasal valve collapse, septal deviations, and turbinate hypertrophy; (2) uvu-

lopharyngopalatoplasty (UPPP), which corrects pharyngeal obstruction by removal of pharyngeal tissue, including soft palate, uvula, tonsillar pillars, and tonsillar tissue; (3) laser-assisted uvulopharyngopalatoplasty (LAUP), which has the same standard procedure as UPPP, but uses a laser to remove the pharyngeal tissue; (4) genioglossus advancement, which corrects by the forward advancement of the insertion of the tongue (usually in conjunction with UPPP or LAUP); and (5) hyoid myotomy, which corrects hypopharyngeal obstruction by suspending the hyoid bone to the superior edge of the larynx (usually in conjunction with UPPP or LAUP).

The surgical approach or combination of approaches (including nonsurgical) chosen for an individual patient is decided on a case-by-case basis and is dependent on the location and the type of obstruction present. Depending on the choice of surgical approach, the effectiveness of the intervention in reducing AHI varies from 48% to 72% and depends on the severity of the SDB and the obstruction. Surgical methods should be approached with caution in the elderly patient, as the effectiveness of the treatment may be lower and their recovery may be longer and more difficult.

### Oral Appliances

Oral devices are appropriate for the management of milder forms of obstructive sleep apnea and snoring. The two most common oral devices are the tongue-retaining device (TRD) and the mandibular advancement device (MAD). These oral appliances are anchored on the patient's teeth or gums and work by moving the tongue or the mandibular forward, thereby preventing obstruction at the hypopharyngeal level. Depending on the type of device used, the effectiveness of this approach in decreasing AHI and increasing blood oxygen saturation levels varies from 40% to 81%. Clinicians need to be aware of possible side effects, including pain or discomfort in the temporomandibular joint or short-term occlusion abnormalities when removing the appliance, which occurs in an estimated 30% of patients. Newer devices can be used with dentures, which make them particularly appropriate for use in the older patient.

### Diet and Lifestyle

There are several dietary and lifestyle factors that can exacerbate SDB, such as obesity, alcohol intake, and smoking. Obesity is a common problem in patients with obstructive sleep apnea, as the additional fatty tissue often results in the obstruction of the upper airways. These patients will benefit significantly from weight loss, which sometimes dramatically reduces or even eliminates apneic events.

Alcohol and certain medications, such as sedative-hypnotics, narcotics, and barbiturates, have a depressant effect on the upper airway musculature and may exacerbate SDB. Furthermore, given the usually high number of prescriptions taken by older patients, clinicians should be diligent when prescribing sedating medications, particularly to those older patients who are at higher risk for SDB. Smoking is also associated with exacerbation of SDB. Although the mechanism is not fully understood at this time, several theories have been suggested, including irritation of oropharynx by cigarette smoke and the possible effect of nicotine on the central nervous system.

For patients with mild SDB, positional SDB, or positional snoring, body position during sleep may account for many of the respiratory events in these cases. The supine position is associated with the majority of the positional apneic events, which are likely

a result of the relaxation of the anterior neck and oropharyngeal structures while in this position. A simple behavioral technique for dealing with positional apnea is to place a tennis ball in a pocket sewn to the back of a night shirt, thereby deterring the patients from sleeping on their back and preventing positional respiratory events.

In general, treatment of SDB in the elderly depends on (1) the severity of the condition, (2) the extent of daytime symptoms, and (3) the presence of other comorbid medical conditions, such as hypertension, cardiac disease, or cognitive deficits. Decision to treat should be made on a case-by-case basis and age of the patient should not be a factor in making this assessment.

## PERIODIC LIMB MOVEMENTS IN SLEEP/RESTLESS LEGS SYNDROME

### Definition

Periodic limb movements in sleep (PLMS) is characterized by clusters of repeated leg (or sometimes arm) jerks that occur approximately every 20 to 40 seconds over the course of the night. These clusters of movements last on an average 0.5 to 5 seconds and cause repeated brief awakenings. The number of limb movements followed by arousals per hour of sleep is called the periodic limb movement index (PLMI). Clinical diagnosis of PLMS is typically given when a patient has a PLMI >5.

Another disorder, often comorbid with PLMS, and believed to be more disruptive, is restless leg syndrome (RLS). RLS is characterized by dysesthesia in the legs, usually described by patients as “a creeping crawling sensation” or as “pins and needles,” which can only be relieved with vigorous movement. These sensations often occur in the evening or whenever the patient is in a restful, relaxed state. About 90% of patients with RLS also have PLMS, but only about 20% of PLMS patients suffer from RLS.

### Epidemiology

The prevalence of PLMS increases significantly with age and is estimated at 45%, compared to 5% to 6% in younger adults. Despite this increase in prevalence, the severity of the condition does not worsen with age. The prevalence of RLS increases with age as well. There is no known gender difference in PLMS, however RLS is twice as common in older women than men.

## Pathophysiology

The exact mechanisms underlying PLMS and RLS are not fully understood; however, current hypotheses suggest possible dysfunction of the dopamine system. These theories are derived from the therapeutic effects of dopamine agonists in RLS and PLMS. Recent studies have also suggested that the pathophysiology of RLS might involve iron homeostatic dysregulation, as ferritin levels in the cerebrospinal fluid are lower in these patients.

### Presentation

The most common complaints of patients with PLMS are sleep initiation insomnia, sleep maintenance insomnia, and excessive daytime sleepiness. Patients may or may not be aware of leg kicks or jerks. Some may complain simply of having difficulty falling asleep or staying asleep with no knowledge that they kick. Often, bed partners may be aware of the leg movements and may have moved into separate beds. Many patients with PLMS also suffer from RLS and therefore may also complain of discomforting sensations in their legs during the day.

### Evaluation

Patients are often unaware of the multiple nighttime awakenings and the associated sleep loss, therefore it is often helpful to have the patient's bed partner present at the assessment interview. An accurate diagnosis of PLMS can only be made by recording limb movements and associated arousals. This can be accomplished via an overnight PSG recording in the sleep disorders laboratory, or in the home with unattended monitoring. Additionally, several actigraphic devices, placed on the ankle, have been validated against PSG for measurement of PLMS.

The diagnosis of RLS is based on the patient's report of uncomfortable sensations in the legs, which are only relieved by movement. Patients with symptoms of RLS should be assessed for anemia, iron deficiency, uremia, and peripheral neuropathy prior to treatment.

### Management

There is some discussion about the significance of PLMS and whether it does in fact constitute a sleep disorder. However, the treatment for PLMS and RLS is the same (Table 55-4). Currently, the first-line treatment for PLMS/RLS consists of dopamine

**TABLE 55-4**

#### Pharmacological Treatment of PLMS/RLS

CLASS	GENERIC	BRAND	DOSE
Dopaminergic agents	Ropinirole	Requip	1.5–4 mg
	Pramipexole	Mirapex	0.25–0.75 mg
	Carbidopa/Levodopa*	Sinemet	25/100–25/250 mg
Benzodiazepines	Clonazepam	Klonopin	0.25–2 mg
	Tempezepam	Restoril	15–30 mg
Opiate agents	Codeine	Tylenol #3/#4	30–60 mg (codeine)
	Propoxyphene hydrochloride	Darvon	65–135 mg

\*Off-label.

agonists, as they reduce or eliminate both the limb jerks and the associated arousals. There are two medications approved by the Food and Drug Administration (FDA) for the treatment of RLS: ropinirole and pramipexole. However, carbidopa/levodopa, has also been shown to be effective. Shifting of limb movements from the nighttime to the daytime may occur with treatment and therefore continued evaluation is needed.

Less effective drugs for these conditions in the elderly include benzodiazepines (e.g., clonazepam, temazepam), which decrease the number of arousals, but do not significantly reduce the number of limb movements; opioids, which decrease the number of limb movements, but do not always decrease the number of arousals; gabapentine, and iron supplements. Long-acting benzodiazepines are contraindicated in patients with SDB and as PLMS is often comorbid with SDB, clinicians should be cautious when prescribing long-acting benzodiazepines. Clinicians should also be aware of possible daytime sedation, particularly in elderly persons, resulting from these longer-acting medications.

## CIRCADIAN RHYTHMS SLEEP DISORDERS

### Definition

Circadian rhythms refer to 24-hour biological rhythms that control many physiologic functions, such as endogenous hormone secretions, core body temperature, and the sleep–wake cycle. These rhythms originate in the suprachiasmatic nucleus (SCN) in the anterior hypothalamus, which houses the internal circadian pacemaker. Circadian rhythms are synchronized to the 24-hour day by other internal rhythms (e.g., hormone secretions), as well as by external zeitgebers (literally time-givers or cues), the most powerful being bright light. The sleep–wake cycle is primarily entrained by internal rhythms, such as core body temperature and the endogenous melatonin cycle, and the external light/dark rhythm, which asserts its effect on the sleep–wake cycle via the retinohypothalamic visual pathway. For example, as core body temperature drops, melatonin secretions increase and individuals start feeling sleepy; as core body temperature rises and melatonin drops, individuals begin waking up.

As people age, several factors may make circadian rhythm less entrained and thereby result in weaker or more disorganized sleep–wake rhythms. Such changes may include (1) slow degeneration of the SCN with age, (2) progressive reduction in endogenous melatonin secretion during the night, and (3) decreased sensitivity to external cues, or alternatively external cues such as bright light may be lacking or weak in older adults. Considerable data have shown that older persons are exposed to significantly less bright light than their younger counterparts. Healthy older adults receive on average only 60 minutes of bright light a day (>2000 lux), whereas elderly demented patients living in the community receive on average 30 minutes of bright light a day (>2000 lux), and demented nursing home patients receive on average no light >2000 lux and only 10 minutes of bright light >1000 lux a day. All these issues may add to the weakening of the sleep–wake circadian rhythm, resulting in more nocturnal awakenings, less consistency of sleep–wake cycles, and heightened daytime sleepiness.

Another common circadian rhythm change in older age is the shifting, or advancing, of the sleep–wake cycle. This circadian rhythm disorder is called advanced sleep phase syndrome (ASPS), a condition in which the sleep–wake rhythm and the core body temperature rhythm are advanced, as compared to those of younger adults. Older adults with ASPS get sleepy in the early evening and wake up in the early morning hours, in part because the core body temperature is dropping earlier in the evening (perhaps at about 7:00 P.M. or 8:00 P.M.) and rising about 8 hours later, at about 3:00 A.M. or 4:00 A.M.

### Epidemiology

Prevalence of ASPS is approximately 1% in middle-aged adults. Although the prevalence in older adults is known to increase, the exact percentage has not been established. This may be partly because these patients have learned to function with the changes in their circadian clocks, and therefore do not present for treatment.

### Pathophysiology

Changes in the sleep–wake cycle are likely caused by changes in the core body temperature cycle, decreased light exposure, and environmental factors. Recent research suggests there may also be a genetic component.

### Presentation

The overall weakening of the circadian rhythm in older age may also result in increased awakenings during the night. The most common complaints of patients with ASPS are being sleepy early in the evening and waking up too early in the morning. If patients with ASPS went to bed as their core body temperature was dropping, for example, around 7:00 P.M. or 8:00 P.M., they would have little difficulty falling asleep and would sleep for a full night, about 8 hours. As explained above, this would result in their waking up somewhere between 3:00 A.M. and 4:00 A.M. An additional problem results when these patients, despite their physiological changes, prefer to maintain more “normative” or “acceptable” sleep–wake schedules, thereby delaying their bedtimes; however, as a result of the phase advance of their circadian rhythm, they continue waking up at the earlier morning times, thereby reducing their time in bed and their nightly sleep duration. A second scenario involves patients falling asleep while reading or watching television in the early evening, and subsequently having difficulty falling asleep, but still awakening in the early morning hours. This significant sleep loss can result in daytime sleepiness, often resulting in daytime naps.

### Evaluation

As symptoms of ASPS may mimic symptoms of sleep-maintenance insomnia, the two highly common conditions in the elderly, clinicians may have difficulty distinguishing between the two disorders. However, in order to implement the correct treatment, appropriate evaluation is imperative. When assessing for ASPS, the clinician should obtain an extensive sleep history and at least 1–2 weeks of sleep diaries (Table 55-5), which can be sent to the patient several weeks prior to their treatment. If possible, the patient should also wear a wrist actigraph for 3–7 days, allowing for the objective

TABLE 55-5

## Sample Sleep Diary

Name: _____	Date: _____ to _____						
	Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday
1. Bed time							
2. Time taken to fall asleep (after lights off)							
3. Number of nighttime awakenings							
4. Wake-up time							
5. Time out of bed (morning)							
6. Total sleep time (night only)							
7. Total wake time (night only)							
8. Nap time (if any)							
9. Medication (time/dosage)							
10. Alcohol (time/dosage)							
11. How was your sleep last night?*							
12. How tired were you in the morning?							

\*1 = excellent to 5 = very poor; 1 = not tired to 5 = very tired.

examination of the shifting of the sleep–wake cycle. If these assessments suggest early evening sleepiness and early evening bedtimes along with early morning awakenings, the clinician should suspect ASPS.

## Management

As shifting of the circadian rhythm is a common and expected development in older age, patients should be educated that ASPS is not a medical disorder and does not necessarily need to be treated. Treatment is dependent on the extent of the discomfort the ASPS has on the day-to-day life of the individual patient. Patients often complain that their waking hours are no longer consistent with societal norms, causing them to be awake (or asleep) when those around them are not.

Nonpharmacologic therapies, focusing on strengthening and entrainment of the sleep–wake rhythm, are the treatments of choice for patients with ASPS, particularly bright-light therapy.

### Bright-Light Therapy

As bright light is the most influential external zeitgeber on the sleep–wake circadian system, it is not surprising that it is also the most appropriate and effective treatment for circadian rhythm disturbances. By increasing light exposure during specific times of the day, it is possible to advance or delay the sleep–wake circadian rhythm. Specifically, exposure to bright light in the early morning will strengthen and advance the rhythm (i.e., patient will become sleepier earlier), whereas exposure to bright light in the late afternoon or early evening will delay the rhythm (i.e., patient will become sleepier later in the day allowing them to stay alert longer). Exposure to bright light will not only shift the sleep–wake circadian rhythm but will also shift related rhythms such as core body temperature and endogenous melatonin.

To delay the advanced sleep–wake rhythm, patients with ASPS should be exposed to bright light for approximately 2 hours a day during the late afternoon to early evening. The best source of bright

light is sunlight, therefore patients should attempt to spend time outdoors in the late afternoon. Because the mechanism of the light is primarily through the eyes, sunglasses should not be worn during this time; however they should be worn in the morning hours to avoid having rhythms advance even more or canceling out the afternoon light exposure. Normal room light is not generally bright enough to shift rhythms. Therefore, if the patient is unable to spend 2 hours a day outdoors, another option is a special commercially available “light box,” which provides a minimum of 2500 lux light exposure, which has been shown to improve sleep consolidation in institutionalized elderly.

## RAPID EYE MOVEMENT SLEEP BEHAVIOR DISORDER

### Definition

Rapid eye movement (REM) sleep behavior disorder (RBD) is characterized by a dissociated state during which complex motoric behaviors occur, most likely resulting from an intermittent lack of skeletal muscle atonia that is typically present during REM sleep. RBD usually occurs during the second half of the night, when REM is more prevalent. Nighttime behaviors in RBD include vigorous and complex body movements and actions, such as walking, talking, and eating.

### Epidemiology

The prevalence of RBD is unknown. However, recent reports suggest elderly men may be at higher risk for developing RBD.

### Pathophysiology

To date, the etiology of RBD remains unknown. Some reports suggest that acute RBD is associated with the intake of tricyclic antidepressants, fluoxetine, and monoamine oxidase inhibitors, and

withdrawal from alcohol or sedatives. In contrast, chronic RBD has been associated with narcolepsy and other idiopathic neurodegenerative disorders such as dementia and Parkinson's disease.

### Presentation

Patients engage in complex motoric behaviors over the course of the night and may be unable to recollect these actions in the morning. Some patients' recollections of their dreams suggest these nighttime activities and movements may be the acting out of patient dreams, made possible by the lack of muscle atonia during REM sleep. At times, movements may be violent and may harm the patient and/or the patient's bed partner.

### Evaluation

Assessment of RBD should include a complete sleep history. Because patients may be unaware of their behaviors over the course of the night, bed partners should also be interviewed. Clinicians should acquire simultaneous overnight PSG and video recording of nighttime behavior in order to examine whether there is a link between REM sleep and the complex behaviors exhibited by the patients. When examining the PSG, clinicians should be attentive to any marked unusual elevations in muscle tone and/or limb movements in the electromyogram (EMG) recording, specifically during REM sleep, when they usually rare.

### Management

#### Pharmacological Interventions

To date, there have been only a few reports of pharmacologic treatments for RBD, with promising initial results. Currently, clonazepam is the most prescribed pharmacological treatment for RBD. Clonazepam acts by inhibiting nighttime motoric movements, without directly affecting muscle tone. It has been shown to result in cessation (partial or complete) of abnormal body movements during the night in about 90% of RBD patients. If the medication is stopped, all symptoms return. Patients may complain of excessive daytime sleepiness because of this drug's long half-life. If clonazepam is contraindicated, several alternative drugs have shown some positive effects in RBD, including tricyclic antidepressants, dopaminergic agents, and melatonin.

#### Lifestyle

Clinicians should educate RBD patients and their bed partners on making changes in bedtime/sleeping routines and environment, in order to make the bedroom safer and to decrease the potential for injurious behavior during the night. For example, heavy curtains should be placed on bedroom windows, and doors and windows should be locked at night if there is risk of the patient wandering out of bed during the night and engaging in complex behaviors. If the patient is extremely active or violent during the night, heavy or breakable objects should be removed from the vicinity of the bed, and if needed, patients may want to sleep on a mattress placed on the floor to avoid falling off the bed and/or hurting themselves or their bed partners.

## INSOMNIA

### Definition

Insomnia is a complaint of low quantity and/or poor quality sleep, resulting in a sense of nonrestorative sleep. There are several different types of insomnia, including sleep onset insomnia (an inability to initiate sleep), sleep maintenance insomnia (an inability to maintain sleep throughout the night), early morning insomnia (awakening early in the morning with an inability to return to sleep), and pathophysiologic insomnia (behaviorally conditioned insomnia associated with maladaptive behaviors). Although older adults can suffer from any of the types of insomnia, the most common complaints in the elderly are of sleep maintenance insomnia and early morning insomnia.

Insomnia is also classified based on the length of time the complaint has persisted, with transient insomnia lasting only a few days prior to (or during) a brief stressful experience, short-term insomnia lasting a few weeks during an extended period of stress and adjustment, and chronic insomnia lasting several months to years, which may have begun following a discrete event, but continues even after the antecedent event is no longer relevant. In many cases of chronic insomnia, the inability to sleep may have become a conditioned response and may be associated with poor sleep hygiene.

### Epidemiology

The prevalence of insomnia is greater in older than younger adults, with a prevalence of 40% to 50% for chronic sleep onset or sleep maintenance insomnia, and an incidence of about 5%. Women report more insomnia complaints than men.

### Pathophysiology

There are multiple factors that may play a causal role in the development of insomnia. Insomnia is most commonly co morbid with medical, psychiatric, or psychosocial conditions, and/or secondary to the treatment of these conditions. Medical illnesses common in the elderly population, such as arthritis, cardiovascular disease, pulmonary disease, chronic pain disorders, and other illnesses associated with physical discomforts, are often associated with insomnia. Major life changes, such as retirement and death of loved ones, can also lead to insomnia. These psychosocial and environmental factors may cause or exacerbate psychiatric and/or sleep difficulties. Depression and anxiety disorders are therefore among the most common comorbid conditions associated with sleep disturbances in the elderly person. Only about 7% of incident insomnia cases in older adults are not related to one of these conditions. In addition, a linear relationship exists between the number of these illnesses and insomnia in older adults.

Polypharmacy has become increasingly common in elderly patients, particularly those suffering from multiple medical and psychiatric conditions. Pharmacologic treatments for these conditions often exert either sedating or alerting properties, however these sleep effects are rarely taken into consideration. For example, alerting or stimulating drugs (Table 55-6), when taken late in the day, may

**TABLE 55-6****Effect of Common Drugs Taken by Older Adults**

SEDATING	ALERTING
Hypnotics	Alcohol/nicotine
Antihypertensives	CNS stimulants
Antihistamines	Thyroid hormones
Antipsychotics	Bronchodilators
Antidepressants	Corticosteroids
	Beta-blockers
	Calcium channel-blockers

cause difficulty falling asleep at night. On the other hand, sedating drugs (see Table 55-6) taken early in the day may lead to excessive daytime sleepiness and daytime napping behavior, which may contribute to sleep onset insomnia or may further exacerbate and maintain the existing insomnia. Therefore it is not the aging process per se that causes insomnia, rather it is the co-occurring conditions and their treatment, which may underlie the higher prevalence of insomnia with increasing age.

### Presentation

Complaints of insomnia may vary significantly from patient to patient. Apart from the inability to sleep at various periods of the night (early, middle, or late), patients often complain of excessive daytime sleepiness, leading to daytime napping and decreased mental functioning.

### Evaluation

Evaluation of insomnia should begin with a thorough medical, psychiatric, and sleep assessment, and a review of recent medication intake (including time of medication ingestion). The clinician should also request 1 to 2 weeks of sleep diaries (and/or actigraphic recordings) in order to obtain an exact description of the nature of the insomnia. In addition, the clinician needs to collect information on the characteristics, onset, duration, and severity of the insomnia, as well as on any factors that may contribute to the sleep condition, such as sleep hygiene practices, diet, alcohol intake, and smoking history.

### Management

There are several behavioral and pharmacological interventions and lifestyle changes that may aid in the management of insomnia. Overall, given the high number of medications prescribed and known changes in rates of metabolism and elimination in this population, clinicians should attempt to implement behavioral treatments prior to pharmacologic interventions.

### Nonpharmacological Interventions

Nonpharmacological treatments include cognitive-behavioral treatments (CBT) and educational approaches. These treatments attempt to change the inappropriate or maladaptive behaviors associated with sleep and are particularly effective in cases of psychophysiological

**TABLE 55-7****Sleep Hygiene Rules for Older Adults**

Check effect of medication on sleep and wakefulness
Avoid caffeine, alcohol, and cigarettes after lunch
Limit liquids in the evening
Keep a regular bedtime–waketime schedule
Avoid naps or limit to 1 nap a day, no longer than 30 min
Spend time outdoors (without sunglasses), particularly in the late afternoon or early evening
Exercise

insomnia where the initial cause of the insomnia may no longer be present.

Many nonpharmacological interventions have been shown to be highly effective in reducing insomnia, producing short-term and long-term positive changes in sleep habits, as well as the subjective perception of better sleep. Below are examples of the most common nonpharmacological interventions.

**Sleep Hygiene** Sleep hygiene is an educational approach designed to give insomniacs, as well as the general population, a list of guidelines on how to maintain healthy sleep–wake routines. Poor sleep habits are associated with a reduction in nighttime sleep quality and difficulties with alertness during the day. When the clinician is collecting the patient's sleep history, information should also be collected on any disruptive nighttime or daytime behaviors that may be affecting the patient's sleep. Table 55-7 summarizes sleep hygiene rules specifically adapted for older adults. Sleep hygiene rules can also be incorporated with other treatments for sleep difficulties.

**Stimulus-Control Therapy** Stimulus-control therapy was developed for the management of psychophysiological insomnia. Patients often have negative associations with the bedroom environment, leading to arousal. These associations can be redefined for the patient by associating the sleep environment with positive and calming cues, thereby promoting sleep.

Stimulus-control therapy is designed to break any preexisting associations between the bed (and bedroom) and wakefulness, which are often the result of maladaptive classical conditioning. It requires patients to stop all in-bed activities other than sleep and only go to bed when feeling tired enough to fall asleep. Patients should avoid any stimulating or arousing activities prior to bedtime, such as watching television, reading exciting books, or watching the alarm clock. If the patient cannot fall asleep within 20 minutes, they should get out of bed (and get out of bedroom if possible) and return to bed only when they feel tired enough to be able to fall asleep. This pattern continues until the patient is able to fall asleep within the 20-minute limit.

For a regular sleep period to develop, the patient should wake up and get out of bed at the same time everyday (including weekends). Napping behavior should be avoided, so that the need for sleep can accumulate. However, some modification is possible in the case of older adults who may be allowed to nap during the day (if absolutely necessary), but for no longer than 30 minutes in the early part of the day, so as not to interfere with sleep onset. These rules should be followed when first attempting to fall asleep in cases of

**TABLE 55-8****Instructions for Stimulus-Control Therapy for Older Adults**

1. Patient should only go to bed when tired or sleepy
2. If unable to fall asleep within 20 min, patient should get out of bed (and bedroom if possible). While out of bed, do something quiet and relaxing.
3. Patient should only return to bed when sleepy
4. If unable to fall asleep within 20 min, patient should again get out of bed
5. Behavior is repeated until patient can fall asleep within a few minutes
6. Patient should get up at the same time each morning (even if only a few hours of sleep)
7. Naps should be avoided

sleep onset insomnia or upon each awakening for patients with sleep maintenance insomnia. [Table 55-8](#) summarizes the instructions for stimulus control therapy. Patients may resist this method because it may require significant effort on their part and may initially reduce the sleep period and increase daytime sleepiness. Therefore, to increase compliance when recommending this method, the clinician should explain the underlying theory behind this approach, and review possible initial discomforts.

**Sleep-Restriction Therapy** Sleep-restriction therapy was developed in response to the clinical observation that patients with sleep difficulties often spend a significant amount of time in bed unsuccessfully attempting to fall asleep. This inability to fall asleep in an appropriate amount of time results in anxiety and frustration, which, over time, can lead to the development of psychophysiological insomnia. In addition, spending too much time in bed can lead to fragmented sleep. This method is designed to reduce the amount of time the patient spends awake in bed, thus increasing sleep efficiency. As described above, sleep efficiency is defined as the amount of time asleep given the amount of time in bed. Ideally, an older adult's sleep efficiency will be 85% or greater.

Sleep-restriction therapy requires the patient to fill out sleep logs for 1 to 2 weeks. Based on these sleep logs, the average amount of time the patient sleeps a night is calculated. The patient is only allowed to spend this amount of time, plus 15 minutes, in bed each night for the following week. For example, if the patient reports sleeping an average of only 5 hours a night, the patient is only allowed to be in bed 5 hours and 15 minutes. Although this reduction in time in bed causes an initial reduction in time spent asleep and possible sleep deprivation, it is likely to lead to shorter sleep onset and sleep consolidation in the long run. Patients should also wake up at the same time each day and avoid daytime napping. In our example, if the patient's normal time to awaken is 6:00 A.M. and they estimate they sleep for only 5 hours, they would not be allowed to go to bed until 12:45 A.M. Once sleep efficiency has reached 85%, the time allowed to spend in bed at night is increased by 15 minutes at the start of the night, so that now the patient would go to bed at 12:30 A.M. This pattern is repeated until the patient is in bed, able to sleep 8 hours, or the number of hours that affords the patient a good night's sleep.

To increase compliance, clinicians should help the patient understand the underlying theory behind this method and educate them on some initial difficulties they should expect, such as initial sleep loss and daytime sleepiness. [Table 55-9](#) summarizes the instructions for sleep-restriction therapy.

**TABLE 55-9****Instructions for Sleep Restriction Therapy for Older Adults**

1. Calculate the average amount of time in bed per night reported by patient
2. Patient is only allowed to stay in bed for this amount of time plus 15 min
3. Patient must get up at the same time each day
4. Daytime napping should be strictly avoided
5. When sleep-efficiency has reached 80% to 85%, patient can go to bed 15 min earlier
6. This procedure should be repeated until patient can sleep for 8 h (or period needed for a good night's sleep)

**Cognitive-Behavioral Therapy** CBT for insomnia involves educational, behavioral, and cognitive components. The educational component involves encouraging the patient to determine which factors might be predisposing, precipitating, or perpetuating the insomnia. The therapist explains that CBT is effective by eliminating the perpetuating factors with behavioral and cognitive strategies. The behavioral component involves the behavioral techniques described above. The cognitive component deals with the maladaptive thoughts or dysfunctional beliefs that the patient has about insomnia.

In an 8-week double-blind treatment longitudinal outcome study, CBT, a long-acting benzodiazepine (temazepam), a combined CBT/temazepam condition, and a placebo condition were compared in a sample of older adults. Compared to baseline, all three active treatments reduced night wakings at posttreatment, however only CBT alone and CBT/temazepam were associated with continued improvement at 3-, 12-, and 24-month follow-up interviews. In addition, one study found that even two 25-minute CBT sessions for insomnia are effective in reducing nocturnal awakenings, which may be a more practical approach in the primary care setting. The NIH 2005 State-of-the-Science conference on insomnia concluded that CBT is the most effective treatment for insomnia. CBT has been found to be as effective as prescription medications for brief treatment of chronic insomnia, and, in contrast to medications, the effects may last well beyond the termination of treatment. There is no evidence that CBT treatment produces adverse effects. In sum, although pharmacologic treatments may be of more immediate help, particularly in the acute treatment phase, in order to maintain long-term clinical gains, nonpharmacological or combined approaches are more effective.

### Pharmacological Interventions

Historically, multiple classes of medications have been used to treat insomnia, such as antidepressants, antihistamines, antipsychotics, and sedative-hypnotics. The 2005 NIH State-of-the-Science Conference on Insomnia concluded that (1) all antidepressants have potentially significant adverse effects, raising concerns about the risk-benefit ratio, (2) barbiturates and antipsychotic medications have significant risks, and thus their use in the treatment of chronic insomnia cannot be recommended and (3) there is no systematic evidence for efficacy of antihistamines, yet there are significant concerns about risks with these agents. The NIH conference also concluded that while the older benzodiazepines are safe in the short-term treatment of insomnia, the frequency and severity of adverse effects are much lower with the newer nonbenzodiazepines.

**TABLE 55-10****Novel Nonbenzodiazepines Approved for Insomnia Treatment by the Food and Drug Administration**

GENERIC	BRAND	DOSE (mg)	TYPE OF INSOMNIA	HALF-LIFE (h)
Zaleplon	Sonata	5–20	Sleep-onset	1
Zolpidem	Ambien	5–10	Sleep-onset	2.5–3
Zolpidem MR	Ambien CR	6.25–12.5	Sleep-onset and sleep maintenance	2.8
Eszopicolone	Lunesta	1–3	Sleep-onset and sleep maintenance	6
Remelteon	Rozerem	8	Sleep onset	1–2.6

Clinicians should exercise caution when prescribing hypnotics to older adults, and often pharmacologic management of insomnia should be accompanied by cognitive-behavioral approaches (see above). If a hypnotic medication is needed for an older patient, clinicians should consider several issues: (1) prescribing the lowest-effective dose, (2) using hypnotics with shorter half-lives, and (3) evaluating possible effects on SDB and daytime alertness and performance. In general, longer-acting hypnotics are contraindicated in this population, as these medications have several sleep-related side-effects, such as changes in sleep architecture (i.e., reduction in delta or deep sleep), morning hangover effects, leading to excessive daytime sleepiness, poor motor coordination, and visuospatial problems, which may be particularly pronounced in the elderly.

If after careful consideration, the best course of treatment is a sleep medication, the approach to consider would be the newer FDA-approved selective shorter-acting nonbenzodiazepine hypnotics (Table 55-10). These novel medications have been repeatedly shown to be the most effective and safest approach for the treatment of insomnia in older adults. One additional FDA-approved drug, ramelteon, a melatonin agonist, has also been shown to be effective in the treatment of sleep-onset insomnia in elderly (see Table 55-10). Successful treatment is dependent on choosing the correct hypnotic and is based on the specific type of insomnia complaint, e.g., sleep onset difficulty versus repeated nighttime awakenings (see Table 55-10) and the time available to the patient to devote to sleeping in bed.

## SPECIAL ISSUES

### Sleep in Institutionalized Elderly Patients and Neurodegenerative Disorders

The sleep of older adults living in nursing homes is known to be extremely disturbed, particularly in those suffering from neurodegenerative disorders such as Alzheimer's disease, Parkinson's disease, Huntington's disease, and some other forms of dementia. Persons with dementia may be more susceptible to sleep disorders as a consequence of the disease processes, causing permanent damage to brain areas regulating sleep. In addition, progression and severity of the dementing condition has been associated with more sleep disturbances. A common reason for the institutionalization of an elderly person is frequent nocturnal awakenings with wandering and confusion.

Sleep disturbances affect elderly persons with neurodegenerative disorders differently than they affect "healthy" older adults. For ex-

ample, Alzheimer's disease patients suffer from progressive increases in the duration and frequency of nocturnal awakenings, increases in daytime napping, and decreases in slow-wave sleep and REM sleep, when compared to healthy older adults. Nursing home patients often suffer from severely fragmented sleep, often to the extent that there is not a single hour in a 24-hour day that is spent fully awake or asleep. Many of the coping strategies summarized in Table 55-11 are also relevant to patients suffering from neurodegenerative disorders, particularly the need for significant light exposure during the day, increasing daytime activity and exercise, and decreasing the need for daytime napping.

Environmental factors in the nursing home may also contribute to the reduction in the quality of sleep. In the nursing home, noise and light exposure occurs intermittently throughout the night and contributes to the disruption of sleep for the patients. Patients in the nursing home spend a significant amount of the 24-hour day in bed, leading them to rapidly cycle between sleep and wake during this time. Changes in sleep hygiene and the sleep environment of nursing home patients may greatly improve the sleep quality in this population. Table 55-11 summarizes a list of strategies for dealing with sleep-wake disturbances in the institutionalized elderly patient. The purpose of these strategies is to help both patients and nursing home staff reduce the nighttime disturbances in the sleeping environment, while promoting stronger and more defined sleep-wake cycles.

It was previously mentioned that older adults have higher rates of SDB than do younger adults. Research also shows that patients suffering from neurodegenerative disorders and patients living in

**TABLE 55-11****Sleep Hygiene Rules for Nursing Homes Patients**

Limited the amount of time in bed, particularly during the day
Limited naps to 1 h once a day, early in the afternoon
Keep regular sleep-wake schedule (if possible similar to prior home routine)
Keep regular meal schedule (if possible patients should not eat in bed)
Avoid caffeinated beverages and food
Limit nighttime noise
Ensure that patient rooms are as dark as possible during the night
Ensure that patient environment is brightly lit during the day
Encourage exercise appropriate for each patient
Match roommates on sleep-wake behavior
Assess patients for possible sleep problems and initiate specific treatment
Check medications for sedating/alerting effects

nursing homes suffer from an even higher prevalence of SDB. One theory postulates this increased risk for SDB in elderly individuals with specific progressive dementias may be caused by the degeneration of brainstem areas managing various sleep-regulated autonomic functions (e.g. respiration). Recent reports also suggest a possible relationship between SDB and exacerbation of cognitive impairments in older adults with dementia. Consequently, clinicians should be even more attentive to symptoms of SDB in this population.

## SUMMARY

Sleep in the older adult may become poorer and more fragmented over time. In healthy older adults, sleep complaints are relatively rare; however, older patients with medical and/or psychiatric illnesses are significantly more likely to suffer from chronic insomnia. The aging process per se does not seem to underlie the increase in sleep disturbances in this population; rather they seem to be associated with a host of physical and psychological illnesses, medication use, circadian rhythm disturbances, and other primary sleep conditions (e.g., SDB). In order to commence appropriate treatment, differential diagnosis of these sleep conditions and their underlying causes are imperative when evaluating this population. Treatment plans should also address the primary medical/psychiatric conditions (if present) including medication regimens, and any other sleep conditions. Nonpharmacological therapies are often effective. When drug treatment is used, short acting agents are preferred. In sum, comprehensive evaluation and treatment management approaches will likely result in improved daytime functioning and higher quality of life in this population.

# Dizziness

*Aman Nanda* ■ *Richard W. Besdine*

## DEFINITION

*Dizziness* is a broad term used to describe various abnormal sensations arising from perceptions of the body's relationship to space or of unsteadiness. Dizziness has been arbitrarily defined on the basis of duration as acute (present for less than 1 or 2 months) or chronic (present for more than 1 or 2 months). The differential diagnosis of acute dizziness is similar in younger and older persons and management of acute dizziness is not qualitatively different in older persons as compared to younger adults, with the possible exception that recovery maybe more prolonged in older adults. This chapter focuses on chronic dizziness.

## EPIDEMIOLOGY

The prevalence of dizziness ranges from 4% to 30% in persons aged 65 years or older, and more commonly is reported by women than men. In one study of persons aged 65 years and older, the likelihood of reporting dizziness increased by 10% for every 5 years of increasing age.

Chronic dizziness is associated with a number of comorbid conditions, including falls, functional disability, orthostatic hypotension, syncope, and strokes. In older persons, chronic dizziness can cause significant adverse effects on a person's quality of life. In one prospective study of older persons with dizziness, after 2 years of follow-up, older persons with dizziness were more likely to become disabled than were those who were not, although mortality was no different. In another study, 197 older persons with chronic dizziness reported poor health-related quality of life, most notably in relation to limitations in the physical and emotional dimensions. Chronic dizziness is also associated with fear of falling, worsening depressive symptoms and self-rated health, and decreased participation in social activities.

## PATHOPHYSIOLOGY

Dizziness is a sensation of postural instability or imbalance. Dizziness can be difficult to diagnose, specifically in older persons, in whom it often represents dysfunction in more than one body system. Maintenance of balance and equilibrium is complex, achieved by integration of sensory information obtained from vestibular, proprioceptive, visual, and auditory systems by the cerebral cortex and cerebellum, leading to appropriate balance-maintaining responses. Abnormal function in any one or a combination of these systems may result in imbalance and the sensation of dizziness.

The vestibular system maintains spatial orientation at rest and during acceleration. Elements of the vestibular system and its connecting pathways include the semicircular canals, utricle, saccule, vestibular nerve, vestibular nuclei, vestibulospinal tracts, and vestibulocerebellar pathways. Diseases affecting this system and producing dizziness include Ménière's disease, benign paroxysmal positional vertigo (BPPV), recurrent vestibulopathy, labyrinthitis/vestibular neuronitis, acoustic neuroma, and drug toxicity (especially aminoglycosides). Age-related changes have also been reported in the sensory (hair) cells in the semicircular canals, saccule, and utricle.

The proprioceptive system consists of mechanoreceptors in the joints, peripheral nerves, and posterior columns, and multiple central nervous system (CNS) connections. Proprioception contributes to equilibrium by providing information about changes in body position, and helping mediate the body's response to position change. Common disorders include peripheral neuropathy associated with diseases such as diabetes or vitamin B-12 deficiency and cervical degenerative disorders. The few data on age-related changes in proprioception have been conflicting with one study reporting a substantial decline in joint position sense with aging, while another found no major changes.

Vision provides important information about spatial orientation, and is relied upon particularly when vestibular and/or proprioceptive

function is impaired. Common ocular diseases include cataracts, macular degeneration, and glaucoma. Age-related visual changes include decrease in each of visual acuity, dark adaptation, contrast sensitivity, and accommodation (see Chapter 43). Hearing also provides spatial clues, but to a lesser extent than vision. Impairment in hearing, common in older persons, maybe secondary to age-related changes or to disease processes (see Chapter 44).

The cerebral cortex and cerebellum, along with their synaptic networks, integrate information and supply the musculoskeletal system with information for appropriate responses. Because of multiple and complex connections, essentially any CNS disorder can lead to imbalance, which may manifest as dizziness.

## PRESENTATION

Dizziness is described using many names, including vertigo, lightheadedness, dysequilibrium, giddiness, wooziness, and spinning. The sensation of dizziness is commonly categorized as vertigo, dysequilibrium, presyncope, and other. In addition to these four types, another category, mixed dizziness, is a combination of two or more of the above types. Mixed dizziness is the most common type of dizziness reported by older persons.

### Vertigo

Vertigo refers to a sensation of spinning, in which the individual perceives movements of the environment in relation to the body (objective vertigo) or vice versa (subjective vertigo). Vertigo is often assumed to result from disorders of the vestibular system and its connecting pathways although other causes of dizziness such as cervical disorders may present as vertigo as well.

### Dysequilibrium

Dysequilibrium refers to feelings of unsteadiness or imbalance primarily involving the lower extremities or trunk rather than the head. The person often expresses the feeling that they are about to fall. Dysequilibrium results mostly from disorders of the proprioceptive system, musculoskeletal weakness, or cerebellar disease.

### Presyncope

Presyncope is a feeling of lightheadedness or impending faintness or the sensation that one is about to pass out. Presyncope usually results from hypoperfusion of the brain; cardiovascular causes (including vasovagal disorders) are common causes in older persons.

### Other and Multifactorial

Often the sensation does not fit any of the above three types. The patient may describe “whirling,” “tilting,” “floating,” and other nonspecific sensations. Furthermore, the correlation between sensations and organ systems is not as consistent among older persons as younger persons. Thus, the sensation reported does not have diagnostic specificity in older patients.

In addition, although dizziness maybe a symptom of one or more discrete diseases, multifactorial etiologies of dizziness are common in older persons. Chronic dizziness is associated with risk factors such

as angina, myocardial infarction, arthritis, diabetes, stroke, syncope, anxiety, depressive symptoms, impaired hearing, and polypharmacy. In a population-based study of community-dwelling older persons, the factors that were independently associated with dizziness included anxiety, depressive symptoms, impaired hearing, the use of five or more medications, postural hypotension, impaired balance, and a past history of myocardial infarction. Almost 70% of patients with five or more of the above risk factors reported dizziness, whereas only 10% of patients with none of these factors reported dizziness. These findings suggest that chronic dizziness, at least in a subset of older persons, maybe a geriatric syndrome that is the result of the accumulated effect of multiple coexisting risk factors and diseases.

As presented in the following section, dizziness maybe the presenting complaint of a discrete disease or the results of contributing multiple factors.

## ETIOLOGY

### Discrete Diseases Causing Dizziness

#### Vestibular Disorders

Vestibular diseases have been reported in anywhere from 4% to 71% of older persons with dizziness. The most common vestibular disorders causing chronic dizziness in older persons are Ménière’s disease, BPPV, recurrent vestibulopathy, the effects of ototoxic medications, and acoustic neuroma.

**Ménière’s Disease** Ménière’s disease, also called endolymphatic hydrops, is reported in 2% to 8% of older patients with dizziness. It is a debilitating disorder of the inner ear, consisting of a triad of recurrent episodic vertigo, tinnitus, and fluctuating sensorineural hearing loss. A sensation of fullness in the inner ear is common. Episodes of true vertigo usually last for 1 to 24 hours. The patient may complain of nausea, vomiting, and headaches during the episodes. The exact cause is unknown, but the pathology is characterized by excess endolymph within the cochlea and vestibular labyrinth. The disease is unilateral in a majority of patients; men and women are affected equally. In a 14-year follow-up study, the episodes of vertigo disappeared in 50% of patients and improved in 28%, while hearing in the affected side was absent in 48% and impaired in 21% of the patients.

**Benign Paroxysmal Positional Vertigo** BPPV has been reported to be the cause of dizziness in 4% to 34% of cases. In this condition, patients report sudden-onset, episodic vertigo, often associated with nausea and/or vomiting, precipitated by changes in the position of the head, such as rolling over in bed, getting in and out of bed, or bending forward to pick something up. It is classically accompanied by rotational nystagmus. In most cases, the etiology is unknown, although some patients have a history of head injury or viral neurolabyrinthitis. BPPV results from freely moving particulate matter within the posterior semicircular canal. These particles most likely are dislodged otoconia, which are tiny calciferous granules that make up part of the receptor mechanism in the otolithic apparatus. It is postulated that movement of these free-floating particles cause alteration in the endolymphatic pressure, resulting in episodes of vertigo

and nystagmus. In one study, researchers reported that otoconia undergo degenerative changes, which may lead to their dislodgment from the utricle. A definitive diagnosis of BPPV can be made by the Dix–Hallpike test described under “Evaluation” later in this chapter.

**Recurrent Vestibulopathy** Recurrent vestibulopathy is an idiopathic disorder characterized by recurrent episodes of vertigo without auditory or neurological symptoms or signs. The vertigo usually lasts from 5 minutes to 24 hours. It is differentiated from Ménière’s disease by the absence of auditory symptoms. Over 8.5 years of follow-up, spontaneous recovery was reported in 62% of patients. The diagnosis was changed to Ménière’s disease or benign positional vertigo in 14% and 8% of patients, respectively.

**Acoustic Neuroma** Acoustic neuroma, also known as cerebellopontine angle tumor, is a benign tumor of the eighth cranial nerve, and is reported in 1% to 3% of older persons with dizziness. Clinical features include tinnitus and progressive unilateral sensorineural hearing loss, particularly for the higher frequencies. Patients complain more often of a feeling of unsteadiness rather than of true vertigo. Patients with large tumors may also complain of occipital headache, diplopia, paresthesias in trigeminal or facial nerve distribution, and/or ataxic gait.

### Central Nervous System Disorders

The frequency of cerebrovascular disease ranges from 4% to 70% among older persons with dizziness. Patients with transient ischemic attack (TIA) or stroke involving vertebrobasilar distribution commonly present with dizziness, along with diplopia, or dysarthria, numbness, or weakness. Dizziness rarely is a presenting symptom in patients with anterior or posterior cerebral artery ischemia or with internal carotid artery disease. The patient may complain of either a rotatory or nonrotatory dizziness along with other neurologic symptoms and signs. A number of specific stroke syndromes present with dizziness, including cerebellar infarction and posterior lateral medullary artery infarction, also known as Wallenberg’s syndrome.

Other central nervous disorder causes of dizziness include Parkinson’s disease and basilar artery migraine. The latter is rare in older persons.

### Psychiatric Disorders

Anxiety, depression, obsessive-compulsive disorder, panic disorder, and other psychiatric conditions are among the most common causes of chronic dizziness in young adults. In older persons as well, psychiatric conditions are often associated with dizziness. Common psychiatric conditions causing or contributing to dizziness in older persons include depressive and anxiety disorders. Recent studies show that depressive symptoms are associated with symptoms of dizziness, while, conversely, persons who have chronic dizziness are at increased risk of depression, suggesting a reciprocal relationship between dizziness and depressive symptoms among older persons.

### Cervical Disorders

Disorders of the cervical spine as a cause of dizziness in older persons have been reported in the range of 0% to 57%. Patients with cervical dizziness usually present with vague lightheadedness or vertigo as-

sociated with turning of the head. Both vascular and proprioceptive mechanisms have been proposed to explain cervical dizziness.

Obstruction of the vertebral arteries is thought to be the most common vascular mechanism of cervical dizziness. One hypothesis suggests that in the presence of atheromatous narrowing of one vertebral artery, rotation of the head may cause sufficient obstruction of the contralateral vertebral artery to produce ischemia of the brainstem. Another hypothesis suggests that turning the head or neck results in compression of adjacent vertebral artery by a strategic osteoarthritic spur, causing a transient disruption of the blood flow.

Degenerative changes in the cervical spine may cause dizziness because of impairment of the cervical proprioceptive mechanoreceptors. These receptors provide information for postural control via the vestibulospinal tract. The patient may present with decreased range of motion and radicular pain in the neck upon movement, as well as dizziness.

### Systemic Causes

Hypothyroidism, anemia, electrolyte imbalance, hypertension, coronary artery disease, congestive heart failure, and diabetes mellitus are commonly found in patients with dizziness, although the frequency of dizziness as a symptom of each is low. Studies have found an independent association between dizziness and a history of hypertension, angina, myocardial infarction, and diabetes mellitus. Systemic disorders may contribute to instability or dizziness by affecting the sensory, central, or effector components. These systemic disorders may also cause decreased cerebral perfusion or oxygen delivery, fatigue, or confusion, each of which may subsequently lead to a sensation of instability or dizziness. Chapter 57 discusses cardiovascular disorders that can cause dizziness as well as syncope.

### Orthostatic Hypotension

Orthostatic hypotension is a primary or contributing cause in 2% to 15% of older persons with dizziness. There is a long list of causes of orthostatic hypotension (see Chapter 57). Although there is no consensus on the definition of orthostatic hypotension in older adults, commonly noted criteria include a 20 mm Hg drop in systolic blood pressure, a 10 mm Hg drop in diastolic blood pressure, or typical symptoms associated with any drop in blood pressure after standing from a supine or sitting position. Another entity reported in literature is postural dizziness, in which patients complain of dizziness on standing from a supine position but have no drop in blood pressure. In these studies, a subset of patients who have orthostatic blood pressure changes do not complain of dizziness, suggesting that orthostatic changes in blood pressure may be asymptomatic, while, conversely, all dizziness with postural changes may not be caused by a drop in blood pressure. Vestibular dysfunction is thought to account for the postural dizziness not accompanied by postural blood pressure drops.

### Postprandial Hypotension

Another important entity to consider in older persons is postprandial hypotension. Postprandial hypotension is defined as a decrease in systolic blood pressure of 20 mm Hg or more in a sitting or standing posture within 1 to 2 hours of eating a meal; dizziness often is a symptom. In a recent study, the effects of postprandial hypotension and orthostatic hypotension were found to be additive but not

synergistic, suggesting that the two entities have different pathophysiological mechanisms. Possible etiologies of postprandial hypotension are discussed in Chapter 57.

### Medications Contributing to Dizziness

Many classes of drugs can cause or contribute to dizziness. Commonly used examples include antihypertensives, antiarrhythmic agents, anticonvulsants, antidepressants, anxiolytics, antibiotics (aminoglycosides, macrolides, and vancomycin analogs), antihistamines, nonsteroidal antiinflammatory agents, and over-the-counter cold and sleep preparations. These agents cause dizziness through different mechanisms. Antihypertensive agents can cause dizziness simply by lowering blood pressure to a level at which the postural drop in pressure becomes symptomatic. Calcium channel-blockers, nitrates, and hydralazine are common offenders. Loop diuretics such as furosemide can cause dizziness by ototoxicity and/or volume depletion. Antiarrhythmics, anticonvulsants, and anxiolytics are responsible for dizziness through their effects on the CNS. Tricyclic antidepressants, antihistamines, and cold preparations cause dizziness via their anticholinergic properties. Antibiotics (e.g., aminoglycosides, macrolides, and vancomycin analogs), nonsteroidal anti-inflammatory agents, and loop diuretics cause dizziness through ototoxicity, especially in the presence of impaired renal function, which decreases their clearance. The aminoglycosides are especially hazardous because of their toxicity to both the kidney and the vestibular system.

Apart from risks conferred by specific toxicity of drugs, studies have also reported an association between dizziness and the number of medications taken, independent of the effect of comorbid diseases.

### EVALUATION

Evaluation of dizziness can be a complex and challenging task for clinicians. The differential diagnosis is broad and the literature offers no evidence-based clinical practice guidelines. Optimal care requires the identification and treatment of the condition or combination of conditions causing dizziness when possible. If treatable conditions cannot be found, then the objective becomes maximum symptomatic improvement of dizziness. Based on these objectives and on the available evidence, a stepwise approach is recommended for the evaluation of chronic dizziness, proceeding from careful history and physical examination to screening laboratory tests. A targeted battery of more elaborate and expensive tests is indicated only when routine evaluation suggests a specific disease entity and the results of these tests are likely to influence the management. For the majority of older persons in whom a routine evaluation does not suggest a single discrete cause, the clinician should try to focus on identifying various factors (Table 56-1) that might be contributing to dizziness, some of which are likely to be modifiable. When etiology is multifactorial, identifying and treating one or more contributing factors may improve, if not eliminate, the dizziness.

### History

Patients should be asked to describe the feelings of dizziness in their own words, supplemented by directed questions. Older patients often describe a vague sensation, such as “whirling,” or “giddiness,”

or a combination of sensations. Before physicians ask leading questions, patients should be encouraged to describe symptoms in their own words. In one retrospective chart review study of 310 older patients, charts documenting patients’ dizziness symptoms in their own words were more likely to have a clinical diagnosis compared to charts without such documentation. Narrowing the differential diagnosis can often occur following a careful history. Determining whether the attacks are episodic or continuous may help in identifying a specific disease. For example, patients with Ménière’s disease or BPPV will usually have episodic dizziness, the latter precipitated by specific movements, while psychogenic dizziness is usually continuous. Frequency and duration of dizziness also should be determined. Episodic dizziness lasting less than 1 minute suggests BPPV, 5 to 120 minutes suggest TIA or migraine, while episodes longer than 120 minutes suggest Ménière’s disease or recurrent vestibulopathy. One should also ask about any precipitating factors of dizziness, such as missing a meal, drinking alcohol, taking a medication, standing from a lying position, rolling over in bed, changing the position of the head or neck such as looking up or from side to side, bending forward to pick something up, micturition, or defecation. Any relationship between the onset of dizziness and meals should be sought, because postprandial hypotension is common, especially in frail older persons. The patient should also be asked about any symptoms associated with dizziness. For example, patients with Ménière’s disease often will complain of tinnitus, fullness in ear, and fluctuating hearing loss. Patients with vertebrobasilar involvement may complain of double vision, dysarthria, or sudden blackouts. Patients with cervical arthritis may also complain of associated pain in the neck on movement. The clinician should also ask about comorbid conditions such as anemia, cardiac diseases, or diabetes, which may contribute to dizziness. One should look for symptoms suggestive of depression or anxiety disorders; use of screening instruments can be helpful (see Chapter 70). Finally, all medications, including over-the-counter medications, should be reviewed as potential contributors to dizziness.

### Physical Examination

The clinician should perform a focused physical examination (see Table 56-1), keeping in mind the complex pathophysiology and broad differential diagnosis of dizziness. The examiner should look for spontaneous nystagmus on cranial nerve testing. The nystagmus is vertical in central lesions and horizontal or rotatory in peripheral lesions. The nystagmus of central lesions is not suppressed by visual fixation; in peripheral lesions, nystagmus can be suppressed by visual fixation. One should also test for near and distant vision. The ear examination should include both a hearing test (Whisper Test or audioscope) and an otoscopic examination to rule out cerumen impaction or any structural abnormalities. Blood pressure and heart rate should be assessed both in supine and standing positions to rule out orthostatic hypotension after at least 5 minutes of quiet lying. One should examine the neck for local tenderness and restrictions in the range of movement, which can result from cervical arthritis. One should also consider that the patient might voluntarily restrict the range of neck movement in order to minimize dizziness secondary to vestibular dysfunction; such patients may respond well to vestibular rehabilitation.

A neurologic examination should include cranial nerves, the motor and sensory systems, and gait and balance. In the cranial nerve

TABLE 56-1

## Possible Contributors to Chronic Dizziness

CONTRIBUTOR	HISTORY	EXAMINATION	POSSIBLE CAUSES	POTENTIAL INTERVENTIONS
Vision	Use of bifocals or trifocals	Abnormalities in near/distant acuity; contrast sensitivity; depth perception	Cataract; glaucoma; macular degeneration; perceptual difficulties with glasses	Appropriate refraction; consider avoiding bifocals or trifocals when walking; drugs for glaucoma; surgery; good lighting without glare
Hearing	Deafness in one or both ears; difficulty hearing in social situations	Abnormal findings with Rinne's test, Weber's test, Whisper Test, or audiometry	Presbycusis; otosclerosis	Hearing aid; surgery (for otosclerosis); hearing rehabilitation; listening devices
Vestibulocochlear system	True vertigo, worse in dark or with specific head positions; tinnitus; history of aminoglycosides, furosemide, aspirin use; ear surgery; ear or mastoid infections	Nystagmus (horizontal or rotary nystagmus suggests a peripheral vestibular disorder; vertical nystagmus suggests a central disorder); decreased neck range of motion; decreased hearing; abnormal Hallpike maneuver; abnormal vestibular testing	Drug toxicity; previous infections, tumor (e.g., acoustic neuroma); previous surgery; vascular (e.g., brain stem infarct); benign positional vertigo; Ménière's disease	Avoid toxic drugs and long-term vestibular suppressants; remove earwax; vestibular rehabilitation; surgery
Peripheral nerves	Worse in dark or on uneven surfaces or inclines	Decreased neck range of motion; signs of radiculopathy or myelopathy; clumsiness with fine motor tasks; mild spastic gait; increased tone	Spondylosis; degenerative or inflammatory arthritis	Treatment of underlying disease; cervical or balance exercises; appropriate assistive device; consider surgery in selected cases
Cerebral hypoperfusion	Presyncope; near fainting	Postural hypotension; signs of underlying disease	See causes for syncope in Chapter 57; cardiovascular and pulmonary diseases; anemia	Treatment of underlying disease
Postprandial hypotension	Symptoms within 1 h of eating	Hypotension after meals	Postprandial hypotension	Small meals; avoid exertion after meals; avoid hypotensive drugs near meals; have caffeine with meals
Postural hypotension	Near fainting—worse when getting up, walking, exercising; complaints consistent with predisposing diseases; maybe asymptomatic; history of predisposing drugs	Blood pressure and heart rate; signs of predisposing diseases	Drugs, volume/salt depletion; deconditioning; Parkinson's syndrome; diabetes; autonomic dysfunction	Treatment of salt and water repletion; reconditioning exercises; ankle pumps or hand clenching; slow rising; elevate head of bed; graduated stockings; lowest effective dosage of essential contributing drugs
Cardiac dysfunction	Variable, depending on specific etiology	Cardiac auscultation, ECG, echocardiography	Cardiac arrhythmias, valvular lesions, myocardial ischemia, myxoma, hypertrophic cardiomyopathy	Variable, depending on specific etiology
Brainstem	Any sensation (e.g., vertigo, near fainting, wooziness); transient neurological symptoms (e.g., slurred speech, visual change, one-sided weakness); symptoms on looking up	Findings maybe transient or fixed; ataxia	Transient ischemic attack; brainstem infarct; vertebrobasilar insufficiency	Low-dose aspirin; assistive device if ataxic
Metabolic diseases	Symptoms of underlying disease	Signs of underlying disease	Any metabolic disease, (e.g., thyroid disorders, diabetes)	Treatment of underlying disease

(continued)

TABLE 56-1

## Possible Contributors to Chronic Dizziness (Continued)

CONTRIBUTOR	HISTORY	EXAMINATION	POSSIBLE CAUSES	POTENTIAL INTERVENTIONS
<i>Medications</i>				
Past	Vestibulocochlear symptoms (see above)	See above under vestibulocochlear system	See above under vestibulocochlear system	See above under vestibulocochlear system
Current	Confusion; fatigue; weakness; dizziness often vague, maybe constant	May have postural hypotension	Specific: nitrates, beta-blockers, antidepressants, antipsychotics, anticholinergics; vestibular depressants, benzodiazepines, others General: total number and dose of all drugs	Eliminate, substitute, or reduce specific offending drugs if possible; reduce all other drugs to lowest effective dose possible; remember over-the-counter drugs
Depression, anxiety	Constant dizziness; multiple somatic complaints; poor concentration; positive results on anxiety or depression screening; vegetative complaints (sleep, appetite)	See Chapter 70	Depression, anxiety	Thorough consideration of risks and benefits of antidepressant drug; counseling

Adapted from Beers MH, Berkow R, eds. *The Merck Manual of Geriatrics*. 3rd ed. Whitehouse Station, NJ: Merck Research Laboratories; 2000:181.

examination, the examiner should look for diplopia, dysarthria, or facial paresthesia to rule out vertebrobasilar involvement. An absence of corneal reflex may suggest acoustic neuroma, especially if accompanied by unilateral hearing loss, tinnitus, and cerebellar signs. The presence of cogwheel rigidity and bradykinesia is suggestive of Parkinsonism. Although most of the abnormalities detected in the balance examination are not specific, the presence of a positive Romberg's sign with the eyes closed is suggestive of an abnormality of proprioception and/or the vestibular system. A wide-based stance, a worsening of the gait with the eyes closed, and an improvement in gait with minimal handheld assistance of the examiner, in combination, suggest a proprioceptive deficit.

In addition to the history and physical examination, clinicians can also perform certain provocative tests at the bedside or in the office, which may help in detecting abnormalities of the vestibular system.

### Provocative Tests

These tests include the Dix–Hallpike maneuver, head-thrust, post-headshake, and stepping tests. The Dix–Hallpike test establishes the diagnosis of BPPV (Figure 56-1). In this test, the patient is asked to sit on an examination table with the head rotated 45 degrees to one side. The patient is then asked to fix their vision upon the examiner's forehead. The examiner, while holding the patient's head firmly in the same position, moves the patient from a seated to a supine position with the head hanging below the edge of the table. If the ipsilateral ear is affected, then this maneuver will result in vertigo and nystagmus. If present, the direction, latency, duration of nystagmus, and duration of vertigo should be noted. The diagnostic criteria for BPPV are (1) vertigo accompanied by a rotatory nystagmus; (2) a latency of 1 to 5 seconds between the completion of the maneuver and the onset of vertigo and nystagmus; (3) paroxysmal nature of the vertigo and nystagmus (lasting for 10 to 20 seconds); and (4) fatigability, which is a decrease in the intensity of the vertigo and nystagmus with repeated testing.

The head-thrust and postheadshake tests can help in determining if the vestibuloocular reflex (VOR) is intact. The VOR helps maintain visual stability during head movement. It functions according to the information relayed by the vestibular nucleus to the sixth cranial nerve nucleus in the pons, as well as to the third and fourth cranial nerve nuclei in the midbrain through the median longitudinal fasciculus. The head-thrust test requires the patient to fix the vision on the examiner's nose, while the head is quickly turned approximately 10 degrees to the left or right. If the VOR is intact, the eyes will stay fixed to the target. But in patients with a vestibular defect, the eyes move with the head away from the target before a corrective saccade back to it. For instance, head thrusts to the left in patients with left-sided vestibular lesions will cause a slipping away of the pupils from the target followed by a corrective movement, whereas head thrusts to the right will produce a normal visual response.

Using Frenzel lenses to eliminate fixation of vision, the post-headshake test calls for the head to be rotated for approximately 10 seconds, either passively by the examiner or actively by the patient at a frequency of approximately 2 Hz in the horizontal plane, after which the examiner checks for nystagmus. If there is a unilateral peripheral vestibular lesion, a horizontal nystagmus will result; the fast phase will usually beat away from the side of the lesion. With central lesions, the nystagmus maybe vertical.

Unterberger originally introduced the stepping test, later modified by Fukuda. A positive stepping test suggests a lesion in the vestibular or vestibulospinal system. In this test, the patient stands at the center of a circle, which is divided into sections with lines intersecting at 30-degree angles. Blindfolded, the patient is asked to stretch out both arms at 90 degrees to the body and then to flex and raise high one knee and then the other, and to continue stepping in place at a normal walking speed for a total of 50 or 100 steps. The blindfolded patient marches and the examiner watches for deviation from the straight line. If there is a unilateral vestibular lesion or acoustic neuroma, a gradual rotation of the body (more than 30 degrees) toward the affected side will occur.

**FIGURE 56-1.** Dix-Hallpike test. (Furman JM, Cass SP. Benign paroxysmal positional vertigo. *N Engl J Med.* 341:1590, 1999. Copyright ©1999 Massachusetts Medical Society. All rights reserved.)

These tests are more useful in detecting unilateral than bilateral vestibular dysfunction. Upon finding any abnormalities, one can proceed with specialized vestibular function tests such as electronystagmography (ENG) and rotational chair test described under “Laboratory Tests.” Clinicians must be aware that compensatory mechanisms may mask a vestibular deficit when these tests are used in patients with longstanding vestibular loss. There are no data addressing the specificity or sensitivity of these tests in older persons.

### Laboratory Tests

There is no standardized approach for laboratory testing for patients with chronic dizziness. However, a modest baseline battery of tests should be done in all elderly persons with chronic dizziness to rule out common modifiable contributors to dizziness. Thus, a hematocrit, basic metabolic panel, thyroid function tests, and vitamin B-12 levels should be done in all patients to rule out anemia, diabetes, azotemia, hypothyroidism, and vitamin B-12 deficiency.

Further testing should be tailored to the situation. Audiometry should be done in patients with a history of fluctuating or gradual hearing loss. An audiogram will reveal sensorineural loss in both Ménière’s disease and acoustic neuroma; the hearing loss will be greater in lower frequencies in Ménière’s disease and in higher frequencies in acoustic neuroma, often unilaterally as opposed to presbycusis, which usually results in bilateral high-frequency hearing loss.

An electrocardiogram is indicated if there is a suspicion of myocardial infarction or cardiac arrhythmia. Holter or event monitoring, or tilt table testing, is indicated only in selected patients with unexplained syncope (see Chapter 57).

In patients with a suspicion of cervical osteoarthritis, radioimaging of the cervical spine can be considered, but the frequency of false-positives is great. Neuroimaging is needed when a stroke or cerebellopontine tumor is suspected. Magnetic resonance imaging (MRI) is preferred over computed tomography scans because of its greater sensitivity, particularly for lesions in the brainstem. Routine MRI is unlikely to reveal specific causes of dizziness. In one study of MRI in patients with dizziness, there were no significant differences in structural abnormalities found in the brain or neck in patients with versus without dizziness. Doppler studies or a magnetic resonance angiogram maybe needed to detect vertebrobasilar insufficiency.

Abnormalities of the peripheral vestibular system can be evaluated by performing special tests, such as ENG including caloric testing, a rotational chair test, and computerized posturography. These tests can provide data that help confirm history and physical examination data. However, abnormalities are common in older persons without dizziness, so a positive test is often nonspecific and nondiagnostic.

In ENG, movements of the eyes (nystagmus) are recorded in the form of tracings with the help of electrodes placed around the eyes. These electrodes record changes in scalp potential produced by the

corneal-retinal potential in response to visual and vestibular stimuli, which can be either spontaneous or provoked by caloric stimuli of warm and cold water in the external ear canal. In caloric testing, each ear is stimulated first with warm water (111°F [44°C]) and then with cold water (86°F [30°C]), each instilled over 30 seconds. When vestibular function is normal, the temperature change will result in nystagmus, but there will be decreased or no response in an ear on the side of peripheral vestibular disorder. The caloric test assesses the symmetry of vestibular function and is useful in detecting unilateral vestibular lesions. However, patients with bilateral vestibular loss or patients in whom caloric testing cannot be performed should undergo rotational chair testing.

A rotational chair test, in addition to quantifying the extent of lesions in patients with bilateral peripheral vestibular loss, also helps reveal the degree of peripheral or central vestibular dysfunction. In this test, the patient is seated on a chair in a dark room, and eye movements are recorded when the chair is rotated at different frequencies.

Computerized posturography evaluates the ability of the patient to maintain balance in response to individual or combinations of visual, vestibular, or proprioceptive stimuli while standing on a platform that can be perturbed in three dimensions. This test maybe helpful in providing additional confirmatory data when there is a suspicion of peripheral vestibular pathology, but ENG and rotational chair testing are equivocal. In addition, computerized posturography maybe the only positive test in the case of central vestibular and extravestibular CNS pathology. Posturography also maybe helpful in determining which patients with dizziness are likely to benefit from vestibular rehabilitation.

## MANAGEMENT

Clinicians often feel frustrated in managing patients with dizziness. As discussed in the previous section, the goal should be to identify and treat modifiable factors either causing (single condition causing) or contributing to (multiple conditions contributing) dizziness. In many patients with chronic dizziness, a single specific diagnosis maybe elusive in the presence of multiple factors contributing to dizziness. In these patients, instead of focusing on a single diagnosis-oriented approach, the examiner should try to identify and treat as many of these contributing or causative factors as possible, recognizing that some may not be modifiable. The result of such an approach usually is a decrease in the disability associated with dizziness.

Systemic disorders such as anemia, metabolic derangements, vitamin B-12 deficiency, and thyroid abnormalities should be corrected. Correction of vision and hearing deficits is very important. Anxiety and depression should be treated, recognizing the dilemma that most antidepressants also cause dizziness. Medications potentially contributing to dizziness, including over-the-counter medicines, should be identified and either withdrawn or reduced. The ideal approach should be to stop a potentially offending medication rather than adding new ones.

## Pharmacological Therapy

Drugs commonly used as vestibular suppressants include antihistamines (e.g., meclizine), anticholinergic agents (e.g., scopolamine), and benzodiazepines (e.g., diazepam). Vestibular suppressants are

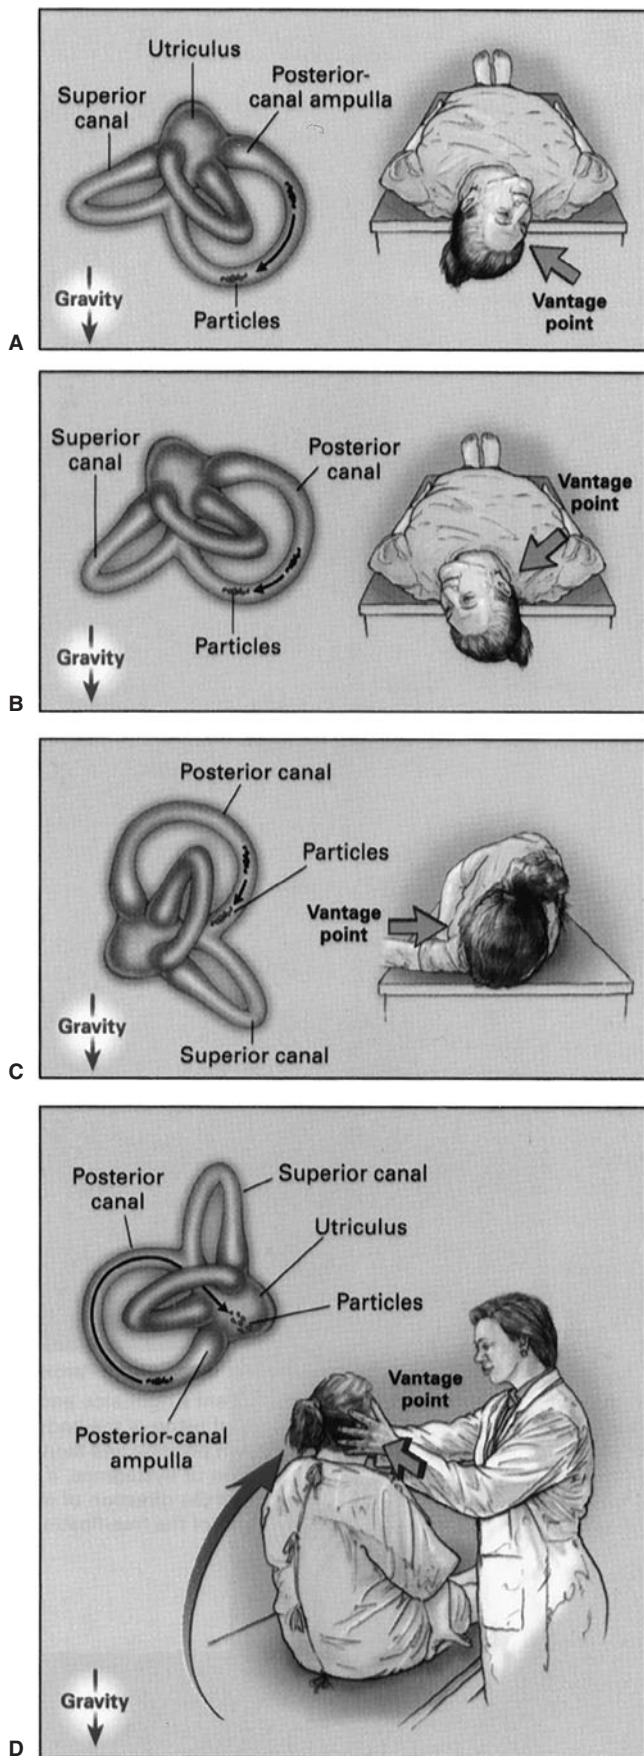

more effective when used for acute episodes of dizziness than for chronic dizziness. Many vestibular suppressants themselves may cause dizziness. Scopolamine should not be used in elderly persons because of its anticholinergic side effects. Meclizine, a weak antihistaminic agent, is usually given in doses of 12.5 to 25 mg three times daily as needed. These medications should be used only temporarily as their prolonged use may compromise central and peripheral adaptation and thus, paradoxically, prolong the dizziness. Benzodiazepines may at times, however, be indicated as a long-term vestibular suppressant in persons with severe unilateral lesions who are not surgical candidates. In one study, selective serotonin reuptake inhibitors were found to be effective in treating chronic dizziness associated with anxiety.

## Vestibular Rehabilitation

Vestibular rehabilitation plays an important role in managing patients with peripheral or central vestibular causes of dizziness by enhancing the adaptation of the vestibular system. Vestibular rehabilitation has been shown to improve symptoms, postural instability, and dizziness-related handicap in patients with chronic dizziness. Vestibular rehabilitation consists of exercises combining movements of eyes, head, and body designed to stimulate the vestibular system. At first, these exercises may worsen the dizziness, but with continued practice and gradual increase in the frequency, these exercises improve dizziness, probably through central adaptation and habituation. These exercises also may help patients alleviate anxiety and fears in performing various activities. Improvement is usually seen after 6 to 8 weeks of vestibular rehabilitation. Patients should perform these exercises initially under the supervision of a trained specialist such as a physical therapist and later independently at home.

In patients with cervical dizziness, physical therapy can substantially decrease the frequency and severity of dizziness and neck pain, and can improve postural stability. Some patients may benefit from cervical collars or cervical traction.

Patients suffering from BPPV can be treated by performing one of two bedside maneuvers, Epley's canalith repositioning procedure, or Brandt's and Daroff's exercises. Epley's canalith repositioning procedure (Figure 56-2) is performed to move free-floating particles from the posterior semicircular canal into the utricle of the labyrinth by the effects of gravity, thereby eliminating fluctuation of the endolymphatic pressure in the semicircular canals. In this five-position procedure, the patient is asked to sit on a table and a vibrator is applied to the ipsilateral mastoid process. Next, the patient is made to lie down supine on the examining table with the head rotated 45 degrees toward the affected ear and hanging below the edge of the table, similar to the Dix-Hallpike test. This position will induce vertigo. Once the vertigo subsides, the head is rotated 45 degrees to the opposite side, which may induce vertigo again. Then the head and body are rotated further in the same direction until the head is facing downward. Subsequently, while holding the head in the same position, the patient sits up. Finally, the head is turned forward with the chin down by about 20 degrees. The examiner holds the head in each of these positions for approximately 10 to 15 seconds or until the vertigo subsides. The patient should be told not to lie flat for the next 24 to 48 hours. Alternatively, a cervical collar can be used to prevent loose particles from sliding back to the posterior semicircular canals. There are no data to support these recommendations. These maneuvers can be performed without using the vibrator although

**FIGURE 56-2.** Epley's canalith repositioning procedure. [Furman JM, Cass SP. Benign paroxysmal positional vertigo. *N Engl J Med.* 341:1590, 1999. Copyright © 1999 Massachusetts Medical Society. All rights reserved.]

the results are said to be not as good. This maneuver can be repeated at weekly intervals until vertigo ceases and the Dix–Hallpike test is negative.

Brandt's and Daroff's exercises can be used in patients who cannot keep their heads upright for 24 to 48 hours as recommended in Epley's maneuver. The patient can do the exercises at home without the presence of a physician or therapist. These exercises probably work by habituation. The patient is asked to sit on the edge of the bed with eyes closed and to rotate the head horizontally by approximately 45 degrees. The patient then lies down on the side opposite to the direction of head rotation and waits for at least 30 seconds or until the vertigo has resolved. The movement is then repeated in the opposite direction. Patients can repeat these exercises every 3 hours and can stop them 2 to 3 days after becoming symptom-free. Improvement usually occurs after 1 to 2 weeks of exercises.

### Surgery

Surgery is reserved for a small group of patients who fail pharmacologic treatment or vestibular rehabilitation, or who have cerebellopontine angle tumors. Patients with uncontrolled Ménière's disease can have a transmastoid labyrinthectomy, or partial vestibular neurectomy, or endolymphatic sac decompression. Very rarely, patients with BPPV who do not respond to repeated canalith repositioning procedures may benefit from disabling of the semicircular canal either by singular neurectomy or by occluding the posterior semicircular canal.

### PATIENT EDUCATION

Patient education plays a very important role in the management of chronic dizziness. Understanding the basic pathophysiology of dizziness often alleviates associated anxiety. Education also helps patients to modify activities appropriately, thus encouraging patients to cope actively with their dizziness. While most patients need to be advised to be more active, some should be told to avoid looking up or bending down, when these motions clearly precipitate cervical dizziness attacks. Home modifications to reduce neck extension can include storing commonly used items on lower shelves. When orthostatic hypotension is present, patients should be instructed to rise slowly from a supine or sitting position. They should also flex their hands and feet a few times before standing and should never try to walk while feeling dizzy. They should avoid over-the-counter medications such as sleeping pills and cold and allergy medicine, and should ingest a sufficient amount of water.

# Syncope

*Rose Anne Kenny*

## DEFINITION

Syncope (derived from the Greek words, “syn” meaning “with” and the verb “koptein” meaning “to cut” or more appropriately in this case “to interrupt”) is a symptom defined as a transient, self-limited loss of consciousness, usually leading to falling. The onset of syncope is relatively rapid, and the subsequent recovery is spontaneous, complete, and usually prompt.

## EPIDEMIOLOGY

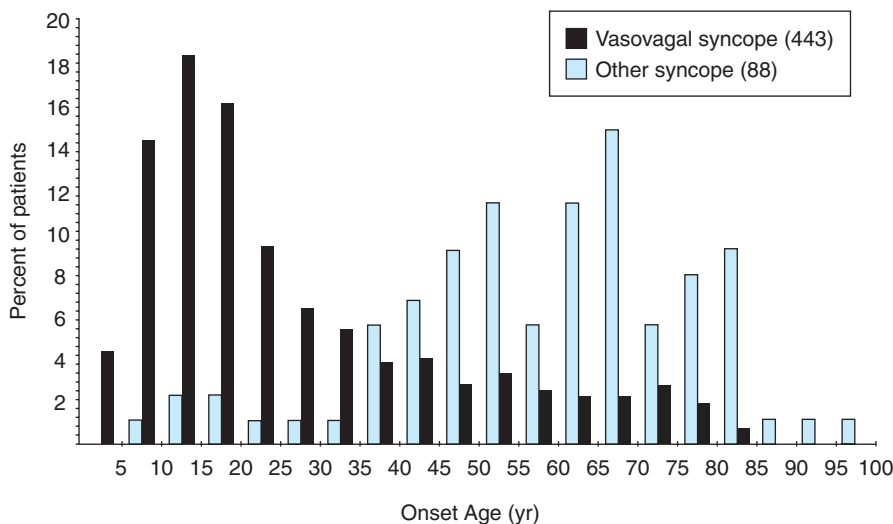

Syncope is a common symptom, experienced by up to 30% of healthy adults at least once in their lifetime. Syncope accounts for 3% of emergency department visits and 1% of medical admissions to a general hospital. Syncope is the seventh most common reason for emergency admission of patients older than 65 years. The cumulative incidence of syncope in a chronic care facility is close to 23% over a 10-year period with an annual incidence of 6% and recurrence rate of 30%, over 2 years. The age of first faint, a commonly used term for syncope, is less than 25 years in 60% of persons, but 10% to 15% of individuals have their first faint after age 65 years.

Syncope because of a cardiac cause is associated with higher mortality rates than syncope from other causes irrespective of age. In patients with a noncardiac or unknown cause of syncope, older age, a history of congestive cardiac failure, and male sex are important prognostic factors of mortality. It remains undetermined whether syncope is directly associated with mortality or is merely a marker of more severe underlying disease. [Figure 57-1](#) details the age-related difference in prevalence of benign vasovagal syncope (faint) compared to other causes of syncope.

## PATHOPHYSIOLOGY

The temporary cessation of cerebral function that causes syncope results from transient and sudden reduction of blood flow to parts of the brain (brain stem reticular activating system) responsible for consciousness. The predisposition to vasovagal syncope starts early and lasts for decades. Other causes of syncope are uncommon in young adults, but much more common as people age.

Regardless of the etiology, the underlying mechanism responsible for syncope is a drop in cerebral oxygen delivery below the threshold for consciousness. Cerebral oxygen delivery, in turn, depends on both cerebral blood flow and oxygen content. Any combination of chronic or acute processes that lowers cerebral oxygen delivery below the “consciousness” threshold may cause syncope. Age-related physiological impairments in heart rate, blood pressure, cerebral blood flow, and blood volume control, in combination with comorbid conditions and concurrent medications account for the increased incidence of syncope in the older person. The blunted baroreflex sensitivity with aging is manifested as a reduction in the heart rate response to hypotensive stimuli. Older adults are prone to reduced blood volume owing to excessive salt wasting by the kidneys as a result of a decline in plasma renin and aldosterone, a rise in atrial natriuretic peptide, and concurrent diuretic therapy. Low blood volume together with age-related diastolic dysfunction can lead to a low cardiac output, which increases susceptibility to orthostatic hypotension and vasovagal syncope. Cerebral autoregulation, which maintains a constant cerebral circulation over a wide range of blood pressure changes, is altered in the presence of hypertension and possibly by aging; the latter is still controversial. In general, it is agreed that sudden mild to moderate declines in blood pressure can affect cerebral blood flow markedly and render an older person particularly vulnerable to presyncope and syncope. Syncope may thus result either from a single process that markedly and abruptly decreases

**FIGURE 57-1.** Comparison of ages of first syncope in 443 patients with vasovagal syncope and 88 patients with syncope of other known causes.

cerebral oxygen delivery or from the accumulated effect of multiple processes, each of which contributes to the reduced oxygen delivery.

### Multifactorial Etiology

Up to 40% of patients with recurrent syncope will remain undiagnosed despite extensive investigations, particularly older patients who have marginal cognitive impairment and for whom a witnessed account of events is often unavailable. Although diagnostic investigations are available, the high frequency of unidentified causes in clinical studies may occur because patients failed to recall important diagnostic details, because of the stringent diagnostic criteria used in clinical studies or, probably most often, because the syncopal episode resulted from a combination of chronic and acute factors rather than from a single obvious disease process. Indeed, a multifactorial etiology likely explains the majority of cases of syncope in older persons who are predisposed because of multiple chronic diseases and medication effects superimposed on the age-related physiologic changes described above. Common factors that, in combination, may predispose to or precipitate syncope include anemia, chronic lung disease, congestive heart failure, and dehydration. Medications that may contribute to, or cause, syncope are listed in [Table 57-1](#).

### Individual Causes of Syncope

Common causes of syncope are listed in [Table 57-2](#). The most frequent individual causes of syncope in older patients are neurally mediated syndromes including carotid sinus syndrome, orthostatic hypotension, and postprandial hypotension as well as arrhythmias including both tachyarrhythmias and bradyarrhythmias. These disease processes are described in the next section. Disorders that may be confused with syncope and that may, or may not, be associated with loss of consciousness are listed in [Table 57-3](#).

## PRESENTATION

The underlying mechanism of syncope is transient cerebral hypoperfusion. In some forms of syncope, there may be a premonitory period in which various symptoms (e.g., light-headedness, nausea,

**TABLE 57-1**

### Drugs That Can Cause or Contribute to Syncope

DRUG	MECHANISM
Diuretics	Volume depletion
Vasodilators	Reduction in systemic vascular resistance and venodilation
Angiotensin-converting enzyme inhibitors	
Calcium channel-blockers	
Hydralazine	
Nitrates	
Alpha adrenergic blockers	
Prazosin	
Other antihypertensive drugs	Centrally acting antihypertensives
Alpha methyl dopa	
Clonidine	
Guanethidine	
Hexamethonium	
Labetalol	
Mecamylamine	
Phenoxybenzamine	
Drugs associated with torsades de pointes	Ventricular tachycardia associated with a prolonged QT interval
Amiodarone	
Disopyramide	
Encainide	
Flecainide	
Quinidine	
Procainamide	
Sotalol	
Digoxin	Cardiac arrhythmias
Psychoactive drugs	Central nervous effects causing hypotension; cardiac arrhythmias
Tricyclic antidepressants	
Phenothiazines	
Monoamine oxidase inhibitors	
Barbiturates	
Alcohol	Central nervous system effects causing hypotension; cardiac arrhythmias

**TABLE 57-2****Causes of Syncope**

## Reflex Syncope Syndromes

- Vasovagal faint (common faint)
- Carotid sinus syncope
- Situational faint
  - acute hemorrhage
  - cough, sneeze
  - gastrointestinal stimulation (swallow, defecation, visceral pain)
  - micturition (postmicturition)
  - postexercise
  - pain, anxiety
- Glossopharyngeal and trigeminal neuralgia

## Orthostatic

- Aging
- Antihypertensives
- Autonomic failure
  - Primary autonomic failure syndromes (e.g., pure autonomic failure, multiple system atrophy, Parkinson's disease with autonomic failure)
  - Secondary autonomic failure syndromes (e.g., diabetic neuropathy, amyloid neuropathy)
- Medications (Table 57-1)
- Volume depletion
  - Hemorrhage, diarrhea, Addison disease, diuretics, febrile illness, hot weather

## Cardiac Arrhythmias

- Sinus node dysfunction (including bradycardia/tachycardia syndrome)
- Atrioventricular conduction system disease
- Paroxysmal supraventricular and ventricular tachycardias
- Implanted device (pacemaker, ICD) malfunction drug-induced proarrhythmias

## Structural Cardiac or Cardiopulmonary Disease

- Cardiac valvular disease
- Acute myocardial infarction/ischemia
- Obstructive cardiomyopathy
- Atrial myxoma
- Acute aortic dissection
- Pericardial disease/tamponade
- Pulmonary embolus/pulmonary hypertension

## Cerebrovascular

- Vascular steal syndromes

## Multifactorial

sweating, weakness, and visual disturbances) offer warning of an impending syncopal event. Often, however, loss of consciousness occurs without warning. Recovery from syncope is usually accompanied by almost immediate restoration of appropriate behavior and orientation. Amnesia for loss of consciousness occurs in many older

**TABLE 57-3****Disorders Commonly Misdiagnosed as Syncope**

Hypoglycemia and other metabolic disorders

Some forms of epilepsy

Alcohol and other intoxications

Hyperventilation with hypocapnia

individuals and in those with cognitive impairment. The postrecovery period may be associated with fatigue of varying duration.

Syncope and falls are often considered two separate entities with different etiologies. Recent evidence suggests, however, that these conditions may not always distinctly be separate. In older adults, determining whether patients who have fallen have had a syncopal event can be difficult. Half of syncopal episodes are unwitnessed and older patients may have amnesia for loss of consciousness. Amnesia for loss of consciousness has been observed in half of patients with carotid sinus syndrome who present with falls and a quarter of all patients with carotid sinus syndrome irrespective of presentation. More recent reports confirm a high incidence of falls in addition to traditional syncopal symptoms in older patients with sick sinus syndrome and atrioventricular conduction disorders. Thus, syncope and falls may be indistinguishable and may, in some cases, be manifestations of similar pathophysiologic processes. The presentation of specific causes of syncope is presented in the following sections.

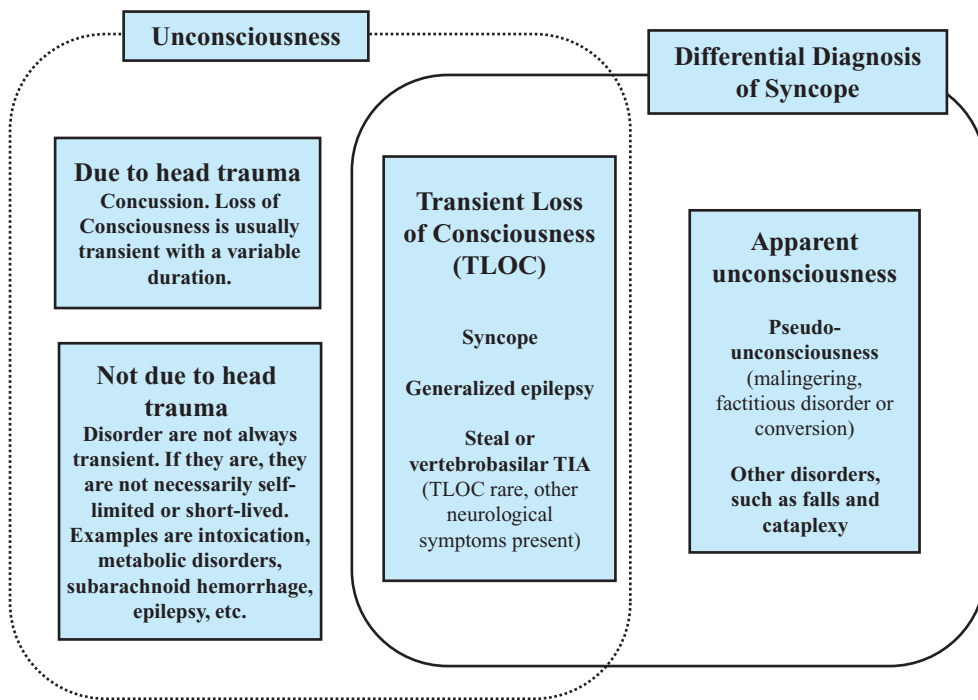

**EVALUATION**

The initial step in the evaluation of syncope is considering whether there is a specific cardiac or neurologic etiology or whether the etiology is likely multifactorial. The starting point for the evaluation of syncope is a careful history and physical examination. A witness account of events is important to ascertain when possible. Three key questions should be addressed during the initial evaluation: (1) Is loss of consciousness attributable to syncope? (2) Is heart disease present or absent? (3) Are there important clinical features in the history and physical examination, which suggest the etiology?

Differentiating true syncope from other 'nonsyncopal' conditions associated with real or apparent loss of consciousness is generally the first diagnostic challenge and influences the subsequent diagnostic strategy (Table 57-3). A strategy for differentiating true and non-syncope is outlined in Figures 57-2 and 57-3. The presence of heart disease is an independent predictor of a cardiac cause of syncope, with a sensitivity of 95% and a specificity of 45%.

Patients frequently complain of dizziness alone or as a prodrome to syncope and unexplained falls. Four categories of dizzy symptoms—vertigo, dysequilibrium, light-headedness, and others—have been recognized (see Chapter 56). The categories have neither the sensitivity nor specificity in older, as in younger, patients. Dizziness, however, may more likely be attributable to a cardiovascular diagnosis if associated with pallor, syncope, prolonged standing, palpitations, or the need to lie down or sit down when symptoms occur.

Initial evaluation may lead to a diagnosis based on symptoms, signs, or ECG findings. Under such circumstances, no further evaluation is needed and treatment, if any, can be planned. More commonly, the initial evaluation leads to a suspected diagnosis (Figure 57-3), which needs to be confirmed by directed testing. If a diagnosis is confirmed by specific testing, treatment may be initiated. On the other hand, if the diagnosis is not confirmed, then patients are considered to have unexplained syncope and should be evaluated following a strategy such as that outlined in Figure 57-2. It is important to attribute a diagnosis, if possible, rather than assume that an abnormality known to produce syncope or hypotensive symptoms is the cause. In order to attribute a diagnosis, patients should have symptom reproduction during investigation and preferably

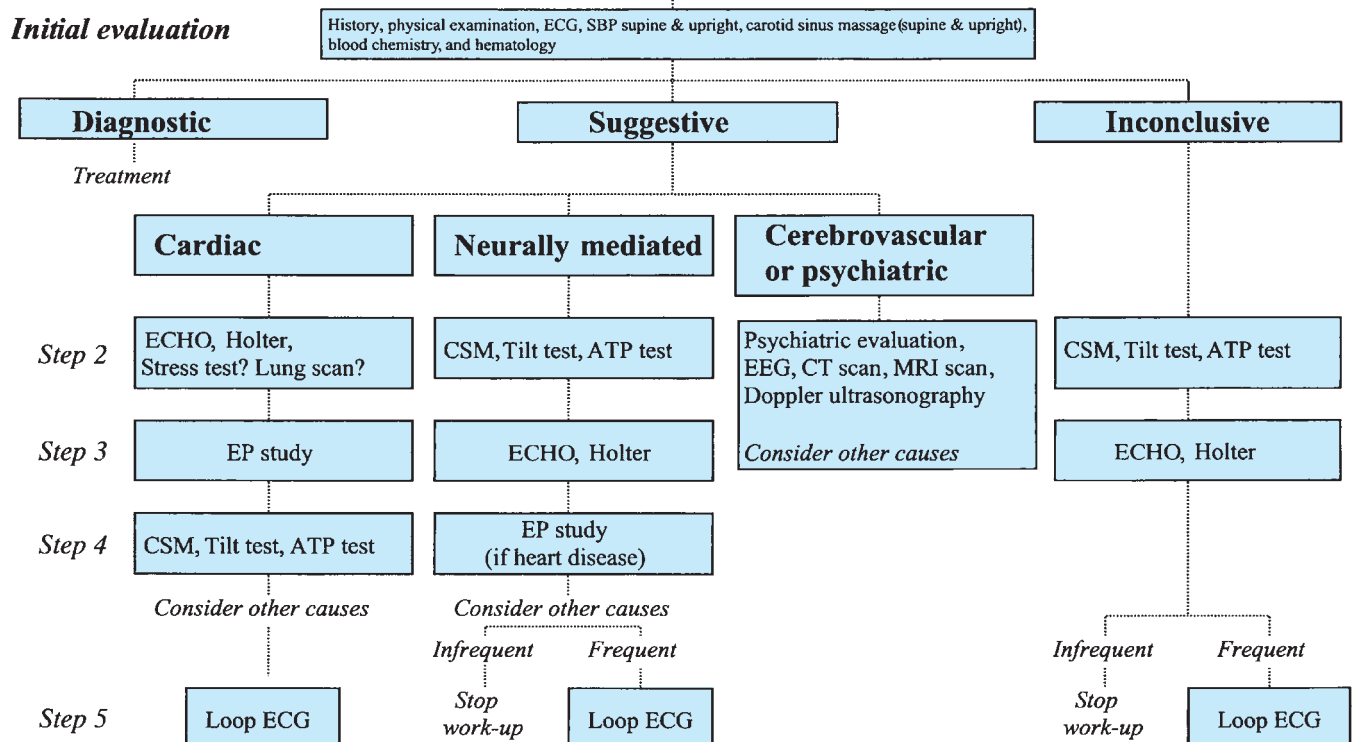

**FIGURE 57-2.** Syncope in relation to real and apparent loss of consciousness.

alleviation of symptoms with specific intervention. It is common for more than one predisposing disorder to coexist in older patients, rendering a precise diagnosis difficult. In older persons, treatment of possible causes without clear verification of attributable diagnosis may often be the only option.

An important issue in patients with unexplained syncope is the presence of structural heart disease or an abnormal ECG. These findings are associated with a higher risk of arrhythmias and a higher mortality at 1 year. In these patients, cardiac evaluation consisting of echocardiography, stress testing, and tests for arrhythmia detection

## Syncope

**FIGURE 57-3.** An approach to the evaluation of syncope for all age groups. ATP test, adenosine provocation test; CSM, carotid sinus massage; ECHO, echocardiogram; EEG, electroencephalogram; EP study, electrophysiologic study; ECG, electrocardiogram.

such as prolonged electrocardiographic and loop monitoring or electrophysiological study is recommended. The most alarming ECG sign in a patient with syncope is probably alternating complete left and right bundle branch block, or alternating right bundle branch block with left anterior or posterior fascicular block, suggesting trifascicular conduction system disease and intermittent or impending high-degree AV block. Patients with bifascicular block (right bundle branch block plus left anterior or left posterior fascicular block, or left bundle branch block) are at high risk of developing high-degree AV block. A significant problem in the evaluation of syncope and bifascicular block is the transient nature of high-degree AV block and, therefore, the long periods required to document it by ECG.

In patients without structural heart disease and a normal ECG, evaluation for neurally mediated syncope should be considered. The tests for neurally mediated syncope consist of tilt testing and carotid sinus massage.

The majority of older patients with syncope are likely to have a multifactorial etiology and thus both predisposing and precipitating causes should be sought in the history, examination, and laboratory evaluation (Tables 57-1 and 57-2), particularly if the initial evaluation does not suggest an obvious single cause.

The evaluation and management of cardiac arrhythmic causes of syncope such as supraventricular and ventricular tachycardia, atrioventricular conduction disorders, and bradyarrhythmias are addressed in Chapter 79. The presentation, evaluation, and management of other common etiologies of syncope are presented in the following sections. These etiologies may occur as the sole cause of a syncopal episode or as one of multiple contributing causes.

## ORTHOSTATIC HYPOTENSION

### Pathophysiology

Orthostatic or postural hypotension is arbitrarily defined as either a 20 mm Hg fall in systolic blood pressure or a 10 mm Hg fall in diastolic blood pressure on assuming an upright posture from a supine position. Orthostatic hypotension implies abnormal blood pressure homeostasis and is a frequent observation with advancing age. Prevalence of postural hypotension varies between 4% and 33% among community living older persons depending on the methodology used. Higher prevalence and larger falls in systolic blood pressure have been reported with increasing age and often signify general physical frailty. Orthostatic hypotension is an important cause of syncope, accounting for 14% of all diagnosed cases in a large series. In a tertiary referral clinic dealing with unexplained syncope, dizziness, and falls, 32% of patients older than 65 years had orthostatic hypotension as a possible attributable cause of symptoms.

### Aging

The heart rate and blood pressure responses to orthostasis occur in three phases: (1) an initial heart rate and blood pressure response, (2) an early phase of stabilization, and (3) a phase of prolonged standing. All three phases are influenced by aging. The maximum rise in heart rate and the ratio between the maximum and the minimum heart rate in the initial phase decline with age, implying a relatively fixed heart rate irrespective of posture. Despite a blunted

heart rate response, blood pressure and cardiac output are adequately maintained on standing in active, healthy, well hydrated, and normotensive older persons because of decreased vasodilatation and reduced venous pooling during the initial phases and increased peripheral vascular resistance after prolonged standing. However, in older persons with hypertension and cardiovascular disease receiving vasoactive drugs, these circulatory adjustments to orthostatic stress are disturbed, rendering them vulnerable to postural hypotension.

### Hypertension

Hypertension further increases the risk of hypotension by impairing baroreflex sensitivity and reducing ventricular compliance. A strong relationship between supine hypertension and orthostatic hypotension has been reported among unmedicated institutionalized older persons. Hypertension increases the risk of cerebral ischemia from sudden declines in blood pressure. Older persons with hypertension are more vulnerable to cerebral ischemic symptoms even with modest- and short-term postural hypotension, because the threshold for cerebral autoregulation is altered by prolonged elevation of blood pressure. In addition, antihypertensive agents impair cardiovascular reflexes and further increase the risk of orthostatic hypotension.

### Medications

Drugs (Table 57-1) are important causes of orthostatic hypotension. Ideally, establishing a causal relationship between a drug and orthostatic hypotension requires identification of the culprit medicine, abolition of symptoms by withdrawal of the drug, and rechallenge with the drug to reproduce symptoms. Rechallenge is often omitted in clinical practice in view of the potential serious consequences. In the presence of polypharmacy, which is common in the older person, it becomes difficult to identify a single culprit drug because of the synergistic effect of different drugs and drug interactions. Thus, all drugs should be considered as possible contributors to orthostasis.

### Other Conditions

A number of nonneurogenic conditions are also associated with postural hypotension. These conditions include myocarditis, atrial myxoma, aortic stenosis, constrictive pericarditis, hemorrhage, diarrhea, vomiting, ileostomy, burns, hemodialysis, salt losing nephropathy, diabetes insipidus, adrenal insufficiency, fever, and extensive varicose veins. Volume depletion for any reason is a common sole, or contributing, cause of postural hypotension, and, in turn, syncope.

### Primary Autonomic Failure Syndromes (see also Chapters 66 and 67)

Three distinct clinical entities, namely, pure autonomic failure, multiple system atrophy or Shy-Drager syndrome, and autonomic failure associated with idiopathic Parkinson's disease are associated with orthostatic hypotension. Pure autonomic failure, the least common condition and a relatively benign entity, was previously known as idiopathic orthostatic hypotension. This condition presents with orthostatic hypotension, defective sweating, impotence, and bowel disturbances. No other neurological deficits are found and resting plasma noradrenaline levels are low. Multiple system atrophy is the most common and has the poorest prognosis. Clinical manifestations

include features of dysautonomia and motor disturbances because of striatonigral degeneration, cerebellar atrophy, or pyramidal lesions. Additional neurological deficits include muscle atrophy, distal sensorimotor neuropathy, pupillary abnormalities, restriction of ocular movements, disturbances in rhythm and control of breathing, life threatening laryngeal stridor, and bladder disturbances. Psychiatric manifestations and cognitive defects are usually absent. Resting plasma noradrenaline levels are usually within the normal range, but fail to rise on standing or tilting.

The prevalence of orthostatic hypotension in Parkinson disease rises with advancing years and with the number of medications prescribed. Cognitive impairment, in particular abnormal attention and executive function, is more common in Parkinson disease with orthostatic hypotension suggesting a possible causal association with hypotension including watershed lesions. Orthostatic hypotension in Parkinson disease can also be owing to autonomic failure and/or to side effects of anti-Parkinsonian medications.

### Secondary Autonomic Dysfunction

Autonomic nervous system involvement is seen in several systemic diseases. A large number of neurological disorders are also complicated by autonomic dysfunction, which may involve several organs leading to a variety of symptoms in addition to orthostatic hypotension including anhidrosis, constipation, diarrhea, impotence, retention of urine, urinary incontinence, stridor, apneic episodes, and Horner syndrome. Among the most serious and prevalent conditions associated with orthostasis caused by autonomic dysfunction are diabetes, multiple sclerosis, brain stem lesions, compressive and noncompressive spinal cord lesions, demyelinating polyneuropathies (Guillain–Barre syndrome), chronic renal failure, chronic liver disease, and connective tissue disorders.

### Presentation

The clinical manifestations of orthostatic hypotension are owing to hypoperfusion of the brain and other organs. Depending on the degree of fall in blood pressure and cerebral hypoperfusion, symptoms can vary from dizziness to syncope associated with a variety of visual defects, from blurred vision to blackout. Other reported ischemic symptoms of orthostatic hypotension are nonspecific lethargy and weakness, suboccipital and paravertebral muscle pain, low back ache, calf claudication, and angina. Several precipitating factors for orthostatic hypotension have been identified including speed of positional change, prolonged recumbency, warm environment, raised intrathoracic pressure (coughing, defecation, micturition), physical exertion, and vasoactive drugs.

### Evaluation

The diagnosis of orthostatic hypotension involves a demonstration of a postural fall in blood pressure after active standing. Reproducibility of orthostatic hypotension depends on the time of measurement and on autonomic function. The diagnosis may be missed on casual measurement during the afternoon. The procedure should be repeated during the morning after maintaining supine posture for at least 10 minutes. Sphygmomanometer measurement will detect hypotension, which is sustained. Phasic blood pressure measurements are more sensitive for detection of transient falls in blood pressure.

Active standing is more appropriate than head-up tilt because the former more readily represents the physiological alpha adrenergic vasodilation because of calf muscle activation. Once a diagnosis of postural hypotension is made, the evaluation involves identifying the cause or causes of orthostasis mentioned above.

### Management

The goal of therapy for symptomatic orthostatic hypotension is to improve cerebral perfusion (Table 57-4). There are several nonpharmacological interventions, which should be tried in the first instance. These interventions include avoidance of precipitating factors for low blood pressure, elevation of the head of the bed at night by at least 20 degrees and application of graduated pressure from an abdominal support garment or from stockings. Medications known to contribute to postural hypotension should be eliminated or reduced. There are reports to suggest benefit from implantation of cardiac pacemakers, in a small number of patients, by increasing heart rate during postural change. However, the benefits of tachypacing on cardiac output in patients with maximal vasodilatation are short lived, probably because venous pooling and vasodilation dominate. A large number of drugs have been used to raise blood pressure in orthostatic hypotension, including fludrocortisone, midodrine, ephedrine, desmopressin, octreotide, erythropoietin, and nonsteroidal anti-inflammatory agents. Fludrocortisone (9-alpha fluhydrocortisone) in a dose of 0.1 to 0.2 mg, causes volume expansion, reduces natriuresis, and sensitizes alpha adrenoreceptors to noradrenaline. In older people, the drug can be poorly tolerated in high doses and for long periods. Adverse effects include

**TABLE 57-4**

#### Management of Orthostatic Hypotension in Older Persons

Identify and treat correctable causes
Reduce or eliminate drugs causing orthostatic hypotension (see Table 57-1)
Avoid situations that may exacerbate orthostatic hypotension
Standing motionless
Prolonged recumbency
Large meals
Hot weather
Hot showers
Straining at stool or with voiding
Isometric exercise
Ingesting alcohol
Hyperventilation
Dehydration
Raise the head of the bed to a 5- to 20-degree angle
Wear waist-high custom-fitted elastic stockings and an abdominal binder
Participate in physical conditioning exercises
Controlled postural exercises using the tilt table
Avoid diuretics and eat salt-containing fluids (unless congestive heart failure is present)
Drug therapy
Caffeine
Fludrocortisone
Midodrine
Desmopressin
Erythropoietin

hypertension, cardiac failure, depression, edema, and hypokalemia. Midodrine is a directly acting sympathomimetic vasoconstrictor of resistance vessels. Treatment is started at a dose of 2.5 mg three times daily and requires gradual titration to a maximum dose of 45 mg/day. Adverse effects include hypertension, pilomotor erection, gastrointestinal symptoms, and central nervous system toxicity. Side effects are usually controlled by dose reduction. Midodrine can be used in combination with low-dose fludrocortisone with good effect. Desmopressin has potent antidiuretic and mild pressor effects. Intranasal doses of 5 to 40  $\mu\text{g}$  at bedtime are useful. The main side effect is water retention. This agent can also be combined with fludrocortisone with synergistic effect. The drug treatment for orthostatic hypotension in older persons requires frequent monitoring for supine hypertension, electrolyte imbalance, and congestive heart failure. One option for treating supine hypertension, which is most prominent at night, is to apply a nitroglycerine patch after going to bed, remove it in the morning and take midodrine  $\pm$  fludrocortisone 20 minutes before rising. This is effective provided that the older person remains in bed throughout the night. Nocturia is therefore an important consideration. In order to capture these coexistent diurnal BP variations of supine hypertension and morning orthostasis, 24 hour ambulatory BP monitoring is the preferred investigation for the management of postural hypotension. Postprandial hypotension caused by splanchnic vascular pooling often coexists with orthostatic hypotension in older patients.

## CAROTID SINUS SYNDROME AND CAROTID SINUS HYPERSENSITIVITY

### Pathophysiology

Carotid sinus syndrome is an important, but frequently overlooked cause of syncope and presyncope in older persons. Episodic bradycardia and/or hypotension resulting from exaggerated baroreceptor mediated reflexes or carotid sinus hypersensitivity characterize the syndrome. The syndrome is diagnosed in persons with otherwise unexplained recurrent syncope who have carotid sinus hypersensitivity. The latter is considered present if carotid sinus massage produces asystole exceeding 3 seconds (cardioinhibitory), or a fall in systolic blood pressure exceeding 50 mm Hg in the absence of cardioinhibition (vasodepressor), or a combination of the two (mixed).

### Epidemiology

Up to 30% of the aged healthy population have carotid sinus hypersensitivity. The prevalence is higher in the presence of coronary artery disease or hypertension. Abnormal responses to carotid sinus massage are more likely to be observed in individuals with coronary artery disease and in those on vasoactive drugs known to influence carotid sinus reflex sensitivity such as digoxin, beta-blockers, and alpha methyl dopa. Other hypotensive disorders such as vasovagal syncope and orthostatic hypotension coexist in one-third of patients with carotid sinus hypersensitivity. In centers that routinely perform carotid sinus massage in all older patients with syncope, carotid sinus syndrome is the attributable cause of syncope in 30%. This frequency needs to be interpreted within the context that these centers evaluate a preselected group of patients who have a higher likelihood of

carotid sinus syndrome than the general population of older persons with syncope. The prevalence in all older persons with syncope is unknown.

Carotid sinus syndrome is virtually unknown before the age of 50 years; its incidence increases with age thereafter. Males are more commonly affected than females, and the majority have either coronary artery disease or hypertension. Carotid sinus syndrome is associated with appreciable morbidity. Approximately half of patients sustain an injury, including a fracture, during symptomatic episodes. In a prospective study of falls in nursing home residents, a threefold increase in the fracture rate in those with carotid sinus hypersensitivity was observed. Indeed, carotid sinus hypersensitivity can be considered as a modifiable risk factor for fractures of the femoral neck. Carotid sinus syndrome is not associated with an increased risk of death. The mortality rate in patients with the syndrome is similar to that of patients with unexplained syncope and the general population matched for age and sex. Mortality rates are similar for the three subtypes of the syndrome.

The natural history of carotid sinus hypersensitivity has not been well investigated. In one study, the majority (90%) of persons with abnormal hemodynamic responses, but without syncopal symptoms, remained symptom free during a follow-up over  $19 \pm 16$  months while half of those who presented with syncope had symptom recurrence. More recent neuropathological research suggests that carotid sinus hypersensitivity is associated with neurodegenerative pathology at the cardiovascular center in the brain stem. Why some persons with carotid sinus hypersensitivity develop syncope as a consequence and others remain asymptomatic is not clear.

### Presentation

The syncopal symptoms are usually precipitated by mechanical stimulation of the carotid sinus such as head turning, tight neckwear, neck pathology, and by vagal stimuli such as prolonged standing. Other recognized triggers for symptoms are the postprandial state, straining, looking or stretching upward, exertion, defecation, and micturition. In a significant number of patients no triggering event can be identified. Abnormal response to carotid sinus massage (see below) may not always be reproducible, necessitating repetition of the procedure if the diagnosis is strongly suspected.

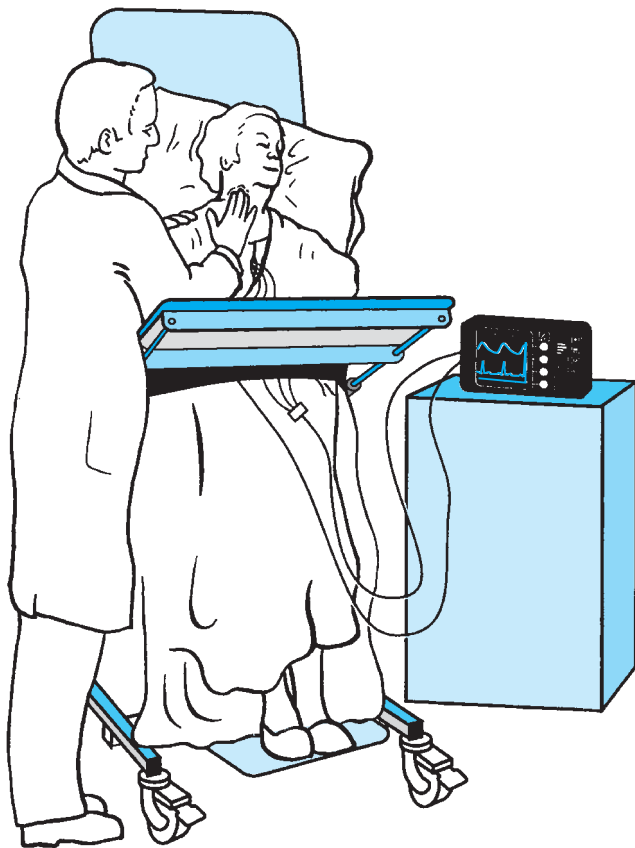

### Evaluation

#### Carotid Sinus Massage

Carotid sinus reflex sensitivity is assessed by measuring heart rate and blood pressure responses to carotid sinus massage (Figure 57-4). Cardioinhibition and vasodepression are more common on the right side. In patients with cardioinhibitory carotid sinus syndrome, more than 70% have a positive response to right-sided carotid sinus massage either alone or in combination with left-sided carotid sinus massage. There is no fixed relationship between the degree of heart rate slowing and the degree of fall in blood pressure.

Carotid sinus massage is a crude and unquantifiable technique and is prone to intra- as well as interobserver variation. More scientific diagnostic methods using neck chamber suction or drug-induced changes in blood pressure can be used for carotid baroreceptor activation, but are not validated for routine clinical use. The recommended duration of carotid sinus massage is from 5 to

**FIGURE 57-4.** Procedure for carotid sinus massage while upright.

10 seconds. The maximum fall in heart rate usually occurs within 5 seconds of the onset of massage (Figure 57-4).

Complications resulting from carotid sinus massage include cardiac arrhythmias and neurological sequelae. Fatal arrhythmias are extremely uncommon and have generally only occurred in patients with underlying heart disease undergoing therapeutic rather than diagnostic massage. Digoxin toxicity has been implicated in most cases of ventricular fibrillation. Neurological complications result from either occlusion of, or embolization from, the carotid artery. Several authors have reported cases of hemiplegia following carotid sinus stimulation, often in the absence of hemodynamic changes. Complications from carotid sinus massage, however, are uncommon. In a prospective series of 1000 consecutive cases, no patient had cardiac complications and 1% had transient neurological symptoms that resolved. Persistent neurological complications were uncommon, occurring in 0.04%. Carotid sinus massage should not be performed in patients who have had a recent cerebrovascular event or myocardial infarction.

Symptom reproduction during carotid sinus massage is preferable for a diagnosis of carotid sinus syndrome. Symptoms reproduction may not be possible for older patients with amnesia for loss of consciousness. Spontaneous symptoms usually occur in the upright position. It may thus be worth repeating the procedure, with the patient upright on a tilt table, even after demonstrating a positive response when supine. This reproduction of symptoms aids in attributing the episodes to carotid sinus hypersensitivity especially in patients with unexplained falls who deny loss of consciousness. In one-third of patients, a diagnostic response is only achieved during upright carotid sinus massage.

## Management

No treatment is necessary in persons with asymptomatic carotid sinus hypersensitivity. There is no consensus, however, on the timing of therapeutic intervention in the presence of symptoms. Considering the high rate of injury in symptomatic episodes in older persons as well as the low recurrence rate of symptoms, it is prudent to treat all patients with a history of two or more symptomatic episodes. The need for intervention in those individuals with a solitary event should be assessed on an individual basis, taking into consideration the severity of the event and the patient's comorbidity.

Treatment strategies in the past included carotid sinus denervation achieved either surgically or by radioablation. Both procedures have largely been abandoned. Dual chamber cardiac pacing is the treatment of choice in patients with symptomatic cardioinhibitory carotid sinus syndrome. Atrial pacing is contraindicated in view of the high prevalence of both sinoatrial and atrioventricular block in patients with carotid sinus hypersensitivity. Ventricular pacing abolishes cardioinhibition, but fails to alleviate symptoms in a significant number of patients because of aggravation of a coexisting vasodepressor response or the development of pacemaker-induced hypotension, referred to as pacemaker syndrome. The latter occurs when ventriculoatrial conduction is intact as is the case for up to 80% of patients with the syndrome. Atrioventricular sequential pacing (dual chamber) is thus the treatment of choice and because this maintains atrioventricular synchrony, there is no risk of pacemaker syndrome. With appropriate pacing, syncope is abolished in 85% to 90% of patients with cardioinhibition.

In a recent report of cardiac pacing in older fallers (mean age of 74 years), who had cardioinhibitory carotid sinus hypersensitivity, falls during 1 year of follow-up were reduced by two-thirds in patients who received dual chamber systems. Syncopal episodes were reduced by half. More than half of the patients in the aforementioned series had gait abnormalities and three-quarters had balance abnormalities, which would render individuals more susceptible to falls under hemodynamic circumstances, thus further suggesting the multifactorial nature of many falls and syncopal episodes.

Treatment of vasodepressor carotid sinus syndrome is less successful owing to poor understanding of its pathophysiology. Ephedrine has been reported to be useful, but long-term use is limited by side effects. Dihydroergotamine is effective but poorly tolerated. Fludrocortisone, a mineralocorticoid widely used in the treatment of orthostatic hypotension, is used in the treatment of vasodepressor carotid sinus syndrome with good results, but its use is limited in the longer term by adverse effects. A recent, small, randomized, controlled trial suggests good benefit with midodrine (an alpha agonist).

## VASOVAGAL SYNCOPE

### Pathophysiology

The normal physiologic responses to orthostasis, as described earlier, are an increase in heart rate, rise in peripheral vascular resistance (increase in diastolic blood pressure), and minimal decline in systolic blood pressure, to maintain an adequate cardiac output. In patients with vasovagal syncope, these responses to prolonged orthostasis are paradoxical. The precise sequence of events leading to vasovagal

syncope is not fully understood. The possible mechanism involves a sudden fall in venous return to the heart, rapid fall in ventricular volume, and virtual collapse of the ventricle because of vigorous ventricular contraction. The net result of these events is stimulation of ventricular mechano-receptors and activation of Bezold–Jarisch reflex leading to peripheral vasodilatation (hypotension) and bradycardia. Several neurotransmitters, including serotonin, endorphins, and arginine vasopressin, play an important role in the pathogenesis of vasovagal syncope possibly by central sympathetic inhibition, although their exact role is not yet well understood.

Healthy older persons are not as prone to vasovagal syncope as younger adults. Owing to an age-related decline in baroreceptor sensitivity, the paradoxical responses to orthostasis (as in vasovagal syncope) are possibly less marked in older persons. However, hypertension, atherosclerotic cerebrovascular disease, cardiovascular medications, and impaired baroreflex sensitivity can cause dysautonomic responses during prolonged orthostasis (in which blood pressure and heart decline steadily over time) and render older persons susceptible to vasovagal syncope. Diuretic or age-related contraction of blood volume further increases the risk of vasovagal syncope.

### Presentation

The hallmark of vasovagal syncope is hypotension and/or bradycardia sufficiently profound to produce cerebral ischemia and loss of neural function. Vasovagal syncope has been classified into cardioinhibitory (bradycardia), vasodepressor (hypotension), and mixed (both) subtypes depending on the blood pressure and heart rate response. In most patients, the manifestations occur in three distinct phases: a prodrome or aura, loss of consciousness, and postsyncope phase. A precipitating factor or situation is identifiable in most patients. Common precipitating factors include extreme emotional stress, anxiety, mental anguish, trauma, physical pain or anticipation of physical pain (e.g., anticipation of venesection), warm environment, air travel, and prolonged standing. The commonest triggers in older individuals are prolonged standing and vasodilator medication. Some patients experience symptoms in specific situations such as micturition, defecation, and coughing. Prodromal symptoms include extreme fatigue, weakness, diaphoresis, nausea, visual defects, visual and auditory hallucinations, dizziness, vertigo, headache, abdominal discomfort, dysarthria, and paresthesias. The duration of prodrome varies greatly from seconds to several minutes, during which some patients take actions such as lying down to avoid an episode. Older patients may have poor recall for prodromal symptoms. The syncopal period is usually brief during which some patients develop involuntary movements usually myoclonic jerks, but tonic-clonic movements also occur. Thus, vasovagal syncope may masquerade as a seizure. Recovery is usually rapid, but older patients can experience protracted symptoms such as confusion, disorientation, nausea, headache, dizziness, and a general sense of ill health.

### Evaluation

Several methods have evolved to determine an individual's susceptibility to vasovagal syncope such as Valsalva maneuvers, hyperventilation, ocular compression, and immersion of the face in cold water. However, these methods are poorly reproducible and lack correlation with clinical events. Using the strong orthostatic stimulus of head-upright tilting and maximal venous pooling, vasovagal syncope can

be reproduced in a susceptible individual. Head-up tilting as a diagnostic tool was first reported in 1986 and since then validity of this technique in identifying susceptibility to neurocardiogenic syncope has been established. Subjects are tilted head up for 40 minutes at 70 degrees. Heart rate and blood pressure are measured continuously throughout the test. A test is diagnostic or positive if symptoms are reproduced with a decline in blood pressure of greater than 50 mm Hg or to less than 90 mm Hg. This may be in addition to significant heart rate slowing. As with carotid sinus syndrome, the hemodynamic responses are classified as vasodepressor, cardioinhibitory, or mixed. The cardioinhibitory response is defined as asystole in excess of 3 seconds or heart rate slowing to less than 40 beats/min for a minimum of 10 seconds.

The sensitivity of head-up tilting can be further improved by provocative agents that accentuate the physiological events leading to vasovagal syncope. One agent is intravenous isoprenaline, which enhances myocardial contractility by stimulating beta adrenoreceptors. Isoprenaline is infused, prior to head-up tilting, at a dose of 1  $\mu\text{g}/\text{min}$  and gradually increased to a maximum dose of 3  $\mu\text{g}/\text{min}$  to achieve a heart rate increase of 25%. Though the sensitivity of head-up tilt testing improves by approximately 15%, the specificity is reduced. In addition, as a result of the decline in beta receptor sensitivity with age, isoprenaline is less well tolerated, less diagnostic, and has a much higher incidence of side effects. The other agent that can be used as a provocative agent and is better tolerated in older persons is sublingual nitroglycerin, which, by reducing venous return caused by vasodilatation, can enhance the vasovagal reaction in susceptible individuals. Nitroglycerin provocation during head-up tilt testing is thus preferable to other provocative tests in older patients. The duration of testing is less, cannulation is not required, and the sensitivity and specificity are better than for isoprenaline.

Because syncopal episodes are intermittent, external loop recording will not capture events unless they occur approximately every 2 to 3 weeks. Implantable loop recorders (Reveal; Medtronic) can aid diagnosis by tracking brady- or tachyarrhythmias causing less frequent syncope. To date, no implantable BP monitors are available with the exception of intracardiac monitors, which are not recommended for diagnosis of a benign condition such as vasovagal syncope.

### Management

Avoidance of precipitating factors and evasive actions, such as lying down during prodromal symptoms, have great value in preventing episodes of vasovagal syncope. Withdrawal or modification of culprit medications is often the only necessary intervention in older persons. Doses and frequency of antihypertensive medications can be tailored by information from 24-hour ambulatory monitoring. Older patients with hypertension who develop syncope—either orthostatic or vasovagal—while taking antihypertensive drugs, present a difficult therapeutic dilemma and should be treated on an individual basis. There is some evidence that captopril may benefit such patients. Beta-blockers and disopyramide have now been shown to have negative effects on postural blood pressure changes.

Many patients experience symptoms without warning, necessitating drug therapy. A number of drugs are reported to be useful in alleviating symptoms. Fludrocortisone (100–200  $\mu\text{g}/\text{d}$ ) works by its volume expanding effect. Recent reports suggest that serotonin antagonists such as fluoxetine (20 mg/day) and sertraline hydrochloride (25 mg/day) are also effective although further trials are neces-

sary to validate this finding. Midodrine acts by reducing peripheral venous pooling and thereby improving cardiac output and can be used either alone or in combination with fludrocortisone but with the caution. Elastic support hose, relaxation techniques (biofeedback), and conditioning using repeated head-up tilt as therapy have been adjuvant therapies. Permanent cardiac pacing is beneficial in some patients who have recurrent syncope owing to cardioinhibitory responses.

## POSTPRANDIAL HYPOTENSION

The effect of meals on the cardiovascular system was appreciated from postprandial exaggeration of angina, which was demonstrated objectively by deterioration of exercise tolerance following food. Postprandial reductions in blood pressure manifesting as syncope and dizziness were subsequently reported, leading to extensive investigation of this phenomenon. In healthy older subjects, systolic blood pressure falls by 11 to 16 mm Hg, and heart rate rises by 5 to 7 beats/min 60 minutes after meals of varying compositions and energy content. However, the change in diastolic blood pressure is not as consistent. In older persons with hypertension, orthostatic hypotension, and autonomic failure, the postprandial blood pressure fall is much greater and without the corresponding rise in heart rate. These responses are marked if the energy and simple carbohydrate content of the meal is high. In the majority of fit as well as frail older persons, most postprandial hypotensive episodes go unnoticed. When systematically evaluated, postprandial hypotension was found in more than one-third of nursing home residents.

Postprandial physiological changes include increased splanchnic and superior mesenteric artery blood flow at the expense of peripheral circulation and a rise in plasma insulin levels without corresponding rises in sympathetic nervous system activity. Vasodilator effects of insulin and other gut peptides, including neurotensin and VIP contribute to hypotension. The clinical significance of a fall in blood pressure after meals is difficult to quantify. However, postprandial hypotension is causally related to recurrent syncope and falls in older persons. A reduction in simple carbohydrate content of food, its replacement with complex carbohydrates or high protein, high fat, and frequent small meals are effective interventions for postprandial hypotension. Drugs useful in the treatment of postprandial hypotension include fludrocortisone and indomethacin, octreotide and caffeine. Given orally along with food, caffeine prevents hypotensive symptoms in fit as well as frail older persons, but should preferably be given in the mornings as tolerance develops if it is taken throughout the day.

## SUMMARY

Syncope is a common symptom in older adults caused by age-related neurohumoral and physiological changes plus chronic diseases and medications that reduce cerebral oxygen delivery through multiple mechanisms. Common individual causes of syncope encountered by the geriatrician are orthostatic hypotension, carotid sinus syn-

drome, vasovagal syncope, postprandial syncope, sinus node disease, atrioventricular block, and ventricular tachycardia. Algorithms for the assessment of syncope are similar to those for young adults, but the prevalence of ischemic and hypertensive disorders and cardiac conduction disease is higher in older adults and the etiology is more often multifactorial. A systematic approach to syncope is needed with the goal being to identify either a single likely cause or multiple treatable contributing factors. Management is then based on removing or reducing the predisposing or precipitating factors through various combinations of medication adjustments, behavioral strategies, and more invasive interventions in select cases such as cardiac pacing, cardiac stenting, and intracardiac defibrillators. It is often not possible to clearly attribute a cause of syncope in older persons who frequently have more than one possible cause, and pragmatic management of each diagnosis is recommended.

# Pressure Ulcers

*Barbara M. Bates-Jensen*

## DEFINITION

Pressure ulcers are areas of local tissue trauma, usually developing where soft tissues are compressed between bony prominences and any external surface for prolonged time periods. A pressure ulcer is a sign of local tissue necrosis. Pressure ulcers are most commonly found over bony prominences subjected to external pressure. The most common locations are sacrum, ischial tuberosities, trochanters, and heels with sacral and heel sites most frequent. Pressure exerts the greatest force at the bony tissue interface; therefore, there may be significant muscle and subcutaneous fat tissue destruction underneath intact skin. Other terms for pressure ulcers include bedsore or decubitus ulcer, both of which imply development only in those confined to bed. Since the major causative factor is pressure, and because pressure ulcers occur in positions other than just lying down, pressure ulcer is the preferred term.

## EPIDEMIOLOGY

The incidence and prevalence of pressure ulcers are high in all health-care settings. Among hospitalized older patients, the prevalence of pressure ulcers is estimated at 15%. Among patients expected to be confined to bed or chair for at least 1 week, the prevalence of stage II and greater pressure ulcers is as high as 28%, and the incidence during hospitalization ranges between 8% and 30%. Pressure ulcers generally occur within the first 2 weeks of hospitalization (the first 5 days in critical care units), and of those patients with an ulcer, more than half develop them after admission.

Pressure ulcers represent a significant health concern for those in nursing homes, rehabilitation systems, and for special populations. The incidence of new lesions varies widely by clinical situation: the highest rates are found among orthopedic populations (9–19% incidence) and quadriplegics (33–60% incidence). Among nursing

homes, prevalence estimates vary from 2.3% to 28%. Incidence is similarly diverse with reports of 2.2% in a database study of a large corporate nursing home chain to 24% in a prospective observational study of 255 nursing home residents in multiple settings. As many as 20% to 33% of persons admitted to nursing homes have a stage II or greater pressure ulcer. Pressure ulcer development among new residents admitted ulcer-free during the initial 4 weeks of nursing home residence is 11% to 14%. Twenty-two percent of those residents admitted ulcer-free develop ulcers within 2 years of residence. African Americans demonstrate a higher incidence of pressure ulcers and more severe pressure ulcers compared to Caucasians in nursing homes with incidence rates reported as 0.56 per person year compared to 0.35 per person year for Caucasians. Incidence of stage II to IV pressure ulcers are nearly two times higher among African Americans than Caucasians. Further, pressure ulcer-associated mortality is higher among blacks than among whites.

Rehabilitation facilities present special concerns related to pressure ulcer development, because patients in these facilities have conditions that limit mobility, such as spinal cord injury, traumatic brain injury, cerebral vascular accident, burns, multiple trauma, or a chronic neurological disorder. Prevalence rates range from 12% to 25%. Individuals with spinal cord injury are at higher risk for pressure ulcer development, with incidence rates reported at 20% for those undergoing spinal surgery, increasing to 30% to 40% over 1 year's time. Prevalence of pressure ulcers in spinal cord injury persons is also high with reports of 33% to 40% during acute rehabilitation and for those living in the community, with recurrence rates up to 40% after an ulcer heals. In the community, the prevalence of pressure ulcers is 6% to 9% in home health-care settings, and 1.6% in outpatient clinic settings. In the home health setting, 20% of the pressure ulcers develop in the first week after admission, and the incidence increases 10% each week through week 4. Of those who develop a pressure ulcer, 50% develop the ulcer within 24 days after admission to home health services.

## MORBIDITY ASSOCIATED WITH PRESSURE ULCERS

Pressure ulcers can lead to pain and disfigurement. Of those persons with pressure ulcers who are able to report pain, across nursing homes, home health, and hospital settings, 87% report pain with dressing changes, 84% report pain at rest, and 42% report pain both at rest and during dressing changes. Further, 18% of those persons reporting dressing change wound pain report pain at the highest level (e.g., “excruciating”). Yet, only 6% of those persons reporting pressure ulcer pain receive any medication for pain. There is some evidence that a higher proportion of persons with stage III or IV ulcers report ulcer pain compared to those persons with stage II ulcers and they report more severe pain than those with stage II pressure ulcers.

Septicemia is the most severe complication from pressure ulcers. The incidence of bacteremia from pressure ulcers is approximately 1.7 per 10 000 hospital discharges. When the pressure ulcer is the source of bacteremia, overall mortality is 48%. Further, septicemia is reported in 40% of pressure ulcer-associated deaths. Clinicians should be aware that transient bacteremia occurs after pressure ulcer debridement in as many as 50% of patients. Other infectious complications of pressure ulcers include wound infection, cellulitis, and osteomyelitis. Infected pressure ulcers are one of the most common infections found in skilled nursing facilities, and are reported in 6% of residents. Of note, pressure ulcers are typically colonized with  $\geq 10^5$  organisms/mL of normal skin flora. Although  $\geq 10^5$  organisms/mL of normal skin flora can cause local infection in intact skin and impair wound healing in flaps and skin grafts, chronic wounds such as pressure ulcers may bear microbial growth at this level for prolonged periods without noticeable clinical manifestations of infection and with evidence of healing. Among patients with nonhealing or worsening pressure ulcers, 26% of ulcers have underlying bone pathology consistent with osteomyelitis, 88% are colonized with *Pseudomonas aeruginosa* species, and 34% with *Providencia* species. The presence of either *P aeruginosa* or *Providencia* species should not be considered typical colonization. Infected pressure ulcers also can serve as reservoirs for infections with antibiotic-resistant bacteria.

Prolonged hospitalization, slow recovery from comorbid conditions, and increased death rates are consistently observed in elderly individuals who develop pressure ulcers in both hospitals and nursing homes. The death rate among bed- and chair-bound patients who develop a pressure ulcer during hospitalization is 60% 1 year after discharge, whereas the death rate for patients who do not develop a pressure ulcer is 38%. In addition, failure of an ulcer to heal or improve has been associated with a higher rate of death in nursing home residents. Nursing home residents whose pressure ulcer healed within 6 months show a lower mortality rate (11% vs. 64%) than residents with ulcers that did not heal within 6 months. It is unclear how pressure ulcers lead to death. The link between pressure ulcers and mortality may be related to an unidentified causal pathway, to pressure ulcers as a marker for coexisting morbidity in frail, sick patients, or to the association between fatal sepsis and pressure ulcers as cause of death. Whatever the link, pressure ulcers are reported as a cause of death among 114 000 persons per year (age-adjusted mortality rate of 3.8 per 100 000 population).

Pressure ulcers have become a quality issue for all areas of health care. Pressure ulcer incidence and severity are used as markers of quality care by regulators in long-term care facilities, home care agencies,

and acute care hospitals. As a result, pressure ulcers are on the national agenda for improving quality. The Institute for Healthcare Improvement’s 5 Million Lives Campaign lists preventing hospital-acquired pressure ulcers as one of 12 interventions that if implemented would dramatically improve the quality of American health care by protecting patients from harm. The Institute of Medicine’s report, *Priority Areas for National Action: Transforming Health Care Quality*, outlines 20 priority areas for improving health-care quality, and preventing pressure ulcers in frail older adults is one of these 20 priority areas. In 2003, the National Quality Forum endorsed 30 “safe practices” that should be universally utilized in applicable health care settings to reduce the risk of harm resulting from processes, systems, or environments of care. This list includes the practice of evaluating each patient upon admission, and regularly thereafter, for the risk of developing pressure ulcers. The Department of Health and Human Services’ health goals for the nation, *Healthy People 2010*, identified a 50% decrease in the prevalence of pressure ulcers in nursing homes as a part of the nation’s health agenda and reducing pressure ulcers in high-risk residents is a top priority for the Medicare Quality Improvement Organization’s 9th scope of work, as well as for a multiorganization campaign to advance excellence in nursing home care initiated in 2007. This emphasis on pressure ulcers across the spectrum of health care settings highlights the importance of the condition for clinicians. Pressure ulcers have also received attention in the courtroom. Organizations have been prosecuted for negligence related to pressure ulcer care and development, and, in a landmark case, one health-care facility operator was found guilty of manslaughter for a resident’s death related to improper care for her pressure ulcers.

## PATHOPHYSIOLOGY

Pressure ulcers are the result of mechanical injury to the skin and underlying tissues. The primary forces involved are pressure, shear, friction, and moisture. Pressure is the perpendicular force or load exerted on a specific area, causing ischemia and hypoxia of the tissues. High-pressure areas in the supine position are the occiput, sacrum, and heels. In the sitting position, the ischial tuberosities exert the highest pressure, and the trochanters are affected in the sidelying position. As the amount of soft tissue available for compression decreases, the pressure gradient increases, thus, most pressure ulcers occur over bony prominences where there is less tissue for compression and the pressure gradient within the vascular network is altered.

The changes in the vascular network allow an increase in the interstitial fluid pressure, which exceeds the venous flow. This results in an additional increase in the pressure and impedes arteriolar circulation. The capillary vessels collapse, and thrombosis occurs. Increased capillary arteriole pressure leads to fluid loss through the capillaries, tissue edema, and subsequent autolysis. Lymphatic flow is decreased, allowing further tissue edema, and contributing to the tissue necrosis.

Pressure, over time, occludes blood and lymphatic circulation, causing deficient tissue nutrition and accumulation of waste products, as a result of ischemia. If pressure is relieved before a critical time period is reached, a normal compensatory mechanism, reactive hyperemia, restores tissue nutrition and compensates for compromised circulation. If pressure is not relieved, the blood vessels collapse and

thrombose. The tissues are deprived of oxygen, nutrients, and waste removal. In the absence of oxygen, cells use anaerobic pathways for metabolism and produce toxic by-products. The toxic by-products lead to tissue acidosis, increased cell membrane permeability, edema, and eventual cell death.

Tissue damage may also be owing to reperfusion and reoxygenation of the ischemic tissues or postischemic injury. Oxygen is reintroduced into tissues during reperfusion following ischemia. This triggers oxygen-free radicals known as superoxide anion, hydroxyl radicals, and hydrogen peroxide, which induce endothelial damage and decrease microvascular integrity.

Pressure is the greatest at the bony prominence and soft tissue interface, and gradually lessens in a cone-shaped gradient to the periphery. Thus, although tissue damage apparent on the skin surface may be minimal, the damage to the deeper structures can be severe. In addition, subcutaneous fat and muscle are more sensitive than the skin to ischemia. Muscle and fat tissues are more metabolically active and, thus, more vulnerable to hypoxia with increased susceptibility to pressure damage.

## PRESENTATION

The first clinical sign of pressure ulcer formation, blanchable erythema, presents as discoloration of a patch or flat, nonraised area of the skin larger than 1 cm. This discoloration presents as redness or erythema that varies in intensity from pink to bright red in light-skinned patients. In dark-skinned patients, the discoloration appears as deeper normal ethnic pigmentation; a purple or blue-gray hue to the skin. Other characteristics include slight edema and increased temperature of the area. The beginning clinical indicators of pressure ulceration all relate to the signs of inflammation in the tissues. This beginning stage of damage is transient if the pressure is relieved. If pressure is not relieved, the damage can progress.

Nonblanchable erythema involves more severe damage to underlying tissues and is commonly the first stage of pressure ulceration (stage I pressure ulcer). The color of the skin is more intense. It varies from dark red to purple or cyanotic in both light- and dark-skinned patients. Dark-skinned patients exhibit deepening of normal skin color, a purple or gray hue to the skin, and changes in skin texture, with induration and an orange-peel appearance. Skin temperature is cool compared with healthy tissues, and the area may feel indurated. This stage of tissue destruction is also reversible, although tissues may take 1 to 3 weeks to return to normal.

The result of further deterioration in the tissues is evidenced as the epidermis is disrupted with subepidermal blisters, crusts, or scaling present (stage II pressure ulcer). If properly treated, the situation may resolve in 2 to 4 weeks. The early pressure ulcer is superficial, with indistinct margins and a red, shiny base, and reflects continued tissue insult and progressive injury. It is usually surrounded by erythema. If not dealt with aggressively, the lesion may progress to a chronic, deep ulcer. Superficial ulcers also may begin at the skin surface as the result of friction and moisture on the skin, the effects of both are increased with pressure. While superficial ulcers may progress to deeper ulcers, many deep ulcers do not originate at the skin surface; they begin at the bony prominence and soft tissue interface, and spread to involve the skin structures.

The chronic, deep, full-thickness ulcer usually has a dusky red wound base and does not bleed easily. It is surrounded by blanchable

or nonblanchable erythema or deepening of normal skin tone, induration, and warmth. Undermining, or pocketing, and tunneling may be present with a large necrotic cavity. Eschar formation may be a result of larger vessel damage below skin surface from shearing forces. Eschar is the formation of an acellular dehydrated compressed area of necrosis, usually surrounded by an outer rind of blanchable erythema. Eschar formation indicates a full-thickness loss of skin.

## ASSESSMENT

Assessment involves screening for risk of developing pressure ulcers, assessment of the severity of the tissue damage (staging), and evaluation of ulcer healing over the course of treatment.

### Risk Assessment

Pressure ulcer development is related to multiple factors, with immobility or severely restricted mobility being the most important risk factor for all populations and a necessary condition for the development of pressure ulcers. A study of geriatric patients, who were monitored for movements using devices on the bed, showed that individuals with greater than 50 movements a night did not develop pressure ulcers compared to 90% of individuals with 20 or fewer spontaneous body movements at night who developed a pressure ulcer.

Incontinence, malnutrition, impaired mental status, and altered sensation or response to pain and discomfort are all risk factors with strong relationships to pressure ulcer development in prospective studies. Fecal incontinence has a more powerful relationship to pressure ulcer development than urinary incontinence. Other risk factors include dry skin, increased body temperature, decreased blood pressure, and advanced age. Identification of age as a risk factor may be related to the concomitant chronic diseases more prevalent in older persons or the age-associated changes in the skin that may play a role in this increased risk.

For practitioners to intervene cost-effectively, a method of screening for risk of developing pressure ulcers is necessary. Use of a risk assessment tool is a screening mechanism to identify those persons at risk of developing pressure ulcers in multiple health-care settings. Risk assessment is recommended in clinical practice guidelines for pressure ulcers. The purpose in identifying patients at risk for pressure ulcer development is to allow for appropriate use of resources for prevention. The use of a risk assessment tool allows targeting of interventions to specific risk factors for individual patients. There is, however, limited evidence to support a direct link between use of risk assessment tools and decreased incidence of pressure ulcers. Multifaceted prevention interventions that have included use of risk assessment tools have shown decreased pressure ulcer incidence levels from 13% to 23% preintervention to 2% to 5% postintervention. The outcome, however, cannot be solely attributed to use of risk assessment tools. Use of risk assessment tools is linked to increased documentation of prevention interventions and may be better than use of clinical judgment alone. While there is no study that provides definitive evidence linking risk assessment directly with pressure ulcer prevention, there is a relationship between conducting risk assessment and initiating preventive interventions leading to decreased pressure ulcer incidence.

Pressure ulcer risk assessment should be performed on admission to the health-care setting and at periodic intervals thereafter. In acute care hospitals, risk assessment should be repeated every 48 hours. Those persons admitted to intensive or critical care units should have risk assessment conducted on admission and if determined at risk, daily thereafter. In home health settings, risk assessment should be conducted weekly for the first 4 weeks with every other week reassessments thereafter depending on patient condition and frequency of home visits. Nursing home residents should be reassessed for pressure ulcer risk status weekly for the first 4 weeks following admission followed by quarterly assessments.

The most commonly used risk assessment tools are the Norton Scale and the Braden Scale for Predicting Pressure Sore Risk. The Norton Scale is the oldest risk assessment instrument. Developed in 1961, it consists of five subscales: physical condition, mental state, activity, mobility, and incontinence. Each parameter is rated on a scale of 1 to 4, with the sum of the ratings for all five parameters yielding a total score, ranging from 5 to 20. Lower scores indicate increased risk, with a score of or below 16 indicating “onset of risk” and scores 12 and below indicating high risk for pressure ulcer formation.

The Braden Scale was developed in 1987 and is composed of six subscales: sensory perception, moisture, activity, mobility, nutrition, and friction and shear. All subscales are rated from 1 to 4, except for friction and shear, which is rated from 1 to 3. The subscales may be summed for a total score, with a range from 6 to 23. Lower scores indicate lower function and higher risk for developing a pressure ulcer. The cutoff score for hospitalized adults is considered to be 16, with scores of 16 and below indicating at-risk status. In older patients, some have found cutoff scores of 17 or 18 to be better predictors of risk status. Levels of risk are based on the predictive value of a positive test. Scores of 15 to 16 indicate mild risk, with a 50% to 60% chance of developing a stage I pressure ulcer; scores of 12 to 14 indicate moderate risk, with a 65% to 90% chance of developing a stage I or II lesion; and scores below 12 indicate high risk, with a 90% to 100% chance of developing a stage II or deeper pressure ulcer.

Specific prevention strategies should be targeted to risk factors identified in individual patients. In those persons in whom prevention is not successful, the continued monitoring of risk status may prevent further tissue trauma at the wound site and development of additional wound sites.

### Assessment of Pressure Ulcer Stage

Pressure ulcers are commonly classified using grading or staging systems based on the observable depth of tissue destruction. The stage is determined on initial assessment by noting the deepest layer of tissue involved. The ulcer is not restaged unless deeper layers of tissue become exposed. The initial method of classifying pressure ulcers was a pathology-based classification system intended to simplify communication for health-care professionals, provide a mechanism for identification of pressure ulcers, and suggest a broad guide for determining whether operative care was needed. Each grade of pressure ulceration was defined by the anatomic limit of soft tissue damage that could be observed. The numeric classification system suggested an orderly evolution of pressure ulceration. However, it is unknown if all pressure ulcers heal or deteriorate in a linear fashion.

The most commonly used staging system is the National Pressure Ulcer Advisory Panel’s (NPUAP) classification system describ-

ing four stages of pressure ulcers. The NPUAP staging system was slightly revised in 2007 and [Table 58-1](#) presents definitions for the four pressure ulcer stages. As part of the staging classification revisions, the NPUAP has also suggested criteria for deep tissue injury (DTI), which is tissue damage that does not fit into the classic four pressure ulcer stages. DTI presents as purple, blue, or black areas of intact skin. These lesions commonly occur on heels and the sacrum, and signal more severe tissue damage below the skin surface. DTI lesions reflect tissue damage at the bony tissue interface, and may progress rapidly to large tissue defects.

### Assessment of Pressure Ulcer Healing

Routine pressure ulcer assessment is the base for maintaining and evaluating the therapeutic plan of care. Initial assessment and follow-up assessments at regular intervals to monitor progress are necessary to determine the effectiveness of the treatment plan. Assessment of ulcer status should be performed weekly and whenever a significant change is noted in the wound. Assessment should not be confused with monitoring the ulcer at each dressing change. Monitoring can be performed by less skilled caregivers; however, assessment should be performed on a routine basis by trained clinicians. At a minimum, the ulcer should be assessed for location, depth and stage, size, and wound bed description such as necrotic tissue, exudate, wound edges for undermining and tunneling, and presence or absence of granulation and epithelialization.

There are two research-based pressure ulcer assessment tools for evaluating wound status and healing, the Pressure Sore Status Tool (now called the Bates-Jensen Wound Assessment Tool [BWAT]) ([Figure 58-1](#)) and the NPUAP’s Pressure Ulcer Scale for Healing tool (PUSH) ([Figure 58-2](#)). Clinical practice guidelines, expert panels, and federal nursing home guidelines recommend standardized assessment of pressure ulcers, and many groups are beginning to recommend use of a standardized tool for pressure ulcer assessment. One prospective study showed improved pressure ulcer healing outcomes when a tool was used for standardized pressure ulcer assessment and interventions were tied to the assessment.

The PUSH tool incorporates surface area measurements, exudate amount, and surface appearance. The clinician measures the size of the wound, using length and width to calculate surface area and chooses the appropriate size category of ten categories. Exudate is evaluated as none (0), light (1), moderate (2), and heavy (3). Tissue type is rated as closed (0), epithelial tissue (1), granulation tissue (2), slough (3), and necrotic tissue (4). Each of the three items is scored, then the three subscores can be summed for a total score. The PUSH tool offers a quick assessment to predict healing outcomes, but assessment of additional wound characteristics may still be needed in order to develop a treatment plan for the pressure ulcer.

The BWAT, developed in 1990 and revised in 2001, evaluates 13 wound characteristics using a 5-point numerical rating scale, and rates them from best (scored as 1) to worst (scored as 5) possible (see [Figure 58-1](#)). Characteristics include: size, depth, edges, undermining or pockets, necrotic tissue type and amount, exudate type and amount, surrounding skin color, peripheral tissue edema and induration, granulation tissue, and epithelialization. Similar to the PUSH tool, once characteristics have been scored, they can be summed for a total score (range 13 to 65). The total score differentiates between early pressure ulcers (stage I and II) and stage III and IV ulcers with mean total scores of 23 versus 32 respectively. A 1-week improvement

TABLE 58-1

## National Pressure Ulcer Advisory Panel, 2007 Pressure Ulcer Staging Classifications

PRESSURE ULCER STAGE	DEFINITION AND CLINICAL DESCRIPTION
Stage I	Intact skin with nonblanchable redness of a localized area usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area. The area may be painful, firm, soft, warmer, or cooler as compared to adjacent tissue. Stage I may be difficult to detect in individuals with dark skin tones. May indicate "at risk" persons (a heralding sign of risk).
Stage II	Partial-thickness loss of dermis presenting as a shallow open ulcer with a red pink wound bed, without slough. May also present as an intact or open/ruptured serum-filled blister. Presents as a shiny or dry shallow ulcer without slough or bruising. This stage should not be used to describe skin tears, tape burns, perineal dermatitis, maceration, or excoriation.
Stage III	Full-thickness tissue loss. Subcutaneous fat may be visible, but bone, tendon, or muscle is not exposed. Slough may be present, but does not obscure the depth of tissue loss. May include undermining and tunneling. The depth of a stage III pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue and stage III ulcers can be shallow. In contrast, areas of significant adiposity can develop extremely deep stage III pressure ulcers. Bone/tendon is not visible or directly palpable.
Stage IV	Full-thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed. Often include undermining and tunneling. The depth of a stage IV pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue and these ulcers can be shallow. Stage IV ulcers can extend into muscle and/or supporting structures (e.g., fascia, tendon, or joint capsule) making osteomyelitis possible. Exposed bone/tendon is visible or directly palpable.
Unstageable	Full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed. Until enough slough and/or eschar is removed to expose the base of the wound, the true depth, and therefore stage, cannot be determined. Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as "the body's natural (biological) cover" and should not be removed.
Suspected Deep Tissue Injury	Purple or maroon localized area of discolored intact skin or blood filled blister due to damage of underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer or cooler as compared to adjacent tissue. Deep tissue injury may be difficult to detect in individuals with dark skin tones. Evolution may include a thin blister over a dark wound bed. The wound may further evolve and become covered by thin eschar. Evolution may be rapid, exposing additional layers of tissue even with optimal treatment.

in the total score demonstrates a positive predictive value of 65% (sensitivity 61%; specificity 52%) for achieving 50% wound healing within a 6-week time period. Both the PUSH tool scores and the BWAT tool scores are highly correlated, and use is based on provider preference.

In general, pressure ulcer healing is accelerated during the initial 3 months after development. In both partial- and full-thickness pressure ulcers, reduction in size after 1 to 2 weeks of therapy has been shown to be predictive of healing outcomes. Clinical practice guidelines suggest pressure ulcers should show evidence of improvement within 2 to 4 weeks after initiating appropriate treatment, and if no improvement is evident, the treatment plan should be re-evaluated. Improvement rates for stage III and IV ulcers are slower than stage II ulcers with 75% of stage II wounds healing in 60 days, while only 17% of stage III or IV ulcers heal in the same time period.

## MANAGEMENT

### Local Treatment

Pressure ulcer management includes debridement of necrotic tissue, adequate wound cleansing, and application of appropriate topical therapy. Wound debridement is necessary to reduce the necrotic

tissue burden, decrease risk for infection, and promote granulation tissue formation. Benefits of debridement also may include removal of senescent fibroblasts and nonmigratory hyperproliferative epithelium, and stimulation of blood-borne growth factor production. Debridement is not indicated for dry eschar presenting on the heel or when the pressure ulcer presents on an ischemic limb.

Five methods of debridement (e.g., surgical or sharp, mechanical, autolytic, enzymatic, biosurgical) are available. Choice of debridement method is currently based on clinician preference and availability rather than any specific evidence. Clinical practice guidelines on pressure ulcer treatment recommend wound debridement with surgical or sharp debridement for extensive necrosis or when obtaining a clean wound bed quickly is important and more conservative methods (autolytic and enzymatic) for those in long-term care or home care environments. Adequate wound debridement is essential to wound bed preparation and healing.

Sharp debridement involves use of a scalpel, scissors, or other sharp instruments to remove nonviable tissue. It is the most rapid form of debridement, and it is indicated over other methods for removing thick, adherent, and/or large amounts of nonviable tissue and when advancing cellulitis or signs of sepsis are present. Health-care professionals who use sharp debridement must demonstrate their competency in sharp wound debridement skills and meet licensing requirements. One multicenter, randomized, controlled trial comparing the effects of topical growth factor versus placebo on

healing noted that independent of treatment effects, centers that used sharp debridement more frequently experienced better healing rates than those that used sharp debridement less frequently. Sharp debridement is rapid, but is also considered nonselective as viable tissues may be inadvertently removed along with necrotic tissue.

Mechanical debridement involves the use of wet-to-dry dressings, whirlpool, lavage, or wound irrigation. Wet-to-dry gauze dressings continue to be used for debridement, despite the significant disadvantages of increased time/labor for application/removal of the

dressings, removing viable tissue as well as nonviable tissue, and pain. This method of debridement should be used cautiously, as it can traumatize new granulation tissue and epithelial tissue, and adequate analgesia should be administered when this method is employed.

Enzymatic debridement involves applying a concentrated, commercially prepared enzyme to the surface of the necrotic tissue, in the expectation that it will aggressively degrade necrosis by digesting devitalized tissue. There are three enzyme ointments available in

	None	Light	Moderate	Heavy			
<b>Tissue Type</b>	<b>0</b>	<b>1</b>	<b>2</b>	<b>3</b>	<b>4</b>		<b>Subscore</b>
	Closed	Epithelial Tissue	Granulation Tissue	Slough	Necrotic Tissue		
							<b>Total Score</b>

**Length x Width:** Measure the greatest length (head to toe) and the greatest width (side to side) using a centimeter ruler. Multiply these two measurements (length x width) to obtain an estimate of surface area in square centimeters (cm<sup>2</sup>). Caveat: Do not guess! Always use a centimeter ruler and always use the same method each time the ulcer is measured.

**Exudate Amount:** Estimate the amount of exudate (drainage) present after removal of the dressing and before applying any topical agent to the ulcer. Estimate the exudate (drainage) as none, light, moderate, or heavy.

**Tissue Type:** This refers to the types of tissue that are present in the wound (ulcer) bed. Score as a "4" if there is any necrotic tissue present. Score as a "3" if there is any amount of slough present and necrotic tissue is absent. Score as a "2" if the wound is clean and contains granulation tissue. A superficial wound that is reepithelializing is scored as a "1". When the wound is closed, score as a "0".

**4 - Necrotic Tissue (Eschar):** black, brown, or tan tissue that adheres firmly to the wound bed or ulcer edges and may be either firmer or softer than surrounding skin.

**3 - Slough:** yellow or white tissue that adheres to the ulcer bed in strings or thick clumps, or is mucinous.

**2 - Granulation Tissue:** pink or beefy red tissue with a shiny, moist, granular appearance.

**1 - Epithelial Tissue:** for superficial ulcers, new pink or shiny tissue (skin) that grows in from the edges or as islands on the ulcer surface.

**0 - Closed/Resurfaced:** the wound is completely covered with epithelium (new skin).

the United States, collagenase, papain-urea, and papain-urea with chorophyllin. Some of the effects noticed with enzymatic agents have been attributed to autolysis. Enzymatic ointments have yielded consistently positive results for their efficacy in wound debridement. Debridement with enzymatic ointments is faster than with autolysis, and more conservative than sharp debridement.

Autolytic debridement is the process of using the body's own mechanisms to remove nonviable tissue. Maintaining a moist wound

environment allows collection of fluid at the wound site, which allows enzymes within the wound fluid to digest necrotic tissue. Autolytic debridement typically involves adequate wound cleansing to wash out the partially degraded nonviable tissue. It is more effective than wet-to-dry gauze dressings, as it selectively removes only the necrotic tissue and therefore protects healthy tissues. Autolytic debridement may be slower to achieve a clean ulcer bed than other methods.

Biosurgery is the fifth method of debridement. Biosurgery is the application of maggots (disinfected fly larvae, *Phaenicia sericata*) to the wound typically at a density of 5 to 8 per square centimeter. Comparative controlled studies evaluating the use of maggot therapy for pressure ulcer debridement have shown a higher proportion of complete debridement in maggot-treated wounds versus standard debridement therapy (80% vs. 48%, respectively). Biosurgery may not be acceptable to all patients, and may not be available in all areas.

Pressure ulcer cleansing at each dressing change is recommended in clinical practice guidelines on pressure ulcer treatment. However, there is evidence that antiseptic solutions such as 5% mafenide acetate (Sulfamylon solution), 10% povidone with 1% free iodine (Betadine), 0.25% sodium hypochlorite (“half strength” Dakin’s solution), 3% hydrogen peroxide, and 0.25% acetic acid have varying effects on wound healing parameters as well as antimicrobial management in an animal wound model yet, how this affects human wounds is unclear.

Use of antiseptic and antimicrobial solutions for cleansing *clean* pressure ulcers is not indicated based on in vitro studies of the toxicity of topical wound cleansers. Findings from in vitro studies have not been confirmed in human wounds. Use of antiseptic and antimicrobial solutions for cleansing pressure ulcers with *necrotic* debris should be employed thoughtfully with attention to the solution chosen, the characteristics of the microorganisms present in the wound, and duration of use (e.g., course of therapy for 2 weeks with evaluation for continuation at that time).

In general, if an ulcer contains necrotic debris or is infected, then antimicrobial activity is more important than cellular toxicity. The chemical and mechanical trauma of wound cleansing should be balanced by the dirtiness of the wound. For wounds with large amounts of debris, more vigorous mechanical force and stronger solutions may be used, while for clean wounds, less force and physiologic solutions such as normal saline should be used.

Topical therapy for pressure ulcers should be provided using moist wound healing dressings. Randomized controlled trials as well as several comparative studies provide compelling support for use of moist wound healing dressings instead of any form of dry gauze dressings (e.g., wet to dry or dry gauze dressing, impregnated gauze dressing) for persons with pressure ulcers. Moist wound healing allows wounds to re-epithelialize up to 40% faster than wounds left open to air. Controlled trials suggest that the use of occlusive dressings such as transparent films and hydrocolloid dressings improves healing of stage II pressure ulcers. These dressings are changed every 3 to 5 days, which allows wound fluid to gather underneath the dressing, facilitating epithelial migration. Moderate evidence exists to specifically support use of hydrocolloid dressings for pressure ulcer care in stage III/IV pressure ulcers. One multicenter, randomized trial demonstrated faster healing in stage III/IV pressure ulcers when treated sequentially with calcium alginate dressings followed by hydrocolloid dressings versus nonsequentially with hydrocolloid dressings. However, the relative merits of different categories of moisture retentive dressings versus another remain unclear. [Table 58-2](#) presents general characteristics of moisture retentive dressing categories.

## Surgery

Surgical treatment of pressure ulcers includes primary closure, a variety of approaches to skin grafts and myocutaneous flaps, and removal

of underlying bony prominences. In patients with large infected pressure ulcers, more aggressive procedures such as amputation and hemi-corporectomy are sometimes required. Surgical complication rates (including dehiscence, infection, necrosis, and hematoma) for both younger paraplegic patients and nonparaplegic elders are as high as 50%, and pressure ulcer recurrence at the same site has been reported ranging from 30% to 70%. Thus, the long-term outcomes have not been ideal even though 70% to 80% of surgically treated pressure ulcers are healed upon discharge from the hospital. Further, while recurrence of pressure ulcers at the same site is lower for elders (40%) compared to younger paraplegic patients (more than 70%), 30% of elders develop new ulcer sites, and mortality in elders ranges from nearly 50% to 68%.

Thus, the benefits of surgical closure for pressure ulcer are uncertain. In addition to questions about the efficacy of surgical intervention, geriatric patients present with multiple chronic diseases and conditions that may make them less than ideal surgical candidates or affect rehabilitation efforts after surgery.

There is some evidence supporting use of negative pressure wound therapy (NPWT) in large stage III and IV nonhealing pressure ulcers with poor granulation tissue or excess exudate. Several clinical practice guidelines and panels have recommended use of NPWT with large stage III and IV pressure ulcers that have failed to improve with standard care with moist wound healing. A case series of 10 patients with stage IV pressure ulcers treated with NPWT showed greater than 50% average reduction in wound volume and depth (55% and 61%, respectively) over 4 weeks.

## Drugs

Pharmacologic interventions for pressure ulcers focus on antibiotics and pain management. Antibiotics may be systemic or local. Clinicians should institute systemic antibiotics for patients exhibiting signs and symptoms of systemic infection such as sepsis or cellulitis with associated fever and an elevated white blood cell count. Systemic antibiotics should be initiated for osteomyelitis or for the prevention of bacterial endocarditis in persons with valvular heart disease and who require debridement of a pressure ulcer. Because of the high mortality of sepsis associated with pressure ulcers despite appropriate antibiotics, broad-spectrum coverage for aerobic gram-negative rods, gram-positive cocci, and anaerobes is indicated pending culture results in patients with suspected bacteremia. Ampicillin–sulbactam, imipenem, meropenem, ticarcillin–clavulanate, piperacillin–tazobactam, and a combination of clindamycin or metronidazole with ciprofloxacin, levofloxacin, or an aminoglycoside are appropriate choices for initial antibiotic therapy. Vancomycin may be required for methicillin-resistant *Staphylococcus aureus*. Prolonged silver release topical dressings have been shown to be effective for pressure ulcers colonized with methicillin-resistant *S aureus*. The most effective strategy for preventing infection and dealing with existing infection is adequate debridement of necrotic tissue. In patients with signs and symptoms of systemic infection and in those who are septic, the appropriate debridement method is surgical debridement.

Topical antibiotics are most appropriate for stage III or IV ulcers when there is evidence of local infection such as erythema surrounding the wound, failure to improve with adequate treatment, or friable granulation tissue. A 2-week trial of a topical antibiotic, such as silver sulfadiazine, can be considered for clean pressure ulcers that are

TABLE 58-2

## General Characteristics of Moisture Retentive Dressing Categories

DRESSING CATEGORY	DEFINITION	USES	NOTES
<b>Composite Dressings</b>	Combine one dressing group with another to address wound characteristics. For example, gauze/foam and transparent film dressing properties, hydrocolloid and alginates, etc.	Absorbent (depends on combination of dressings used in the composite) Wicks away excess moisture Nonadherent to wound bed Use depends on the combination of dressings used in the composite	<ul style="list-style-type: none"> <li>Some may be difficult to apply</li> <li>If nonadherent to wound bed then requires secondary dressing to hold in place</li> <li>Can be confusing to caregivers as combines various dressing category properties.</li> </ul>
<b>Transparent Film Dressings</b>	Polyurethane and polyethylene membrane film coated with a layer of acrylic hypoallergenic adhesive. Moisture vapor transmission rates (MVTR) vary	Appropriate for partial-thickness wounds Promotes epithelialization Semipermeable Bacterial barrier Autolysis Wound visible Protects against friction Self adhesive	<ul style="list-style-type: none"> <li>May reinjure area on removal</li> <li>Nonabsorbent so can lead to wound edge maceration</li> <li>Tendency to remove prematurely</li> <li>Indicated for minimal exudate, does not absorb drainage</li> <li>Not indicated for moderate to heavy exudate.</li> </ul>
<b>Hydrocolloids</b> Regular or thin wafers, paste, granules	Gelatin, pectin, carboxymethylcellulose in a polyisobutylene adhesive base with a polyurethane or film backing	Absorbs low to moderate wound fluid, Autolysis Thermal insulation Bacterial barrier Reduces pain Translucent to opaque Easy to apply Controls odor (until dressing removed) Impermeable to semipermeable	<ul style="list-style-type: none"> <li>Not indicated for heavy exudate, limited absorbent abilities when used alone</li> <li>Use with other products increases absorbent abilities</li> <li>Odor on removal</li> <li>Regular wafers are opaque, thin wafers allow some wound visualization</li> <li>Edges may melt down and stick to linens</li> <li>Some difficult to remove</li> <li>Possible sensitivity to adhesive backing</li> <li>Use with close supervision on immunosuppressed and diabetic patients, extensive burns, infected lesions</li> </ul>
<b>Hydrogels</b> Sheets, wafers Amorphous gels Impregnated gauze	May or may not be supported by a fabric net, high water content, varying amounts of gel-forming material (glycerin, copolymer, water, propylene glycol, humectant)	Absorbs low to moderate drainage Autolysis Nonadhesive, may have adhesive borders Semipermeable or impermeable depending on backing Thermal insulation Reduces pain Conformable Carrier for topical medication	<ul style="list-style-type: none"> <li>Can dry out</li> <li>May macerate surrounding tissues</li> <li>Requires secondary dressing or tape to keep in place</li> <li>Does not cause reinjury upon removal</li> <li>Cooling effect can help relieve wound pain</li> <li>Candidiasis may present from inappropriate usage</li> </ul>
<b>Wound Fillers (Exudate absorbers)</b> Beads, flakes Pastes, powders	Consists of copolymer starch, dextranomer beads or hydrocolloid paste that swell on contact with wound fluid to form gel, dextranomers, polysaccharides, starch, natural polymers, and colloidal particles	Moisture retentive Absorptive (moderate to large) Useful to fill cavities, pockets, undermining Can be used with topical medications	<ul style="list-style-type: none"> <li>Nonadhesive</li> <li>Requires a secondary dressing to hold in place</li> <li>May have burning sensation on application</li> <li>May have odor</li> <li>Some require mixing</li> <li>Some require wound irrigation for nontraumatic removal</li> </ul>
<b>Alginates</b> Ropes, pads, wafers	Calcium-sodium salts of alginic acid (naturally occurring polymer in seaweed)	Absorptive (moderate to large) Useful to fill cavities, pockets, undermining Moisture retentive Can use with topical medications or on infected wounds Reduces pain Thermal insulation	<ul style="list-style-type: none"> <li>Nonadherent, requires secondary dressing to hold in place</li> <li>Hemostatic properties</li> <li>May require wound irrigation for removal</li> <li>No reinjury on removal</li> <li>May dry out, should not be used on wounds with low exudate.</li> </ul>

(Continued)

TABLE 58-2

## General Characteristics of Moisture Retentive Dressing Categories (Continued)

DRESSING CATEGORY	DEFINITION	USES	NOTES
<b>Foams</b> Wafers (thick or thin), pillows, composite dressings with thin film covers, available with surfactant impregnated or charcoal layer	Inert material that is hydrophilic and nonadherent, modified polyurethane foam	Absorptive (moderate to large) Autolysis Can be used with topical medications & on infected wounds Conformable Thermal insulation	<ul style="list-style-type: none"> <li>• Nonadhesive unless used with composite dressing</li> <li>• Requires tape or secondary dressing to hold in place</li> <li>• Nontraumatic removal</li> <li>• Opaque</li> <li>• Waterproof, inert</li> </ul>
<b>Hydrofibers</b> Pads, wafers, ropes	Soft nonwoven pad or ribbon dressings made from sodium carboxymethyl-cellulose fibers, similar absorbent material used in hydrocolloid dressings	Absorptive (moderate to large) Autolysis Thermal insulation Reduces pain	<ul style="list-style-type: none"> <li>• Nonadherent, requires secondary dressing to hold in place</li> <li>• Hemostatic properties</li> <li>• May require wound irrigation for removal</li> <li>• No reinjury on removal</li> </ul>

not healing after 2 to 4 weeks of optimal management. Use of a prolonged silver release dressing may also be appropriate in this situation. On the other hand, clinicians should not use povidone–iodine, iodophor, sodium hypochlorite, hydrogen peroxide, or acetic acid as topical therapies on *clean* pressure ulcers. These antiseptic agents have been shown to be toxic to fibroblasts and to impair wound healing in *in vitro* laboratory studies, and how these solutions affect human wounds is unclear. There is no evidence for using prolonged silver release dressings in routine management of healing pressure ulcers.

There is limited evidence to guide clinicians on appropriate management of pressure ulcer related pain. The pressure ulcer alone may not require routine pain medication, but medication prior to procedures is essential. Lower levels of pain may be manageable with appropriate wound dressing choice and topical wound analgesia. Nonpharmacological techniques useful for noncyclic and cyclic wound pain associated with procedures (e.g., debridement, dressing changes) include use of distraction (e.g., talking to the patient while performing the procedure), allowing the patient to call a “time-out” during the procedure, allowing the patient to control and participate in the procedure. Pharmacological strategies for wound pain include providing opioids and/or nonsteroidal anti-inflammatory drugs 30 minutes prior to the procedure and afterwards, and administering topical anesthetics or topical opioids using hydrogels as a transport media. Two options have been successful for use in chronic wound pain, EMLA cream and diamorphine gel. EMLA cream (eutectic mixture of lidocaine 2.5% and prilocaine 2.5%) reduces debridement pain scores in chronic venous ulcers, and may have a vasoactive effect cutaneously. Use of EMLA cream in venous ulcers has been associated with a reduction in pain scores (measured on a 100 mm scale) of 20.6 mm. Low-dose topical morphine (diamorphine) has been used in several small, randomized, placebo controlled studies to successfully control pressure ulcer related pain.

## Nutrition

Multiple studies have demonstrated a relationship between different markers of malnutrition (e.g., serum albumin level, dietary protein intake, inability to feed self, and weight loss) and pressure ulcer formation. Other studies have demonstrated that the severity of the

pressure ulcer is associated with the severity of the malnutrition. Although it seems intuitive, it has proven difficult to define a causal relationship between malnutrition and pressure ulcer development. Modest evidence exists to support providing nutritional support to persons at risk for pressure ulcers with relative reduction in pressure ulcer incidence of 25%. There is some evidence that use of high-protein nutritional supplements (24–25% protein) improves pressure ulcer healing, and the goal should be to provide 30 to 35 kcal/kg/d and 1.25 to 1.5 g/kg of protein daily. However, provision of nutritional supplementation by tube-feeding to persons with pressure ulcers has not achieved positive results. No evidence exists for use of supplemental vitamins or minerals (e.g., vitamin A, E, C, zinc, arginine) in persons with pressure ulcers and no coexisting specific vitamin/mineral deficiency to improve pressure ulcer healing. Persons with pressure ulcers or at risk of developing pressure ulcers who also demonstrate malnutrition should have a nutritional assessment to identify deficits and nutrition support as indicated. A daily multivitamin and mineral supplement that provides recommended daily allowances of vitamins and minerals is recommended for persons with suspected nutritional deficiencies.

## PREVENTION

Pressure ulcer prevention involves scheduled turning and repositioning programs, use of support surfaces to reduce/relieve pressure, nutritional support (discussed above), and general skin care. Prevention interventions should be implemented for persons at risk for pressure ulcer development and those with existing pressure ulcers as part of the treatment plan.

Patients at risk for pressure ulcers that are unable to move independently should be placed on scheduled repositioning programs. The recommended time interval for full change of position or turning while in bed is every 2 hours, depending on the individual patient profile and the use of support surfaces. Pressure-reducing support surfaces (e.g., foam, air, gel-filled mattress overlays, low-air-loss therapy devices) may reduce the frequency of repositioning required in some patients. One controlled clinical trial evaluating the effects of four different turn intervals in conjunction with standard hospital mattress versus a pressure reduction support surface found

differences in pressure ulcer incidence. The four turn intervals evaluated were: 2 hours on standard mattress (2 h), 3 hours on standard mattress (3 h), 4 hours on pressure reducing surface (4 h), 6 hours on pressure reducing surface (6 h) and a control group with usual care (no specified turning schedule). Over 4 weeks, 838 geriatric nursing home residents were evaluated. Although there was no difference in the incidence of stage I pressure ulcers or erythema, stage II pressure ulcer incidence was significantly decreased in the 4 h group compared to all other groups (3% compared to 20%, no turns; 14.3%, 2 h; 24.1%, 3 h; and 15.9%, 6 h).

Repositioning patients to avoid placing pressure on bony prominences, in particular the malleolus and trochanter. To avoid placing pressure on the trochanter and outer malleolus, position the patient at a 30-degree side-lying position (e.g., 30-degree angle to the support surface) instead of the commonly used 90-degree side lying position, which increases tissue compression over the trochanter and malleolus. Maintain the head of the bed at the lowest degree of elevation consistent with medical conditions, and limit the amount of time the head of the bed is elevated. This will decrease exposure of the sacral area to shearing forces that may predispose to deep-tissue injury. Use of footboards and pillows under the lower legs to prevent sliding and to maintain position, are also helpful in reducing shear effects on the skin when in bed.

There are techniques to make turning patients easier and less time-consuming. Turning sheets, draw sheets, and pillows are essential for passive movement of patients in bed. Turning sheets are useful in repositioning the patient to a side lying position, and draw sheets are used for pulling the patient up in bed and help to prevent dragging the patient's skin over the bed surface. Pillows should be used to position patients with minimal tissue compression between the medial knees, the medial malleolus, and the heels. Place pillows between the knees, between the ankles, and under the heels as well as behind the back and under the arms for comfort.

Similar approaches are useful for patients in chairs. Full-body change of position involves standing the patient and resitting them in the chair. Observation of the patient when sitting is also important, because patients who slide out of the chair are at high risk for shear injury. Use of footstools and the foot pedals on wheelchairs and appropriate 90-degree flexion of the hip (may be achieved with pillows, special seat cushions, or orthotic devices) can help in preventing chair sliding. Attention to proper alignment and posture is essential. Individuals at risk for pressure ulcer development should avoid uninterrupted sitting in chairs and should be repositioned every hour. The rationale behind the shorter time is the extremely high pressure generated on the ischial tuberosities in the seated position. When possible, individuals should be taught to shift weight every 15 minutes while seated.

Pressure reducing/relieving support surfaces should be initiated for beds and chairs of persons determined at risk for developing pressure ulcers. Use of pressure reducing support surfaces instead of standard hospital mattresses results in relative reduction in pressure ulcer incidence of 60%. Additionally, clinicians should advocate for use of support surfaces in the operating room to reduce postoperative pressure ulcer incidence. Use of pressure reduction support surfaces such as mattress overlays (e.g., foam, gel, or alternating air pads) or low-air-loss therapy is appropriate for many patients at risk for pressure ulcers or with stage I or II pressure ulcers. However, for persons with existing pressure ulcers, use of air-fluidized therapy may improve healing rates. One retrospective, multisite, compar-

ison study showed faster healing of existing pressure ulcers with air-fluidized therapy compared to both pressure reduction support surfaces and low-air-loss therapy (mean healing rate of 5.2 cm<sup>2</sup>/wk for the air-fluidized surface group compared to 1.5 cm<sup>2</sup>/wk for pressure reduction support surface group and 1.8 cm<sup>2</sup>/wk for low-air-loss therapy group). In addition, the odds of showing improvement in pressure ulcers are more than five times greater when air-fluidized therapy and 4 hour repositioning is implemented compared to alternating air mattresses and 2 hour repositioning in hospitals. Although air-fluidized therapy increased the odds of ulcer improvement, only 12% of hospitalized patients achieved healing of the largest pressure ulcer. In nursing home residents, a randomized, controlled trial suggests that pressure ulcer areas decrease three times faster when low-air-loss beds are used compared with conventional care. Additional controlled trials are needed to define the optimal repositioning schedules for patients on a variety of support surfaces.

Providing topical preparations to eliminate or reduce the surface tension between the skin and the bed linen or support surface will assist in reducing friction-related injury. Use of appropriate techniques when moving patients so that skin is not dragged across linens will lessen friction-induced skin breakdown. Patients who exhibit voluntary or involuntary repetitive body movements (particularly of the heels or elbows) require stronger interventions. Use of a protective film, such as a transparent film dressing or a skin sealant; a protective dressing, such as a thin hydrocolloid; or protective padding will help to eliminate the surface contact of the area and decrease the friction between the skin and the linens. Even though heel, ankle, and elbow protectors do nothing to reduce or relieve pressure, they can be effective aids against friction.

General skin care should include routine skin inspection, incontinence assessment and management, and skin hygiene interventions to maintain skin health. Routine skin inspection should occur daily with particular attention to bony prominences. Reddened areas should not be massaged. Massage can further impair the perfusion to the tissues. The skin should be evaluated for dryness and cracking, use of moisturizers can be helpful. Attention should also be focused on gentle handling to prevent skin tears. Incontinence assessment and management with scheduled toileting or prompted voiding programs and for those unresponsive to these programs, check and change schedules are important. Prompt cleansing after incontinent episodes with warm water and gentle cleansers and use of protective ointments and creams help maintain perineal skin health. [Table 58-3](#) presents general prevention interventions directed at risk factors for pressure ulcer development.

## SPECIAL ISSUES

Some patients will benefit most from a palliative care approach. Palliative pressure ulcer care means that the goals are comfort and limiting the extent or impact of the pressure ulcer but without the intent of healing. Palliative care may be indicated for terminally ill patients such as those with end-stage cancer or in the terminal stages of other diseases. Institutionalized older adults with multiple comorbidities or older adults with severe functional decline may also benefit from palliative care. Palliative pressure ulcer care includes adequate debridement of necrotic tissue, identification and treatment of infection, provision of moist wound healing with management of exudate and odor, and prevention interventions. Prevention should

**TABLE 58-3****Pressure Ulcer Prevention Interventions**

RISK FACTOR	PREVENTION INTERVENTIONS
Immobility	Scheduled repositioning programs, use of pressure reduction/relief surfaces in bed and chairs.
Inactivity, limited mobility	Use of trapeze bars for self-movement in bed, encourage ambulation, rehabilitation as appropriate.
Decreased sensory perception	Scheduled repositioning programs, verbal reminders to move/reposition, use of pressure reduction/relief surfaces in bed and chairs.
Malnutrition	Nutritional assessment to determine deficits, nutritional supplementation (high protein) and daily multivitamin if indicated and appropriate to goals.
Excess moisture and incontinence	Scheduled toileting or prompted voiding programs if responsive, routine check and change programs with pads and adult briefs for persons who do not respond to scheduled toileting or prompted voiding, use of skin creams and ointments for protection from moisture.
Friction and shearing	Use of trapeze bars for those with upper body strength, turn sheets & draw sheets for moving in bed, use of cornstarch or lubricants to limit friction between surfaces, thin film or dressings, and pads over bony prominences subject to friction, use of footboards to help prevent sliding while in bed.
Dry skin	Use warm water, gentle cleansers, and limited force for cleansing when soiled and for routine bathing, lubricate and moisturize dry skin, inspect skin daily paying particular attention to bony prominences, avoid massage of reddened areas.

still consist of use of pressure reducing support surfaces and attention to scheduled repositioning, although time frames may be adjusted or lengthened to ease the burden on the patient. Providing pain medication 30 to 40 minutes prior to repositioning activity and use of positioning devices may help those with pain on movement.

## SUMMARY

Pressure ulcers are chronic wounds and as such, require patience and diligence by clinicians. Many pressure ulcers never heal, and most require long periods of treatment with slow progress. Partial-thickness stage II pressure ulcers are more likely to heal than full-thickness stage III or IV pressure ulcers. In fact, stage II pressure ulcers are 5.2 times more likely to heal in 6 months than stage IV pressure ulcers. Among nursing home residents, up to 75% of stage II wounds heal within 60 days, while only 17% or fewer full-thickness pressure ul-

cers heal in the same time period. The best healing rate reported even after 6 months of treatment is 59%. Thus, identification of persons at risk for developing pressure ulcers and aggressive prevention interventions to actively avoid ulcer development is essential. Prevention includes screening for risk with risk assessment tools and implementing targeted prevention interventions based on identified risk factors. Scheduled repositioning programs, use of pressure reduction support surfaces, and assessment and management of nutrition are key prevention strategies. More research is needed to define optimal turning intervals for various support surfaces and to better elucidate the effect of nutrition interventions on both preventing pressure ulcers and healing pressure ulcers.

For those persons who do develop pressure ulcers, clinicians should provide appropriate treatment during early ulcer stages to capitalize on healing progress in the initial 3 months. Adequate debridement of necrotic tissue, identification and treatment of infection, and providing a moist wound environment are the key tenets of appropriate pressure ulcer care. All preventive and therapeutic interventions, and progress of the ulcer, should be carefully documented in the medical record. Unfortunately, no intervention or combination of interventions has demonstrated the ability to completely eliminate pressure ulcers. Thus, even as we develop more refined and specific screening, detection, and prevention interventions, it is likely we will continue to see pressure ulcers in all health-care settings. The guidelines presented in this chapter should provide a foundation for developing a successful approach to both those at risk for pressure ulcer development and those with existing pressure ulcers.

# Incontinence

*Theodore M. Johnson II* ■ *Joseph G. Ouslander*

## DEFINITION AND EPIDEMIOLOGY

Defined as the complaint of any involuntary leakage of urine, urinary incontinence is a common and bothersome condition in elderly persons. The prevalence of incontinence increases with age and with increasing frailty, and is 1.3 to 2.0 times greater in older women than in older men. Among community-dwelling older women, the prevalence of any urinary incontinence is approximately 35%; among older men, it is approximately 22%. The prevalence of daily urinary incontinence in older community-dwelling persons is approximately 12% for women and 5% for men. The prevalence approaches 60% among nursing home residents. Incontinence ranges in severity from occasional episodes of dribbling small amounts of urine to continuous urine leakage with concomitant fecal incontinence. In addition, many older people who do not “leak urine” still may have bothersome lower urinary tract symptoms such as urgency, frequency, and nocturia that require changes in lifestyle and/or the use of pads.

Physical health, psychological well-being, social status, and the costs of health care can all be adversely affected by incontinence. Urinary incontinence can be cured or greatly improved, especially in those who have adequate mobility and mental functioning. Even when not curable, incontinence can always be managed to allow for more patient comfort, make life easier for caregivers, and minimize costs of caring for the condition. Because many elderly patients are embarrassed to discuss their incontinence and may not be aware that treatment is available, it is essential for specific questions about incontinence to be included in periodic assessments and for incontinence to be noted as a problem (Table 59-1). This chapter briefly reviews the pathophysiology of incontinence in older persons and provides detailed information on the evaluation and management of this condition.

## PATHOPHYSIOLOGY AND CLASSIFICATION

Continence requires effective functioning of the lower urinary tract, adequate cognitive and physical functioning, motivation, and an appropriate environment (Table 59-2). Anatomic and physiologic aspects of the lower urinary tract, as well as functional, psychological, and environmental factors, contribute to the pathophysiology of incontinence in older persons. Normal urination is a complex process; the neurophysiology of urination remains incompletely understood. Proper bladder filling and emptying are influenced by higher centers in the brainstem, cerebral cortex, and cerebellum. The brainstem facilitates urination and the cerebral cortex exerts a predominantly inhibitory influence. Additionally, the loss of the central cortical inhibitory influences over the sacral micturition center from diseases such as stroke can produce incontinence in older patients. Even in the absence of specific, overt neurological lesions, poor bladder control has been shown to be associated with inadequate activation of the orbitofrontal cortex. Disorders of the brainstem and suprasacral spinal cord can interfere with the coordination of bladder contraction and urethral relaxation. Interruptions of the sacral innervation can cause impaired bladder contraction and problems with continence.

At the most basic level, urination is governed by a reflex centered in the sacral micturition center. During normal bladder filling, afferent pathways (via somatic and autonomic nerves) carry information on bladder volume to the spinal cord. Motor output is adjusted accordingly (Figure 59-1). Sympathetic tone closes the bladder neck and inhibits parasympathetic tone (thus relaxing the dome of the bladder); somatic innervation maintains tone in the pelvic floor musculature (including striated muscle around the urethra). Voluntary pelvic floor muscle contracture also leads to inhibition of parasympathetic tone. For bladder emptying, sympathetic and somatic tones diminish, and parasympathetic, cholinergically-mediated impulses

**TABLE 59-1****Asking About Urinary Incontinence**

Questions about incontinence should be open-ended and phrased in language easily understood by the patient:

"Tell me about any problems you are having with your bladder?"

"Tell me about any trouble you are having holding your urine (water)?"

If the responses to the above questions are negative, following up with questions may be helpful:

"How often do you lose urine when you don't want to?"

"How often do you wear a pad or other protective device to prevent urinary accidents?"

Adapted from Fantyl JA, Newman DK, Colling J, et al. *Urinary Incontinence in Adults: Acute and Chronic Management. Clinical Practice Guideline No. 2, 1996 Update*. Rockville, MD: U.S. Dept of Health and Human Services, Public Health Service, Agency for Health Care Policy and Research; 1996. AHCPR publication 96-0682.

cause the bladder to contract. Normal urination is a dynamic process, requiring the coordination of several physiologic processes. Under normal circumstances, as the bladder fills, bladder pressure remains low ( $\leq 15$  cm H<sub>2</sub>O). The bladder volume at first urge to void is variable, but generally occurs at between 150 and 350 mL; normal bladder capacity is 300 to 600 mL. When normal urination is initiated, the detrusor contracts and detrusor pressure increases until it exceeds urethral resistance (which lowers immediately prior to bladder contraction). Urine flow occurs. If at any time during bladder filling, total bladder pressure exceeds outlet resistance, urinary leakage occurs. Transmitted intra-abdominal pressure alone by coughing or sneezing may cause leakage in someone with low outlet resistance pressure or urethral sphincter weakness. Alternatively, the bladder can contract involuntarily and cause urinary leakage.

**Basic Causes**

Urologic, neurologic, psychological, and functional factors may contribute to incontinence. As is the case for a number of other common geriatric problems, multiple disorders often interact to cause urinary incontinence. Determining the cause or causes facilitates proper management. Overall, aging is associated with increasing incontinence. The prevalence of stress incontinence likely does not

**TABLE 59-2****Requirements for Continence**

Effective lower urinary tract function

**Storage**

- Accommodation by bladder of increasing volumes of urine under low pressure
- Closed bladder outlet
- Appropriate sensation of bladder fullness
- Absence of involuntary bladder contractions

**Emptying**

- Bladder capable of contraction
- Lack of anatomic obstruction to urine flow
- Coordinated lowering of outlet resistance with bladder contractions

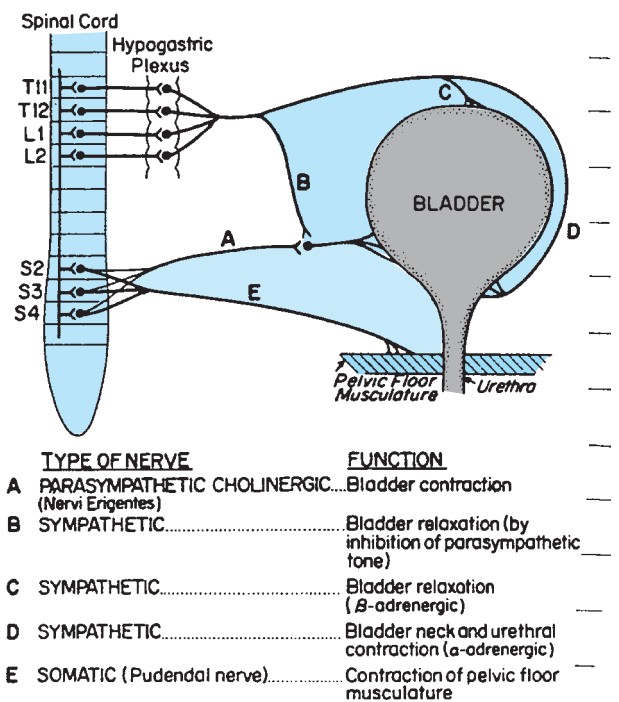

Adequate mobility and dexterity to use toilet

Adequate cognitive function to recognize toileting needs

Motivation to be continent

Absence of environmental and iatrogenic barriers

**FIGURE 59-1.** Peripheral nerves involved in micturition. (Reprinted with permission from Kane RL, Ouslander JG, Itamar B, et al. *Essentials of Clinical Geriatrics*. 5th ed. New York, New York: McGraw-Hill; 2004.)

increase in women, while the prevalence of urge incontinence and mixed stress–urge incontinence does increase.

Several age-related changes can contribute to the development of urinary incontinence. In general, residual urine volume following voiding is greater with increasing age. While a decline in functional bladder capacity has been associated with advanced age, this may be because of the higher prevalence of involuntary bladder contractions and detrusor overactivity in older persons. Involuntary bladder contractions are found in 40% to 75% of elderly incontinent patients, but also in 5% to 10% of elderly continent women and in up to one-third of elderly men with no or minimal urinary symptoms. Detrusor overactivity has been associated with specific anatomical findings (protrusion junctions and ultra-close abutment of detrusor muscle cells) on bladder biopsy. While involuntary bladder contractions do not always result in urinary incontinence, when combined with impaired mobility, these contractions likely account for a substantial proportion of incontinence in elderly functionally disabled patients. Aging is also associated with a decline in bladder outlet and urethral resistance pressure in women. While there is a recognition that laxity of pelvic structures associated with prior childbirths (either via vaginal deliveries or Caesarean section) may result in a greater risk of future incontinence, the association between parity and incontinence is weak in women older than 65 years. Additionally, in older populations, poor vaginal support is more closely associated with obstructive urinary symptoms than with urinary leakage and urgency. Obesity, deconditioned muscles, and hysterectomy predispose women to future development of incontinence. Racial or ethnic characteristics are likely important; white women are more likely, as a group, to have stress urinary incontinence than are African-American women.

Older men with prostatic enlargement may have decreased urine flow rates and detrusor motor instability. Aging is also associated with higher rates of nocturia, which may in part be related to higher urine production at night (see Chapter 88). Many older individuals

of both genders have impaired bladder contractility, often in combination with detrusor hyperactivity (a condition termed *detrusor hyperactivity with impaired contractility*, or DHIC). These individuals have evidence of widespread muscle degeneration on detrusor muscle biopsy.

### Acute and Reversible Causes

The distinction between acute (or reversible) forms of incontinence and persistent (or established) incontinence is clinically important although not always distinct. *Acute incontinence* refers to those situations in which the incontinence is of sudden onset, usually related to an acute illness or an iatrogenic problem, and subsides once the illness or medication problem has been resolved. *Persistent incontinence* refers to incontinence that is unrelated to an acute illness and persists over time. Several of the reversible factors discussed below also can contribute to persistent forms of incontinence.

The potentially reversible causes of urinary incontinence are outlined in [Table 59-3](#). These causes include impaired ability (or willingness) to reach a toilet, conditions that affect the lower urinary tract, conditions that cause or contribute to polyuria, and iatrogenic factors. Because of urinary frequency and urgency, many older persons, especially those limited in mobility, carefully arrange their schedules (and may even limit social activities) in order to be close to a toilet. Thus, an acute illness can precipitate incontinence by disrupting this

delicate balance. Hospitalization, with its attendant environmental barriers (such as bed rails), and the delirium and immobility that often accompany acute illnesses in older patients can contribute to acute incontinence. Acute incontinence in these situations is likely to resolve with resolution of the underlying acute illness. In a substantial proportion of patients, incontinence may persist for several weeks after hospitalization and should be further evaluated.

Fecal impaction is a common problem in both acutely and chronically ill elderly patients. Impaction may cause mechanical obstruction of the bladder outlet that can prevent adequate bladder emptying and cause reflex bladder contractions induced by rectal distension. Relief of a fecal impaction can lead to resolution of urinary, as well as fecal, incontinence. Urinary incontinence with a high postvoid residual should be considered in any patient who suddenly develops urinary incontinence. Immobility; anticholinergic, narcotic, calcium channel blocking, and beta adrenergic medications ([Table 59-4](#)); and fecal impaction can all precipitate incontinence with a high postvoid residual in an older patient. In addition, urinary retention may be an acute manifestation of an underlying process causing spinal cord compression or occur after a stroke.

Inflammation of the lower urinary tract may precipitate or exacerbate incontinence. Atrophic vaginitis and urethritis are common among older women, and can cause dysuria, urgency, and frequency that can contribute to incontinence. Physical signs include patchy erythema and increased vascularity of the labia minora and

**TABLE 59-3**

#### Reversible Conditions That Cause or Contribute to Urinary Incontinence in Older Persons

CONDITION	MANAGEMENT
Conditions affecting the lower urinary tract	
Urinary tract infection (symptomatic with frequency, urgency, dysuria, etc.)	Antimicrobial therapy (not for asymptomatic bacteriuria)
Atrophic vaginitis/urethritis	Topical estrogen
Postprostatectomy (incontinence will often resolve during first yr)	Behavioral interventions
Stool impaction	Avoid further surgical therapy until it is clear condition will not resolve
	Disimpaction; appropriate use of stool softeners, bulk-forming agents, and laxatives if necessary; implement high fiber intake, adequate mobility and fluid intake
Drug side effects (see <a href="#">Table 59-4</a> )	Discontinue or change therapy if clinically appropriate. Dosage reduction or modification (e.g., flexible scheduling of rapid-acting diuretics) may also help
Increased urine production	
Metabolic (hyperglycemia, hypercalcemia)	Better control of diabetes mellitus; therapy for hypercalcemia depends on underlying cause
Excess fluid intake	Reduction in intake of diuretic fluids (e.g., caffeinated beverages)
Volume overload	
Venous insufficiency with edema	Support stocking
	Leg elevation
	Sodium restriction
	Diuretic therapy
Congestive heart failure	Medical therapy
Impaired ability or willingness to reach a toilet	
Delirium	Diagnosis and treatment of underlying cause(s) delirium (see Chapter 53)
Chronic illness, injury, or restraint that interferes with mobility	
	Regular toileting
	Use of toilet substitutes
	Environmental alterations (e.g., bedside commode, urinal)
Psychological	Remove restraints if possible
	Appropriate pharmacologic and/or nonpharmacologic treatment

**TABLE 59-4****Medications That Can Potentially Affect Continence**

TYPE OF MEDICATION	POTENTIAL EFFECTS ON CONTINENCE
Diuretics	Polyuria, frequency, urgency
Anticholinergics	Urinary retention, overflow incontinence, stool impaction
Psychotropics	
Antidepressants	Anticholinergic actions, sedation
Antipsychotics	Anticholinergic actions, sedation, immobility
Sedative-hypnotics	Sedation, delirium, immobility, urethral muscle relaxation
Narcotic analgesics	Urinary retention, fecal impaction, sedation, delirium
Alpha adrenergic blockers	Urethral relaxation
Alpha adrenergic agonists	Urinary retention
Angiotensin-converting enzyme inhibitors	Cough precipitating stress incontinence
Beta adrenergic agonists	Rarely may contribute to urinary retention
Calcium channel-blockers	May contribute to urinary retention
Alcohol	Polyuria, frequency, urgency, sedation, delirium, immobility
Caffeine	Polyuria, bladder irritation

Adapted from Kane RL, Ouslander JG, Itamar B, et al. *Essentials of Clinical Geriatrics*. 5th ed. New York, New York: McGraw-Hill; 2003.

vaginal epithelium, petechiae and friability, and urethral erythema often with an inflamed caruncle (dark or bright red epithelium usually at the inferior aspect of the urethra). Topical estrogen therapy, as discussed under “Drug Treatment” later in this chapter, may be helpful in older women with these findings. Acute urinary tract infection also can precipitate or exacerbate incontinence. However, urine loss

among older patients with *chronic* incontinence, especially frail nursing home residents, with otherwise asymptomatic bacteriuria (with or without pyuria) does not appear to improve when the bacteriuria is eradicated. These patients, therefore, should not be treated with antibiotics because of the costs and risks unless the incontinence is new or acutely worsened.

Diuretics (especially rapid-acting loop diuretics) and conditions that cause polyuria, including hyperglycemia and hypercalcemia, can precipitate acute incontinence. Patients with volume-expanded states, such as those with congestive heart failure and lower extremity venous insufficiency, may have polyuria at night, which can contribute to nocturia and nocturnal incontinence. As is the case in many other conditions in geriatric patients, a wide variety of medications can play a role in the development of incontinence in elderly patients (see Table 59-4). Whether the incontinence is acute or persistent, the potential role of these medications in causing or contributing to a patient's incontinence should be considered. When feasible, stopping the medication, switching to an alternative, or modifying the dosage schedule can be beneficial and may be the only necessary treatment for incontinence. In addition to medications, drinking caffeinated beverages can cause urinary frequency and urgency, which may precipitate incontinence.

### Persistent Incontinence

Table 59-5 lists the clinical definitions and common causes of persistent urinary incontinence. These types can overlap with each other, and an individual patient may have more than one type simultaneously. Three of these types of incontinence—stress, urge, and overflow—result from one or a combination of two basic abnormalities in lower genitourinary tract function:

1. failure to store urine, caused by a hyperactive or poorly compliant bladder or by diminished outflow resistance; and/or

**TABLE 59-5****Basic Types and Causes of Persistent Urinary Incontinence**

TYPE	DEFINITION	COMMON CAUSES
Stress	Involuntary loss of urine (usually small amounts) with increases in intra-abdominal pressure (e.g., cough, laugh, exercise)	Weakness of pelvic floor musculature and urethral hypermobility Bladder outlet or urethral sphincter weakness Postprostatectomy sphincter weakness
Urge	Leakage of urine (variable but often larger volumes) because of inability to delay voiding after sensation of bladder fullness is perceived	Detrusor hyperactivity, isolated or associated with one or more of the following: Local genitourinary condition such as tumors, stones, diverticuli, or outflow obstruction CNS disorders such as stroke, dementia, parkinsonism, spinal cord injury
Mixed (stress & urge) Functional	Combination of above Urinary accidents associated with inability to toilet because of impairment of cognitive and/or physical functioning, psychological unwillingness, or environmental barriers	Severe dementia and other neurological disorders Psychological factors such as depression and hostility
High postvoid residual (Formerly referred to as “Overflow”)	Leakage of urine (usually small amounts) resulting from either mechanical forces on an overdistended bladder resulting in stress leakage or from other effects of urinary retention on bladder and sphincter function contributing to urge leakage	Anatomic obstruction by prostate, stricture, cystocele Acontractile bladder associated with diabetes mellitus or spinal cord injury Neurogenic (detrusor-sphincter dyssynergy), associated with multiple sclerosis and other suprasacral spinal cord lesions Medication effect (see Table 59-4)

Adapted from Kane RL, Ouslander JG, Itamar B, et al. *Essentials of Clinical Geriatrics*. 5th ed. New York, New York: McGraw-Hill; 2003.

2. failure to properly empty the bladder, caused by a poorly contractile bladder or by increased outflow resistance.

*Stress incontinence* is common in elderly women, especially in ambulatory clinic settings. The symptoms of stress incontinence are very specific: leakage coincident with increases in intra-abdominal pressure caused by coughing, sneezing, laughing, or exercising. Stress incontinence may be infrequent and involve very small amounts of urine. It may need no specific treatment in women who are not bothered by it; on the other hand, it may be so severe and/or bothersome that it renders the person housebound. Among women, it is most often associated with weakened supporting tissues, resulting in hypermobility of the bladder outlet and urethra and caused by lack of estrogen, obesity, previous vaginal deliveries, and/or surgery. Some women, generally those who have had previous lower urinary tract surgery, have intrinsic urethral weakness with failure of the urethra to coapt and prevent urine loss. These patients tend to have severe incontinence and occasionally have constant wetting. Stress incontinence is unusual in men, and it mainly occurs following transurethral surgery for benign conditions or after surgical or radiation therapy for lower urinary tract malignancy when the anatomic sphincters are damaged.

*Urge incontinence* can be caused by a variety of lower genitourinary and neurologic disorders (see [Table 59-5](#)). This type of incontinence is characterized by a sudden strong desire to void, accompanied by a fear of leakage, and followed by urine loss. The amount of urine lost is variable and largely dependent on sphincter function and the ability of the patient to abort a bladder contraction. Urge incontinence, when it occurs along with urinary urgency, daytime urinary frequency, and nocturia, has been called “*wet* overactive bladder”. Urge incontinence is most often, but not always, associated with involuntary bladder contractions. Some patients have a poorly compliant bladder without involuntary contractions (e.g., interstitial cystitis or following irradiation). A subgroup of elderly incontinent patients with detrusor hyperactivity also has impaired bladder contractility, emptying less than one-third of their bladder volume with involuntary contractions on urodynamic testing. These patients may be predisposed to significant urinary retention and may require training to learn to completely empty their bladder with voiding.

There has been a recommendation *against* the usage of the term “overflow incontinence” in favor of terms such as *acute* or *chronic urinary retention* and (either stress or urge) *incontinence with a high post-void residual*. *Acute retention of urine* is “a painful, palpable or percussable bladder, when the patient is unable to pass any urine”; and *chronic retention of urine* is where the patient has a “nonpainful bladder, which remains palpable or percussable after the patient has passed urine. . . (and) the patient may be incontinent.” A high postvoid residual can result from anatomic or neurogenic obstruction to urinary outflow, a hypotonic or acontractile bladder, or both. The most common causes include prostatic enlargement, diabetic neuropathic bladder, and urethral stricture. Low spinal cord injury and anatomic obstruction in women (caused by pelvic prolapse and urethral distortion) are less common causes of overflow incontinence in older patients. Several types of drugs also can contribute to this type of persistent incontinence (see [Table 59-4](#)). Some patients with suprasacral spinal cord lesions (e.g., multiple sclerosis) develop detrusor–sphincter dyssynergy and consequent urinary retention, which must be treated similarly to overflow incontinence; in some instances, a sphincterotomy is necessary.

*Functional incontinence* results when an elderly person is unable or unwilling to reach a toilet on time. Recognizing and removing these barriers to continence are critical. Factors such as inaccessible toilets and psychological disorders also can exacerbate other types of persistent incontinence. Patients with incontinence that appears to be predominantly related to functional factors also may have abnormalities of the lower genitourinary tract, most commonly detrusor overactivity. In some patients, it can be very difficult to determine whether the functional factors or the genitourinary factors predominate without a trial of specific types of treatment.

Many older patients have more than one type of incontinence. Most common are combinations of urge and stress incontinence (often called *mixed incontinence*) among older women and a combination of urge and functional incontinence among nursing home residents. In addition, many older patients have a syndrome of “overactive bladder,” which results in bothersome urinary urgency, frequency, and nocturia, but may be continent. These patients should be assessed and treated similar to patients with symptoms of urge incontinence.

## EVALUATION

Federal clinical practice guidelines, including an older guideline developed by the Agency for Health Care Policy and Research (now the Agency for Healthcare Research on Quality), and the Resident Assessment Instrument for nursing homes (which includes a section on continence in the Minimum Data Set and a Resident Assessment Protocol on continence and catheter management) recommend a basic diagnostic evaluation. This evaluation includes a history (which can be enhanced by a bladder record), a physical examination, a urinalysis, and a postvoid residual determination (PVR). The recommendation to obtain a PVR in all older patients with incontinence is controversial, and a reasonable approach may be to do this procedure only in patients at risk for urinary retention (see below). A number of other diagnostic studies are indicated in selected patients ([Table 59-6](#)). [Figure 59-2](#) summarizes the recommended diagnostic evaluation of incontinent older patients.

The objectives of the basic evaluation are threefold:

1. To identify potentially reversible conditions that might be contributing to the incontinence (see [Table 59-3](#)).
2. To identify conditions that require further diagnostic tests and/or referral for gynecologic or urologic evaluation.
3. To develop a management plan; this may include referral for further evaluation or a therapeutic trial of behavioral and/or pharmacologic therapy.

In patients with the sudden onset of incontinence (especially when associated with an acute medical condition and hospitalization), the potentially reversible causes of acute incontinence (see [Table 59-3](#)) can be ruled out by a brief history, a physical examination, and basic laboratory studies including urinalysis, culture, and tests for serum glucose or calcium, if indicated.

The history should focus on the characteristics of the incontinence, on current medical problems and medications, and on the impact of the incontinence on the patient and caregivers. The incontinence should be characterized in terms of frequency, timing, and amount of leakage; and symptoms of voiding difficulty including hesitancy, intermittent stream, and straining to void. Symptoms of

†The recommendation for a postvoid residual determination in all incontinent elderly patients is controversial (see text).

Adapted from Kane RL, Ouslander JG, Itamar B, et al. *Essentials of Clinical Geriatrics*. 5th ed. New York, New York: McGraw-Hill; 2003.

urge versus stress incontinence should be sought, recognizing that symptom history does not perfectly predict subtype of urinary incontinence. Bladder records, such as the one shown in Figure 59-3, can be helpful in characterizing symptoms, as well as in following the response to treatment. The physical examination includes abdominal, rectal, and genital examinations, as well as an evaluation of lumbosacral innervation. The abdominal examination is insensitive for an elevated postvoid residual or chronic urinary retention, but gross bladder distention (e.g.,  $\geq 500$  mL) can usually be detected. In acute urinary retention, the distended bladder is a firm, midline mass that emanates from the pelvis and is dull to percussion. In gross distention with either acute or chronic retention, the superior margin of the bladder is often identifiable by either palpation or percussion.

The pelvic examination in women includes inspection for significant prolapse, signs of inflammation suggestive of atrophic vaginitis, and a cough test to detect stress incontinence. The latter is best done in the standing position while the patient has a comfortably full bladder, but not a strong sense of urgency. The patient should be positioned over a pad or towel next to a commode and then should be asked to cough forcefully. Leakage simultaneously with coughing documents stress incontinence; delayed leakage (e.g., after 3 seconds) or the initiation of voiding generally indicates a cough-induced bladder contraction. The cough test for stress incontinence has excellent specificity and interrater reliability, but poor sensitivity.

**FIGURE 59-2.** Summary of assessment of geriatric urinary incontinence.

Special attention during the examination should be given to mobility and mental status, because impairments may be either causing the incontinence or interacting with urologic and neurologic disorders to worsen the condition. Patients with nocturia or nocturnal incontinence should be examined for signs of congestive heart failure or venous insufficiency with edema.

Urinalysis should be performed to look for signs of infection, hematuria, and glucosuria. Clean urine specimens are often difficult to obtain from frail incontinent patients, but can be performed reliably without first resorting to in-and-out catheterization. For men who cannot void spontaneously, a condom-type catheter can be used after cleaning the penis to collect a specimen that accurately reflects bladder urine. While there is a clear relationship between acute symptomatic urinary tract infection and incontinence, the relationship between asymptomatic bacteriuria and incontinence is controversial. In nursing home populations, there is no benefit to treating bacteriuria in patients with chronic, stable incontinence. For patients in other settings, it is difficult to make clear recommendations. For the initial evaluation of incontinence among noninstitutionalized incontinent patients, it is reasonable to initially eradicate the bacteriuria and observe the effect on the incontinence.

## BLADDER RECORD

Day: \_\_\_\_\_ Date: \_\_\_\_\_ / \_\_\_\_\_  
 month day

## INSTRUCTIONS:

- 1) In the 1st column make a mark every time during the 2-hour period you urinate into the toilet
- 2) Use the 2nd column to record the amount you urinate (if you are measuring amounts)
- 3) In the 3rd or 4th column, make a mark every time you accidentally leak urine

Time Interval	Urinated in Toilet	Amount	Leaking Accident	Or	Large Accident	Reason for Accident*
6-8 am						
8-10 am						
2-4 pm						
4-6 pm						
6-8 pm						
8-10 pm						
10-12 pm						
Overnight						

Number of pads used today: \_\_\_\_\_

\*For example, if you coughed and have a leaking accident, write "cough".  
 If you had a large accident after a strong urge to urinate, write "urge".

**FIGURE 59-3.** Example of a bladder record for ambulatory care settings. (Reprinted with permission from Kane RL, Ouslander JG, Itamar B, et al. *Essentials of Clinical Geriatrics*. 5th ed. New York, New York: McGraw-Hill; 2004.)

A determination of postvoid residual should be performed to exclude significant urinary retention. Neither the history nor the physical examination is sensitive or specific enough for this purpose in geriatric patients. Although performing a PVR on all patients may not be necessary, patients at risk for retention should have this procedure. This includes diabetic patients, patients with neurological disorders, patients with symptoms of voiding difficulty or a history of urinary retention, and patients on anticholinergic medications. The PVR determination can be done by portable ultrasonography if equipment is available. To be accurate, the PVR determination should be done within a few minutes of a spontaneous continent or incontinent void. PVR values of less than 100 mL in the absence of straining to void generally reflect adequate bladder emptying in geriatric patients, whereas PVR values greater than 200 mL are abnormal; values in between must be interpreted in the context of other patient symptoms.

Clinical practice guidelines do not recommend that all incontinent elderly patients undergo a complex urologic, gynecologic, or urodynamic evaluation. Many patients can be treated with a trial of behavioral and/or drug therapy after the initial evaluation is completed and potentially reversible factors are addressed. Table 59-7 lists examples of criteria for referring incontinent geriatric patients for further urologic, gynecologic, and/or urodynamic evaluations. Among men, a noninvasive measurement of urinary flow rate can be very helpful in excluding obstruction and/or bladder contractility

problems. Many urologists and continence clinics that see elderly men have such devices.

## MANAGEMENT

Several therapeutic modalities are used in managing incontinent patients (Table 59-8). Special attention should be paid to the management of acute incontinence, which is common in elderly patients in acute care hospitals. A common approach to elderly incontinent patients in acute hospitals is indwelling catheterization. In some instances, this practice is justified by the need for accurate measurement of urine output during the acute phase of an illness. In many instances, however, it is unnecessary and poses a substantial and unwarranted risk of catheter-induced infection and may prolong immobilization. Although other procedures may be more difficult and time-consuming, making toilets and toilet substitutes accessible and combining this accessibility with some form of scheduled toileting is a more appropriate approach. Using launderable or disposable and highly absorbent bed pads and undergarments may be more costly than catheters, but results in less morbidity than catheter use. All the factors that can cause or contribute to a reversible form of incontinence (see Table 59-3) should be attended to in order to maximize the potential for regaining continence.

TABLE 59-7

## Examples of Criteria for Referral of Incontinent Geriatric Patients for Further Urologic, Gynecologic, or Urodynamic Evaluation

CRITERIA	DEFINITION	RATIONALE
<i>History</i>		
Recent history of lower urinary tract or pelvic surgery or irradiation	Surgery or irradiation involving the pelvic area or lower urinary tract within the past 6 months	A structural abnormality relating to the recent procedure should be sought
Recurrent symptomatic urinary tract infections	Three or more symptomatic episodes in a 12-month period	A structural abnormality or pathologic condition in the urinary tract predisposing to infection should be excluded
<i>Physical Examination</i>		
Marked pelvic prolapse	A prominent cystocele that descends the entire height of the vaginal vault with coughing during speculum examination	Anatomic abnormality may underlie the pathophysiology of the incontinence, and selected patients may benefit from surgical repair
Marked prostatic enlargement and/or suspicion of cancer.	Gross enlargement of the prostate on digital examination; prominent induration or asymmetry of the lobes.	An evaluation to exclude prostate cancer may be appropriate.
<i>Postvoid Residual</i>		
Difficulty passing a 14-French straight catheter	Impossible catheter passage, or passage requiring considerable force or a large, rigid catheter	Anatomic blockage of the urethra or bladder neck may be present
Postvoid residual volume $\geq 200$ ml	Volume of urine remaining in the bladder within a few minutes after the patient voids spontaneously in as normal a fashion as possible	Anatomic or neurogenic obstruction or poor bladder contractility may be present
<i>Urinalysis</i>		
Hematuria	Greater than 5 red blood cells per high-power field on microscopic exam in the absence of infection	A pathologic condition in the urinary tract should be excluded
<i>Therapeutic Trial</i>		
Failure to respond to adequate trials of behavioral and/or pharmacologic therapy	Persistent symptoms that are bothersome to the patient after adequate trials of behavioral and/or drug therapy	Urodynamic evaluation may help guide specific therapy

Adapted from Kane RL, Ouslander JG, Itamar B, et al. *Essentials of Clinical Geriatrics*. 5th ed. New York, New York: McGraw-Hill; 2003.

Management should be guided by the type of incontinence, and more importantly by patient and/or family preferences. Patients should be carefully questioned about the degree of bother the incontinence is causing, and how much risk and cost they are willing to undertake to treat it. Supportive measures are critical in managing all forms of incontinence and should be used in conjunction with other, more specific treatment modalities. Education, environmental manipulations, appropriate use of toilet substitutes, avoidance of iatrogenic contributions to incontinence, modifications of diuretic and fluid intake patterns (especially caffeine), treatment of constipation, and good skin care are all important.

Specially designed incontinence undergarments and pads can be very helpful in many patients, but they must be used appropriately. Although they can be effective, several caveats should be raised:

1. garments and pads are a nonspecific treatment;
2. many patients are curable if treated with specific therapies, and some have potentially serious factors underlying their incontinence that must be diagnosed and treated;
3. patients often prefer more specific incontinence therapy designed to restore a normal pattern of voiding and continence;
4. incontinence garments and pads are expensive and rarely covered by third-party payers.

To a large extent, the optimal treatment of persistent incontinence depends on identifying the type or types. Table 59-9 outlines the primary treatments for the basic types of persistent incontinence in the geriatric population. Each treatment modality is briefly discussed below.

## Behavioral Interventions

Many types of behavioral interventions have been described for the management of urinary incontinence. These are either **patient dependent** (i.e., require adequate function and motivation of the patient), in which the goal is to restore a normal pattern of voiding and continence, or **caregiver dependent**, which can be used for functionally disabled patients, in which the goal is to keep the patient and the environment dry. Table 59-10 summarizes these interventions. The patient-dependent interventions generally involve the patient's continuous, self-monitoring use of a record such as the one depicted in Figure 59-3. In several studies, behavioral therapies have been shown to be equivalent to drug therapy, with approximately three-fourths of patients reporting improvement. Frequently, these behavioral interventions are a preferred treatment modality by the patients.

To be successful, patient-dependent interventions require a functional, motivated patient capable of learning and practice. These interventions also require a skilled, enthusiastic trainer and frequent patient contact, though positive results can be achieved by motivated patients who are self-directing their behavioral treatment with assistance of a pamphlet or book. Pelvic floor muscle (Kegel) exercises can be effective in men and women for the treatment of urge, stress, mixed stress–urge incontinence, and incontinence following prostatectomy. These exercises consist of repetitive contractions of the pelvic floor muscles. These exercises can be taught by brief verbal or written instructions, or instruction provided by having a patient squeeze the examiner's inserted finger during a vaginal or rectal examination (without doing a Valsalva maneuver, which is opposite

**TABLE 59-8****Treatment Options for Geriatric Urinary Incontinence***Behavioral Interventions* (see Table 59-10)

## Patient-dependent

- Pelvic muscle exercises
- Bladder training
- Bladder retraining
- Adjunctive techniques
  - Biofeedback
  - Electrical stimulation
  - Vaginal cones

## Caregiver dependent

- Scheduled toileting
- Habit training
- Prompted voiding

*Drugs* (see Table 59-12)

- Bladder relaxants
- Alpha agonists
- Alpha antagonists
- Estrogen
- Periurethral Injections

*Surgery*

- Bladder neck suspension (retropubic suspension or sling procedure)
- Removal of obstruction or pathologic lesion
- Sacral neuromodulation

*Mechanical Devices*

- Urethral plugs
- Artificial sphincters
- External penile clamps

*Nonspecific Supportive Measures*

- Education
- Modifications of medication intake
- Avoid caffeine
- Use of toilet substitutes
- Environmental manipulations
- Garments and pads

*Catheters*

- External
- Intermittent
- Indwelling

*Adapted from Kane RL, Ouslander JG, Itamar B, et al. Essentials of Clinical Geriatrics. 5th ed. New York, New York: McGraw-Hill; 2003.*

of the intended effect). Once learned, the exercises should be practiced many times throughout the day (e.g., three sets of 15–20 contractions building up from 3 seconds to 10 seconds in duration). Computer-assisted or manual biofeedback can be especially helpful for teaching patients who bear down (increasing intra-abdominal pressure) when attempting to contract pelvic floor muscles. Biofeedback involves the use of bladder, rectal, or vaginal pressure or electrical activity recordings, or the examiner's finger in the vagina or rectum with a hand placed on the abdomen, to train patients to contract pelvic floor muscles while leaving the abdominal muscles relaxed. Electrical stimulation, introduced either vaginally or rectally, and magnetic stimulation have also been used to help identify and train muscles in the management of stress incontinence and inhibit involuntary bladder contractions in patients with urge incontinence. The applicability of pelvic floor electrical or magnetic stimulation is somewhat limited because of equipment needs and that it may not be acceptable to many older patients in the United States.

**TABLE 59-9****Primary Treatments for Different Types of Geriatric Urinary Incontinence**

TYPE OF INCONTINENCE	PRIMARY TREATMENTS
Stress	Pelvic muscle (Kegel) exercises Other behavioral interventions Alpha adrenergic agonists (none are approved for use in the United States) Periurethral injections Surgical bladder neck suspension
Urge	Bladder training Bladder relaxants
Functional	Behavioral interventions (caregiver dependent) Environmental manipulations Incontinence undergarments and pads
High postvoid residual	Surgical removal of obstruction Intermittent catheterization (if practical) Indwelling catheterization

*Adapted from Kane RL, Ouslander JG, Itamar B, et al. Essentials of Clinical Geriatrics. 5th ed. New York, New York: McGraw-Hill; 2003.*

Once these muscles are strengthened, and better muscle control is achieved, the patient must be taught to use the exercises in everyday life under circumstances that precipitate the incontinence in order for them to be effective. A pelvic floor muscle contraction can be done coincidence with a cough, laugh, or sneeze to assist with stress incontinence; and used in rapid serial contractions to abort detrusor contractions associated with urinary urgency. Pelvic floor muscle exercises have also been shown to be effective in certain situations to prevent urinary incontinence and, if done preoperatively, will allow a more rapid return to continence in the postoperative period.

Other forms of patient-dependent interventions include bladder training and bladder retraining. Bladder training involves the educational components taught during biofeedback, without the use of biofeedback equipment. Patients are taught pelvic muscle exercises and strategies to manage urgency and are taught to use bladder records regularly. There is some evidence that these techniques are as effective as biofeedback in a selected group of cognitively intact, motivated elderly patients. Bladder retraining as described here is used primarily after a period of temporary bladder catheterization. Table 59-11 is an example of a bladder-retraining protocol. This protocol is applicable to patients who have had an indwelling catheter for monitoring of urinary output during a period of acute illness or for treatment of urinary retention with overflow incontinence. Such catheters always should be removed as soon as possible, and this type of bladder-retraining protocol should enable most indwelling catheters to be removed from patients in acute care hospitals as well as some residents in long-term care settings. A patient who continues to have difficulty voiding after 1 to 2 weeks of such a bladder-retraining protocol should be examined for other potentially reversible causes of voiding difficulties. When difficulties persist, a urologic referral should be considered to rule out correctable lower genitourinary pathologic conditions.

The goal of caregiver-dependent intervention such as scheduled toileting, habit training, and prompted voiding is to prevent incontinence episodes rather than to restore a normal pattern of voiding and complete continence. Highly motivated caregivers and cooperative

TABLE 59-10

## Examples of Behavioral Interventions for Urinary Incontinence

PROCEDURE	DEFINITION	TYPES OF INCONTINENCE	COMMENTS
<i>Patient-Dependent</i>			
Pelvic floor muscle (Kegel) exercises	Repetitive contraction and relaxation of pelvic floor muscles with use in everyday situations that precipitate leakage	Stress and urge	Requires adequate function and motivation; biofeedback often helpful for teaching
Bladder training	Use of education, bladder records, pelvic muscle, and other behavioral techniques	Stress and urge	Requires trained therapist, adequate cognitive and physical functioning, and motivation
Bladder retraining	Progressive lengthening or shortening of intervoiding interval, with intermittent catheterization used in patients recovering from overdistension injuries with persistent retention	Acute (e.g., postcatheterization with urge or overflow, poststroke)	Goal is to restore normal pattern of voiding and continence; requires adequate cognitive and physical function and motivation
<i>Caregiver-Dependent</i>			
Scheduled toileting	Routine toileting at regular intervals (scheduled toileting)	Urge and functional	Goal is to prevent wetting episodes; can be used in patients with impaired cognitive or physical functioning; requires staff or caregiver availability and motivation
Habit training	Variable toileting schedule based on patient's voiding patterns	Urge and functional	Goal is to prevent wetting episodes; can be used in patients with impaired cognitive or physical functioning; requires staff or caregiver availability and motivation
Prompted voiding	Offer opportunity to toilet every 2 hours during the day; toilet only on request; social reinforcement; routine offering of fluids	Urge, stress, mixed, functional	Same as above; 25–40% of nursing home residents respond well during the day, and can be identified during a 3-day trial

Adapted from Kane RL, Ouslander JG, Itamar B, et al. *Essentials of Clinical Geriatrics*. 5th ed. New York, New York: McGraw-Hill; 2003.

patients are essential for these interventions to be successful on an ongoing basis. Scheduled toileting involves putting the patient on the toilet at regular intervals, usually every 2 hours during the day and every 4 hours during the evening and night regardless of the presence or absence of the patient's expressed desire to void. Habit training involves a schedule of toileting that is individually modified according to the patient's pattern of continent voids and incontinence episodes. *Prompted voiding* is a behavioral protocol that involves focusing the patient's attention on his or her bladder by asking if the patient is wet or dry, asking (prompting) the patient to attempt to void (up to three times) every 2 hours during the day, toileting the patient if he or she responds positively, giving personal interaction as a social reward for attempting to toilet and maintaining continence, and offering fluids routinely. Between 25% and 40% of nursing home residents respond very well to daytime prompted voiding, and these responders can be identified by carrying out a 3-day trial of the intervention. Care for incontinence at night should be individualized. Routine incontinence care can be very disruptive to sleep. Because older people tend to awaken frequently at night, one way to individualize toileting is to check on the patient every hour or two, and only prompt to toilet when the patient is found awake.

## Drug Treatment

Table 59-12 lists the drugs used to treat incontinence. Better data for efficacy in older patients are now available for some drugs. In general, carefully selected older research participants have been able to achieve roughly equivalent efficacy from drug treatment compared to their younger counterparts. Drug treatment should generally be prescribed in conjunction with one or more behavioral interventions.

For urge incontinence, antimuscarinic drugs with anticholinergic and bladder smooth-muscle relaxant properties are used. These drugs are available in immediate release, controlled release, and topical preparations. Most studies suggest a reduction of 60% to 70% in the frequency of incontinence episodes with drug therapy in selected older adults. While different drugs are likely equivalent on average, a particular patient who does not respond to one drug (either because of lack of efficacy or presence of adverse effects) may benefit from a trial on a different agent within the category. These drugs may have bothersome systemic anticholinergic side effects, especially dry mouth and constipation. They should be used carefully in patients with glaucoma and severe gastroesophageal reflux. Antimuscarinic agents may rarely precipitate urinary retention in some patients; men with some degree of outflow obstruction, diabetic patients, and patients with impaired bladder contractility are at the highest risk and should be followed carefully. For older men with overactive bladder symptoms (with or without urinary incontinence), alpha adrenergic antagonists may likely be a better choice for first-line drug therapy. Antimuscarinic bladder relaxants may also be used as single drug therapy in men, and the combination of an antimuscarinic and an alpha antagonist may be more effective in many older men. Patients with Alzheimer's disease must be followed for the development of drug-induced delirium when placed on antimuscarinic medications because of their anticholinergic effects, although it is unusual. Studies suggest that cognitive impairment, especially of memory and learning are associated antimuscarinic drug therapy. The results of these studies should not, however, preclude a treatment trial in this patient population when they make frequent attempts to toilet yet remain incontinent. The use of long-acting antimuscarinic drugs for urge incontinence has become commonplace, but it is

TABLE 59-11

## Example of a Bladder-Retraining Protocol

**Objective:** To restore a normal pattern of voiding and continence after the removal of an indwelling catheter.

1. Remove the indwelling catheter (clamping the catheter before removal is not necessary)
2. Treat urinary tract infection if present
3. Initiate a toileting schedule. Begin by toileting the patient:
  - a. Upon awakening
  - b. Every 2 hours during the day and evening
  - c. Before getting into bed
  - d. Every 4 hours at night
4. Monitor the patient's voiding and continence pattern with a record that allows for the recording of:
  - a. Frequency, timing, and amount of continent voids
  - b. Frequency, timing, and amount of incontinence episodes
  - c. Fluid intake pattern
  - d. Postvoid catheter volume
5. If the patient is having difficulty voiding (complete urinary retention or very low urine outputs, e.g.,  $\leq 240$  mL in an 8-hour period while fluid intake is adequate):
  - a. Perform bladder ultrasonography or in-and-out catheterization, recording volume obtained, every 6 to 8 hours until residual values are  $\leq 200$  mL
  - b. Instruct the patient on techniques to trigger voiding (e.g., running water, stroking inner thigh, suprapubic tapping) and to help completely empty bladder (e.g., bending forward, suprapubic pressure, double voiding)
  - c. If the patient continues to have high residual volumes after 3 to 4 weeks, consider urodynamic evaluation
6. If the patient is voiding frequently (i.e., more often than every 2 hours):
  - a. Perform postvoid residual determination to ensure the patient is completely emptying the bladder
  - b. Encourage the patient to delay voiding as long as possible and instruct the patient to use techniques to help completely empty bladder
  - c. If the patient continues to have frequency and nocturia, with or without urgency and incontinence:
    - (1) Rule out other reversible causes (e.g., urinary tract infection medication effects, hyperglycemia, and congestive heart failure)
    - (2) Consider trial of bladder relaxant if postvoid residuals are low

*Adapted from Kane RL, Ouslander JG, Itamar B, et al. Essentials of Clinical Geriatrics. 5th ed. New York, New York: McGraw-Hill; 2003.*

important to recognize that the cheaper, immediate release preparations are equally efficacious, but require more frequent dosing and have a higher incidence of bothersome side effects (particularly dry mouth).

Drug treatment for stress incontinence is less efficacious than is drug treatment for urge incontinence, and no drug is approved for this indication in the United States. Stress incontinence drug treatment involves a combination of an alpha agonist and topical estrogen therapy (in women). Pseudoephedrine is now the most commonly used oral agent for stress incontinence. Duloxetine, a drug approved for depression in the United States, also has alpha adrenergic effects on the lower urinary tract through a spinal cord mechanism, and is approved for the treatment of stress incontinence in several countries. Drug treatment is appropriate for motivated patients who (1) have mild to moderate degrees of stress incontinence, (2) do not have a major anatomic abnormality such as a large cystocele, and

(3) do not have a contraindication to alpha agonists drug therapy, such as poorly controlled hypertension. Previous data on the use of oral estrogen for urinary incontinence, using hormonal replacement dosages, had shown equivocal benefits. More recent studies have shown, for either opposed or unopposed oral conjugated estrogen therapy, an increased risk for previously continent women of developing and worsening of incontinence. Other forms of oral estrogen (estradiol) and topical estrogen are still used, either chronically or on an intermittent basis (i.e., 1- to 2-month courses), and may be effective for the treatment of irritative voiding symptoms and urge incontinence in women with atrophic vaginitis and urethritis. Although no specific topical treatment regimen has been shown to be more effective than others, therapy usually involves 0.5 to 1 g of vaginal cream nightly for 1 to 2 months and then a maintenance dose two or three times per week or a controlled, slow-release vaginal ring. Several months of therapy are often necessary to observe therapeutic benefit.

Many elderly women have symptomatically and urodynamically a combination of both urge and stress incontinence. If urge incontinence is the predominant symptom, a combination of estrogen and bladder relaxant would be appropriate. Behavioral interventions are also an effective approach for women with mixed incontinence.

Drug treatment in the setting of chronic urinary retention or urinary incontinence with high postvoid residual, with either a cholinergic agonist or an alpha adrenergic antagonist, is usually not efficacious. Although alpha adrenergic blockers and 5-alpha reductase inhibitors are useful for treatment of symptoms suggestive of benign prostatic hyperplasia, they may not obviate the need for surgical intervention or requirement for catheter drainage in patients with bladder outlet obstruction who have chronic urinary retention or urinary incontinence with high postvoid residuals (i.e., residuals consistently greater than 200–300 mL).

## Surgical Approaches

Surgery is a well-established treatment for stress urinary incontinence. Surgery should be considered for elderly women with stress incontinence and for women with a significant degree of pelvic prolapse associated with stress incontinence or incontinence with urinary retention who are unresponsive to nonsurgical treatment. As with many other surgical procedures, patient selection and the experience of the surgeon are critical to success. Any woman being considered for surgical therapy should have a thorough evaluation, including urodynamic tests, before undergoing the procedure. In general, surgical treatment is designed to correct urethral closure problems and to remedy defects in support of the urethra-vesicular angle. Newly modified techniques of bladder neck suspension, tension-free vaginal tapes, and the use of periurethral collagen injections can be done with minimal risks. Periurethral injections appear to be most appropriate for women with intrinsic urethral weakness. Two or more sessions of injections are usually necessary to maintain effectiveness. Many elderly women with severe incontinence associated with intrinsic urethral weakness require a sling procedure rather than a simple bladder neck suspension. Men with stress urinary incontinence (and usually with continuous urinary leakage) can be treated with the implantation of an artificial urinary sphincter (or other similar mechanical device designed to reversibly block urine outflow in the penile urethra). Newer "sling" procedures have been used in men, also.

TABLE 59-12

## Drugs Commonly Used in the United States To Treat Urinary Incontinence

DRUGS	DOSAGES	MECHANISMS OF ACTION	TYPE OF INCONTINENCE	POTENTIAL ADVERSE EFFECTS
Antimuscarinic and antispasmodic agents	In general, reduced dosages for renal and hepatic impairment			
Oxybutynin (Ditropan, immediate release, available as generic)	2.5–5.0 mg tid	Increase bladder capacity; diminish involuntary bladder contractions	Urge or mixed with urge predominant	Anticholinergic (dry mouth, blurry vision, elevated intraocular pressure, delirium, constipation)
Darifenacin (Enablex)	7.5–15 mg qd			Anticholinergic, lower dose if reduced hepatic function
Oxybutynin (extended release) (Ditropan XL)	5–30 mg qd (most often 10 mg qd)			Above, but with less dry mouth
Patch (Oxytrol)	3.9 mg qd	Patch applied twice weekly		
Solifenacin (Vesicare)	5–10 mg qd			Anticholinergic, lower for severe renal impairment or reduced hepatic function
Tolterodine (Detrol LA)	4 mg qd			Above, but with less dry mouth
Trospium chloride (Sanctura)	20 mg bid			20 mg once daily qhs with severe renal impairment
Alpha adrenergic agonists				
Pseudoephedrine (Sudafed)	30–60 mg tid	Increase urethral smooth-muscle contraction		Headache, tachycardia, elevation of blood pressure
Estrogens				
Topical	0.5–1.0 g per application	Strengthen periurethral tissues	Urge associated with atrophic vaginitis	
Vaginal ring (Estring) (estradiol acetate)	One ring every 3 months			
Alpha adrenergic antagonist				
Doxazosin (available as generic, or Cardura)	1–8 mg qhs	Relax smooth muscle of urethra and prostatic capsule	Urge incontinence associated with prostatic enlargement	Postural hypotension, dizziness, lowers blood pressure
Terazosin (available as generic, or Hytrin)	1–10 mg qhs			Same as above
Prazosin (Minipress)	1–2 mg tid			Same as above
Alfuzosin (Uroxatral)	10 mg qhs			Less effects on blood pressure
Tamsulosin (Flomax)	0.4–0.8 mg qd			Less effects on blood pressure (when used at 0.8 mg dose, greater blood pressure effects)

Adapted from Kane RL, Ouslander JG, Itamar B, et al. *Essentials of Clinical Geriatrics*. 5th ed. New York, New York: McGraw-Hill; 2004.

While surgical approaches have previously been considered only for stress incontinence, there are recently developed approaches for the treatment of urge incontinence that remains unresponsive to medical and behavioral treatment. Newer approaches include sacral nerve neuromodulation, where a two-stage operation involving general anesthesia and implantation of a pacemaker-like generator near the hip and sacral leads to stimulate the pudendal and sacral nerves. The procedure can be a safe, effective, and durable treatment, though cure rates for older adults and those with multiple medical comorbidities have been lower than in younger, healthier populations. Also, the use of botulinum toxin A for refractory urge incontinence has proven effective in several randomized, double-blinded, controlled studies, though this indication has not yet been approved by the U.S. Food and Drug Administration. Botulinum toxin A is accomplished via cystoscopic injections into multiple bladder sites under

direct visualization. Benefit is believed to be because of an effect on both efferent and afferent pathways, and early trial results suggest that the therapy lasts 6 months and is equally effective in older and younger age groups.

Surgery may be indicated in men in whom incontinence is associated with outflow obstruction. Men may have either chronic urinary retention, or acute urinary retention that is *precipitated* (use of an anticholinergic drug, recent instrumentation, or alpha agonist drug) or *spontaneous*. Those who have had complete acute urinary retention requiring mechanical drainage, and particularly those with *spontaneous* retention, are likely to have another episode within a short period of time and should be evaluated for a prostatic resection, as should men with incontinence associated with enough residual urine to be causing recurrent symptomatic infections or hydronephrosis. In men who do not meet these criteria, the decision should be based

on weighing carefully the degree to which the symptoms bother the patient, the potential benefits of surgery (obstructive symptoms often respond better than irritative symptoms), and the risks of surgery (which may be minimal with newer prostate resection techniques).

## MECHANICAL DEVICES, UNDERGARMENTS, CATHETERS, AND OTHER SUPPORTS

Three basic types of catheters and catheterization procedures are used for the management of urinary incontinence: external catheters, intermittent straight (“in-and-out”) catheterization, and chronic indwelling catheterization. External catheters generally consist of some type of condom connected to a drainage system. Improvements in design and observance of proper procedure and skin care when applying the catheter decrease the risk of skin irritation, as well as the frequency with which the catheter falls off. Existing data suggest that patients with external catheters are at increased risk of developing symptomatic infection compared to incontinent adults depending upon absorbent pads or diapers. External catheters should be used only to manage intractable incontinence in male patients who do not have urinary retention and who are extremely physically dependent. An external catheter for use in female patients is available commercially, but is not widely used.

Intermittent catheterization can help in the management of patients with urinary retention and overflow incontinence. The procedure can be carried out by either the patient or a caregiver and involves straight catheterization two to four or more times daily, depending on residual urine volumes. The goal is to keep residual urine volume generally less than approximately 300 to 400 mL. In the home setting, the catheter should be kept clean (but not necessarily sterile). Studies conducted largely among younger paraplegic patients show that this technique is practical and reduces the risk of symptomatic infection compared with the risk associated with chronic catheterization. Self-intermittent catheterization is also feasible for elderly female outpatients who are functional and willing and able to catheterize themselves. The technique may be especially useful following removal of an indwelling catheter in a bladder-retraining protocol (see Table 59-11). However, elderly nursing home residents, especially men, may be difficult to catheterize. Anatomic abnormalities commonly found in the lower urinary tracts of elderly patients may increase the risk of infection because of repeated straight catheterizations. In addition, using this technique in an institutional setting, which may have an abundance of organisms relatively resistant to many commonly used antimicrobial agents, may yield an unacceptable risk of nosocomial infections. Using sterile catheter trays for these procedures would be very expensive. Thus, it may be extremely difficult to implement such a program in a typical nursing home setting.

Chronic indwelling catheterization, when used for periods of months to years, has been shown to increase the incidence of a number of complications, including chronic bacteriuria, bladder stones, periurethral abscesses, and even bladder cancer. Elderly nursing home residents managed by this technique, especially men, are at relatively high risk of developing symptomatic infections. The limited evidence available to date does not suggest that routine changing of indwelling catheters is warranted, though this is a common practice. Given these risks, it seems appropriate to recommend that the use of chronic indwelling catheters be limited to certain specific situations

**TABLE 59-13**

### Indications for Chronic Indwelling Catheter Use

Urinary retention that
Is causing persistent overflow incontinence, symptomatic infections, or renal dysfunction
Cannot be corrected surgically or medically
Cannot be managed practically with intermittent catheterization
Skin wounds, pressure sores, or irritations where incontinent urine contributes to excessive moisture and results in poor healing
Care of terminally ill or severely impaired for whom bed and clothing changes are uncomfortable or disruptive
Patient preference

*Adapted from Kane RL, Ouslander JG, Itamar B, et al. Essentials of Clinical Geriatrics. 5th ed. New York, New York: McGraw-Hill; 2004.*

(Table 59-13). When indwelling catheterization is used, certain principles of catheter care should be observed in an attempt to minimize complications (Table 59-14). In situations where there is reduced urinary output, increased leakage around the catheter, or increased pain, it is important to perform an abdominal and genital examination to make certain the catheter is in the bladder and not obstructed. In these situations, it is often necessary to replace the catheter.

In men with postprostatectomy urinary incontinence who are not a candidate for or do not desire surgical therapy, an external penile clamp for compression of the urethra may be a useful adjunctive therapy. Patients must be able to monitor and remove the clamp every two hours. Some women with urinary incontinence and pelvic prolapse may respond well to use of a vaginal pessary, which is a device to slow the progression of prolapse by adding support to the

**TABLE 59-14**

### Key Principles of Chronic Indwelling Catheter Care

#### SUMMARY OF MAJOR RECOMMENDATIONS

<i>Category I. Strongly Recommended for Adoption</i>
Educate personnel in correct techniques of catheter insertion and care
Catheterize only when necessary
Emphasize hand washing
Insert catheter using aseptic technique and sterile equipment
Secure catheter properly
Maintain closed sterile drainage
Obtain urine samples aseptically
Maintain unobstructed urine flow
<i>Category II. Moderately Recommended for Adoption</i>
Periodically re-educate personnel in catheter care
Use smallest suitable bore catheter
Avoid irrigation unless needed to prevent or relieve obstruction
Refrain from daily meatal care with povidone-iodine solution as this may result in an increased infection rate
Do not change catheters at arbitrary fixed intervals
<i>Category III. Weakly Recommended for Adoption</i>
Consider alternative techniques of urinary drainage before using an indwelling urethral catheter
Replace the collecting system when sterile closed drainage has been violated
Spatially separate infected and uninfected patients with indwelling catheters
Avoid routine bacteriologic monitoring

*Wong ES, Hooton TM. Guideline for prevention of catheter-associated urinary tract infections. [http://www.cdc.gov/ncidod/dhqp/gl\\_catheter\\_assoc.html](http://www.cdc.gov/ncidod/dhqp/gl_catheter_assoc.html). Accessed March 22, 2007.*

vagina and increasing tightness of the tissues and muscles of the pelvis. Pessaries are made of rubber, plastic, or silicone, and come in a variety of types. Conclusive trials about which devices are better than others, or how well the devices compare to other treatments have not yet been reported. The ideal device would be easy to insert, be of low cost, have few adverse effects, and would control leakage. Often patients need to be individually fitted with the device.

There are a variety of available absorbent products and undergarments that can help patients contain leakage, including disposable inserts, reusable and single-use adult diapers, and disposable underwear. Additionally, there are pads that can protect beds and/or chairs. Controlled studies have been performed comparing one type to another, and criteria for success of these devices revolve around fit, odor control, cost, and ability to hold urine. More frequent changing of pads is expensive and inconvenient, but frequently helps control odor. Less frequent changing leaves skin wetter and likely more vulnerable to friction and abrasion. Most consumers select products by trial and error and are unaware of the range of products and services available. These products are available at drug stores, supermarkets, and medical supply stores.

In general, older adults want general information on urinary incontinence and sources of help. There are multiple consumer advocacy groups for those with incontinence that are dedicated to improving the lives of patients with urinary incontinence, e.g., the National Association for Continence ([www.nafc.org](http://www.nafc.org)), and the Simon Foundation ([www.simonfoundation.org](http://www.simonfoundation.org)) that provide educational materials, reviews of available products, and links to researchers and manufacturers who provide incontinence materials.

## FECAL INCONTINENCE

Fecal incontinence is less common than urinary incontinence. Its occurrence is relatively unusual in elderly patients who are continent of urine. Thirty to fifty percent of elderly patients in institutional settings with frequent urinary incontinence, however, also have episodes of fecal incontinence. This coexistence suggests common pathophysiologic mechanisms.

Defecation, like urination, is a physiologic process that involves smooth and striated muscles, central and peripheral innervation, coordination of reflex responses, mental awareness, and physical ability to get to a toilet. Disruption of any of these factors can lead to fecal incontinence.

The most common causes of fecal incontinence are problems with constipation and laxative use, neurologic disorders, and colorectal disorders (Table 59-15). In patients who are fed by enteral tubes, hyperosmotic feedings can precipitate diarrhea and fecal incontinence. Diluting the feedings or using slow continuous infusion is sometimes helpful. Constipation is extremely common in elderly persons and, when chronic, can lead to fecal impaction and incontinence. The hard stool (or scybalum) of fecal impaction irritates the rectum and results in the production of mucus and fluid. This fluid leaks around the mass of impacted stool and precipitates incontinence. Constipation is difficult to define; technically, it indicates fewer than three bowel movements per week, although many patients use the term to describe difficult passage of hard stools or a feeling of incomplete evacuation. Poor dietary and toilet habits, immobility, and chronic laxative abuse are the most common causes of constipation in elderly persons. Appropriate management of constipation prevents

**TABLE 59-15**

### Causes of Fecal Incontinence

Fecal impaction
Constipation
Laxative overuse or abuse
Hyperosmotic enteral feedings
Neurologic disorders
Dementia
Stroke
Spinal cord disease
Colorectal disorders
Diarrheal illnesses
Diabetic autonomic neuropathy
Rectal sphincter damage

fecal impaction and resulting fecal incontinence. The management of constipation is discussed thoroughly in Chapter 93.

Fecal incontinence is sometimes amenable to biofeedback therapy, although many elderly demented patients are unable to cooperate. For those patients with end-stage dementia, a program of alternating constipating agents (if necessary) and laxatives in a routine schedule (such as giving laxatives and enemas three times a week) is effective in controlling defecation in many patients with fecal incontinence. Functionally dependent patients should be toilet-ed regularly after a meal to take advantage of, or possibly regain, the gastrocolic reflex. Experience suggests that these measures should permit management of even severely cognitively impaired patients. As a last resort, specially designed incontinence undergarments are sometimes helpful in managing fecal incontinence and preventing skin irritation and other complications.

# Elder Mistreatment

Mark S. Lachs

## DEFINITIONS

In the broadest context, *elder mistreatment* subsumes a variety of activities perpetrated upon an older person by others. Some proposed strategies for defining or classifying elder mistreatment have been based on the type of abuse (e.g., physical vs. verbal abuse), motive (e.g., intentional vs. unintentional neglect), perpetrator relationship (e.g., family vs. paid caregiver), and setting (e.g., community vs. nursing home). There is as yet no universally agreed definition or classification of elder mistreatment. Nonetheless, the clinician attempting to care for a victimized older person or to understand the spectrum of elder mistreatment will encounter several thematically similar definitions. For example, the older Americans Act of 1975 defines elder abuse as “the willful infliction of pain, injury, or mental anguish.” This definition has been adopted, and/or modified, by many state protective service agencies that investigate cases of abuse. A more recent and encompassing definition created by an expert panel convened by the National Academy of Sciences adopted the definition that elder mistreatment in all its forms involves *a trusting relationship between an older person and another individual in which that trust is violated in some way*. Table 60-1 lists other representative definitions and examples of elder mistreatment. Whatever definition is employed, a consistent and important feature of elder mistreatment, and other forms of family violence, is that multiple types of mistreatment, such as physical and verbal abuse, neglect, and financial exploitation frequently coexist in the same abuser–victim dyad.

Virtually all experts, clinicians, and reasonable laypersons will agree that egregious instances of physical violence such as punching, hitting, slapping, or assaulting an older person with a gun or other weapon are elder abuse. The most contentious definitional (and clinical) area relates to elder neglect, because the term neglect immediately implies that a caregiving obligation—such as providing food, medicines, or care—has not been met. This, in turn, raises difficult questions that must, with clinical judgment and experience, be considered in the context of the older adult’s environment. For ex-

ample, what are reasonable community standards for the frequency of bathing an assaultive spouse with Alzheimer’s disease? Does that standard change if the designated caregiver also suffers from chronic diseases that preclude perfect hygiene for their impaired family member? What if this inadequate care enables the “victim” to live at home long after other families would have considered nursing home placement? Who exactly is the responsible caretaker, especially when multiple adult children are available to assume that role, but only one has “stepped up” because of birth order or some other arbitrary circumstance? And is it fair to label that adult child an “elder neglector” when caregiving becomes physically or psychologically impossible?

These difficult questions also highlight the fact that clinicians caring for elder abuse victims often find themselves working closely with alleged perpetrators of abuse and neglect, as these individuals are often the primary caregivers.

## EPIDEMIOLOGY

However it is defined, elder mistreatment is common. Over the past 15 years, several prevalence studies have been conducted in different countries. These studies have used primarily self-report for case finding and validated family violence scales for case definition (typically an adopted version of the conflicts tactics scale, a common employed instrument used in all forms of family violence). The methodology assumes that all families have conflict, and that it is how that conflict is addressed or resolved that is the measurable and relevant aspect of mistreatment. Using this methodology, Pillemer and Finkelhor conducted the most commonly cited study in the United States. Surveying residents of metropolitan Boston by telephone, the investigators calculated a prevalence of 32 per 1000 population (i.e., 3.2% of the 2010 individuals surveyed reported having been victims of elder mistreatment at least once since turning age 65 years). In this study, cases of abuse exceeded cases of neglect. In the subsequent 20 years that have followed, most studies in western societies have

**TABLE 60-1****Representative Definitions of Elder Mistreatment**

<b>MISTREATMENT CATEGORY</b>	<b>DEFINITION</b>	<b>EXAMPLES</b>
Physical abuse	Acts of violence that may result in pain, injury, impairment, or disease	? Pushing, striking, slapping, force-feeding ? Incorrect positioning ? Improper use of restraints or medications ? Sexual coercion or assault
Neglect	The failure to provide the goods or services necessary for optimal functioning or to avoid harm	? Withholding of health maintenance care ? Failure to provide physical aids such as eyeglasses, hearing aids, false teeth ? Failure to provide safety precautions
Financial or material abuse	The misuse of the elderly person's income or resources for the financial or personal gain of a caretaker or advisor	? Denying the older person a home ? Stealing money or possessions ? Coercing the older person into signing contracts
Psychological or verbal abuse	Conduct that causes mental anguish	? Verbal berating, harassment, or intimidation ? Threats of punishment or deprivation ? Treating the older person like an infant ? Isolating the older person from others
Violation of a trusting relationship	Meant to encompass all forms of abuse in that all forms involve the older person relying on and trusting another party, who through acts of omission or commission, violates that trust, without regard to intent.	

Data from Aravanis SC, Adelman RD, Breckman D, et al. Diagnostic and treatment guidelines on elder abuse and neglect. *Archives of Family Medicine* 1993;2:371.

produced a remarkably stable and similar prevalence in the 2% to 5% range. Recently, the World Health Organization has embarked on a coordinated series of studies addressing prevalence and screening across several countries. This effort indicates growing worldwide interest in elder abuse.

A less-consistent epidemiologic picture emerges when one attempts to discern risk factors for elder mistreatment from the literature (Table 60-2). The most consistent findings relate to the relationship of the abuser to victim; most studies report that spouses and adult children are the most common perpetrators. Studies also show that when adult children are the abusers, sons and daughters are often equally implicated. At least one study found daughters to be the more common abuser. These findings must be viewed cautiously in that women are far more likely to be the de facto or designated care providers to frail older adults and are, therefore, more "at risk" for being accused of mistreatment should caregiving fall short of any arbitrary standard.

The most discordant literature is in the area of victim risk factors. Here the literature has produced inconsistent findings with respect to gender, functional disability, cognitive impairment, social network, and a variety of other factors proffered by elder abuse theorists. A particularly contentious area has been spawned by the "dependency theory" of mistreatment, which holds that mistreatment occurs when the victim becomes inordinately dependent upon the caregiver for a variety of medical and nonmedical needs. Again, studies show an inconsistent relationship between functional disability and elder mistreatment. In fact, a more consistent finding in the literature is the converse—the perpetrators are often dependent upon the victims for financial support and housing. Characteristically, an adult child unable to achieve independence is reliant on the older person for these needs.

The disparate findings probably derive from two major factors. The first is the methodologic quality of the studies, which have been highly variable and rife with susceptibility and other biases. The

**TABLE 60-2****Possible Risk Factors for Elder Mistreatment**

<b>FACTOR</b>	<b>MECHANISM</b>
Victim's poor health and functional disability	Disability reduces elder's ability to seek help and/or defend self.
Cognitive impairment	Aggression toward caregiver and disruptive behaviors resulting from dementia precipitate abuse. Higher rates of abuse have been found among patients with dementia.
Abuser deviance	Abusers likely to abuse alcohol or drugs and to have serious mental illness, which, in turn, leads to abusive behavior.
Abuser dependency	Abusers are very likely to depend on the victim financially, for housing, and in other areas. Abuse results from relative's (especially adult children's) attempts to obtain resources from the elder.
Living arrangement	Abuse much less likely among elders living alone. A shared living situation provides greater opportunities for tension and conflict that generally precede abusive incidents.
External stress	Stressful life events and chronic financial strain decrease the family's resistance and increase likelihood of abuse.
Social isolation	Elders with fewer social contacts more likely to be victims.  Isolation reduces the likelihood that abuse will be detected and stopped. In addition, social support can buffer against the impact of stress.
History of violence	Particularly among spouses, prior history of violence in the relationship may be predictive of elder abuse in later life.

Reprinted with permission from Lachs MS, Pillemer K. Current concepts: abuse and neglect of elderly persons. *N Engl J Med*. 1995;332:437.

second relates to the heterogeneous nature of elder abuse cases. Elderly protective services workers and clinicians experienced in elder mistreatment know that the term elder mistreatment subsumes many situations—abusive spousal relationships that have “aged,” caregivers to dementia patients who lash out in frustration, and physically abusive adult children with poorly managed mental health or substance abuse problems, are but a few examples. Epidemiologic studies that attempt to discern risk factors without acknowledging this reality probably are measuring an “average” effect, thus possibly missing important sets of risk factors among subgroups of abused or neglected elderly populations.

Whatever risk factors are identified in previous and future research should not foster a complacency wherein an absence or paucity of such factors causes the clinician to lower his or her guard. Elder mistreatment crosses all ethnic and socioeconomic boundaries. A high index of clinical suspicion is paramount for identification.

## PATHOPHYSIOLOGY

Theories of elder mistreatment abound; three deserve detailed treatment here, because they may have clinical relevance with regard to the types of interventions contemplated in confirmed cases of mistreatment. The most commonly cited theory contends that family violence is a learned behavior; abused children grow up to potentially abuse not only their children, but also perhaps spouses and their parents. This is sometimes referred to as the transgenerational violence theory of mistreatment.

The dependency theory of mistreatment holds that abuse is fostered by situations in which victims have a degree of functional and/or cognitive disability that results in activities of daily living impairment and overwhelming care needs. Closely associated with this paradigm is another theory—that of the “stressed caregiver.”

The psychopathology of the abuser theory shifts focus away from the victim and argues that elder mistreatment is firmly rooted in mental health problems of the abuser. Examples include personality disorders, poorly or undertreated schizophrenia, alcoholism, and other substance abuse problems.

Discerning the underlying causes of elder mistreatment is essential in fashioning an intervention plan (see “Management” later in this chapter).

## PRESENTATION

For a variety of reasons, the identification of elder mistreatment is one of the most difficult clinical challenges in geriatric medicine. First, many highly prevalent chronic diseases in older adults may have clinical manifestations that mimic abuse. If elder abuse is present, the clinician may ascribe those findings to chronic disease rather than family violence. Conversely, the clinician may erroneously attribute findings from another disease to elder mistreatment. Second, the setting in which an elder mistreatment evaluation occurs is often quite challenging. The environment may be hurried (e.g., the emergency department). The presence of the suspected abuser only adds pressure to what is already likely to be a stressful encounter. Lastly, the competent identification and management of mistreatment propel the clinician into a world that he or she is likely to be unfamiliar with—a world that includes mandatory reporting statutes, adult protective service workers, and a criminal justice system with a vo-

cabulary that is foreign to many medical professionals. Given these educational, emotional, and systemic obstacles, it is not surprising that elder mistreatment often is missed or unreported in the context of “customary care.”

Elder abuse forensics is a recent area of intense interest. Of particular interest has been whether there are diagnostic and/or clinical signs and symptoms of abuse presentations, either during life or at autopsy that enables clinicians to opine definitively that abuse exists as in cases of child abuse (e.g., shaken baby syndrome). So far such studies have not been fruitful. For example, one group of investigators undertook a detailed longitudinal study of spontaneous bruising in older people; observers could not accurately date bruises by color (a long held belief in elder abuse evaluation). Additionally, many older subjects were unaware of bruising, a good proportion of which were spontaneous. This “negative” study should not be viewed as disappointing. Such painstaking work is needed to move the field forward with scientific rigor.

Without such markers, clinicians need to consider elder mistreatment in the differential diagnosis of many or most of the clinical presentations they encounter. Fractures may result from osteoporosis or force or both. Depression may be related to neurotransmitter imbalances or a hopeless abusive environment. Malnutrition may be the result of any number of chronic illnesses inexorably worsening, or from the withholding of sustenance.

Dramatic injuries or neglect pose no particular diagnostic challenge. Fractures, burns, contusions, and lacerations, in concert with a credible history, immediately lead to the diagnosis. At the other extreme, subtle presentations that mimic chronic disease are highly challenging. Examples include chronic diseases that frequently decompensate despite a care plan and adequate resources (e.g., repeated emergency department visits for congestive heart failure or chronic obstructive pulmonary disease exacerbation). Indeed, because elder mistreatment can be defined so broadly, there are very few presenting signs or symptoms in the geriatric patient for which elder mistreatment is not in the differential diagnosis.

Many instruments have been devised for the screening or evaluation of elder mistreatment, but they are not applicable to all settings and have not been validated against an external standard. Such a standard would be difficult to create. Rather, they can serve as useful “checklists” for a thorough evaluation. [Table 60-3](#) suggests a system-by-system approach. The importance of heightened awareness cannot be overemphasized in considering the diagnosis. Frequently, clues about potential mistreatment come from ancillary staff members (e.g., office reception staff) or home care nurses who observe the abuser–victim dyad away from the health care provider. A general sense that something is amiss in the patient’s environment such as caustic interaction between parties, poor hygiene or dress, frequently missed medical appointments, or failure to adhere with a clearly designated treatment strategy can all be important clues.

The patient and the alleged perpetrator should be interviewed separately and alone. Although there is an emerging consensus that patients of all ages should be routinely screened for family violence, an optimal strategy or instrument has not emerged. Patients should be asked candidly and calmly about the etiology of any unexplained injuries or other findings. Often patients are at first unwilling to speak candidly about being an elder abuse victim for reasons of embarrassment, shame, or fear of retribution from the perpetrator who is frequently a caregiver.

Interview of the suspected abuser is a tricky and potentially dangerous undertaking. On the one extreme, elder abusers who are

**TABLE 60-3****Clinical Manifestations of Potential Mistreatment with Recommended Assessment**

TARGET	ASSESSMENT
History from elder	Interview patient alone; directly inquire regarding physical violence, restraint use, or neglect; ascertain precise details about nature, frequency and severity of events. Assess functional status (amount of dependence with activities of daily living [ADL]). Determine who the designated caregiver is if ADL disability is present.
History from abuser	Potential abuser should also be interviewed alone; this interview is best done by professionals with experience in this area; avoid confrontation in the information-gathering phase. Interview other sources if possible. Assess recent psychosocial factors (e.g., bereavement, financial stresses) Ascertain caregiver understanding of patient's illness (e.g., care needs, prognosis, etc.) Elicit caregiver's explanations for injuries or physical findings
Behavioral observation	Withdrawal Infantilizing of patient by caregiver Caregiver who insists on providing the history
General appearance	Hygiene Cleanliness and appropriateness of dress
Skin/mucous membranes	Skin turgor, other signs of dehydration; multiple skin lesions in various stages of evolution Bruises, decubiti; evidence of care for established skin lesions
Head and neck	Traumatic alopecia (distinguishable from male pattern alopecia on the basis of distribution) Scalp hematomas Lacerations, abrasions
Trunk	Bruises, welts; shape may suggest implement (e.g., iron/belt)
Genitourinary	Rectal bleeding Vaginal bleeding Decubiti, infestations
Extremities	Wrists or ankle lesions suggest restraint use or immersion burn (stocking/glove distribution)
Musculoskeletal	Examine for occult fracture, pain; observe gait
Neurological/psychiatric	Thorough evaluation to assess focality of neurological deficits Depressive symptoms, anxiety
Mental status	Formal mental status testing (e.g., Mini-Mental State Examination); cognitive impairment suggests delirium or dementia and plays a role in assessing decision-making capacity Psychiatric symptoms including delusions and hallucinations
Imaging	As indicated from the clinical evaluation
Laboratory	As indicated from the clinical evaluation (drug levels) Albumin, blood urea nitrogen, and creatinine toxicology
Social and financial resources	Determine whether there are other members of social network available to assist the elder; financial resources These resources are crucial in considering interventions that include alternate-living arrangements and home services

Reprinted with permission from Lachs MS, Pillemer K. Current concepts: abuse and neglect of elderly persons. *N Engl J Med.* 1995;332:437.

presented with an empathetic, nonjudgmental ear to describe their stresses and actions will sometimes describe their situations at great length and in great detail. On the other hand, all forms of domestic abuse share a pattern wherein abusers gain and control access to their victims. An elder abuser graphically confronted with allegations of mistreatment may move to sequester a frail victim in such a way that a frail isolated older adult loses access to critically needed medical and social services. Whenever possible, assistance from providers skilled in elder abuse evaluation and management should be enlisted to assist in such undertakings.

## MANAGEMENT

Elder abuse is morbid and mortal. In one longitudinal study, victims had a threefold risk of death and nursing home placement compared to nonabused controls, even after adjusting for many risk factors

for these outcomes, including comorbidity. Thus, intervention is critical.

Unfortunately, there are no randomized trials of reasonable quality addressing interventions for elder mistreatment. The clinician confronted with a confirmed case of elder abuse is best served by a resourceful approach that combines experience, clinical judgment, and local resources. One relatively new and noteworthy trend is the creation of large multidisciplinary groups who convene regularly to discuss cases of mistreatment, not only for the purpose of planning intervention, but also to consider case-by-case forensics, cross train disciplines, and provide general support to one another in this difficult field. Again, however, there is no evidence-based evaluation of this strategy.

Whatever the approach to intervention, a dogmatic or algorithmic strategy to address all elder mistreatment cases is likely misguided. A rigid, inflexible approach ignores the enormous heterogeneity of the entity, including the type(s) of mistreatment being

concurrently perpetrated, the underlying mechanisms, patient comorbidities, caregiver burden issues, and the available resources (both familial and community) that can be brought to bear on the issue. A more sensible approach may be the multipronged strategy increasingly used to treat other geriatric syndromes that have multifactorial etiologies. The paradigm may be a useful one in that elder mistreatment can be likened to geriatric syndromes. That is, there may be multiple “host” and environmental contributors; decompensation may be accelerated by other medical and social problems; and some of the contributors may be more remediable than others. The elder physical abuse victim with severe chronic obstructive pulmonary disease and an abusive schizophrenic child-caregiver will need an entirely different series of interventions than the spouse with progressive dementia who has suffered life-long domestic violence that is now worsening.

The first step in confronting any confirmed case of family violence is ensuring the safety of the victim. First, the immediate threat of danger to the victim should be ascertained. Even if there is no immediate threat, a *safety plan* is critical in the management of all forms of family violence (Table 60-4). What are the specific steps the victim should take if the perpetrator of mistreatment becomes acutely violent? Options include calling the local police department, accessing shelters, emergency department use/hospital admission, or

respite care in some evolved systems of long-term care. Additionally, in most states, cases of elder abuse must be reported to adult protective services agencies. This typically results in a home visit to adjudicate the veracity of such a report. State protective service agencies vary widely with respect to their caseloads and available resources; ideally a coordinated approach that brings to bear their expertise and resources in collaboration with the physician and multidisciplinary team produces the best response.

However, the safety plan paradigm will have limited utility in many cases of elder mistreatment because of victim frailty and/or cognitive impairment that limits the use of self-protective behaviors. Frequently, clinicians find themselves in the predicament of caring for an elder mistreatment victim who lacks capacity. Here the likely intervention will involve the appointment of a guardian in collaboration with adult protective service agencies or other elder social service programs in the community that serve such functions. In such a proceeding, the clinician’s role is to provide objective evidence that documents the lack of decision-making capacity. The clinician may also have a role in ensuring the alleged perpetrator of mistreatment does not become the guardian.

One of the most frustrating situations for professionals working with victims of family violence is the individual who retains decision-making capacity, but insists on remaining in an abusive environment. Here the clinician’s role is to educate the patient about the tendency of family violence to escalate and to review the safety plan created. The clinician should also explain to the patient that even if services are refused, the physician remains an important and available resource, should the situation change.

In general, the physician who suspects elder abuse would do well to employ the same creative strategies he or she uses to manage a variety of clinical problems in older adults. There may be local social services agencies in the community who provide an array of services such as meals on wheels or friendly visit. These services could represent a new resource for the patient, but also additional “eyes and ears” to ascertain what the home situation is like. A local adult day care referral might also enable a more detailed ongoing evaluation of a client while decompressing a stressful caregiving situation. A financial management program for the patient with cognitive impairment can shed light on the possibility of financial exploitation. The physician need not diagnose elder abuse while these useful services are being proffered.

## SPECIAL SITUATIONS

Elder mistreatment may also occur in institutional settings. The physician and nurse have roles in detecting these cases as well. Substantial regulatory safeguards have been progressively enacted since the 1970s to protect residents of long-term care facilities. These safeguards include mandatory criminal background checks of all employees, ombudsman programs to adjudicate complaints of mistreatment, and components of the omnibus budget reconciliation act of 1987, which includes residents’ rights provisions (e.g., minimization of restraints). In some contexts, the failure to create or follow a reasonable plan of care for the long-term care residents may be viewed as abusive or neglectful.

While the focus of elder abuse in long-term care has been on staff abuse of residents, this is probably far less common than in decades past when regulatory scrutiny was lacking. Recently, resident on resident abuse has been identified as a far more common

**TABLE 60-4**

### Safety Plan for Victims of Elder Mistreatment or Other Victims of Family Violence with Capacity Who Insist on Remaining in an Abusive Environment

TIME FRAME	ACTIVITY
Prior to violent or abusive episode	<p>Recognize patterns that lead to abusive behavior (e.g., abuser alcohol use).</p> <p>Determine who in the social network is available to assist when such an episode occurs through explicit conversations with neighbors, friends, other relatives.</p> <p>Be aware of elder domestic violence programs, shelters, and other resources in the local community available to assist; know their contact numbers.</p> <p>Have essential resources readily available if the patient needs to leave quickly (e.g., money, ATM cards, credit cards, driver’s license, keys, identification, social security card, other important documents).</p> <p>Practice implementing safety plan (e.g., mock 911 call). Consider creating a “code” with a friend or neighbor so that the patient can communicate danger in the presence of the abuser.</p>
During violent or abusive episode	<p>Implement safety plan quickly and with discretion.</p> <p>Consider appeasing abuser briefly (if this does not cause a danger) so that safety plan may be implemented.</p> <p>Use of self-protective behaviors such as a weapon should be considered with the utmost caution.</p>
After violent or abusive episode	<p>Recognize that family violence is a chronic problem that usually recurs and escalates.</p> <p>Change locks as soon as possible.</p> <p>Strongly consider order of protection.</p> <p>Let neighbors and landlord know that abusive individual no longer lives in the home.</p>

and pervasive problem among nursing home residents. Although there are no prevalence data on the phenomenon, several indirect lines of evidence suggest that it is highly prevalent. For example, more than 50% of nursing aides in long-term care report the personal experience of being physically hit by a resident in the previous year, typically in the course of providing direct care. Given that the prevalence of dementia and associated behavioral disturbance in long-term care facilities is high, it stands to reason that behavior of this type occurs frequently between residents.

Another recent area of interest has been abuse and neglect that occurs in long-term care environments other than nursing homes (e.g., assisted-living and board and care environments), because these facilities generally are under considerably less regulation. Interest in abuse in assisted-living facilities has also grown in recent years as much sicker patients begin to inhabit these institutions; many believe the higher acuity and generally lower levels of staff and supervision are a dangerous admixture in which abuse and neglect are more likely to occur. No data yet exist on the prevalence of abuse, or on the type of abusers, in these settings.

Physicians and other care providers have an important role in the detection of these institutional cases, because they may see potential manifestations of nursing home elder mistreatment in facilities or emergency departments as part of providing customary care. Physicians who suspect institutional abuse have an obligation to immediately report their suspicions to the nursing home ombudsman in their state. A complete list of reporting contact information can be found at <http://www.elderabusecenter.org/default.cfm?p=statehotlines.cfm>.

## SUMMARY

Elder mistreatment is a prevalent problem with many potential manifestations. The epidemiology of injuries and other clinical findings is not completely understood, but this does not preclude the clinician from taking an active role in its detection and management. Studies show elder mistreatment victims to be at substantial independent risk of death and quality-of-life decline. The syndrome should be afforded the same vigilance that health care providers devote to other “traditional” medical problems in geriatrics.

# ORGAN SYSTEMS AND DISEASES

*This page intentionally left blank*

# Cellular and Neurochemical Aspects of the Aging Human Brain

*Mark P. Mattson*

Many cellular and molecular aspects of brain aging are shared with other organ systems, including increased oxidative damage to proteins, nucleic acids and membrane lipids, impaired energy metabolism, and the accumulation of intracellular and extracellular protein aggregates. However, as a result of the molecular and structural complexity of neural cells, which express approximately 50 to 100 times more genes than cells in other tissues, there are age-related changes that are unique to the nervous system. For example, complex cellular signal transduction pathways involving neurotransmitters, trophic factors, and cytokines that are involved in regulating neuronal excitability and plasticity are subject to modification by aging. This chapter describes cellular and molecular changes that occur in the brain during aging and how such changes may predispose neurons to degeneration in disorders such as Alzheimer's disease (AD), Parkinson disease (PD), and Huntington disease (HD).

## STRUCTURAL CHANGES IN THE AGING BRAIN

All of the major cell types in the brain undergo structural changes during aging. These changes include nerve cell death, dendritic retraction and expansion, synapse loss and remodeling, and glial cell (astrocytes and microglia) reactivity. Such structural changes may result from alterations in cytoskeletal proteins and the deposition of insoluble proteins such as tau and  $\alpha$ -synuclein inside of cells and amyloid in the extracellular space. Alterations in cellular signaling pathways that control cell growth and motility may contribute to both adaptive and pathological structural changes in the aging brain.

### Cytoskeletal and Synaptic Changes

The cell cytoskeleton consists of polymers of different sizes and protein compositions. The three major types of polymers are actin microfilaments (6 nm in diameter); microtubules (25 nm in diameter),

comprising of tubulin; and intermediate filaments (10–15 nm in diameter), which are made of specific intermediate filament proteins that are different in different cell types (e.g., neurofilament proteins in neurons and glial fibrillary acidic protein in astrocytes). To regulate the processes of filament assembly and depolymerization, and to link the cytoskeleton to membranes and other cell structures, neurons and glial cells employ an array of cytoskeleton-associated proteins. For example, neurons express several microtubule-associated proteins (MAPs) that are differentially distributed within the complex architecture of the cells; MAP-2 is present in dendrites but not in the axon, whereas tau is present in axons but not in dendrites. While there are no major changes in the levels of the most abundant cytoskeletal proteins with aging, there are changes in the cytoskeletal organization and in posttranslational modifications of cytoskeletal proteins. For example, increased amounts of phosphorylated tau occur in some brain regions, particularly those involved in learning and memory (e.g., hippocampus and basal forebrain). In addition, there is evidence that calcium-mediated proteolysis of MAP-2 and spectrin (a protein that links actin filaments to membranes) is increased in some neurons during aging. Oxidation of certain cytoskeletal proteins is suggested by studies demonstrating their modification by glycation and covalent binding of the lipid peroxidation product 4-hydroxynonenal (see “Free Radicals and the Aging Brain” later in this chapter). A consistent feature of brain aging in humans and laboratory animals is an increase in levels of glial fibrillary acidic protein, which may represent a reaction to subtle neurodegenerative changes.

Synapses are dynamic structural specializations where neurotransmission and other intercellular signaling events occur. There is considerable evidence for synaptic “remodeling” in the brain as we age, which is likely related to changes in dendritic arbors and neuronal numbers. For example, there may be decreases in synaptic numbers in some brain regions, but these may be offset by increases in the size of the remaining synapses. In other brain regions, no loss of synapses can be discerned.

**FIGURE 61-1.** Neuronal cytoskeletal pathology in Alzheimer's disease is mimicked in experimental systems by insults that increase intracellular calcium levels and induce oxidative stress. (A) Section of hippocampal tissue from an AD patient immunostained with an antibody against the microtubule-associated protein tau. Note strong staining of degenerating "tangle-bearing" neuronal cell bodies (arrowheads). (B) Section of hippocampus from an adult rat that had been administered the seizure-inducing excitotoxin kainate 6 hours previously. The section was immunostained with an antibody against the microtubule-associated protein tau. Note strong staining of degenerating neurons (arrowheads). (C) Human embryonic cerebral cortical neurons in culture that were left untreated (control) or were exposed for 2 hours to a calcium ionophore. Cells were then stained with an antibody against ubiquitin, a stress-responsive protein present in degenerating neurons in AD.

In contrast to usual aging, striking alterations in the neuronal cytoskeleton and synapses occur in neurodegenerative disorders such as AD, PD, and HD. Neurofibrillary tangles are filamentous accumulations of tau protein that form in the cytoplasm of degenerating neurons (Figure 61-1). Neurons with tangles have a decreased number of microtubules and often exhibit accumulations of MAP-2 and tau in the cell body. Tau is excessively phosphorylated in neurofibrillary tangles, which may result from reduced phosphatase activity as a consequence of oxidation or covalent modification by lipid peroxidation products. In PD, structures called Lewy bodies form in neurons and comprise abnormal accumulations of neurofilaments, with associated MAPs (particularly MAP-1b) and actin-related proteins such as gelsolin. In amyotrophic lateral sclerosis (ALS), lower motor neurons are filled with massive accumulations

of neurofilaments that concentrate in proximal regions of the axon. While the specific molecular events involved in formation of the cytoskeletal alterations in different neurodegenerative disorders have not been established, there is increasing evidence for major roles of aberrant elevation of intracellular calcium levels and increased oxidative stress. Conditions that elevate intracellular calcium levels (e.g., exposure to glutamate or calcium ionophores) and induce oxidative stress (e.g., exposure to  $\text{Fe}^{2+}$  and amyloid  $\beta$ -peptide [ $\text{A}\beta$ ], or expression of mutant Cu/ZnSOD) can elicit changes in the cytoskeleton in experimental animal and cell culture models that are similar to those seen in the human disorders (Figures 61-1 and 61-2).

Synapse loss occurs in neurodegenerative disorders and is strongly correlated with clinical symptoms. Accumulating data suggest that

**FIGURE 61-2.** Histologic and experimental evidence that amyloid deposition plays a role in the neurodegenerative process in Alzheimer's disease. (A) Section of hippocampal tissue from an AD patient immunostained with an antibody against the microtubule-associated protein tau. Note strong staining of degenerating "tangle-bearing" neuronal cell bodies (arrowheads) and neurites associated with amyloid plaques (arrow). (B and C) Phase-contrast micrographs of cultured rat hippocampal neurons that had been exposed for 24 hours to amyloid  $\beta$ -peptide ( $\text{A}\beta$ ) alone (B) or in combination with corticosterone (C). Note that neurites in the culture exposed to  $\text{A}\beta$  alone are beginning to exhibit signs of damage (arrow), while the neuronal cell bodies still appear undamaged (arrowhead). Corticosterone exacerbated the damage to neurons exposed to  $\text{A}\beta$ . (See Goodman et al. *J Neurochem.* 1996;66:1836.)

synaptic degeneration, resulting from excitotoxic events localized to synapses, may initiate the neuronal death process in AD, PD, HD, and stroke. Glutamate receptors are highly concentrated in post-synaptic dendritic spines, which represent sites of massive calcium influx during normal physiologic synaptic transmission. Age-related decreases in energy availability and increases in oxidative stress, and disease-specific alterations such as  $A\beta$  accumulation in AD and trinucleotide expansions of the huntingtin protein, may render synapses vulnerable to excitotoxic injury (see below).

### Vascular Changes

As in other organ systems, vessels that supply blood to the brain are vulnerable to age-related atherosclerosis and arteriosclerosis, which render the vessels susceptible to occlusion or rupture (stroke), a major cause of disability and death in the elderly population. Reduced brain perfusion in the absence of overt stroke may play a role in age-related cognitive dysfunction. Decreased cerebral blood flow occurs with advancing age and is accompanied by declines in cerebral metabolic rate for oxygen and glucose use. Age-related changes in cerebral vasculature are generally similar to those that occur in vessels elsewhere in the body and are therefore likely to result from common cellular and molecular changes, including oxidative damage to vascular endothelial cells and an inflammatory response in which macrophages may penetrate the blood–brain barrier (Figure 61-3).

Age-dependent cerebral vascular changes are strongly linked to heart disease and hypertension. Interestingly, apolipoprotein E polymorphisms are linked to increased risk of both atherosclerosis and AD, with the apolipoprotein E4 increasing the risk. This association suggests that age-related vascular changes may make an important contribution to the neurodegenerative process in AD. Finally,

**FIGURE 61-3.** Adverse effects of aging and Alzheimer's disease on endothelial cells and the blood–brain barrier. Vascular endothelial cells (EC) and associated astrocyte (ast) processes form the blood–brain barrier (BBB), which plays important roles in transporting nutrients (e.g., glucose) into the brain, while at the same time preventing movement of toxic substances and blood cells such as macrophages (MP). With aging, and more so in AD, oxidative damage to endothelial cells results from exposure to oxidized LDL and amyloid  $\beta$ -peptide ( $A\beta$ ). Oxidative stress impairs transport functions of the EC and promotes penetration of MP into the brain parenchyma. Such compromise of the vasculature results in reduced nutrient availability to neurons and inflammatory processes that promote degeneration of neurons.

important transport functions of cells (endothelial cells and astrocytes) that comprise the blood–brain barrier may also be impaired in the aging brain and more so in AD. Many of the same behavioral and dietary approaches now recognized to forestall cardiovascular disease may also forestall cerebrovascular disease; these include engaging in physical and mental activities, a low calorie intake, and a high antioxidant intake.

### Amyloid Accumulation

$A\beta$  is a 40- to 42-amino-acid peptide that arises from a much larger membrane-spanning  $\beta$ -amyloid precursor protein (APP). During normal aging, and to a much greater extent in AD,  $A\beta$  forms insoluble aggregates (plaques) in the brain parenchyma and vasculature (Figure 61-4).

Amyloid plaques accumulate most heavily in brain regions involved in learning and memory processes such as the hippocampus and entorhinal cortex. In AD, the accumulation of  $A\beta$  in the brain is correlated with the amount of neuronal degeneration and with the severity of cognitive impairment. Although the cause(s) of the majority of cases of AD is unknown, some AD cases are caused by mutations in APP, presenilin-1, or presenilin-2; mutations in each

**FIGURE 61-4.** Amyloid deposits in the brain parenchyma and cerebral vessels: evidence that amyloid damages vascular endothelial cells. (A) Section of hippocampal tissue from an AD patient. The section was immunostained with an antibody against amyloid  $\beta$ -peptide ( $A\beta$ ). Note numerous  $A\beta$  deposits of various sizes in the brain parenchyma (arrowheads point to large plaques) and cerebral blood vessels (arrows). (B and C) Cultured vascular endothelial cells were exposed for 24 hours to saline (B) or  $A\beta$  (C), and were then stained with the fluorescent deoxyribonucleic acid (DNA)-binding dye HOECHST 33342. The nuclear DNA in cells not exposed to  $A\beta$  exhibits the normal diffuse uniform distribution, while the chromatin in the cells exposed to  $A\beta$  exhibits condensation and fragmentation consistent with apoptotic death. (Adapted from Blanc EM, Toborek M, Mark RJ, et al. Amyloid  $\beta$ -peptide disrupts barrier and transport functions and induces apoptosis in vascular endothelial cells. *J Neurochem.* 1997;68:1870.)

of these proteins result in increased production of self-aggregating neurotoxic forms of  $A\beta$ .  $A\beta$  can be neurotoxic, and can increase neuronal vulnerability to metabolic, excitotoxic, and oxidative insults. The sequence of events involved in  $A\beta$ -induced neuronal injury and death may involve induction of membrane lipid peroxidation, which generates a toxic aldehyde called 4-hydroxynonenal that covalently modifies proteins involved in maintenance of cellular ion homeostasis and energy metabolism, including the plasma membrane  $Na^+/K^+$  and  $Ca^{2+}$  ATPases (adenosine triphosphatases), glucose transporters, and glutamate transporters. This may lead to excessive elevation of intracellular calcium levels, mitochondrial dysfunction, and a form of cell death called apoptosis. In addition to its likely involvement in the neurodegenerative process,  $A\beta$  may also disrupt neurotransmitter signaling pathways. For example,  $A\beta$  impairs coupling of muscarinic acetylcholine receptors to their downstream GTP (guanosine triphosphate)-binding effector protein, an action that likely contributes to the well-established deficits in cholinergic signaling pathways in AD. Finally,  $A\beta$  may also contribute to vascular damage and inflammatory processes in the aging brain.

## FREE RADICALS AND THE AGING BRAIN

A free radical is any molecule with an unpaired electron in its outer orbital; in biological systems, oxygen-based molecules are the predominant free radical species (Figure 61-5). A major oxyradical in cells  $O_2^-$  is superoxide ( $O_2^-$ ), which is generated during the mitochondrial electron transport process; superoxide dismutases (Mn-SOD and Cu/ZnSOD) eliminate  $O_2^-$  by converting it to hydrogen peroxide ( $H_2O_2$ ).  $H_2O_2$  can be converted to hydroxyl radical ( $OH^\bullet$ ) via the Fenton reaction, which is catalyzed by  $Fe^{2+}$  and  $Cu^+$ . Peroxynitrite ( $ONOO^-$ ) arises from the interaction of nitric oxide (NO) with  $O_2^-$ ; calcium influx is a major stimulus for NO production. While  $OH^\bullet$  and  $ONOO^-$  can cause direct damage to proteins and deoxyribonucleic acid (DNA), their major means of damaging cells is by attacking fatty acids in membranes and initiating a process called lipid peroxidation. Studies of aging have provided compelling evidence that there is an increase in production and accumulation of oxyradicals in essentially all tissues in the body during the aging process, including in the brain.

**FIGURE 61-5.** Possible sources of oxidative stress contributing to dysfunction and degeneration of neurons in aging and Alzheimer's disease. (A) Section of hippocampal tissue from an AD patient. The section was immunostained with an antibody that recognizes lipid peroxides that are by-products of membrane lipid peroxidation. Note immunoreactivity associated with neuritic plaques (p) and neurofibrillary tangles (arrowheads). (B) The major cellular source of reactive oxygen species in neurons is mitochondria where  $O_2^-$  is generated during the electron transport process. The superoxide dismutase enzymes (SOD) convert  $O_2^-$  to  $H_2O_2$ .  $Fe^{2+}$  catalyzes the production of  $OH^\bullet$  from  $H_2O_2$ , while glutathione peroxidase (GSHPx) and catalase detoxify  $H_2O_2$ . Peroxynitrite can be formed by the interaction of  $O_2^-$  with nitric oxide (NO). Both  $OH^\bullet$  and peroxynitrite induce membrane lipid peroxidation (MLP), which may occur in the plasma membrane, mitochondrial membranes, and endoplasmic reticulum (ER) membranes. During aging and in age-related neurodegenerative disorders, agents such as amyloid  $\beta$ -peptide ( $A\beta$ ) can induce MLP. MLP liberates the aldehyde 4-hydroxynonenal (HNE), which impairs the function of membrane transporters (glucose and glutamate transporters, and ion-motive ATPases) and ion channels, and thereby alters their activities. Reduced glutathione (GSH) binds and detoxifies HNE, thereby serving an important neuroprotective role. The antiapoptotic gene product Bcl-2 may act, in part, by suppressing MLP in plasma, mitochondrial, and ER membranes. Elevation of intracellular calcium levels, as induced by glutamate, promotes oxyradical production and MLP by inducing NO and  $O_2^-$  production, and by activating phospholipases resulting in production of arachidonic acid, which is then acted upon by cyclooxygenases (COX) and lipoxygenases (LOX). (Modified from Mattson MP. *Trends Neurosci.* 1997;20:395.)

## Lipid Peroxidation

Levels of lipid peroxidation products such as lipid peroxides and 4-hydroxynonenal are significantly elevated in the brain parenchyma and cerebrospinal fluid in AD (see Figure 61-5). Immunohistochemical analyses of brain tissue from AD and PD patients, and spinal cord tissue from ALS patients, using antibodies directed against 4-hydroxynonenal adducts revealed increased levels of 4-hydroxynonenal in association with degenerating neurons and neuritic plaques suggesting a role for this aldehyde in the neurodegenerative process. Studies of cell culture and animal models of AD and ALS show that lipid peroxidation can impair the function of the plasma membrane glucose and glutamate transporters and renders neurons vulnerable to excitotoxicity and apoptosis. Administration of antioxidants such as vitamin E to cultured cells and transgenic mice expressing mutations that cause AD or ALS can retard the neurodegenerative process, suggesting a causal role for lipid peroxidation in these diseases.

## Protein Oxidation

Levels of protein oxidation, measured as protein carbonyls, are significantly elevated in the brains of aged rodents, and such age-associated protein oxidation can be prevented by administration of antioxidants. Studies of membrane structure have provided evidence for oxidation-related alterations in membrane protein conformation in old rodents. Studies of brain tissues of patients with AD and PD have revealed increased levels of protein oxidation in vulnerable brain regions and, in particular, in degenerating neurons. Oxidation of proteins impairs their function and is therefore a likely contributor to age-related cellular dysfunction and neuronal degeneration. Progressive addition of sugar residues to many different proteins occurs during the aging process. This process, called glycation, may promote oxidative stress in cells. Two proteins that have been shown to be heavily glycosylated in AD are A $\beta$  and tau, the major components of plaques and neurofibrillary tangles, respectively.

## DNA Damage

Very little nuclear DNA damage occurs in the nervous system during usual aging, but DNA damage may contribute to the pathogenesis of neurodegenerative disorders. Damage to nuclear DNA in striatum of HD patients, and in hippocampus and vulnerable cortical regions of AD patients, has been documented. Specifically, levels of 8-hydroxyguanosine are increased. This DNA damage may be caused by oxyradicals, with hydroxyl radical and peroxynitrite being the major culprits. Progressive oxidative damage to mitochondrial DNA occurs during aging, and may be exacerbated in neurodegenerative disorders. Mitochondrial DNA is particularly prone to damage because this organelle is the site where the vast majority of free radicals are generated and because cells do not possess effective systems for repair of damaged mitochondrial DNA. Damage to mitochondrial DNA can lead to failure of electron transport and reduced adenosine triphosphate (ATP) production. Moreover, the important calcium sequestering function of mitochondria may be compromised as the result of age-related DNA damage, which may increase neuronal vulnerability to excitotoxicity and apoptosis.

## Mechanisms that Promote Oxidative Stress in Aging and Neurodegenerative Disorders

Mitochondria-derived oxyradicals are likely to play a central role in the cumulative oxidative damage to various cellular constituents that accrues with aging. Age-related impairments in energy availability and metabolism may contribute to an acceleration of oxyradical production with aging. The importance of mitochondrial oxyradical production in aging, in general, is underscored by recent studies of the mechanism whereby caloric restriction extends life span in rodents and nonhuman primates. Levels of cellular oxidative stress (as indicated by oxidation of proteins, lipids, and DNA) are decreased in many different non-neural tissues of rats and mice maintained on a calorie-restricted diet (30–40% reduction in calories). Recent studies suggest that levels of oxidative stress are also reduced in the brains of calorie-restricted rodents. The current dogma for the underlying mechanism is that reduced mitochondrial metabolism because of reduced energy availability results in a net decrease in mitochondrial ROS production over time, and hence less radical-mediated cellular damage. Thus, one factor contributing to brain aging is simply the constant production of oxyradicals and resultant progressive damage to cellular components.

In addition to the oxyradical damage that accrues with usual aging, there are specific initiators of oxidative stress that appear to play key roles in different age-related neurodegenerative disorders. For example, in AD the increased generation and accumulation of A $\beta$  may be a pivotal event that enhances oxidative stress in neurons. There is evidence that increased levels of Fe<sup>2+</sup> in the substantia nigra plays a role in the degeneration of dopaminergic neurons in PD. The damage to neurons in the brain of individuals who had a stroke is the result of a combination of factors including excessive calcium influx and the presence of blood components such as Fe<sup>2+</sup> and thrombin. In HD, the presence of trinucleotide repeats in the huntingtin protein may induce oxidative stress in striatal neurons by a yet-to-be-determined mechanism.

## ALTERATIONS IN ENERGY METABOLISM AND MITOCHONDRIAL FUNCTION IN THE AGING BRAIN

During the aging process, changes that occur in cerebral blood vessels, as well as in the neural cells themselves, appear to result in reduced energy availability to neurons. These age-related changes may be accelerated in several different neurodegenerative disorders including AD and PD.

### Cerebral Metabolism

Reduced glucose use, and changes in enzymes involved in energy metabolism, may occur during normal aging, but are not dramatic. Studies of aging rodents document decreases in glucose and ketone body oxidation, oxygen consumption, local cerebral glucose use, and glycolytic compounds (e.g., fructose-1,6-diphosphate). Additional studies show that brain cells in older animals exhibit increased vulnerability to metabolic stresses. Incorporation of glucose into amino acids declines in the brains of aging mice, and older people are much more vulnerable to metabolic encephalopathy than are young people. In contrast to normal aging, activities of several enzymes

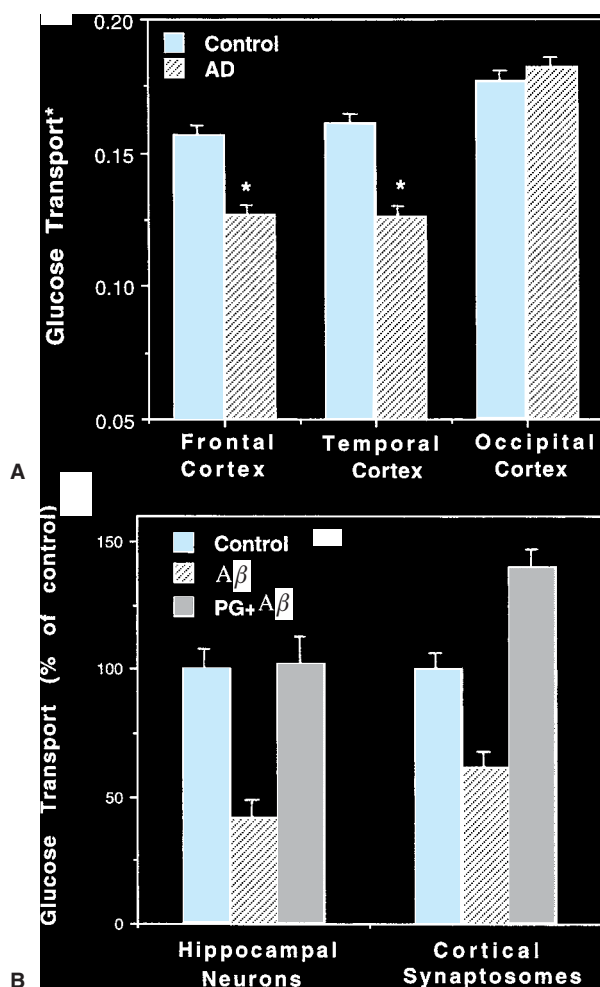

involved in energy metabolism are severely reduced in AD brain tissues. Three such enzymes, which are involved in mitochondrial oxidative metabolism, are the pyruvate dehydrogenase complex, the  $\alpha$ -ketoglutarate dehydrogenase complex, and cytochrome c oxidase. These defects may result from age-associated oxidative damage to the DNA encoding these enzyme systems and/or reduced activity of the proteins in these systems.

Another factor that may contribute to reduced neuronal energy metabolism is impairment of the function of glucose transporter proteins in neuronal membranes. Studies of postmortem brain tissues of patients with AD document reduced levels of glucose transporters, and experimental studies of cultured hippocampal neurons and synaptosomes show that insults relevant to the pathogenesis of

AD (exposure to  $A\beta$  and oxyradical-generating agents) can impair glucose transport (Figure 61-6). Impairment of glucose transport and mitochondrial dysfunction would be expected to lead to ATP depletion and render neurons vulnerable to excitotoxicity.

### Mitochondrial Function

Age-related structural changes in synaptic mitochondria have been reported and include a decrease in numbers and increase in size. During normal aging, levels of mitochondrial protein synthesis are unchanged. However, decreases in synthesis of specific mitochondrial proteins that are components of the electron transport chain occur in aging rodents. Damage to mitochondrial DNA progressively increases in somatic cells during the aging process, with the most pronounced damage occurring in postmitotic cells such as neurons. Mitochondrial dysfunction has been linked to several neurodegenerative disorders (Figure 61-7). In PD, there are marked decreases in complex I and  $\alpha$ -ketoglutarate dehydrogenase activities. Exposure of cultured dopaminergic neurons to insults relevant to the pathogenesis of PD (e.g., MPTP and  $Fe^{2+}$ ) cause mitochondrial dysfunction. In AD, cytochrome c oxidase and  $\alpha$ -ketoglutarate dehydrogenase activity levels are markedly reduced in vulnerable brain regions. Interestingly, mitochondrial deficits are also observed in non-neuronal cells, including platelets and fibroblasts, of AD patients. When mitochondria from platelets of AD patients are introduced into cultured neuroblastoma cells, levels of oxidative stress are increased suggesting an important contribution of mitochondrial alterations to the increased oxidative stress present in neurons in AD brain. Mitochondrial alterations in neurons have been documented in studies of mouse models of AD (APP and presenilin mutant mice), PD ( $\alpha$ -synuclein mutant mice), HD (huntingtin mutant mice), and stroke (middle cerebral artery occlusion).

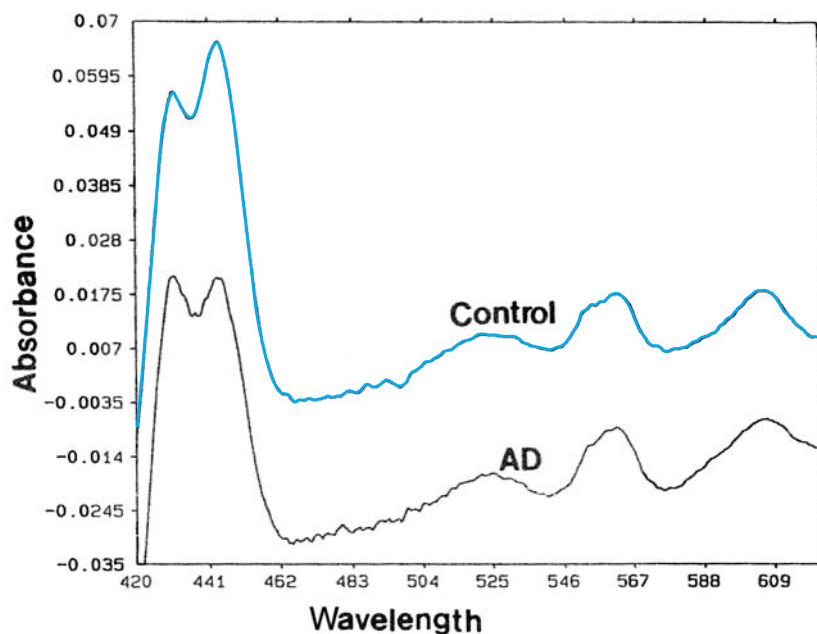

**FIGURE 61-6.** Evidence for reduced glucose transport in Alzheimer's disease. (A) Levels of glucose uptake into different brain regions of the patients with Alzheimer's disease and age-matched control subjects were quantified by dynamic positron emission tomography using [ $^{18}F$ ]-fluorodeoxyglucose. Values are the rate constant  $K_1$  expressed in mL/g/min and reflect glucose transport across the blood-brain barrier and into brain cells. \* $p \leq 0.05$  compared to corresponding value for control subjects. (B) Cultured embryonic rat hippocampal neurons, or cortical synaptosomes from adult rats, were pretreated with vehicle or the antioxidant propyl gallate (PG), and were then exposed for 2 hours to saline (control) or  $A\beta$ . Glucose transport was quantified. Note that  $A\beta$  caused a decrease in glucose transport, and that PG blocked the effect of  $A\beta$ . [Part A data from Jagust et al. *J Cereb Blood Flow Metab.* 1991;11:323. Part B data from Mark et al. *J Neurosci.* 1997;17:1046, and Keller et al. *J Neurochem.* 1997;69:273.]

### NEURONAL ION HOMEOSTASIS IN THE AGING BRAIN

Among the properties of neurons that set them apart from many other cell types is their excitability, which is regulated by a complex array of neurotransmitters and ion channels. Neurons express voltage-dependent sodium channels, as well as multiple types of calcium and potassium channels that are differentially expressed among neuronal populations, and are segregated in different cellular compartments (e.g., L-type calcium channels in the cell body, N-type calcium channels in the dendrites, and T-type calcium channels in presynaptic terminals). In addition, neurons possess ion-motive ATPases that play critical roles in re-establishing ion gradients following neuronal stimulation. A variety of age-related alterations in electrophysiological parameters of neurons has been described in rodents and, in some cases, in humans, including increased thresholds for induction of action potentials in cranial nerves, increased after hyperpolarizations in hippocampal neurons, and impaired long-term potentiation of synaptic transmission in the hippocampus. Moreover, a generalized decrease in neuronal inhibition appears to occur during the aging process.

The calcium ion plays fundamental roles in regulating neuronal survival and plasticity in both the developing and adult nervous system. Calcium mediates the effects of neurotransmitters and

**FIGURE 61-7.** Evidence for mitochondrial dysfunction neurodegenerative disorders. (A) Reduced-oxidized difference spectra in isolated brain mitochondria from control and Alzheimer's disease (AD) patients. The spectra reflect levels of electron transport function in the mitochondria. Note reduced levels of cytochromes  $b$ ,  $c_1$ , and  $aa_3$  in mitochondria from the AD patients. (B) Confocal laser scanning microscope image of mitochondrial reactive oxygen species levels (dihydrorhodamine 123 fluorescence) in cultured rat hippocampal neuron that had been exposed to amyloid  $\beta$ -peptide for 4 hours. Note high levels of fluorescence in mitochondria indicating the presence of extensive mitochondrial oxidative stress. (Part A adapted from Parker et al. *Neurology*. 1994;44:1090. Part B Mark et al. *Brain Res*. 1997;756:205.)

neurotrophic factors on neurite outgrowth, synaptogenesis, and cell survival in many different regions of the developing nervous system, and in the adult nervous system, calcium regulates neurotransmitter release from presynaptic terminals and postsynaptic changes associated with learning and memory processes. Aging may result in decreases in the activity of the plasma membrane calcium ATPase and in levels of calcium-binding proteins, while increasing calcium influx through voltage-dependent channels and increasing the activation of calcium-dependent proteases. The factors that promote impaired calcium homeostasis in neurons in aging and age-related

neurodegenerative disorders likely include increased levels of oxidative stress and metabolic compromise (see above).

## NEUROTRANSMITTER SIGNALING IN THE AGING BRAIN

A number of alterations in different neurotransmitter systems have been documented in studies of aging rodents, and in analyses of brain tissues from humans with age-related neurodegenerative

disorders. While some of these alterations likely result from neuronal degeneration, others appear to occur in the absence of cell injury.

### Cholinergic Systems

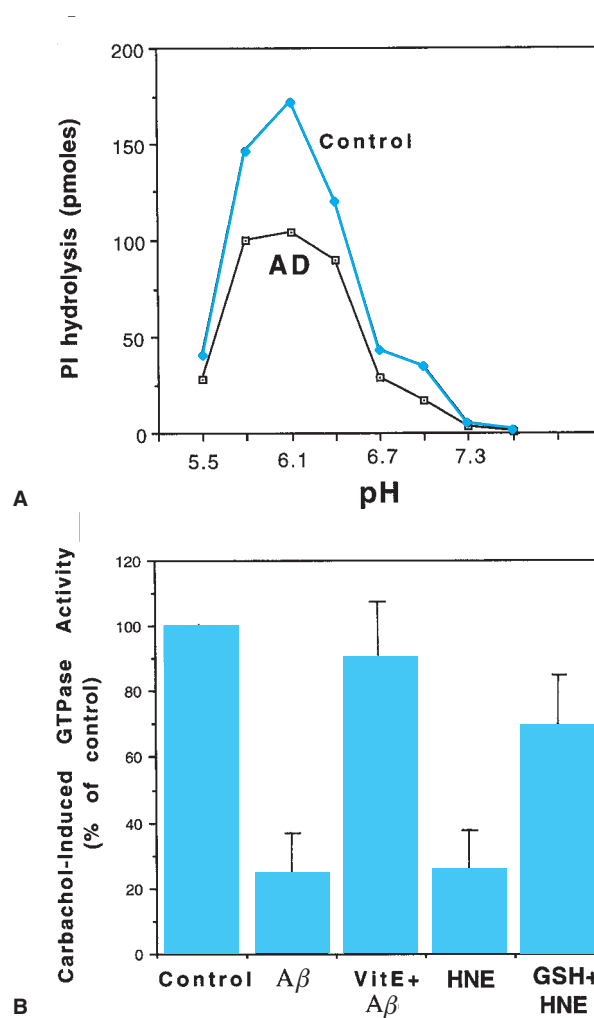

Acetylcholine is employed as a neurotransmitter in select populations of neurons in the brain, prominent among which are basal forebrain neurons that innervate widespread regions of neocortex and to the hippocampus; these cholinergic neurons are known to play key roles in learning and memory processes in humans and rodents. Deficits in one or more aspects of cholinergic signal transduction may occur with aging including choline transport, acetylcholine synthesis, acetylcholine release, and coupling of muscarinic receptors to their GTP-binding effector proteins. Cholinergic deficits are much more severe in patients with AD and also differ qualitatively from the changes observed during normal aging. Particularly striking is a reduced ability of muscarinic agonists to activate GTP-binding proteins in cortical neurons (Figure 61-8). Increased levels of membrane lipid peroxidation in neurons may contribute to impaired cholinergic signaling; for example,  $A\beta$ ,  $Fe^{2+}$ , and the lipid peroxidation product 4-hydroxynonenal can impair coupling of muscarinic receptors to the GTP-binding protein  $G_{q11}$  (see Figure 61-8).

### Dopaminergic Systems

Very prominent reductions in both pre- and postsynaptic aspects of dopaminergic neurotransmission occur during brain aging. Decreases in dopamine levels and dopamine transporter levels in the striatum occur with advancing age, and there is an age-related decrease in levels of  $D_2$  receptor-binding sites in striatum. As with cholinergic signal transduction, there also appears to be an age-related impairment of coupling of dopamine receptors to their GTP-binding effector proteins. The contribution of oxidative stress to changes in dopaminergic signaling has not been established, although the prominent role of oxyradicals in the pathogenesis of PD argue that similar oxidative processes contribute to dopaminergic dysfunction during normal aging. These changes in dopaminergic signaling likely play a role in age-related deficits in motor control and may explain the fact that the elderly are susceptible to extrapyramidal effects of dopamine receptor antagonist drugs.

### Monoaminergic Systems

Norepinephrine and serotonin are the major monoamine neurotransmitters in the brain. Noradrenergic neurons are located primarily in the locus ceruleus and serotonergic neurons in the raphe nucleus; both types of neurons project to widespread regions of cerebral cortex. There are several subtypes of receptors for norepinephrine, which each couple to GTP-binding proteins. There are also several subtypes of serotonin receptors, some of which couple to GTP-binding proteins and others of which are ligand-gated ion channels. There appear to be increased levels of norepinephrine with aging in some brain regions, while levels of  $\alpha_2$ -adrenergic receptors may decrease in cerebral cortex with advancing age. Levels of serotonin may decrease in the striatum, hippocampus, and cerebral cortex. Age-related decreases in levels of evoked serotonin release and of serotonin binding sites have been reported, and may contribute to affective disorders such as depression.

**FIGURE 61-8.** Impact of oxidative stress and Alzheimer's disease on muscarinic cholinergic signal transduction. (A) Levels of [ $^3H$ ]-PI hydrolysis induced by  $GTP\gamma S$  plus carbachol (muscarinic acetylcholine receptor agonist) in membranes from brains of AD patients and age-matched controls. Note reduced levels of ligand-induced PI hydrolysis in the membranes from the AD patients. (B)  $A\beta$  and membrane lipid peroxidation impair coupling of muscarinic receptors to the GTP-binding protein  $G_{q11}$  in cultured cerebral cortical neurons. Cultured rat cortical neurons were exposed for 3 to 4 hours to vehicle (control),  $A\beta$ , vitamin E (VitE) plus  $A\beta$ , 4-hydroxynonenal (HNE), or glutathione ethyl ester (GSH) plus HNE. Membranes were then isolated and levels of carbachol-induced GTPase activity were quantified. Note that  $A\beta$  and HNE impaired coupling of the muscarinic receptors to the GTP-binding protein, and that the antioxidants vitamin E and GSH attenuated the impairments. (Part A adapted from Jope et al. *Neurobiol Aging*. 1997;15:221. Part B data from Kelly et al. *Proc Natl Acad Sci U S A*. 1996;93:6753, and Blanc EM et al. *Amyloid  $\beta$ -peptide disrupts barrier and transport functions and induces apoptosis in vascular endothelial cells*. *J Neurochem*. 1997;68:1870.)

### Amino Acid Transmitter Systems

The amino acid glutamate is the major excitatory neurotransmitter in the human brain. Glutamate stimulates ionotropic receptors that flux calcium and sodium; excessive activation of ionotropic glutamate receptors may play a role in the degeneration of neurons in several age-related disorders including stroke, AD, PD, and HD. Levels of ionotropic glutamate receptors were reported to decrease with aging, but these decreases may be the result of degeneration of the neurons expressing the receptors. The contribution of dysfunction

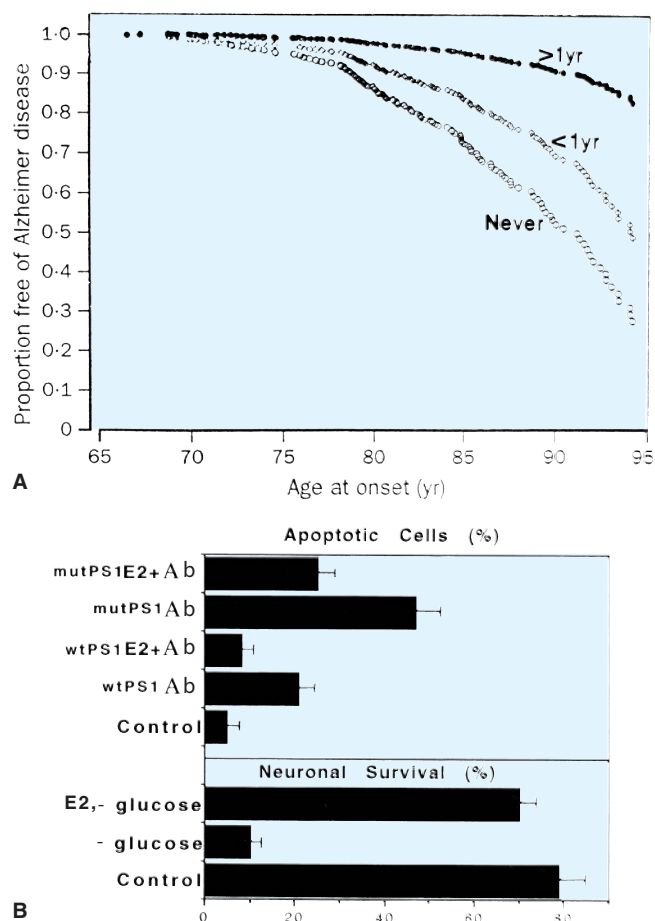

of glutamatergic transmission, in the absence of neuronal death, to age- and disease-related deficits in brain function is unknown. The major inhibitory neurotransmitter in the human brain is  $\gamma$ -aminobutyric acid (GABA). Relatively little information is available concerning the impact of aging on GABAergic systems, although levels of glutamate decarboxylase and GABA-A binding sites may be decreased. Interestingly, GABAergic interneurons are typically spared in various neurodegenerative disorders including AD.

## NEUROENDOCRINE CHANGES IN THE AGING BRAIN

A variety of age-related alterations in neuroendocrine systems has been documented. Of particular importance for human brain aging and neurodegenerative disorders are changes in levels of steroid hormones, particularly glucocorticoids and estrogens. There is considerable evidence for age-related alterations in the diurnal regulation of circulating glucocorticoid levels, and an increase in the mean level. Moreover, regulation of the hypothalamic–pituitary–adrenal axis is altered in AD patients, such that plasma levels of glucocorticoids are increased. Increased levels of glucocorticoids, including those induced by physiological or psychological stress, can increase the vulnerability of hippocampal neurons to injury and death induced by ischemic and excitotoxic insults, suggesting that glucocorticoids may have a negative impact on the outcome of both acute (e.g., stroke) and chronic (e.g., AD) age-related neurologic disorders. Estrogen ( $17\beta$ -estradiol) may have a beneficial effect on brain aging. Epidemiologic studies suggest a reduced risk of AD in postmenopausal women who take estrogen replacement therapy (Figure 61-9), and elderly women who take estrogens perform better on cognitive tasks. Animal and cell culture studies have shown that  $17\beta$ -estradiol can protect neurons from being damaged and killed by insults relevant to ischemia and AD including glucose deprivation, exposure to  $A\beta$ , and expression of AD-linked presenilin mutations (see Figure 61-9).

## IMMUNOLOGIC FACTORS IN BRAIN AGING

While the blood–brain barrier limits access of circulating lymphocytes to neurons in the brain, it is becoming increasingly evident that the brain is by no means devoid of immune responses. The brain possesses resident immune effector cells called microglia that may respond to age- and disease-related neurodegenerative processes. Some data suggest that a decline in peripheral immune function during aging may lead to an autoimmune-like phenomenon in the brain wherein microglia are activated. Inflammatory processes are associated with, and contribute to, the neurodegenerative process in AD and other age-related neurodegenerative disorders; these include activation of microglia in the affected brain regions, increased local cytokine production in association with the neuropathological changes, and activation of components of the complement cascade system. Moreover, epidemiological and clinical data suggest that anti-inflammatory agents may suppress the development of AD. Collectively, the emerging data suggest a role for chronic inflammatory reactions in the pathogenesis of at least some neurodegenerative disorders.

**FIGURE 61-9.** Estrogen protects women against Alzheimer's disease, and protects cultured neurons against genetic and environmental factors linked to Alzheimer's disease. (A) Plot of proportion of the study group free of Alzheimer's disease as a function of age in postmenopausal women receiving estrogen replacement therapy more than 1 yr, less than 1 yr, or not at all. (B) The lower portion of the graph shows data from cultured rat hippocampal neurons that were deprived of glucose (–glucose) for 24 hours in the absence or presence of  $17\beta$ -estradiol (E2); control cultures were not deprived of glucose. The percentage of neurons surviving was quantified. Note that  $17\beta$ -estradiol largely prevented neuronal death. The upper portion of the graph shows data from cultured PC12 cells overexpressing either wild-type presenilin-1 (wtPS1) or mutant presenilin-1 (mutPS1). Cultures were exposed to either  $A\beta$  alone or in combination with  $17\beta$ -estradiol (E2); control cultures were not exposed to  $A\beta$ . The percentage of cells undergoing apoptotic cell death was quantified. Note that apoptosis was enhanced in cells expressing mutant PS-1, and that  $17\beta$ -estradiol largely prevented the apoptosis. (Part A adapted from Tang et al. *Lancet*. 1996;348:429. Part B adapted from Goodman et al. *J Neurochem*. 1996;66:1836.)

## NEUROTROPHIC FACTORS IN THE AGING BRAIN

### Neurotrophic Factors Counteract Age- and Disease-Related Neurodegeneration

Cells in the nervous system produce a variety of proteins that serve the function of promoting neuronal survival and growth, and protecting the neurons against injury and death. Examples of such “neurotrophic factors” include nerve growth factor, basic fibroblast growth factor (bFGF), brain-derived neurotrophic factor (BDNF),

and insulin-like growth factor. Neurotrophic factors are remarkable in that they can protect neurons against a variety of insults relevant to the pathogenesis of age-related neurodegenerative conditions. For example, bFGF can protect hippocampal and cortical neurons against metabolic, oxidative, and excitotoxic insults, and can greatly reduce brain damage in rodent models of stroke. One or more neurotrophic factors have also been shown to protect particular neuronal populations against neurodegenerative disorder-specific insults. Thus, BDNF protects dopaminergic neurons against MPTP toxicity (PD model), while bFGF and sAPP (secretory domain of the  $\beta$ -amyloid precursor protein) protect hippocampal neurons against  $A\beta$  toxicity (AD model). There appear to be two general mechanisms whereby neurotrophic factors prevent neuronal degeneration; they increase cellular resistance to oxidative stress and stabilize cellular calcium homeostasis. These actions of neurotrophic factors appear to result from induction of the expression of antioxidant enzymes (e.g., superoxide dismutases and glutathione peroxidase) and calcium-regulating proteins (e.g., the calcium-binding protein calbindin). In addition to preserving existing neurons, neurotrophic factors may stimulate the production of new neurons from so-called stem cells. Such neural stem cells may be able to replace lost or damaged neurons, and are therefore receiving considerable attention for their potential use in the treatment of neurodegenerative disorders.

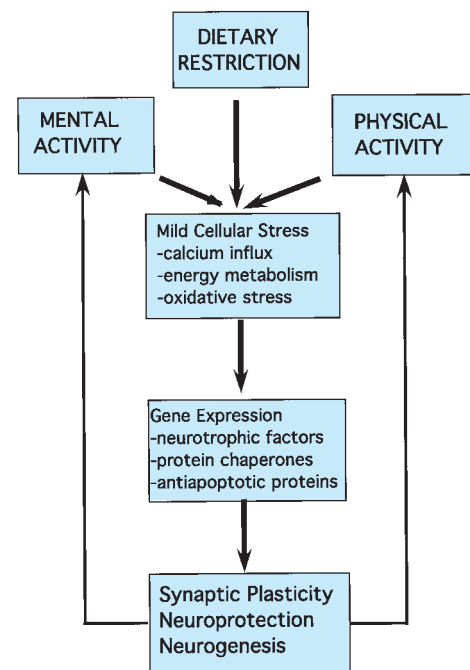

### “Use It or Lose It”

An intriguing feature of neurotrophic factors is that their expression is increased by activity in neuronal circuits. Experimental studies in cell culture and in vivo show that such activity-dependent production of neurotrophic factors plays a major role in promoting neuronal survival and neurite outgrowth. Rearing of rodents in an “intellectually enriched” environment results in expansion of dendritic arbors and increased numbers of synapses in hippocampus and certain regions of cerebral cortex. Moreover, epidemiologic data suggest that humans with “active” minds have a reduced risk for developing AD as they age. When taken together with data showing that neurotrophic factors can protect brain neurons against insults relevant to usual brain aging and neurodegenerative disorders (oxidative, metabolic, and excitotoxic insults), these findings suggest a “use it or lose it” scenario of brain aging in which brain activity induces expression of neurotrophic factors that, in turn, promote neuronal growth and plasticity (Figure 61-10).

## GENETIC FACTORS IN BRAIN AGING AND NEURODEGENERATIVE DISORDERS

### Longevity Genes

Individuals inherit two apolipoprotein E alleles, of which there are three isoforms (E2, E3, and E4). The E2 allele has been linked to increased life span and reduced incidence of AD; this “longevity gene” may act, in part, by reducing atherosclerotic processes in the vasculature. Another possible longevity gene is that encoding an isoform of angiotensin-converting enzyme, although its mechanistic links to aging are unclear. Finally, the multigene major histocompatibility system appears to influence life span, and may act by sustaining functions of the immune system.

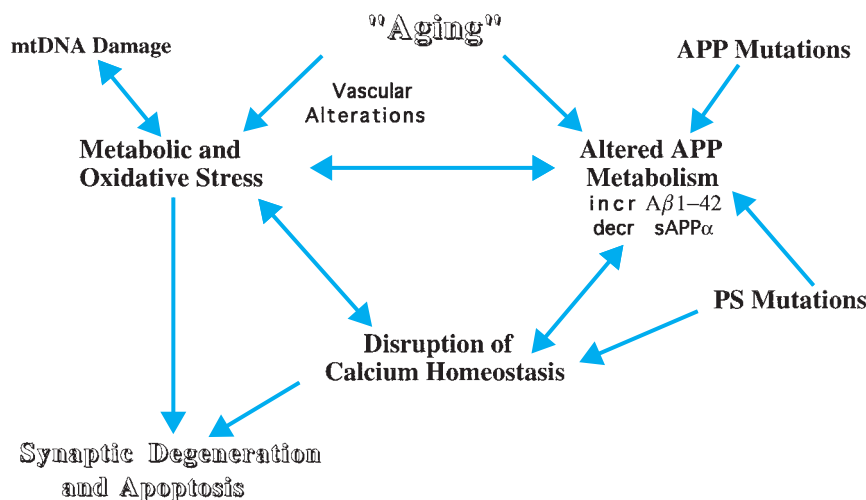

**FIGURE 61-10.** Mechanisms whereby dietary restriction and mental and physical activities promote successful brain aging. Dietary restriction and stimulation of activity in neuronal circuits by mental and physical activities induce mild stress in neurons as the result of reduced energy availability, calcium influx, and oxidative stress. The neurons respond to the stress by upregulating the expression of genes that encode proteins that promote neuronal plasticity and survival including neurotrophic factors, heat shock proteins, and antiapoptotic proteins. These changes increase the resistance of neurons to age-related diseases by promoting synaptic plasticity, cell survival, and neurogenesis.

### Disorder-Specific Genes

Considerable progress has been made in identifying genetic factors that play roles in AD. Three different genes have been identified in which mutations cause early-onset autosomal dominant familial AD (Figure 61-11). Mutations in the APP gene on chromosome 21 are located immediately adjacent to the  $A\beta$  sequence. Expression of mutant APP in cultured cells and transgenic mice results in an increase in production of  $A\beta$  and a decrease in production of sAPP $\alpha$ . The increase in  $A\beta$  may promote plaque formation and associated neurotoxicity. The decrease in sAPP $\alpha$  levels may also play an important role in the neurodegenerative consequences of APP mutations, because sAPP $\alpha$  normally promotes neuronal survival and plasticity and can protect neurons against excitotoxic and oxidative injury. The two other genes causally linked to early onset familial AD are called presenilin-1 (PS-1) and presenilin-2 (PS-2). PS-1 is located in chromosome 14 and PS-2 is located in chromosome 1. PS-1 and PS-2 are integral membrane proteins localized in the endoplasmic reticulum of neurons throughout the brain. Studies of cultured cells and transgenic mice expressing PS-1 mutations have shown that the mutations increase  $A\beta$  production and sensitize neurons to death induced by metabolic and oxidative insults. The pathogenic action of presenilin mutations may involve perturbed regulation of endoplasmic reticulum calcium.

Some cases of PD are inherited and have an early age of disease onset. Mutations in several different genes have been shown to cause inherited PD including  $\alpha$ -synuclein (PARK1), LRRK (PARK8);

**FIGURE 61-11.** Interactions of aging and genetic factors in the pathogenesis of neurodegenerative disorders: Alzheimer's disease as an example. The aging process is associated with increases in cellular oxidative stress and metabolic impairment. Metabolic and oxidative stress disrupt neuronal calcium homeostasis and promote excitotoxic synaptic degeneration and apoptotic cell death. Mutations in the  $\beta$ -amyloid precursor protein (APP) and presenilins (PS) result in altered proteolytic processing of APP, increased production of amyloid  $\beta$ -peptide (A $\beta$ 1–42) and decreased sAPP $\alpha$  production. The result of these mutations is impaired calcium homeostasis and increased age-related oxidative stress. Vascular alterations contribute to reduced energy availability to neurons and increased oxidative stress. (Data from Mattson *Mol Cell Biol.* 2000;1:120.)

leucine-rich repeat kinase 2) and UCHL1 (PARK5; ubiquitin C-terminal hydrolase L1), Parkin (PARK2), DJ-1 (PARK7) and PINK1 (PARK6; PTEN induced putative kinase 1). Mutations in the gene encoding the mitochondrial serine protease HTRA2 (PARK13; high temperature requirement A2) have also been linked to PD in several families. Impaired proteasomal degradation of  $\alpha$ -synuclein and mitochondrial dysfunction are key alterations caused by the different PD-causing mutations.

Several age-related inherited neurodegenerative conditions are caused by trinucleotide repeats in specific genes. The best known such disorder is HD in which polyglutamine repeats in the huntingtin gene promote degeneration of neurons in the caudate/putamen and cerebral cortex. Other examples include spinal and bulbar muscular atrophy, fragile X syndrome, spinocerebellar ataxia type 1, and Machado–Joseph disease. Trinucleotide repeat mutations do not follow strict rules of mendelian inheritance, as they are unstable and change size in successive generations. The mechanism(s) whereby expansions of trinucleotide repeats cause neuronal degeneration has not been established, but recent findings suggest roles for protein aggregation and oxidative stress. ALS is a disorder in which lower motor neurons in the spinal cord, and to a lesser extent neurons in the motor cortex, degenerate resulting in progressive paralysis. A small percentage of cases of ALS are caused by mutations in the gene encoding the antioxidant enzyme Cu/ZnSOD, which appear to alter the properties of the enzyme so that it produces hydroxyl radical and peroxynitrite. Finally, several “predisposition” genes have been identified in which polymorphisms or mutations increase the risk for developing one or more age-related neurodegenerative disorders. For example, inheritance of the E4 allele or mutations in the mitochondrial DNA encoding cytochrome c oxidase increase the risk for AD.

## DIETARY FACTORS IN BRAIN AGING AND NEURODEGENERATIVE DISORDERS

It recently became evident that diet can affect one's risk of age-related neurodegenerative disorders. In particular, emerging findings indicate that several dietary risk factors for prominent age-related diseases including cardiovascular disease, cancer, and diabetes are also risk factors for AD, PD, and stroke.

## Calorie Intake

The only known means of increasing the life span of rodents and nonhuman primates is by decreasing their calorie intake; both maximum and mean life span can be increased by up to 40%. The average life span of humans is certainly decreased by overeating, although it remains to be determined whether maximum life span can be increased. Epidemiologic data suggest that individuals with a low calorie intake are at a reduced risk for AD and PD. Biochemical markers of aging and deficits in learning, memory, and motor function are retarded in rodents maintained on dietary restriction. Recent studies show that neurons in the brains of rats and mice maintained on dietary restriction are more resistant to dysfunction and death in experimental models of AD, PD, HD, and stroke. The mechanism whereby caloric restriction increases the resistance of neurons to the adverse effects of aging is by stimulating the expression of genes that promote neuronal plasticity and survival (see Figure 61-10). These genes include those that encode neurotrophic factors such as BDNF and nerve growth factor, protein chaperones such as heat shock protein-70, and glucose-regulated protein-78. Thus, the benefits of dietary restriction may result from a hormesis mechanism akin to the beneficial effects of physical exercise on skeletal muscle and blood vessels.

## Folic Acid (Homocysteine)

It was recognized long ago that folic acid deficiency can cause abnormalities in the developing nervous system. Subsequently, it was shown that people with low levels of folic acid tend to have elevated levels of homocysteine and that this condition is associated with increased risk of cardiovascular disease and stroke. Homocysteine is produced during metabolism of methionine, and folic acid plays an important role in removing homocysteine via remethylation. Epidemiological findings suggest that people with elevated homocysteine levels may be at increased risk of AD and PD. Animal studies support a cause–effect relationship between elevated homocysteine levels and neuronal vulnerability to neurodegenerative disorders. For example, hippocampal neurons of APP mutant mice (AD model), and substantia nigra dopaminergic neurons in mice given MPTP (PD model), exhibit increased vulnerability to degeneration when maintained on a folic acid-deficient diet. By increasing homocysteine levels, folic acid deficiency may promote accumulation of

DNA damage by inhibiting DNA repair. In neurons, the increased DNA damage can trigger apoptosis, particularly under conditions of increased oxidative or metabolic stress, as occur during aging.

### Antioxidants

Neurons are clearly subjected to increased levels of oxidative stress during normal aging, and more so in neurodegenerative disorders. It is therefore reasonable to consider the possibility that dietary antioxidants might promote successful brain aging. Epidemiologic findings support a protective effect of antioxidants in fruits and vegetables against stroke, and possibly AD. Studies of animal models of AD, PD, HD, stroke, and ALS have documented beneficial effects of some antioxidants. Positive effects have been reported for several commonly used dietary supplements, including vitamin E, creatine, and ginkgo biloba. However, the effects of such antioxidants are relatively subtle compared to the quite striking neuroprotective effects of dietary restriction.

### Stimulatory Phytochemicals

Epidemiological findings suggest that individuals who regularly consume vegetables and fruits have a lower risk of developing an age-related neurodegenerative disorders compared to those who eat few such plant products. Several phytochemicals have been reported to enhance neuronal plasticity and survival in studies of animal models of neurodegenerative disorders. Examples include sulforaphane, curcumin, resveratrol, and allicin. Instead of functioning as direct antioxidants, many of these beneficial phytochemicals may stimulate mild adaptive stress responses that result in increased production of antioxidant enzymes, neurotrophic factors, and other protective proteins in neurons. The possible therapeutic benefits of several such stimulatory phytochemicals are currently being tested in human subjects with age-related neurological disorders.

## CONCLUSION

Structural changes occur in the brain during aging and appear to be compensatory responses to adverse changes in cellular metabolism that occur during the aging process. There are several biochemical processes that may predispose neurons to dysfunction and death in aging and neurodegenerative disorders. At the cellular and molecular levels these changes include, increased levels of oxidative stress, impaired mitochondrial function, and energy metabolism, and dysregulation of neuronal calcium homeostasis. Disease-specific initiators of neuronal degeneration are being identified and include increased production of A $\beta$  and reduced production of sAPP $\alpha$  in AD; trinucleotide repeat expansions in HD and related disorders; and dopamine- and Fe<sup>2+</sup>-mediated free radical production in PD. As in many other organ systems, untoward changes in blood vessels may contribute greatly to age-related declines in cell function and tissue damage in the brain. A role for chronic inflammatory processes involving microglial activation is implicated in the pathogenesis of some neurodegenerative disorders. Neurodegenerative cascades may

be countered by neurotrophic signaling pathways that promote neuronal survival and adaptation; these pathways are stimulated by brain activity, such that individuals with a high level of “intellectual” activity have a reduced risk for AD. Genetic causal and risk factors for neurodegenerative disorders are being identified and characterized, leading to new insights into disease pathogenesis. Successful brain aging may be promoted through dietary manipulations with dietary restriction and supplementation with folic acid and stimulatory phytochemicals being the most notable.

# Cognitive Changes Associated with Normal and Pathological Aging

Suzanne Craft ■ Brenna Cholerton ■ Mark Reger

“Age does not depend upon years, but upon temperament and health. Some men are born old, and some never grow so.”

*Tyron Edwards*

“A man is as old as his arteries.”

*Thomas Sydenham*

The dogma that aging brings inevitable cognitive decline is being challenged by studies of the rapidly expanding oldest segment of our society, adults older than 60 years. Although some aspects of cognition are affected by aging, many changes in cognition previously considered the unavoidable consequence of brain senescence may instead result from incremental insults on brain function associated with aging-related medical conditions. The detection of such changes, which may stabilize or even reverse with appropriate intervention, and their differentiation from the cognitive changes associated with neurodegenerative disease or other neurological disorders is a critical task. The primary goal of this chapter is to describe changes in various cognitive abilities that occur with normal aging and with common age-related medical and neurological conditions.

## THE EFFECTS OF NORMAL AGING ON COGNITIVE FUNCTION

### General Intellectual Functioning

Intelligence is generally measured by summing the scores on a variety of verbal and performance subtests. Studies of aging have consistently shown that subtests measuring verbal abilities remain stable with normal aging. In contrast, subtests that require nonverbal creative thinking and new problem solving strategies show a slow decline with age. Crystallized abilities (information and skills gained from experience)

remain relatively intact with aging, while fluid intelligence, which involves flexible reasoning and problem solving approaches, declines. Numerous studies have documented this general pattern in both cross-sectional and longitudinal research designs. Below, we review the literature on the effects of normal aging on specific cognitive functions (Table 62-1).

### Attention

Attention involves the ability to focus on one or more pieces of information (auditory or visual) long enough to register and make meaningful use of the data. Attention requires both simple and complex immediate processing and provides a foundation for working memory and other cognitive functions. Sustained attention, or vigilance, entails attending to one type of information over a period of time. After controlling for reaction time and sensory changes, sustained attention and strategies for maintaining vigilance do not appear to change significantly with age. Divided attention, or the ability to concentrate on more than one piece of information at a time, may worsen with age, though research in this area has produced mixed results. Increased distractibility (difficulty blocking out irrelevant or salient stimuli), decreased use of effective strategies, and reduced processing speed may be responsible for some of the noted declines in divided attention. Pronounced impairment of attention is not typical of normal aging, however, and a complete evaluation of medical and psychosocial issues is warranted for individuals who demonstrate such changes. Attention can be negatively impacted by perceptual or sensory changes, illness, chronic pain, certain medications, and psychological disturbance (in particular, depression and anxiety), all of which are common in an older population. As the ability to effectively attend is a requisite for nearly all other cognitive functions, it is important to identify the cause/s of attentional impairment whenever possible and to implement any changes in medications or treatment that may help to resolve these problems.

**TABLE 62-1****Cognitive Effects of Normal Aging**

	<b>PRESERVED COGNITIVE FUNCTIONS</b>	<b>COGNITIVE FUNCTIONS SHOWING DECLINE</b>
General intellectual functioning	Crystallized, verbal intelligence	Fluid, nonverbal intelligence, speed of information processing
Attention	Sustained attention, primary attention span	Divided attention (possibly)
Executive function	"Real world" executive functions	Novel executive tasks
Memory	Remote memory, procedural memory, semantic recall	Learning and recall of new information
Language	Comprehension, vocabulary, syntactic abilities	Spontaneous word finding, verbal fluency
Visuospatial skill	Construction, simple copy	Mental rotation, complex copy, mental assembly
Psychomotor functions		Reaction time

## Executive Functions

Executive functions include the ability to control and direct behavior, make meaningful inferences and appropriate judgments, plan and carry out tasks, manipulate multiple pieces of information at one time (working memory), complete complex motor sequences, and solve abstract and complex problems. Neuropsychological test performance on executive tasks declines slightly with age, and several current theories posit that deficits in working memory and executive function underlie many age-related changes in cognition. Neurocognitive tasks that require response inhibition, such as the Wisconsin Card Sort Test, Stroop Color–Word Test, and Brown–Peterson Distractor Test, may be affected.

Alternatively, many have suggested that a reduction in cognitive processing speed rather than executive function per se may be, at least in part, responsible for decreased performance on executive tasks. It should be noted that changes in the executive system that occur with normal aging are much less severe than the deficits associated with dysexecutive syndromes, including those caused by stroke, heavy and prolonged alcohol use, head injury, and some neurodegenerative diseases. In fact, successful aging appears to produce little impact on "real world" executive functions requiring planning and executing multiple tasks. Thus, it is important to assess an individual's actual functional abilities in addition to performance on neuropsychological tests of executive function.

## Memory

Memory changes are perhaps the most common cognitive complaints reported by older adults. Patients often wonder if their subjective concerns reflect normal age-related changes, or some pathological condition. For patients with a family history of Alzheimer's disease or other dementia, even minor memory failings can cause significant anxiety. One of the difficulties in answering such questions lies in the complex nature of the memory process. Different forms of memory are invoked when learning new information (declarative memory), recalling prior life events (remote memory), recalling general knowledge not tied to a specific event (semantic memory), and remembering procedures for performing tasks such as riding a bicycle (procedural memory). In addition, some conditions result in modality-specific deficits, differentially affecting verbal or visual memory.

A number of models describe the different stages or processes involved in forming and recalling memories. One example, the modal model, describes memory processes in terms of sensory memory, short-term (working) memory, and long-term memory. First, when

a patient senses and attends to a given stimulus, a large amount of information is briefly held in sensory memory. Information is then rehearsed or manipulated in short-term or working memory. Although many factors are involved in determining what information is transferred to long-term storage, sufficient rehearsal is a common requirement for successful transfer. Thus, it is clear that when a patient complains of memory changes, additional information is required to make sense of the problem.

Although it is true that some older adults continue to demonstrate memory performances comparable to young adults, on average even healthy older adults do show changes in some aspects of memory. For example, when a large group of healthy, nondemented elderly subjects was followed over a 7-year period, a general memory factor showed significant decline with time. Other studies have attempted to describe which aspects of memory change with healthy aging. In general, older adults without significant illness demonstrate increased difficulty learning new information compared to younger cohorts. When older adults are given repeated chances to practice learning new information, they demonstrate a slower learning curve and a lower total amount learned.

Although healthy older adults may retain slightly less information after a delay than do younger adults, this effect is less pronounced than the slowed learning rate. For delayed memory tests, patients are generally asked to recall information 15 to 60 minutes after the initial exposure. Although patients recall less information at the delay with age, they generally retain a stable proportion of the information that they initially learned. In general, longitudinal studies of aging show only small declines in delayed memory with age, particularly on tests of visual memory. Some older adults also appear less likely to use cognitive strategies to aid memory than younger subjects. This may be owing to generational differences in learning style. However, it may be significant because the use of memory strategies (i.e., grouping vegetables and clothing items for easier recall) reduces the age effect observed on free recall tests.

A number of memory processes do not appear to change with successful aging. Remote memory, that is recall of events that occurred in the distant past, remains relatively intact, as does sensory memory. In addition, while elderly patients often have medical problems that limit physical movement, procedural memory appears to be unaffected by healthy aging. Lastly, semantic memory, such as vocabulary and general information about the world, remains largely unchanged by aging until very late in life.

Longitudinal studies have consistently shown that as groups age, the variability in cognitive performance increases. Overall, studies of healthy aging suggest that there are some statistically significant

declines in memory in late life. However, the memory functions of patients who age successfully are typically adequate for the demands of independent living.

## Language

Language abilities incorporate multiple levels of processing, and general language functions tend to remain relatively stable with increasing age. Some linguistic abilities, however, particularly those involving language output, show reliable declines in older adults. As with other cognitive functions, there are multiple potential intervening factors, including trauma, illness, and sensory disruption, that may lead to more severe changes in the language functions.

### Language Comprehension

Language comprehension involves discerning the simple and complex rules of language and incorporating both visual and auditory information into a meaningful concept; language comprehension is generally associated with few age-related impairments. The ability to recognize basic word structure and word representation is typically measured using “lexical-decision” tasks (in which letters are rapidly presented and the person is asked to identify whether or not it is a word), and simple word reading tasks. While some studies have suggested an inverse relationship between performance on these tasks and age, it is generally believed that such changes are the result of decreased reaction time and processing speed rather than the ability to comprehend word structure and meaning. In addition, there is some indication that the level of lexical processing changes slightly with age, in that older adults tend to rely more on word recognition than do younger adults, while ignoring other factors such as word length. Phonological understanding of language does not appear to change significantly with age, although hearing loss may appear to reduce auditory comprehension. Overall, it is generally accepted that language comprehension remains relatively intact throughout the lifespan.

### Language Production

Basic syntactic abilities do not appear to change significantly with advancing age, although minor repetitions, longer pauses, and an increased use of pronouns and other vague words while speaking have been noted. Additionally, a recent longitudinal study suggests a decline in spoken grammatical complexity during the eighth decade of life. The authors note, however, that there is high interindividual variability throughout the lifespan in terms of syntactic aptitude.

Semantic abilities involve aptitude with naming and retrieving long-stored information. There is a steady increase in vocabulary knowledge throughout middle adulthood, and such knowledge typically remains stable in the later years. A frequent complaint from older adults, however, involves the “tip-of-the-tongue” phenomenon, in which there is a notable struggle with spontaneous word finding. In contrast to the dysnomia that often accompanies dementia, however, such changes appear to result primarily from difficulties retrieving rather than storing information, and thus there is usually a marked improvement when cues are given. Verbal fluency, the rate at which a person can spontaneously produce words belonging to a single phonemic or semantic category, also appears

to change somewhat with age. Multiple research findings support a decrease in semantic fluency (“name all the animals you can”) while phonemic fluency (“tell me as many words as you can that begin with the letter F”) generally remains stable. In terms of strategy, it has been suggested that younger adults tend to produce more words and to change categories more frequently than do older adults on semantic fluency tasks, while older subjects generate the same amount of words but more “clusters” on tasks of phonemic fluency. Thus, older subjects likely rely more on structural word knowledge than on word meaning.

## Visuospatial Skills

Visuospatial skills are commonly tested by constructional tasks in which patients are asked to draw figures or assemble objects. In general, as patients age, they become slower at completing visuospatial tasks. However, as noted, one of the more consistent findings in the field is that normal aging is associated with general slowing of psychomotor and cognitive speed. Therefore, performance on tests of visuospatial functioning is often confounded by slowing. Some studies have attempted to separate the effects of the two domains. For instance, after controlling for processing speed and executive functioning, the effects of age on the commonly used Wechsler Block Design test were dramatically reduced. Similarly, an 11-year follow-up of elderly subjects analyzed both speed and quality of performance (errors) on a parallelogram test. As expected, speed declined with age, but the quality of the performance actually improved significantly. This body of literature suggests that declining speed contributes to some of the findings that report visuospatial processing deficits in normal aging.

Speed does not appear to account for all of the visuospatial changes observed in healthy aging, however. Mental rotations of objects or spatial coordinates, accurate copy of complex geometric designs, and mental assembly of objects typically worsen with age even when unlimited time is allowed to perform such tasks. Furthermore, when speed is included in scoring, some studies have reported disproportionate slowing on visuospatial tasks compared to verbal tasks. Overall, some studies may exaggerate the visuospatial decline observed in normal aging because of the role speed plays in many tasks used to assess visuospatial function. However, abstract spatial abilities may decline with age, even when speed is controlled.

## Psychomotor Functions

An age-associated increase in reaction time, related to both a general reduction in the speed of cognitive processing and to changes in peripheral motor skills, has been consistently reported. Age-related declines in brain dopamine activity and periventricular white matter changes may be associated with reduced cognitive speed and basic motor functions. As a result, performance on tests requiring speed and quick reaction to stimuli is likely to decline. As previously noted, increased psychomotor speed and reaction time are believed to underlie many of the age-related changes noted on neurocognitive testing, particularly tasks involving perceptual speed, attention, and working memory. In addition, changes in psychomotor functions can be associated with changes in real world tasks, such as driving. As a result, it is important to monitor the manner in which physical changes are impacting an individual’s level of safety in performing daily activities.

## COGNITIVE EFFECTS OF COMMON AGE-RELATED MEDICAL CONDITIONS

In the following section we review cognitive symptoms associated with common diseases affecting older adults. A summary of these symptoms is presented in [Table 62-2](#).

### Cardiovascular Disease

In addition to increasing the risk for developing stroke and/or vascular dementia, cardiovascular disease potentially jeopardizes cognitive function via multiple mechanisms.

Cognitive impairment subsequent to coronary artery bypass graft (CABG) surgery has been reported in up to 80% of patients, and older age significantly increases the risk for development of such complications. A wide range of cognitive deficits, including problems with attention and concentration, processing speed, memory, and visuospatial function, has been noted in patients immediately following surgery. Initial reports suggested that postoperative cognitive function stabilizes or even improves after a period of approximately 12 months in those patients who demonstrate initial decline. However, recent longitudinal data provide evidence that such patients are at high risk for continued cognitive deterioration 5 years postsurgery. For example, one study found that 42% of patients showed a significant decline in one or more areas of cognitive function 5 years postsurgery, including verbal and visual memory, attention and concentration, and general cognition. Notably, post-CABG neurocognitive status is related to overall quality of life, and current recommendations underscore the importance of closely monitoring cognitive status in the years following cardiac surgery.

### Hypertension

Essential hypertension has been associated with cognitive impairment independent of secondary disease or organ damage, particularly in older patients. Potential cognitive effects of primary hypertension include reductions in mental status, slowed reaction time, reduced attention and vigilance, weakened executive function, poor verbal fluency, and impaired visual organization and construction. Memory functions, including spatial recall, verbal recall, and word recognition, may also be affected in some hypertensive patients. In addition, secondary effects of hypertension may lead to an increased risk for cognitive decline in older age. For example, uncontrolled hypertension potentiates the development of subcortical white matter lesions, and adversely impacts cerebral blood flow and energy substrate delivery. While there is currently debate concerning the extent to which hypertension and related subcortical effects overtly impact cognition, recent findings suggest that hypertension is a significant risk factor for dementia, and treating hypertension reduces this risk. In particular, mid-life hypertension increases the risk of later-life cognitive impairment. Interestingly, blood pressure often declines in the period immediately preceding the onset of Alzheimer's disease, and it has been suggested that low blood pressure in persons of advanced age may compromise brain function as a result of hypoperfusion. In particular, aggressive sudden lowering of blood pressure in older adults with long-term hypertension may potentially interact with their chronically upregulated cerebral vascular resistance and induce cerebral hypoperfusion. Thus, careful monitoring of blood

pressure and gradual titration of medication regimens is of particular importance. Additional interest has been focused on the question of whether different methods of treating hypertension may confer particular protective effects on cognition. A recent epidemiologic study observed a reduced risk of dementia associated with the use of potassium-sparing diuretics. However, no adequately controlled, randomized trials have been conducted to definitively answer this question.

### Nutritional Deficiency

Older adults are at considerable risk for nutritional deficiencies as a consequence of poor diet and malabsorption syndromes. Much research in this area has focused on deficiencies of B vitamins. A recent meta-analysis concluded that reduced folate levels may be associated with lowered cognitive function and increased risk of Alzheimer's disease; however, the accumulated evidence did not support a similar relationship for B-12 and B-6. Some studies have suggested that supplementation may improve cognitive performance in deficient individuals.

B vitamins play an important role in homocysteine metabolism. Homocysteine is an independent risk factor for cerebrovascular and cardiovascular disease. In patients with both Alzheimer's disease and vascular dementia, elevated plasma homocysteine levels have been reported, and recent studies suggest that homocysteine levels are related to cognitive function in normal aging. Reduced performance on tests of mental status, nonverbal pattern abstraction, construction, and processing speed are reported in patients with high plasma homocysteine. Given that plasma homocysteine and folate levels are inversely related, it is conceivable that such cognitive deficits are related to reduced folate rather than to increased homocysteine per se. Recent data suggest, however, that homocysteine increases the risk for cognitive decline independent of both folate levels and other vascular risk factors.

### Type 2 Diabetes Mellitus

Much attention has been given to the rampant epidemic of type 2 diabetes mellitus (T2DM) in older adults, a trend thought to be largely attributable to obesity and physical inactivity. Current prevalence estimates suggest that 20% of adults older than 65 years are afflicted with T2DM. The negative impact of T2DM on multiple medical systems is well known. The clear impact of T2DM on cognitive function in older adults is less-widely known, but accruing evidence demonstrates that these patients show pronounced impairment in attention and verbal memory when compared to healthy age-matched adults, and show accelerated cognitive decline over time. Complex attentional impairment is most common, involving the inability to handle multiple streams of information or attend to information in the face of competing stimuli. Verbal memory deficits typically affect the ability to encode new verbal information. The magnitude of such impairment may vary from subtle subjective complaints to pronounced impairment that interferes with daily activities and may interfere with the patient's ability to adhere to complex treatment regimens. The mechanisms causing attentional and memory impairments are likely multifactorial and include vascular factors, as described above, in addition to the potential negative effects of hyperglycemia and glucose toxicity thought to cause oxidative injury. Recent work also suggest that insulin resistance, independent

**TABLE 62-2**

**Possible Cognitive Effects of Common Age-Related Medical Conditions**

	SYMPTOM COURSE	INCREASED RISK FOR DEVELOPING DEMENTIA?	INCREASED RISK FOR DEVELOPING DEMENTIA?						
			MEMORY	ATTENTION	EXECUTIVE FUNCTIONS	LANGUAGE	VISUOSPATIAL FUNCTION	PSYCHOMOTOR FUNCTION	BEHAVIOR
Cardiac surgery	Symptom onset immediate after surgery, improvement noted in first year, then further decline possible in some patients	AD, VaD	Verbal and visual memory deficits possible several years after surgery	Reduced attention	Variable	No significant changes noted	May lead to impaired visual organization and construction	Reduced reaction time, general slowing	Depression common after surgery
Hypertension	May improve with antihypertensive treatment	AD, VaD	Verbal and visual recall and recognition deficits in some patients	Reduced attention and vigilance	Impairment in working memory and other executive function	Reduced verbal fluency	May lead to impaired visual organization and construction; more likely with comorbid diabetes	Reduced reaction time, general slowing	Variable
Diabetes	May improve with insulin or insulin-sensitizing agents	AD, VaD, PD	Verbal memory impairment related to deficits in encoding new information	Reduced complex attention, simple attention variable	Impairments in abstract reasoning and concept formation	No significant changes noted	Variable, more likely with comorbid hypertension	No significant changes noted	Depression common
COPD	May improve with oxygen therapy	AD, VaD	Verbal and visual memory deficits	Reduced attention	Impairment in abstract thinking	No significant changes noted	No significant changes noted	Reduced reaction time, general slowing	Depression common
Sleep apnea	May improve with CPAP treatment	Unknown	Verbal and visual memory deficits	Reduced attention	Impairment in general executive function; esp. working memory	No significant changes noted	No significant changes noted	Reduced reaction time, general slowing	Depression and irritability related to sleep disruption
Nutritional deficiency	May improve with supplementation, although effects of low vitamin B-12 may persist	Wernicke–Korsakoff syndrome	Recall deficits	Reduced attention	Impairment in abstract thinking	No significant changes noted	Nonverbal pattern abstraction, construction impaired in high homocysteine	Reduced processing speed in patients with high homocysteine	Variable
Hypothyroidism	May improve with thyroid treatment, although some patients do not return to baseline	AD	Recall deficits, intact recognition	Variable	Variable	No significant changes noted	Reduced visuospatial function	Reduced reaction time, general slowing	Depression

AD, Alzheimer’s disease; COPD, chronic obstructive pulmonary disease; PD, parkinsonian dementia; VaD, vascular dementia; CPAP, continuous positive airway pressure.

of hyperglycemia, may have negative consequences on brain systems mediating memory and attention. This intriguing possibility has implications for therapeutic approaches to treating T2DM, suggesting that strategies focused on improving insulin sensitivity may be preferable to those focused on augmenting insulin levels. Successful treatment of T2DM has been shown to improve cognitive function. The importance of treating and preferably preventing T2DM has been underscored by recent findings that it is a risk factor for various forms of neurodegenerative disease, including Alzheimer's disease, vascular dementia, and Parkinson disease.

## Oxygen Deprivation

### Chronic Obstructive Pulmonary Disease

Emphysema and chronic bronchitis obstruct airflow, resulting in hypoxemia and hypercapnia. Cognitive dysfunction is commonly observed in chronic obstructive pulmonary disease, although the specific skills affected appear to be broad and diffuse. Deficits in verbal and visual memory, attention, abstraction, psychomotor speed, information processing speed, and IQ have all been reported. These changes in cognition appear to be caused by hypoxemia. The decrease in arterial oxygen partial pressure correlates with neuropsychological impairments, and most studies indicate that oxygen therapy results in modest improvements in cognition. Depression is also common in chronic obstructive pulmonary disease and must be considered as another cognitive risk factor.

### Obstructive Sleep Apnea

The prevalence of obstructive sleep apnea (OSA) increases in geriatric populations. Many patients remain unaware of the disorder and report associated symptoms only when specifically queried. Cognitive changes in OSA can be diverse, but generally include attention, concentration, executive functioning, verbal and visual learning, and working memory. Tests of global functioning have also revealed differences compared to healthy elderly without OSA. There is debate regarding whether the cognitive deficits are caused by hypoxia, hypersomnolence, or both. However, severity of hypoxemia appears to relate to cognitive functioning, and continuous positive airway pressure treatment improves cognitive functioning in many patients.

## Thyroid Dysfunction

There are a number of thyroid disorders that result in hypo- or hyperthyroidism. Hypothyroidism appears to be associated with cognitive changes. Deficits may be observed in visuospatial skills, psychomotor speed, and memory. There is some evidence that the memory deficits are related to retrieval rather than immediate recall or learning; thus, disproportionately better performance may be observed on tests of cued or recognition memory than on free recall tests. Thyroid replacement therapy frequently improves cognitive functioning, although skills may not return to baseline levels in some patients. Hyperthyroid episodes may result in cognitive changes that last for many years. Symptoms may include attention and executive functioning deficits, and memory impairment. Hyperthyroid dementia is less common than in hypothyroidism, and is also generally less severe. The evidence supporting cognitive deficits in adults with subclinical thyroid disease is equivocal. Thyroid hormone abnormalities

occur in a large proportion of patients with dementia. Therefore, levels should be routinely monitored as a treatable contributor to cognitive decline.

## Depression

Depression is an increasingly common problem in older adults, with prevalence estimates ranging from 11% to 30%. Multiple situational risk factors for depression in older age include the loss of social support, death of family members and close friends, changing social roles, and physical limitations. Depressive symptoms, including lack of initiation, impaired executive function, cognitive slowing, poor attention and concentration, and mild memory impairment can mimic early signs of dementia and may potentially lead to misdiagnosis and/or lack of appropriate medical intervention. As depression is a potentially reversible cause of cognitive impairment, the differential diagnosis between depression and dementia is vital when evaluating elderly patients. Factors that are useful in discriminating between depression and dementia include the clinical course of symptoms, relationship to a specific crisis or stressful event, history of previous psychiatric problems, quality of effort, and level of impaired processing on cognitive evaluation (Table 62-3).

Recent findings suggest that late-onset depression is an independent risk factor for the development of neurodegenerative diseases, such as Alzheimer's disease and vascular dementia, and some hypothesize that depression may actually represent a preclinical phase of progressive dementia. In patients with early cognitive loss, depressive symptoms may represent realistic self-evaluation of such decline and/or may coincide with actual changes in neuroendocrinological status. In the absence of predisposing situational factors, late-onset affective disorders are quite rare. Subcortical vascular ischemic changes are frequently noted in patients with new-onset depression in late life, and such patients frequently have vascular risk factors such as hypertension, cardiovascular disease, and diabetes. For such cases, cognitive ability and independent functional status must be carefully evaluated, and an in-depth qualitative analysis of depressive symptoms may be useful. Major depressive disorder is associated with a range of affective, cognitive, and vegetative symptoms, while depressive symptoms in early dementia are more likely to include cognitive and motivational symptoms (e.g., poor concentration, lack of initiation) in the relative absence of central affective disturbance. Continued monitoring of the cognitive status of depressed elderly patients is essential in order to rule out progressive cognitive decline.

## Medications

A number of medications have the potential to cause both subtle cognitive changes and alterations in overall mental status, particularly in the elderly. Medications known to adversely affect cognitive status include opiates and opioid-like analgesics, benzodiazepines, anticonvulsants, antipsychotic and antidepressant medications, antiparkinsonian agents, central nervous system stimulants, antihistamines and decongestants, and certain cardiovascular medications. A variety of other medications, particularly those that readily cross the blood-brain barrier, may impact cognitive function in certain individuals. In addition, drug interactions in older adults can lead to more serious physiological and cognitive consequences than those observed in younger adults, and adverse medication interactions are more likely to occur in an older population. As a result, changes in

TABLE 62-3

## Depression Versus Alzheimer's Disease

	DEPRESSION	ALZHEIMER'S DISEASE
Symptom History		
Onset	Distinct, often related to a specific traumatic event or loss	Insidious onset
Progression	Rapid	Slow
Patient's description of symptoms	Detailed	Few details
Psychiatric symptoms/history		
Depressive symptoms	Affective, vegetative, cognitive	Cognitive, some vegetative
Psychiatric history	History of one or more depressive episodes usual	May or may not have a history of depression
Cognition		
Effort on testing	Often poor	Usually effortful
Memory		
Recent	Recall improves with cuing/recognition	Impaired, recall does not improve with cuing/recognition
Remote	May be impaired, may have memory "gaps"	Not impaired until late in disease
Procedural	May be impaired	Not impaired
Attention/concentration	Impaired	Impaired
Language	Assisted by semantic strategies	Unable to use semantic strategies

cognitive status must be carefully evaluated in light of a patient's current medication profile.

Certain medications may in fact enhance cognitive function in older adults and aid in the prevention of cognitive decline. The cholinesterase inhibitors donepezil, rivastigmine, galantamine, and tacrine have been shown to stabilize and even improve general cognitive function in some patients with Alzheimer's disease. Medications currently being evaluated for potential reduction of risk for cognitive decline in both healthy aging and dementia include statins, Non-steroidal Antiinflammatory Drugs (NSAIDs), antioxidant vitamin supplements, and estrogen replacement therapy.

## Delirium

Older adults are at a significantly increased risk for developing delirium, particularly following surgery or in response to medication changes or interactions. Delirium is a reversible condition that can be distinguished from most neurodegenerative diseases by a rapid onset of symptoms that include significant disorientation and disturbance in consciousness, reduced awareness of the environment, and attention deficits. While recent memory is generally impaired, altered consciousness is the primary indicator of delirium. Hallucinations, delusional thinking, and other disturbed thought processes may also be present. Delirium usually resolves quickly, but may persist for several weeks. It should also be noted that postoperative delirium may signify the presence of a beginning dementia. A primary concern is to identify and treat the underlying cause while providing a supportive and nonthreatening environment for the patient.

## NEURODEGENERATIVE DISEASE

The following section reviews the cognitive and behavioral profiles associated with common neurodegenerative disorders (Table 62-4). Early identification of such disorders, many of which are diagnosed solely on these parameters, has become increasingly important owing to potential therapies that may delay disease progression.

## Alzheimer's Disease

Alzheimer's disease (AD), the most prevalent of the primary neurodegenerative disorders, causes profound progressive cognitive and functional impairments. While confirmatory diagnostic procedures require histopathologic evaluation at autopsy, probable AD may be diagnosed on the basis of a thorough clinical assessment. The most widely accepted diagnostic standards for probable AD are the National Institute of Neurological and Communicative Disorders and Stroke (NINCDS) and the Alzheimer's Disease and Related Disorders Association (ADRDA) criteria, and include the following: (1) dementia as noted on clinical examination and established by neuropsychological testing, (2) significant impairment in two or more areas of cognition, (3) progressive memory decline, and (4) absence of other medical or psychiatric conditions, including delirium, as the cause for memory impairment. Current debate surrounds the value of an almost purely exclusionary diagnosis, and as a result potential cerebrospinal fluid markers (elevated beta amyloid or tau proteins), structural and functional changes on brain scan, and genetic factors are under close scrutiny for their potential diagnostic utility. In the absence of such tools, however, the current conventional diagnostic criteria are considered to be reasonably accurate, particularly when the evaluation is comprehensive and includes a complete medical and psychosocial history, medical evaluation, and neurocognitive testing.

### Patient History

A complete medical and psychosocial history is a vital component of any dementia assessment. Such a history should be obtained both from the patient and a reliable informant, preferably someone who has regular contact with the patient and who has an adequate opportunity to observe patient's daily functional abilities. Typically, a patient in the earliest stages of AD will not exhibit deficits in basic self-care. However, more complex daily tasks, including driving, finances, shopping, and other chores and activities, are likely to be affected. A gradually progressive course and insidious onset of

**TABLE 62-4****Early Cognitive Symptoms Associated with Different Dementia Types**

	SYMPTOM ONSET	PROGRESSION RATE	MEMORY			
			Recent	Recognition Intact?	Remote Intact?	Procedural Intact?
Alzheimer's disease (AD)	Insidious	Steady, gradual	Significantly impaired declarative recall	N	Y	Y
Vascular dementia (VaD)	May be insidious or acute	Stepwise or gradual	Possible deficits	Y	Y	Y
Frontotemporal dementia (FTD)	Insidious	Steady, rapid	Relatively preserved	Y	Y	Y
Primary progressive aphasia (PPA)	Insidious	Steady, varied	Preserved recall, may score poorly on verbal memory tests	Y	Y	Y
Parkinson disease (PD)	Insidious	Varied	Possible deficits	Y	Y	N—possible impairments
Dementia with Lewy bodies (DLB)	Insidious	Steady, gradual	Mild impairment, less than AD	Variable	Y	Y
Progressive supranuclear palsy (PSP)	Insidious	Steady, gradual	Mild impairment, less than AD	Variable	Y	Y
Persistent alcohol dementia	Deficits persist after d/c alcohol use	May worsen over time	Impairment on recall, not more than other functions	Variable	Y	Y
Wernicke-Korsakoff syndrome	Acute (initial phase)	Steady, gradual (chronic phase)	Significant impairment on declarative recall relative to other deficits (semantic memory spared)	N	N	Variable
Prion disease	Insidious	Steady, rapid	Nonspecific impairments reported	Y	Y	Y
Normal pressure hydrocephalus (NPH)	Insidious	Varied, potentially reversible	Not prominently impaired	Y	Y	Y
Human immunodeficiency virus (HIV)	Usually later in the disease course	Varied	Variable	Variable	Y	Y
Neurosyphilis	Many years after initial infection	Varied, potentially reversible	Variable	Variable	Y	Y

ATTENTION	EXECUTIVE FUNCTIONS	LANGUAGE	VISUOSPATIAL FUNCTION	PSYCHOMOTOR FUNCTION	BEHAVIOR
Intact primary span; impaired selective/divided attention	Mildly impaired working memory, response inhibition, general problem-solving	Semantic organizational abilities significantly impaired, mild anomia	Simple construction intact, complex visual reasoning impaired	If present, symptoms are mild	Depression common
Intact primary span; impaired selective/divided attention	Significantly more impaired than AD and relative to performance on verbal memory tasks	Verbal fluency impaired	Relatively preserved, although may be affected by executive impairments	Slowing, possible discrete motor problems depending on distribution of vascular changes	Depression common
Intact primary span; impaired selective/divided attention	Impaired across a range of executive functions	Verbal fluency impaired	Relatively preserved, although may be affected by executive impairments	May exhibit ideational apraxia	Significant behavioral changes: apathy/blunting, disinhibition, lack of insight, etc.
Preserved	Preserved	<i>Nonfluent PPA</i> : Anomic aphasia, poor articulation, dysarthria, relatively preserved comprehension; <i>Fluent PPA</i> : Impaired comprehension, anomia, intact speech rate & prosody	In semantic dementia, may have visual agnosia	<i>Nonfluent PPA</i> : Buccofacial apraxia	Changes unlikely
Intact primary attention span, impaired selective/divided attention	Difficulty planning/shifting set	Verbal fluency, mechanical aspects of speech impaired	May be impaired	Resting tremor, bradykinesia, rigidity, postural instability, shuffling gait	Depression common, may exhibit hallucinations/delusions, less common than DLB
Significant fluctuations in attention	Variable	Variable; fluency may be impaired	Impaired construction, copy, visuospatial planning and problem-solving	May exhibit a range of parkinsonian symptoms	Hallucinations, delusions, depression
Impaired selective/divided attention	Impaired across a range of executive functions	Verbal fluency impaired	May be impaired	Vertical supranuclear gaze palsy, postural instability	Apathy, disinhibition
Impaired sustained attention	Abstraction, mental flexibility, perseveration, confabulation, impaired judgment, reduced ability to care for self	Preserved	Visual scanning, visuospatial organization impaired	May exhibit cerebellar tremor, impaired gait	Apathy, depression
Impaired across all attentional functions	Similar profile to persistent alcohol dementia	Preserved	Visual scanning, visuospatial organization impaired	Impaired gait, abnormal reflexes, other movement abnormalities	Personality change prominent feature, inappropriate behavior
Nonspecific impairments reported	Reduced problem solving ability	Generally preserved	Generally intact	May exhibit impaired reflexes and coordination	Apathy, emotional lability, impaired sleep, appetite loss
Primary deficits in attention	Nonspecific impairments in executive function reported	Generally preserved	Generally intact	Wide-based gait or other balance disturbance, urinary incontinence	May present with a confusional state
Nonspecific impairments reported	Nonspecific impairments in executive function reported	Generally preserved	Generally intact	Generally intact	Depression common
Variable	Variable	Generally preserved	Generally intact	May be ataxic	Hallucinations, delusions, personality change, mood disturbance

cognitive symptoms is a hallmark of the AD, and thus a careful history regarding the nature and timing of symptom onset and progression must be obtained. An inventory of all current medical concerns, past major medical problems, and medications must be evaluated in order to rule out conditions that may be either causing cognitive problems or influencing their expression.

### Medical Examination

An important goal of the medical evaluation is to exclude the presence of medical conditions that may be responsible for the observed cognitive deficits. It is critical to investigate potentially reversible causes of dementia such as uncontrolled liver or kidney disease, adverse reactions to medications, and delirium. Laboratory blood tests can aid in ruling out systemic illnesses or organ malfunction. Structural brain scans are used to evaluate major cerebrovascular events, tumors, normal pressure hydrocephalus, and other neurologic conditions, while functional brain scans identify patterns of activity that may be useful in classifying dementia type.

### Neuropsychological Assessment

Neuropsychological assessment of cognitive function not only provides confirmatory evidence for cognitive impairment, but may also aid in clarification of dementia type. Given the extensive variation in rate of AD progression among patients, regular neuropsychological examinations can also provide information regarding an individual's rate of progression and remaining cognitive strengths. Perhaps one of the most valuable assets of neuropsychological evaluation is the sensitivity of the tests to early cognitive decline. While there has been debate regarding the usefulness of providing an early AD diagnosis, it is generally accepted that such a diagnosis will allow the patients to avail themselves of current and emerging therapies, as well as to make decisions regarding health care, finances, and legal issues while still competent. In a typical neuropsychological evaluation, patients are given tests that sample a variety of domains of cognitive function. Results are compared to normative data based on age, and also to an individual's estimated premorbid abilities (based on educational and occupational background and performance on tests that tend to remain stable over time). Pattern analysis of test results, in combination with data from the patient history and medical evaluation, is then used to generate diagnostic possibilities. The following sections discuss cognitive impairment patterns typical in patients with AD.

**Memory.** The hallmark of AD, and most often the first cognitive symptom of the disorder, is anterograde amnesia, evidenced by difficulty with learning new information. Deficits are noted in declarative memory as a result of prominent impairment in information encoding, retrieval, and in particular, storage of new material. Patients are likely to exhibit deficits in recent episodic recall, and they or their caregivers often report misplacing items, forgetting recent events or conversations, and frequently repeating questions or statements. In contrast to impaired episodic recall and difficulty learning new information, procedural memory is rarely impaired, and remote memory remains relatively intact until later stages of the disease.

In order to adequately evaluate short-term memory loss and establish a pattern of impaired retrieval, neuropsychological evaluations include tests of both immediate and delayed verbal and visual recall. Tests such as the Folstein Mini Mental Status Examination

(MMSE) and other diagnostic screening instruments assess general mental status and orientation, but are not adequate for a comprehensive understanding of memory impairment. To satisfactorily assess a person's true memory ability, Zec recommends using tasks that are high in cognitive demand, that exceed the primary memory span (such as story recall and list learning tasks that include at least 10 items), and that have a recognition component. On neuropsychological examination, verbal and visual free immediate and delayed recall and recognition are significantly impaired in patients with AD relative to same-age peers, and patients typically exhibit a high number of intrusion errors and repetitions. Semantic recall is generally the most predominantly impaired, and thus verbal recall tasks are often the most sensitive to early memory loss.

**Attention and Executive Function.** Certain aspects of attention and concentration are often impaired early in the disease process, and recent research has supported that it may in fact be one of the earliest abilities affected in AD. While patients with AD are likely to have relatively intact simple attention (e.g., primary memory span), tests requiring selective and divided attention are likely to be impaired, particularly as task demands increase. This pattern of performance strongly supports the presence of a deficit in working memory (the ability to simultaneously attend, process, and respond to multiple pieces of information) early in the disease process, and a converging body of evidence supports a primary executive component in AD.

In addition to problems on tasks of complex attention and working memory, patients are likely to exhibit mild deficits in response inhibition, evidenced by intrusion errors and perseverative responses, on neuropsychological testing. Deficits in abstract reasoning, general problem solving ability, and making appropriate judgments are also commonly noted. In assessing for judgment and abstraction, patients may be asked the meaning of proverbs (e.g., "you can lead a horse to water but you can't make it drink"), and are often given hypothetical situations in which they must decide an appropriate course of action (e.g., "what would you do if you were in a crowded shopping mall and saw smoke and fire?"). On these tasks, even patients in their early stage of AD may provide incorrect or inappropriate responses.

**Language.** Semantic processing is considered the primary language deficit in AD, and is present in more than half of all patients with AD at the time of diagnosis. Word finding problems are commonly reported in both AD and normal aging, but patients with AD have more severe deficits and are more likely to produce a significantly higher number of semantic paraphasias and circumlocutions. Patients are generally impaired on tasks of confrontational naming, and, unlike changes that occur with normal aging, are not likely to be assisted by cues. Syntactic processing, in contrast to semantic processing, is typically unaffected in mild AD. For example, patients with early AD can typically process even complex sentences at the same level as their healthy counterparts, and generally remain unimpaired on repetition and fluent speech. Verbal fluency tasks are particularly useful in evaluating both semantic and syntactic processing. Semantic, or category fluency (e.g., "tell me as many animals as you can") is generally impaired disproportionately to syntactic, or phonemic fluency (e.g., "tell me as many words that begin with the letter \_\_\_\_") in AD. While decreased information processing and working memory may impair an AD patient's responses on certain syntactic processing tasks, and comprehension and intelligible speech are likely to decline slowly as the disease advances, patients

who present first with nonfluent aphasia or impaired comprehension should be carefully evaluated for other conditions.

**Visuospatial Function.** Deficits in visuospatial abilities are frequently seen in patients with AD, although they generally appear later than memory and language deficits. Patients may become lost in familiar places (e.g., grocery store) or while driving. Eventually, disorientation may lead to confusion in one's own home and subsequent wandering behavior. Early deficits, however, are more likely to involve visuospatial problem solving. Neuropsychological tests commonly used involve comparing simple construction or copying, typically not impaired early in the disease, to complex visual reasoning. The presence of constructional apraxia early in the disease may indicate greater pathology in visual processing areas of the brain and has been associated with more rapid symptom progression. In general, more complex drawing tasks, such as three-dimensional figure copy, may be more precise measures of the most common early visual spatial deficits in AD than simple copying tasks.

**Motor Function.** While motor dysfunction has not been typically considered to be a defining symptom of AD, recent research suggests that patients with AD may display impairments in gait, motor speed, and general level of activity even in the mild stages of the disease. In addition, converging evidence provides support for greater overlap between AD and Lewy body dementia, making motor changes such as tremor or gait disturbance more likely in these patients. Importantly, there have been reports of gait disturbance in patients taking cholinesterase inhibitors, a factor that should be carefully monitored when prescribing these medications.

Patients with AD may also exhibit mild ideomotor and ideational apraxia (deficits in skilled movements) as a result of concrete responses, lack of sufficient external cues, or a disruption in conceptualization ability. However, moderate to severe apraxia is not generally present until later stages of the disease. Incorporating an apraxia assessment into a dementia evaluation is useful, however, particularly for excluding other disorders that may initially present with more severe skilled movement disorders.

### Behavioral Changes

As mentioned previously, depression is common in patients with AD, and may manifest as apathy, indifference, poor initiation, or emotional lability. Irritability, agitation, and paranoid ideation are also common in AD, and may worsen with disease progression, prompting wandering behavior and aggressive outbursts. Repetitive and aimless behavior may also increase as the disease progresses. More severe psychotic symptoms, such as hallucinations and severe delusions, have been reported in some patients with early AD, but are typically rare in the absence of coexisting disorders. Given the wide range of behaviors that may be exhibited in an AD patient, it is imperative that the patient's family be provided with ample dementia education, that they have access to social support, and that they possess the coping skills necessary to provide adequate care.

### Awareness of Deficits

Patients in the early stages of AD typically vary in their level of deficit awareness. Whatever the starting point, deficit awareness declines

with disease progression. Even when patients do acknowledge their cognitive decline, however, such awareness may not be "complete" as a result of deficits in executive function. For example, patients may be unable to translate cognitive problems into functional problems, and as a result may not understand how their deficits affect certain activities, such as driving, cooking, and finances. Again, providing the patient's caregivers with access to education can increase the likelihood that patients will comply with physician recommendations to limit certain unsafe behaviors.

### Variant AD Presentations

While most often the primary early deficit in AD involves recent memory, there are several reported cases of variant forms of AD that involve primary deficits in language, visuospatial function, or central executive function. In such cases, differential diagnoses including frontotemporal dementia, primary progressive aphasia, Lewy body dementia, and others must be carefully considered prior to assigning a diagnosis of AD.

### Mild Cognitive Impairment

The term "mild cognitive impairment" (MCI) has been used to describe cognitive impairment in aging that does not meet the criteria for dementia and that is not the result of a known medical condition. Petersen and colleagues have proposed a set of criteria used to diagnose MCI that includes the following: (1) subjective memory concerns, (2) objective impairment in memory on neuropsychological testing, (3) absence of dementia, and (4) absence of functional complaints. Longitudinal research suggests that 80% of those diagnosed with MCI will go on to develop AD within 5 to 8 years, and will convert at a rate of approximately 10% to 15% per year compared to general population conversion rates of 1% to 2%. The term "amnesic" MCI is currently used to differentiate between isolated impairment in memory versus impairments in other cognitive functions. Given the above noted conversion rates, it is proposed that amnesic MCI may actually be a preclinical stage of AD, while non-amnesic MCI may represent early onset of other forms of dementia, including frontotemporal, Lewy body, and vascular dementias (Figure 62-1). Neuropsychological assessment can be particularly useful in distinguishing between normal age-related changes and MCI.

### Vascular Dementia

The constructs of vascular dementia (VaD) and vascular cognitive impairment are undergoing rapid development. One evolving view describes vascular cognitive impairment as an umbrella term that subsumes the condition of VaD. Progress in achieving a coherent nosology is hindered by the likely heterogenous nature of these conditions, which complicates efforts to identify characteristic cognitive profiles. According to NINDS–AIREN criteria, six vascular "subtypes" ascribe dementia to multiple large infarcts, strategic single infarcts, small vessel disease, hypoperfusion, hemorrhage, or miscellaneous vascular insult. It is likely that dementia caused by small vessel disease is the most common form of VaD and provides the most uniform pattern of cognitive impairment. Cognitive profiles of these patients at early stages typically reveal executive function deficits, reduced verbal fluency, and slowing, with preservation of cued memory and an absence of intrusions. Depression, irritability,

**FIGURE 62-1.** Heterogeneity of the term “mild cognitive impairment.” (Reproduced by permission of Petersen R, Doody R, Kurz A, et al. *Current concepts in mild cognitive impairment.* *Arch Neurol.* 2001;58:1987. Copyright 2001 American Medical Association.)

and lack of initiative are also common. Difficulty in differentiating VaD from AD occurs in part because current criteria for dementia require memory impairment, and impairment in one additional cognitive domain. For adults with VaD, memory impairment may not occur until later in the disease process; thus, these patients have more progressed dementia and greater cognitive impairment at the time of diagnosis. A review of studies differentiating between early-stage AD and VaD found that the latter group had more pronounced deficits in executive function on tests such as the Wisconsin Card Sorting tests and the executive function scale of the Mattis Dementia Rating Scale than did adults with AD. Interestingly, performance between the two groups was similar on tests of selective attention and working memory such as the Trail-Making Test and Stroop Color–Word Interference test. In contrast, patients with VaD had better performance than patients with AD on tests of verbal learning and story recall, such as the California Verbal Learning Test and the Logical Memory subtest of the WMS-R, with fewer intrusions. It is important to note that as both VaD and AD progress, the cognitive profiles become more similar, so that differentiating mid-stage disease is very difficult. In addition, recent neuropathological studies have shown that many patients previously diagnosed with VaD caused by presence of vascular risk factors such as diabetes, hypertension, and radiologic evidence of ischemia have prominent AD pathology as well. Prevalence estimates of the co-occurrence of AD and VaD range from 20% to 40% of patients with dementia. Few studies have attempted to differentiate between mixed AD/VaD and either form of dementia on a neuropsychological basis, although it has been suggested that mixed dementia most closely resembles VaD from a cognitive perspective. Vascular pathology increases the likelihood that patients with neuropathological AD will show significant cognitive impairment. Finally, cognitive profiles for other forms of VaD such as multiple large vessel or single strategic infarcts are highly idiosyncratic, depending on lesion location and volume.

### Frontotemporal Dementia

Frontotemporal dementia (FTD) is a diagnostic category that has been used to describe a number of conditions including Pick disease, progressive aphasia, semantic dementia, behavioral disorder and dysexecutive syndrome, familial chromosome 17-linked frontal lobe dementia, FTD of the non-Alzheimer type, and other histopathological classifications. FTD has been estimated to account for 3% to 20% of dementia cases. Prototypical symptoms of FTD include personality change and slowly progressive executive dysfunction. Patients often present with behavioral disturbance that includes disin-

hibition, a lack of conformity to social norms, perseveration, emotional blunting, and a lack of insight. Neuropsychological testing generally reveals impaired selective and divided attention, difficulty shifting mental set, poor abstraction, and impaired verbal fluency. Perseverative errors are common. Spatial skills are relatively preserved, except when organizational skills are required for completion of the task. Unfortunately, the MMSE is not very helpful in diagnosing early FTD since many patients score within normal limits.

Both the personality changes and cognitive dysfunction observed at early stages of FTD exceed those seen in normal aging. The most difficult differential diagnosis is between FTD and AD. Age of onset for FTD is typically in the late 50s or early 60s, although exceptions are observed. Therefore, on average, patients with FTD show symptoms around a decade earlier than patients with AD. As with AD, patients with FTD show insidious onset of symptoms with a gradual progression. Although comparisons of AD and FTD groups do not always reveal significantly different cognitive profiles, in general, patients with FTD show relatively spared memory performance in comparison to their executive and language functioning, especially when memory cues are provided. Apraxia is also more common than in AD. Often a multidisciplinary approach may be most helpful in the differential diagnosis since studies indicate that up to 75% of pathologically confirmed patients with FTD also appear to meet clinical criteria for probable AD.

### Primary Progressive Aphasia

Primary progressive aphasia (PPA) has been described as the fifth most common cause of dementia. The diagnosis of PPA requires isolated language dysfunction for 2 years, with all other areas of cognition remaining largely intact, and the absence of radiological evidence of cerebrovascular or other neurological injury that would account for the aphasia. In the initial stages of PPA, anomia is inevitably present consisting of impaired object naming, impaired word finding, or both. Two broad categories of PPA are defined by the presence of additional language impairment. Nonfluent PPA is characterized by labored articulation, occasional dysarthria, dyscalculia and buccofacial apraxia, with preserved comprehension except for complex sentences with embedded clauses. In fluent PPA (also called PPA with verbal semantic comprehension deficits), word-finding pauses may still be evident, although speech rate and prosody are largely preserved. Comprehension is impaired, and patients may have difficulty both with naming objects and with pointing to objects when given their names. They are still able to demonstrate the use of such objects appropriately, however, reflecting intact knowledge of object

meaning. As the disease progresses, speech becomes empty and paraphasic. A related condition, semantic dementia, is diagnosed when fluent PPA is accompanied by impairment in visual recognition of objects, and the semantic meaning of both words and objects is lost. Patients with semantic dementia display prominent visual agnosias and can no longer demonstrate object use accurately.

Because anomia and other language deficits may occur in a number of neurodegenerative conditions, the differential diagnosis of PPA rests on the clear demonstration that nonlinguistic cognitive and behavioral functions are intact for the first 2 years of the disease. The examiner must carefully determine whether poor performance on memory and other nonlanguage tests is caused by language deficits such as impaired comprehension of instructions. The onset of PPA is typically in the fifth or sixth decade of life, and its rate of progression varies greatly. As the disease progresses, however, other cognitive functions become impaired, as does the patient's ability to carry out functional activities, thus, making a diagnosis of mid-stage PPA difficult, at best. Differential diagnosis is also complicated by the heterogeneous etiologies of PPA. The majority of patients have nonspecific focal atrophy of perisylvian language areas. A subgroup has AD-like pathology although not in brain regions typically associated with AD. Another subgroup have FTD and/or Pick pathology, although not the flagrant behavioral and executive function deficits of typical Pick disease.

### Lewy Body Disease

Although the following diseases have a number of different neuropathological features, a common shared characteristic is the presence of Lewy bodies, abnormal intracytoplasmic inclusion deposits, on neuropathological examination.

### Parkinson Disease

At its early stages, Parkinson disease (PD) can be difficult to differentiate from normal aging. Most patients initially present with a resting tremor. Other cardinal symptoms include bradykinesia, rigidity, and postural instability. Patients may also present with a shuffling gait, masked facies, and depression. Although there has been significant variability across estimates of the frequency of dementia in PD, it appears that approximately one-third of these patients develop dementia. Relatively healthy elderly patients can present with a number of these symptoms for unrelated problems. For instance, essential tremors are not uncommon and patients with arthritis often show slowed motor movements.

Typically, even nondemented patients with PD show slight cognitive deficits across a range of cognitive domains that are often conceptualized as executive dysfunction. PD with dementia is usually characterized by visuospatial deficits, attentional impairment, difficulty planning or shifting to a new stimulus, slowed information processing speed, and mildly impaired memory recall. Memory impairment is most frequently attributable to a retrieval deficit since recognition is generally intact. Procedural learning may be impaired, a pattern atypical in normal aging or in AD. Some language skills are intact, such as vocabulary, while others that tap additional cognitive domains, such as verbal fluency, are impaired. Mechanical aspects of speech are often impaired as well. Although PD has been characterized as a subcortical dementia to distinguish it from cortical dementias such as AD, this characterization has been criticized more
