in elderly patients. Renally excreted drugs are affected by decreased nephron mass in elderly patients.

The potential for response and degree of toxicity for various regimens in elderly patients appear to constitute a spectrum depending predominantly on the aggressiveness of the therapeutic regimen. The major limiting factor for most drugs is bone marrow reserve. Decreased reserve capacity has been demonstrated in both experimental animals and humans, but clinical toxicity depends on the degree to which bone marrow reserve is stressed. Age is an independent risk factor for neutropenia in elderly patients with lymphomas and leukemias. Other toxicities, such as the pulmonary toxicity of bleomycin, the cardiotoxicity of doxorubicin, and the peripheral nerve toxicity of vincristine, also appear to be increased somewhat, although, again, depending on the aggressiveness of the regimen. Comorbidity has a negative effect on survival in patients with cancer, and one study found that hospitalization for chemotherapy-induced toxicity in older patients increased significantly with their comorbidity score. Patients with stage II and III colon cancer treated with adjuvant therapy had a higher rate of cancer recurrence and mortality and grade 3 or 4 diarrhea if they also had concurrent diabetes mellitus.

Despite these risks in older people, a number of studies of adjuvant chemotherapy indicate similar benefits and toxicities in equivalently selected younger and older patients. Yet, older age is associated with less use of adjuvant chemotherapy in elderly patients with breast cancer independent of comorbidities. The phenomenon of “risk aversion” is underdosing in an attempt to avoid toxicities, but it effectively abrogates chances of a positive therapeutic response. This occurred in trials of adjuvant chemotherapy for breast cancer wherein poor results were seen in those elderly women who had lower than the prescribed dosage of adjuvant therapy, presumably in an attempt to avoid toxicities. In contrast, in those older women who had received doses of therapy equivalent to those of younger women, an equal effect was noted. The use of adjuvant hormonal therapy as with tamoxifen increases after the age of 65 years, peaking at 68% in women 70 to 79 years of age. Still, in patients who are 85 years or older, there is undertreatment with tamoxifen, placing these patients at risk for recurrence of their primary cancer.

When one considers somewhat more aggressive combination chemotherapy, such as for small-cell carcinoma of the lung, equivalent response rates have been obtained for older individuals, but this has come at the cost of increased marrow toxicity. However, 78% of patients younger than 65 years are actively treated for their lung cancer compared to only 49% of those older than 75 years. Similarly in a study of ~2000 patients with colorectal cancer, 88% of patients younger than 55 years were treated with chemotherapy compared to only 11% of those 85 years or older. Comorbidities and advanced age seem to be more common reasons for not using therapy in patients 75 years or older than was patient refusal.

Likewise, elderly patients with non-Hodgkin’s lymphoma are more likely to be treated with lower chemotherapy doses and with less aggressive regimens than those given to younger patients. This is despite the evidence that responses and survival in older patients are better with more aggressive multi-agent chemotherapy regimens. The addition of rituximab, a monoclonal antibody against the CD-20 antigen, to routine chemotherapy has significantly increased the complete response rates and overall survival in patients between 60 and 80 years without a clinically significant increase in toxicity.

Also, in elderly patients, AML, attenuated chemotherapy, or palliative chemotherapy leads to worse response rates and survival when compared to patients who receive traditional remission-induction chemotherapy. However, early treatment-related toxicity especially as a result of myelosuppression is significant. A monoclonal antibody against the CD-33 antigen has now been approved for use for AML relapse in patients who are 60 years or older.

When approaching decisions about chemotherapy in treating the elderly patient, the clinician should use those modalities that in the prescribed dosages have acceptable responses with acceptable levels of toxicity. In those tumor types that require extremely aggressive therapy, the physician may need to seek modifications and new approaches in order to achieve lower levels of toxicity. Such situations may be amenable to clinical trials (but in which elderly subjects are currently underrepresented) so that the best approaches to therapy can be delineated.

### Supportive Care

The effects of cancer and its treatment may be devastating to elderly patients and may require substantial supportive care. The goal of such therapy is to maximize the ability of patients to tolerate the treatment as well as the disease. Underlying problems requiring symptomatic relief need to be actively sought by the physician, because elderly patients more frequently underreport their symptoms. Many of the specific aspects of supportive care are covered in other chapters and are only mentioned here to stress their importance for the management of the elderly cancer patient. These include the extreme importance of effective pain management (see Chapter 30); maintenance of appropriate nutritional support (see Chapter 40); the supportive role of nursing and team care (see Chapter 26); the importance of patient, physician, and family discussions concerning decisions regarding terminal care and other issues (see Chapters 31–34); and the utility of hospice care (see Chapter 31).

One complication frequently seen in treatment of the elderly patient with cancer is nausea and vomiting. These side effects can seriously compromise the ability to deliver effective chemotherapy, and they create a considerable degree of morbidity. General guidelines to prevent morbidity from nausea and vomiting include (1) all elderly patients on chemotherapy should be well hydrated; (2) eliminate environmental factors, such as food and other odors, that may trigger vomiting; (3) if oral feeding is attempted, patients should use dry bland foods that are generally well tolerated; and (4) avoid high-protein diets. The importance of the prophylactic administration of antiemetics is recognized by various evidenced-based U.S. guidelines. All these guidelines recommend antiemetic prophylaxis with a 5-HT<sub>3</sub>-receptor antagonist in combination with a steroid in patients receiving moderately to highly emetogenic chemotherapy or radiotherapy. In all patients receiving cisplatin, a corticosteroid plus a 5-HT<sub>3</sub>-receptor antagonist is recommended for the prevention of delayed and anticipatory chemotherapy-induced nausea and vomiting. In patients receiving high-risk, noncisplatin regimens, a prophylactic corticosteroid with or without either a 5-HT<sub>3</sub>-receptor antagonist or metoclopramide is suggested. Overall, the prophylactic use of the most effective antiemetic regimen appropriate to the chemotherapy employed is suggested to prevent acute, delayed, and anticipatory nausea and vomiting. Such regimens must be used with the initial chemotherapy in order to prevent the occurrence of symptoms, rather than waiting to assess the patient's emetic response with

less effective treatment. These general guidelines can also be applied to elderly cancer patients.

Other side effects from chemotherapeutic agents that elderly patients are predisposed to include constipation from vincristine, and neuropathy from platinum analogues and taxanes.

Another significant problem as a result of the cancer itself or therapy for cancer is the occurrence of fatigue in elderly patients. This is one of the most common symptoms and significantly affects a patient's quality of life. In one systematic review, the prevalence of fatigue was 40% to 90% during treatment and 19% to 80% after completion of treatment. The etiology of fatigue is multifold ranging from immobility and deconditioning to anemia, depression, pain, poor nutrition, drugs, and metabolic causes. Treatment of fatigue is to usually treat the underlying causes, e.g., treat anemia with hematinics, iron, B-12, folate. Exercise programs can play a very positive role in the treatment of cancer-related fatigue. Drugs like methylphenidate and modafinil have been used to treat cancer-related fatigue, but have yet to be studied in older cancer patients.

Cytopenias resulting from the bone marrow suppressive effects of chemotherapeutic agents should be appropriately treated with transfusion of blood products or use of growth stimulating factors. The American Society of Clinical Oncology 2006 guidelines recommend preventive use of white blood cell growth factors for patients whose risk of febrile neutropenia is 20% or higher. The indications include elderly patients with diffuse aggressive lymphomas treated with curative intent and patients with AML older than 55 during induction and consolidation chemotherapy. Different types of white cell growth factors somewhat reduce the incidence of infections during aggressive chemotherapy in elderly patients, but they have had little impact on treatment outcomes and on survival. The cost-benefit ratios of these therapies must be weighed carefully.

Finally, the all important area of psychological support for elderly patients with cancer and their caregivers must be considered. This begins with effective physician-patient communication and acknowledgment of the patient's views and values at every stage of the disease. When appropriate, caregiver involvement can be critical. An assessment of the patient's coping skills and strategies will be very helpful. Acknowledgment and support of those who appear to work best for the patient are important. The patient's spiritual state and use of religious coping strategies are also important to assess and support. It is ironic that despite the increase in physical frailty and other decrements in function with age, older cancer patients appear to cope better with the psychological stress of the illness than do younger patients. This may be a result of the development of effective coping strategies from dealing with many other stressors over the years.

### CONCLUSION

Cancer occurs with great frequency in elderly patients. The relationship of cancer to aging poses a challenge to our scientific understanding of these processes as well as to our clinical approach to the elderly patient. Further research is required to resolve the former, but a systematic, logically developed diagnostic and treatment plan can produce effective and gratifying results in the latter.

# Breast Disease

Gretchen G. Kimmick ■ Hyman B. Muss

The breast, or mammary gland, is a fibrofatty organ that produces all the necessary nutrients for a newborn. In women of childbearing age, the breast responds to cyclic hormone production and contains an abundance of epithelial structures and stroma that enable the production of milk. In postmenopausal women, declining ovarian function in late menopause leads to regression of these structures. The postmenopausal breast contains a ductal system, but the lobules shrink and collapse, leaving an organ that is composed primarily of fat. While a breast lump in a premenopausal woman is likely to be a benign problem related to cyclic hormonal changes, in a postmenopausal woman, this is not the case and the most important breast disease is cancer.

Cancer is the leading cause of death in women aged 55 to 74 years and is second to heart disease in women aged 75 and older. The incidence of cancer increases dramatically with age. In particular, breast cancer—the most common cancer in American women—is a major health concern. According to 2007 American Cancer Society estimates, breast cancer is the most common cancer in women, accounting for 31% of all newly diagnosed malignancies (178 480 new cases) and the second leading cause of cancer-related death (40 460 deaths). Moreover, U.S. incidence and mortality data from the 1980s suggest that 12% of all women will be diagnosed with breast cancer during their lifetime and that 3.5% will die from it.

Approximately half of the cases of breast cancer occur in women older than age 65 years. In addition, 1999 National Vital Statistics indicate that the incidence increases dramatically with age (Figure 95-1) from an invasive breast cancer rate of 15 per 1000 in women aged 40 to 50 years to a rate of 43 per 1000 in women aged 70 to 80 years. Older age has also been associated with a lower breast cancer specific survival rate (Figure 95-1).

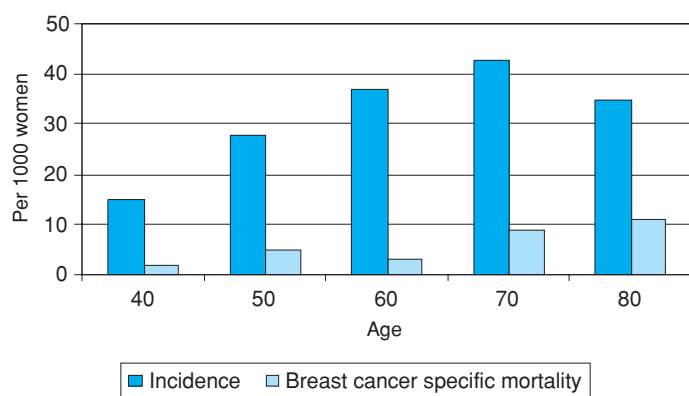

Breast cancer is a major health concern and will become of even greater importance as the size of the older population grows. Although breast cancer is more common in older women, they are also less likely to be appropriately screened, more likely to present for care at a more advanced stage and to receive inferior surgical

and postoperative management, and are less likely to be entered into clinical trials.

## RISK FACTORS AND BIOLOGY

The specific cause of breast cancer is unknown. Many factors associated with increased risk have been identified. These include the following: increasing age, white race, family history of breast cancer (especially in a first-degree relative), early menarche, late age at birth of first child (older than 30 years), late menopause, history of benign breast disease (hyperplasia or atypical hyperplasia), heavy radiation exposure, obesity, increasing height, postmenopausal estrogen replacement therapy, and moderate to excessive alcohol use. Most of these factors are associated with relative risks in the range of 1.4 to 2 times the risk in the general population. There is a breast cancer risk assessment tool, based on the Gail Model, available. This tool calculates the 5-year risk of breast cancer, using risk factors of age, age at first menses, age at first live birth, presence of first-degree relatives with breast cancer, number of past breast biopsies and whether or not atypical hyperplasia was found, and race/ethnicity. There is also geographic, economic, and racial variability in breast cancer incidence, with the highest incidence being found in affluent white populations. The reason for these differences is probably related to risk factor distribution, as well as genetic and environmental factors. Although breast cancer incidence differs among racial groups, such differences are minimized or lost when racial groups that are at low risk migrate to a high-risk environment.

A family history of breast cancer, implying a genetic defect, may be important in 5% to 20% of all cases of breast cancer. Genetic predisposition is particularly important in early-onset breast cancer (diagnosed before age 50 years), but is probably not a major factor in the geriatric population. BRCA1 accounts for approximately 45% of familial breast cancers. Another gene, BRCA2, is responsible for approximately 35% of genetic abnormalities in high-risk families.

**FIGURE 95-1.** Breast cancer incidence and mortality by age.

Both BRCA1 and BRCA2 portend increased risks for breast cancer and ovarian cancer, ranging from 36% to 85% for breast cancer and 16% to 60% for ovarian cancer. There are many modifying factors, including genetic, hormonal, and environmental, that determine whether a genetic mutation will lead to cancer.

Most breast cancers originate from ductal epithelium. Comparisons of older and younger patients with breast cancer reveal that infiltrating ductal carcinoma is the most common histological type in both groups, accounting for 75% to 80% of cases, with lobular carcinoma accounting for approximately 5% to 10%. Mucinous carcinoma and papillary carcinoma, histological types that are associated with a somewhat lower risk of recurrence, are more common in older patients, while inflammatory carcinoma, an aggressive lesion with a poor prognosis, is extremely uncommon in such persons. Cancers in older patients are more likely to be well-differentiated and moderately differentiated, be estrogen and progesterone receptor positive (60–70% of patients), have lower rates of tumor proliferation (the number of cells synthesizing deoxyribonucleic acid [DNA]), and less frequently express the HER2 oncogene, when compared with cancers in younger patients. These data suggest that breast cancer in older patients is biologically less aggressive than it is in younger women. Mortality from breast cancer, however, is not lower in older women, leading us to explore issues associated with treatment choice and other patient- and tumor-related factors that might affect disease specific survival.

## DIAGNOSIS

### Primary Prevention, Screening, and Diagnosis

#### Primary Prevention

Except for draconian measures such as prophylactic mastectomy, which is not 100% effective, there is no known effective means of preventing breast cancer. As the pathogenesis of breast cancer is likely to be related to interactions of estrogens, other hormones, and breast tissue, current research efforts toward prevention focus on the use of agents that lower breast tissue estrogen exposure, such as selective estrogen receptor modulators (SERMs) and aromatase inhibitors.

The SERMs, tamoxifen and raloxifene, decrease incidence of hormone receptor–positive breast cancer. Data from the Early

Breast Cancer Trialists' Collaborative Group meta-analysis involving 75 000 patients with early-stage breast cancer suggest that the use of tamoxifen decreases contralateral breast cancer risk by 40% to 50% in postmenopausal women. A national trial (National Surgical Adjuvant Breast Project [NSABP] P1) comparing tamoxifen with placebo as a means of prevention in women at high risk for breast cancer (a risk of 1.66% of invasive breast cancer over 5 years) showed that tamoxifen decreased the incidence of noninvasive and invasive breast cancer by approximately 40%, with the majority of the benefit in decreasing the risk of hormone receptor–positive breast cancer and no decrease in risk of hormone receptor–negative breast cancer. Thirty percent of women in this trial were older than 60 years and 6% were older than 70 years; similar risk reductions were seen in all age groups. A second, large randomized trial proved that raloxifene was as effective as tamoxifen in decreasing the incidence of hormone receptor–positive breast cancer. The SERMs, however, are also weakly estrogenic and increase the risk of thromboembolism. Further, tamoxifen, but not raloxifene, increases the risk of endometrial cancer. In clinical practice, the benefit of SERM treatment must be weighed against risk and can be estimated from a model developed from Gail and colleagues. At present there are large trials studying the use of aromatase inhibitors, which do not increase thromboembolic risk, compared to SERMs, to decrease the risk of breast cancer in postmenopausal women; older patients should be encouraged to participate in these trials. Maintaining an ideal body mass and exercise should also be encouraged.

#### Screening

Breast cancer screening in a postmenopausal woman includes mammography and a physical examination. After menopause, as estrogen levels diminish, breast glandular tissue and ductal tissue decrease and fat tissue increases. In addition, postmenopausal patients have fewer cysts and fibroadenomas. These age-related biological changes in breast tissue, especially the increased percentage of fat tissue, allow for improved contrast between small foci of malignancy and the surrounding breast tissue, resulting in fewer false-negative mammographic examinations. Several studies show that the routine use of screening mammography in women aged 50 through 70 years improves survival by detecting breast carcinoma at an earlier stage and before metastatic dissemination.

It is estimated that a 25% to 30% reduction in 5-year breast cancer mortality could be achieved if all women aged 50 to 70 years received appropriate screening with mammography. Controversy persists, however, because data are sparse in women older than 70 years. An overview analysis did suggest that mammography will be of benefit in this group. The average life expectancy of a healthy older woman who is 75 years old is 10 more years, and for a healthy woman aged 85 years, it is 7 more years, making it important to decrease cancer-related morbidity. When the estimated life expectancy exceeds 5 years, it is prudent to offer yearly screening mammogram.

Ten to twenty percent of all breast cancers are not visualized on a mammogram. Physical examination by health professionals and breast self-examination, therefore, remain essential and complementary adjuncts to mammographic screening. The patient–physician interaction is also important because, as several studies show, the most important factor for the physician to inducing an older patient to have a screening mammogram is to personally recommend it to the patient. Medicare law provides for payment for screening

**TABLE 95-1****Screening Guidelines for Breast Cancer in Women Older Than 70 Yrs**

	FREQUENCY	COMMENT
Breast self-examination	Monthly	Value uncertain, but many breast cancers are still detected by the patient
Physical examination	Yearly	By physician or other health professional; detects 15% of cancers <i>not</i> discovered on screening mammogram
Mammography	Every 1–2 yr	Value in improving survival in women older than 75 yr is unproven, but extrapolation of data from studies in postmenopausal patients suggests benefit if life expectancy is 5 yr or more

mammography on an annual basis. [Table 95-1](#) presents our recommendations for the screening of older women.

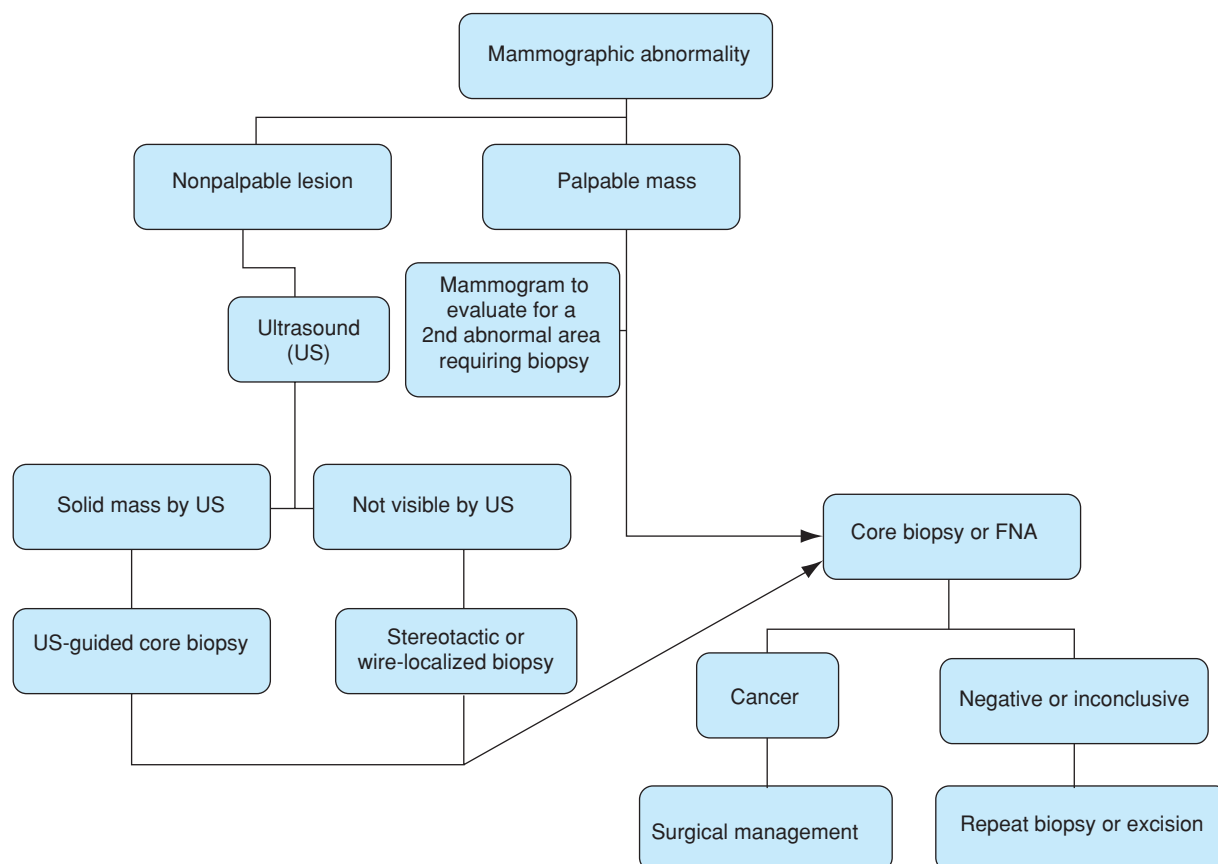

### Diagnosis

Breast cancer usually presents either as a breast mass or as a suspicious finding on a mammogram. The discovery of a breast mass in a

postmenopausal woman requires prompt attention, as the majority of palpable masses in this age group are malignant. All breast masses require biopsy in this patient population. Although it is not essential to the diagnosis in a woman who presents with a mass, mammography helps to define the nature of a mass and finds other nonpalpable lesions; it is, therefore, indicated when a breast mass is found. New mammographic findings also prompt evaluation. Typically, a step-wise process of diagnosis and definitive surgery is followed, as depicted in [Figure 95-2](#). This allows pathological confirmation of cancer and time to contemplate surgical treatment choice.

For palpable lesions, core-needle biopsy is preferable to fine-needle aspiration biopsy, because core biopsy can distinguish invasive from in situ lesions in most patients. Although concerns have been expressed that needle biopsy may be associated with tracking of malignant cells and a higher risk of local recurrence, such fears are unfounded. If the core biopsy or fine-needle aspiration is negative or inconclusive, unless the mass proves to be a cyst and resolves after aspiration, further biopsy, preferably excision, is necessary. For patients who have a mass that is characteristic of malignancy on physical examination or mammography, initial excision of the lesion or intraoperative biopsy to confirm invasive cancer and then lumpectomy or mastectomy, with or without sentinel lymph node biopsy or axillary dissection, may be preferable to a two-stage procedure involving a needle, core, or excisional biopsy.

For nonpalpable lesions that are found mammographically, ultrasound is recommended for further evaluation. If ultrasound finds a solid, suspicious lesion, ultrasound-guided biopsy can be done. If not visible by ultrasound, either stereotactic biopsy or needle-localized

**FIGURE 95-2.** Approach to a suspicious breast lesion in an older woman.

biopsy will be necessary. Stereotactic biopsy uses mammographic guidance to obtain a core biopsy specimen and is preferred because it allows pathologic diagnosis without anesthesia. The prone position required for the stereotactic procedure, however, may be difficult for some older patients. Needle-localized biopsy uses mammographic guidance to place a needle within the area of suspicion, after which the area is surgically excised, a procedure that typically involves anesthesia. If atypical hyperplasia is found on core biopsy, excisional biopsy is required, because a small proportion of suspicious lesions for which core biopsy finds only atypical hyperplasia will also contain in situ or invasive cancer when excised.

When biopsy is diagnostic of malignancy or definitive surgery is scheduled, preoperative evaluation includes a complete history and physical examination, a complete blood count and chemistry profile, and a chest x-ray. MRI of the breasts may also be helpful in management of older women, but is not recommended for routine screening. These studies are generally more helpful in determining the presence of comorbid illness than they are in finding metastases. Bone, computerized tomographic, or magnetic resonance imaging scans should be done to investigate signs or symptoms suggestive of metastasis, but are not necessary in asymptomatic patients. Bilateral mammography should be performed on all these patients to evaluate both the ipsilateral breast and the contralateral breast for other nonpalpable lesions.

It is important to remember that mammography is normal in 20% of patients with cancer. A palpable lesion in a postmenopausal woman always requires biopsy; mammography is of value mainly for detecting nonpalpable lesions in either the involved or the contralateral breast.

## Staging

The American Joint Committee for Cancer (AJCC) guidelines set the standard for breast cancer staging. This system categorizes the extent of malignancy according to the size of the primary lesion (T), the extent of nodal involvement (N), and the occurrence of metastasis (M). [Table 95-2](#) presents the AJCC breast cancer staging criteria. Tumor size (the largest diameter of the infiltrating component) and the extent of nodal involvement (the number of axillary nodes removed and the number positive) are determined from pathologic examination and are included in the pathology report. Less than 5% of the time, breast cancer presents as a diffuse infiltrating lesion and cannot be measured accurately. Nodal assessment is done either by sentinel lymph node biopsy or by axillary dissection. Sentinel lymph node mapping and sampling is preferred as it allows identification and assessment of the one to four nodes most likely to contain cancer. In an axillary dissection specimen, a sample of at least six nodes should be removed to reflect the prognosis accurately.

Other key prognostic information from the pathology report includes the following: histologic type and tumor grade, assessment of vascular or lymphatic invasion and skin involvement, and percentages of ductal carcinoma in situ and invasive carcinoma in the primary lesion. Paraffin-embedded tumor is then analyzed for other prognostic markers. Immunohistochemical analysis of the invasive cancer cells is also done to determine estrogen receptor (ER), progesterone receptor (PR), and human epidermal growth factor receptor-2 (HER2) status. An intermediate result for HER2 by immunohistochemistry necessitates analysis by fluorescent in situ hybridization

(“FISH”). Other markers, such as epidermal growth factor receptor and proliferative indices, are not of consistent benefit and are not needed on a routine basis.

After definitive surgical management, asymptomatic patients who have had an unremarkable preoperative evaluation, including history and physical examination, mammography, chest x-ray, complete blood count, and serum chemistries (with liver function tests and calcium), require no further staging procedures. The use of tumor markers, such as the carcinoembryonic antigen and mucin antigens (CA27.29 and CA15.3), in patient management is controversial and is not recommended on a routine basis.

## TREATMENT OF BREAST CANCER

### Carcinoma In Situ

The more widespread use of screening mammography has led to a major increase in the diagnosis of ductal carcinoma in situ (DCIS). Before the common use of screening mammograms, DCIS was uncommon, usually detected on physical examination, was large in size and the cure rate exceeded 95% with mastectomy. In a screened population, most DCIS lesions are nonpalpable and small and are suggested by microcalcifications found on screening mammography. Mastectomy cures almost all patients, but breast conserving procedures followed by breast irradiation are as effective for patients with smaller lesions.

Axillary dissection or sentinel node biopsy finds metastases in less than 1% of patients and is generally not recommended. Excision alone, without local radiation therapy, may be appropriate for patients with lesions less than 2.5 cm with generous (>1 cm) margins of normal tissue surrounding the in situ component.

Lobular carcinoma in situ (LCIS) is more common in premenopausal patients, lacks clinical and mammographic signs, is bilateral in 25% to 35% of cases, and is usually an incidental finding at breast biopsy. It is not a palpable lesion. Treatment options range from observation to bilateral mastectomy. Of note, 20% to 40% of patients with LCIS subsequently develop infiltrating ductal cancer, with both the ipsilateral breast and the contralateral breast at similar risk. LCIS serves as a high-risk marker for subsequent invasive cancer, and treatment selection must rest on the desires of the patient. Most experts recommend close follow-up of these patients, without aggressive surgery.

### Management of Early Localized Lesions (Stage I and II)

#### Local Management

Once a diagnosis of breast cancer is made, a woman is counseled about surgical choices, radiation therapy, and systemic therapy. With regard to local therapy, breast-conserving procedures result in virtually identical relapse-free and overall survival compared with more extensive surgical treatment, including simple, modified-radical, and radical mastectomy. Reasonably healthy older women tolerate simple or modified mastectomies as well as younger women do, but should be offered the option of breast-conserving surgical procedures when clinically appropriate.

TABLE 95-2

## AJCC Staging Criteria for Breast Cancer (Sixth Edition, 2002)

SYMBOL	MEANING
<b>TNM SYSTEM</b>	
Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ; intraductal carcinoma, lobular carcinoma in situ, or Paget disease of the nipple with no tumor
T1	Tumor $\leq$ 2 cm in greatest dimension T1a $\leq$ 0.5 cm in greatest dimension T1b $>$ 0.5 cm but not $>$ 1 cm in greatest dimension T1c $>$ 1 cm but not $>$ 2 cm in greatest dimension
T2	Tumor $>$ 2 cm but not $>$ 5 cm in greatest dimension
T3	Tumor $>$ 5 cm in greatest dimension
T4	Tumor of any size with direct extension to chest wall or skin (includes inflammatory carcinoma)
Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed (e.g., previously removed)
N0	No regional lymph-node metastasis; no additional examination for isolated tumor cells (ITCs, defined as single tumor cells or small clusters not greater than 0.2 mm, usually detected only by immunohistochemical or molecular methods but which may be verified on hematoxylin and eosin [H & E] stains). ITCs do not usually show evidence of malignant activity (e.g., proliferation or stromal reaction) <ul style="list-style-type: none"> <li>• pN0 (i -): No histologic nodal metastasis, and negative by immunohistochemistry (IHC)</li> <li>• pN0 (i +): No histologic nodal metastasis but positive by IHC, with no cluster greater than 0.2 mm in diameter</li> <li>• pN0 (mol -): No histologic nodal metastasis and negative molecular findings (by reverse transcriptase polymerase chain reaction, RT-PCR)</li> <li>• pN0 (mol +): No histologic nodal metastasis but positive molecular findings (by RT-PCR)</li> </ul>
N1	Metastasis in 1–3 ipsilateral axillary lymph node(s) and/or in internal mammary nodes with microscopic disease detected by SLND but not clinically apparent <ul style="list-style-type: none"> <li>• pN1mi: Micrometastasis (greater than 0.2 mm, none greater than 2.0 mm)</li> <li>• pN1a: Metastasis in 1–3 axillary lymph nodes</li> <li>• pN1b: Metastasis to internal mammary lymph nodes with microscopic disease detected by SLND but not clinically apparent</li> <li>• pN1c: Metastasis in 1–3 ipsilateral axillary lymph node(s) and in internal mammary nodes with microscopic disease detected by SLND but not clinically apparent. If associated with more than 3 positive axillary nodes, the internal mammary nodes are classified as N3b to reflect increased tumor burden.</li> </ul>
N2	Metastasis in 4–9 axillary lymph nodes or in clinically apparent internal mammary lymph nodes in the absence of axillary lymph nodes <ul style="list-style-type: none"> <li>• pN2a: Metastasis in 4–9 axillary lymph nodes (at least one tumor deposit <math>&gt;</math>2 mm)</li> <li>• pN2b: Metastasis in clinically apparent internal mammary lymph nodes in the absence of axillary lymph nodes</li> </ul>

**Management of the Breast.** The breast-conserving approach to breast cancer management involves removing the tumor mass with a clear margin of several millimeters of surrounding normal breast tissue (lumpectomy, tylectomy, quadrantectomy, etc.), assessing axillary lymph nodes, and delivering local breast irradiation after surgery. Ipsilateral axillary node assessment is recommended by most medical, surgical, and radiation oncologists to provide important prognostic data. Breast-conserving procedures require close cooperation among the radiologist, surgeon, pathologist, and radiation oncologist in order to locate and remove the area of concern, assure negative margins, and provide the best cosmetic result with lowest risk of local recurrence. Breast irradiation after removal of tumor mass reduces the likelihood of recurrence in the affected breast from 40% to less than 10% and may improve survival. Most breast relapses occur in or in close proximity to the previously resected lesion. Other techniques, such as brachytherapy (localized radiation therapy [RT] may prove to be as effective as whole-breast RT and can be completed over a period of several days. Two trials have shown that lumpectomy and tamoxifen confers the same short-term survival benefit as lumpectomy, tamoxifen, and breast RT, but that breast RT is better than tamoxifen in preventing in-breast recurrence. For healthy older patients at high risk for in-breast recurrence and reasonable life expectancy, breast radiation is recommended.

Contraindications to breast-conserving surgery include two or more gross tumors in separate quadrants of the breast, diffuse indeterminate or malignant-appearing microcalcifications, and a history of therapeutic irradiation of the breast region. Relative contraindications to breast-conserving surgery include the following: large tumor/breast size ratio (mass more than 5 cm in size), which interferes with cosmesis; large breast size, which makes radiation delivery difficult and interferes with cosmesis; and a history of collagen vascular disease, which has been reported anecdotally to increase the likelihood of fibrosis associated with radiation. It is important, however, not to underestimate the value to a patient of preserving her own breast, with sensation intact, even if the cosmetic appearance is not perfect. It is now well established that preoperative (“neoadjuvant”) chemotherapy or endocrine therapy (for women with ER- or PR-positive breast cancer) can shrink large breast cancers, allowing breast conservation for many patients without sacrificing distant recurrence or survival outcomes and without the need for preoperative chemotherapy.

Breast-conservation is more costly than mastectomy because of the time, inconvenience, and monetary expense of postoperative RT. Nevertheless, such treatment is preferred by many women, irrespective of age. The option for breast-conserving surgery provides motivation for detecting early-stage lesions through screening. Patients who have had breast-conserving procedures also have higher self-appraisals of body image and sexuality than do women who have had more extensive surgical intervention.

**Breast Reconstruction.** For older women who have had a mastectomy, breast reconstruction represents another option for restoring body image. Many physicians, because of personal bias, are unlikely to discuss reconstruction with older patients. This procedure can be done safely in an older patient and should be discussed, with subsequent surgical consultation if desired.

**Radiation After Mastectomy.** The likelihood of local recurrence is directly proportional to both the size of the primary lesion and

the number of involved axillary nodes. Postoperative adjuvant irradiation, therefore, is recommended for patients with large primary lesions (greater than 5 cm) or with four or more positive nodes. It is also considered reasonable for any woman with breast cancer that involves lymph nodes to receive postmastectomy “adjuvant” irradiation therapy to the chest wall and the contiguous regional lymph nodes (internal mammary, supraclavicular, and upper axilla), because it reduces the likelihood of local recurrence (recurrence in the mastectomy site or contiguous nodal areas) by 70% and improves overall breast cancer–specific survival rates by several percent. Delaying postoperative irradiation for 4 to 6 months to allow the completion of adjuvant chemotherapy is feasible and does not increase the risk of subsequent local recurrence.

**Axillary Assessment.** Tumor size and axillary nodal status are the most consistent predictors of the risk of recurrence and, therefore, key in making decisions about the risk/benefit ratio of adjuvant systemic treatment. Node involvement is found in 5% to 37% of women with very small tumors (less than 1 cm), and physical examination is only of modest benefit in predicting nodal involvement, with false-negative and false-positive rates of 35% and 25%, respectively. Because arm problems, such as swelling (lymphedema), pain, numbness, weakness, and impaired shoulder mobility, may complicate axillary dissection, the argument has been made that its prognostic benefit is not worth the risk of side effects in women with primary tumors less than 1 cm in size. Sentinel lymph node mapping and sampling, with its lower risk of arm morbidity, is the procedure of choice, if axillary assessment is deemed necessary.

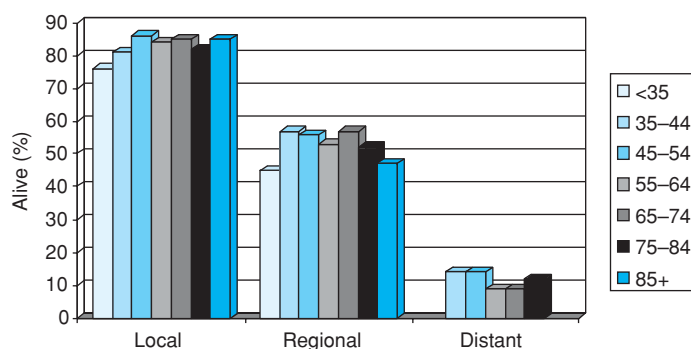

In older women, the role of assessing axillary nodes is quite controversial because of the risk of arm morbidity. If adjuvant chemotherapy is not a consideration because of physician or patient choice, the risk of axillary dissection is not worth its prognostic yield, regardless of the primary tumor size. It is generally acceptable to omit axillary assessment in older women with small (2 cm or less), clinically node-negative, ER-positive breast cancer, who will take adjuvant hormonal therapy for at least 5 years.

Lymphatic mapping with sentinel node biopsy is associated with less arm morbidity and is the standard method to assess axillary lymph nodes in women who have breast cancer and in whom there are no clinically evident ipsilateral axillary nodes. This procedure allows identification and sampling of the first nodes in the lymphatic basin to receive lymphatic flow, that is, presumptive removal of the initial site of metastatic nodal involvement. When the sentinel lymph node(s) is positive, the likelihood of finding further positive nodes after a more complete axillary dissection is approximately 50% and, therefore, a standard level I and II node dissection is indicated. Standard axillary dissection should be performed in any woman with breast cancer who has clinically palpable axillary lymph nodes.

## Adjuvant Systemic Therapy

Adjuvant systemic therapy involves preoperative, perioperative, or postoperative administration of endocrine therapy and/or chemotherapy to patients with localized breast cancer for the purpose of reducing risk of and delaying relapse and improving survival. Such treatment is aimed at eradicating occult, clinically undetectable metastasis.

Figure 95-3 shows 8-year breast cancer survival by age and stage and Table 95-3 describes 10- and 15-year overall survival according

**FIGURE 95-3.** Eight-year breast cancer survival by age and stage.

to current breast cancer staging criteria. Adjuvant therapy is chosen on the basis of the risk:benefit ratio. The anticipated risk reduction for metastatic disease is weighed against the risk of toxicity from adjuvant therapy. Estimated improvements in relapse-free and overall survival for adjuvant systemic therapy are provided by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) (Table 95-4). This group provides collaborative meta-analyses of 194 randomized trials studying adjuvant chemotherapy and hormonal therapy every 5 years and was last updated in 2005, with the ability to show 15-year effects. These data clearly confirm the benefits of adjuvant endocrine therapy and chemotherapy in significantly reducing the risk of recurrence and death in women with early breast cancer. Table 95-5 summarizes the overview of results of adjuvant therapy for postmenopausal patients by age. Table 95-5 depicts the benefits of adjuvant therapies by age group.

In postmenopausal women, the majority of trials using adjuvant endocrine therapy compared tamoxifen with either no treatment or with chemotherapy and tamoxifen. In women older than 70 years, there was a significant decrease in the annual recurrence rate (51%) and deaths (37%) among those treated with approximately 5 years of tamoxifen versus not. Patients with positive ER or PR derived greatest benefit from tamoxifen. In addition, tamoxifen significantly decreased the annual odds of developing contralateral breast cancer by approximately 40%. Several studies have confirmed that tamoxifen decreases cardiovascular morbidity, lowers cholesterol and low-density lipoprotein levels, and increases or preserves vertebral bone density in postmenopausal women, but there is a small increased risk of thrombotic events and of endometrial cancer. Based on this information, adjuvant hormonal therapy for 5 years is recommended

for most women with estrogen and/or progesterone-receptor node-negative and node-positive early breast cancer.

Newer data, not included in the EBCTCG meta-analysis, show that the aromatase inhibitors (anastrozole, letrozole, and exemestane), compounds that inhibit the enzyme involved in estrogen production, are more effective and less toxic alternatives to tamoxifen as adjuvant treatment for hormone receptor–positive breast cancers in postmenopausal women. Use of the aromatase inhibitors (AIs) is not associated with increased blood clot risk or endometrial cancer and, overall, studies show that AIs have fewer side effects than tamoxifen. Based on results from clinical trials, AIs are acceptable and, in most cases, preferable agents to tamoxifen in the adjuvant setting, unless there is another reason to prefer tamoxifen, such as the presence of osteoporosis. Side effects of AIs include menopausal symptoms, musculoskeletal aches and pains, and accelerated osteoporosis. In women who have osteopenia or osteoporosis, bone density is monitored carefully during treatment with AIs. There are three options for use of AIs in the adjuvant setting: (1) 2 to 3 years of tamoxifen followed by 2 to 3 years of an AI to complete a 5-year course of adjuvant hormonal therapy, (2) 5 years of an AI, or (3) 5 years of tamoxifen followed by an AI for 2–5 years. The optimal duration of

adjuvant hormonal therapy with AIs is not yet defined and may be longer than 5 years.

The overview found a significant decrease in the annual odds of recurrence and death for both node-negative and node-positive tumors in women aged 50 to 70 years who were treated with combination chemotherapy (polychemotherapy); unfortunately, not enough data were available to see a statistically significant benefit of chemotherapy in patients older than 70 years. In postmenopausal women in general, however, the combination of tamoxifen and chemotherapy was superior to tamoxifen alone in prolonging relapse-free and overall survival. Chemotherapy programs using anthracycline-containing combinations were superior to nonanthracycline regimens in improving both relapse-free and overall survival. Current controversies revolve around the optimal duration and intensity of adjuvant chemotherapy and the choice of adjuvant therapy based on the breast cancer cell type.

With regard to the optimal duration of adjuvant chemotherapy, short treatment courses of 3 to 6 months appear to be as effective as treatment of longer duration. With regard to the optimal dose intensity of adjuvant chemotherapy (the dose administered during a specific time period), more intense regimens are more effective, even in older patients. Adjuvant chemotherapy regimens that have shown a survival benefit for women aged 50 to 70 years are also well tolerated in healthy women older than 70 years. Although high-dose

regimens, necessitating stem cell rescue, have not proven to be superior to current polychemotherapy regimens, more intense regimens, such as 8 versus 4 cycles and delivered every 2 versus every 3 weeks, are more effective in women with high risk of recurrence. Current standard polychemotherapy regimens include the following: cyclophosphamide, methotrexate, and 5-fluorouracil (CMF); doxorubicin (Adriamycin) and cyclophosphamide (AC); cyclophosphamide, doxorubicin, and 5-fluorouracil (CAF); cyclophosphamide, epirubicin, and 5-fluorouracil (CEF); cyclophosphamide, epirubicin, and 5-fluorouracil followed by docetaxel (CEF-T); docetaxel, doxorubicin, and 5-fluorouracil (TAC); docetaxel and cyclophosphamide (TC); and AC plus a taxane (paclitaxel and docetaxel) (AC-T). Unlike tamoxifen, however, chemotherapy had little effect on the risk of developing contralateral breast cancer in the overview analysis.

With regard to tumor type, molecular strategies have defined three categories of breast cancer—hormone receptor positive, HER2 positive, and hormone receptor/HER2 negative (triple negative)—and future research may further classify subtypes and define sensitivity to adjuvant treatments. Benefit of adjuvant therapy for women who have hormone receptor-positive breast cancer is derived primarily from hormonal agents, and the additional benefit of chemotherapy is questionable. Techniques to define risk—based on the molecular profile of these tumors, especially those that are node-negative—are increasingly used in practice to help decide which patients are at high enough risk to justify the addition of chemotherapy to hormonal adjuvant therapy. The addition of trastuzumab (Herceptin<sup>TM</sup>), a humanized monoclonal antibody targeted against the HER2 gene product, to adjuvant chemotherapy for HER2-positive tumors further decreases the risk of recurrence by 50% and the risk of death by 30%, according to randomized trials with 3 years of follow-up. Cardiac monitoring, with echocardiogram or MUGA scan to evaluate cardiac ejection fraction at least every 3 months, is recommended during treatment, as trastuzumab may cause reversible decline in cardiac function. Up to one-fifth of the women will not complete the entire year of therapy owing to asymptomatic decline in ejection fraction (15%), development of congestive heart failure or other cardiac event (5%). For patients with hormone receptor- and HER2-negative tumors, more intense chemotherapy regimens are generally utilized.

As a result of the paucity of data, the role of adjuvant chemotherapy in the management of older patients remains unclear to most oncologists. More carefully designed trials of chemotherapy for older women are needed and should include drug combinations that provide dose intensity similar to that of other currently effective therapies. One such trial, comparing standard chemotherapy with an oral chemotherapeutic agent (capecitabine) (Cancer and Leukemia Group B trial 49907; www.calgb.org), completed accrual and showed a significant benefit for standard chemotherapy in improving both relapse-free and overall survival.

### Follow-up for Women with Early Breast Cancer

There is good evidence that close follow-up after diagnosis or adjuvant therapy does not result in improved overall survival, but that detection of early skin or lymph node (soft tissue) recurrence may result in more effective palliation. Mammography is an exception and should be performed yearly to detect new primary lesions. Because a history of breast cancer is a risk factor for another breast cancer, follow-up visits do provide an opportunity for patients to

TABLE 95-6

## Follow-up of Early Breast Cancer After Diagnosis and Initial Treatment

	FREQUENCY OF EXAMINATION		
	1-3 YR	3-5 YR	5+ YR

Breast self-examination	Monthly	Monthly	Monthly
Mammogram*	Yearly	Yearly	Yearly
Gynecologic examination†	Yearly	Yearly	Yearly
Other‡	PRN	PRN	PRN

\*In patients treated with lumpectomy and breast irradiation, more frequent mammograms of the radiation-treated breast (every 6 months) may be recommended for the first 3 yrs. Breast MRI are not recommended as part of routine screening.

†Yearly gynecologic examinations are recommended; they are required for women on tamoxifen who have an intact uterus.

‡Tumor marker studies, complete blood count, and automated chemistry studies, chest and skeletal x-rays, ultrasound, and radionuclide, computer tomographic, and positron emission tomographic scans are not necessary in asymptomatic patients. Appropriate studies should be obtained for patients with signs or symptoms of recurrence.

Data from Recommended Breast Cancer Surveillance Guidelines. American Society of Clinical Oncology, 2006.

express concerns and for physicians to give them reassurance. Extensive laboratory and radiologic procedures are now available for the detection of metastatic disease, but trials have indicated that a brief, focused history and a limited physical examination (skin, chest, breast, and abdominal examination) detect more than 75% of metastases. Because of the growing concern over health care costs, many organizations are formulating guidelines for follow-up.

Table 95-6 presents guidelines developed by the American Society of Clinical Oncology. In addition to mammograms and follow-up visits with the oncologist and gynecologist, patients should be educated about the symptoms of breast cancer recurrence so that those symptoms are reported and evaluated promptly.

### Treatment of Metastatic Disease

Patients with metastatic breast cancer are currently incurable and have a median survival of approximately 2 to 7 years after the discovery of recurrence, depending on what series is considered. Nevertheless, patients may derive considerable palliative benefit from judiciously chosen therapy. Bone, soft-tissue (skin and lymph nodes), pleural, and pulmonary metastases are the most common sites of breast cancer recurrence. Women with localized symptomatic lesions in brain, skin, lymph nodes, and bone should be considered for palliative radiation therapy, which relieves symptoms in the majority of patients.

Patients with disseminated metastases should be considered for palliative systemic treatment. Table 95-7 describes endocrine and cytotoxic agents used in the treatment of breast cancer and their common and major side effects. Endocrine therapy usually is associated with minimal toxicity, while the toxicity associated with chemotherapy is frequently substantial and, in a small percent of patients, may be life threatening. Provided that metastases are not rapidly progressive or life threatening, all women with metastatic breast cancer should have a trial of endocrine therapy, irrespective of the ER and PR status of the tumor. Even in receptor-negative patients, endocrine therapy results in complete and partial response (greater than 50% shrinkage of the tumor mass) in 10% to 20% of those treated. Chemotherapy should be considered when metastases become refractory to endocrine treatment; such a strategy has been shown to be safe and most likely maintains the highest quality of life for the longest time period.

The choice of initial hormone agent for therapy of metastatic breast cancer is dependent on which agent was used in the adjuvant setting and if the patient is still taking that agent. If relapse occurs soon after starting adjuvant hormonal therapy, it is reasonable to try on more, noncross-resistant hormonal agent. If the tumor progresses soon after changing to the second hormonal agent, it is generally deemed hormone refractory and chemotherapy is used. If relapse occurs 6 months or more after starting adjuvant hormonal therapy, another hormonal agent is generally tried. Historically, the most experience is with tamoxifen and response rates of approximately 30% are seen in unselected patients. As first-line treatment for metastatic disease, AIs (agents that block the synthesis of estrogens in postmenopausal women) are as effective as or more effective than tamoxifen. Responses to endocrine treatment generally last an average of 1 year, but in a small percentage of patients, response may last many years. Patients with receptor-positive tumors, time intervals greater than 2 years from initial diagnosis to recurrence, soft-tissue or bone metastases, or a prior response to endocrine therapy are the most likely to respond. For patients who have responded to one agent or who have prolonged periods where the tumor does not grow (stable disease), other hormonal agents should be used in succession, until it is clear that the metastases are refractory to endocrine therapy. Patients who respond to one endocrine agent are likely to respond to another at the time of progression; the use of successive endocrine agents in patients with minimally symptomatic metastases is an excellent treatment strategy. In addition to tamoxifen and AIs, pure anti-estrogens, progestins and estrogens may be effective; moreover, patients who have previously responded or had prolonged stable disease and then had tumor progression may respond to the same agent after being treated with other therapy.

Once breast cancer is deemed refractory to hormonal therapy, chemotherapy is the treatment of choice. Older patients with metastatic disease, whose general health is otherwise satisfactory, display response and toxicity profiles to chemotherapy similar to those of their younger counterparts. Most cytotoxic drugs are metabolized in the liver with only a select few dependent on renal excretion (methotrexate, carboplatin, and cisplatin); major liver dysfunction probably is required to alter drug metabolism significantly. Chemotherapy-related myelosuppression is more common in older patients as a result of diminished bone marrow reserve with aging; nausea and vomiting are seen less frequently than they are in younger

**TABLE 95-7****Endocrine and Cytotoxic Agents Used in the Treatment of Breast Cancer**

Vinorelbine	M, neuropathy, vesication
<i>Immunotherapy</i>	
ErbB-2 (Her2/neu) tyrosine kinase inhibitor	Cardiomyopathy, infusion reactions (rarely fatal)
Trastuzumab	
Epidermal growth factor receptor (EGFR) and ErbB-2 (Her2/neu) dual tyrosine kinase inhibitor	Diarrhea, rash, decrease in left ventricular function
Lapatinib	
Anti-angiogenesis (anti-VEGF antibody)	Slow or incomplete wound healing, thrombosis, hypertension, reversible posterior leukoencephalopathy syndrome, nephrotic syndrome, M, N+V, congestive heart failure
Bevacizumab	

patients. Of importance, psychosocial adjustments to chemotherapy appear to be better for older than for younger patients. Complete and partial responses to most single chemotherapy agents range from 20% to 30%, while responses to combination chemotherapy average 50% to 70%. The use of sequential single agents to maximize quality of life, yet maintain tumor control, is as effective as treatment with several agents in combination, and is a less toxic strategy. Re-

sponses generally last an average of 6 to 12 months; response rates to subsequent "salvage" regimens are generally low and last only several months.

Biologically engineered monoclonal antibodies with antitumor activity are showing efficacy in treatment of cancer. For breast cancer, the following have been shown to be beneficial for use in combination with chemotherapy agents: trastuzumab (Herceptin<sup>TM</sup>), the

humanized-monoclonal antibody that inhibits erbB-2 (Her2/neu) tyrosine kinase; lapatinib (Tykerb<sup>TM</sup>), an epidermal growth factor receptor (EGFR) and ErbB-2 (Her2/neu) dual tyrosine kinase inhibitor; and bevacizumab (Avastin<sup>TM</sup>), an anti-angiogenesis, anti-VEGF antibody. Trastuzumab is approved for use in women with metastatic breast cancer whose tumors over-express the HER2 gene. It is well tolerated and associated with tumor response rates of approximately 25% when used as a single agent. Concomitant use of trastuzumab and chemotherapy improves in response rates when compared to chemotherapy alone. Lapatinib is approved for use in combination with capecitabine for treatment of HER2-overexpressing advanced or metastatic breast cancer that has been previously treated with an anthracycline, a taxane, and trastuzumab. Bevacizumab is approved for first-line use in breast cancer patients in combination with paclitaxel. Compared to younger patients, older patients have higher risks of thrombosis and bleeding events with bevacizumab.

**SPECIAL CONSIDERATIONS****Endocrine Therapy as Initial Treatment**

For many older patients, especially those with advanced but localized lesions (T3 and T4) and those with significant comorbidity or frailty, initial treatment with hormonal therapy is appropriate. Tumor shrinkage occurs in 40% to 70% of patients. Although surgery is more likely to be effective (and potentially curative) in patients with small lesions, several randomized trials comparing surgery with hor-

monal treatment for initial therapy suggest that long-term survival is not changed by using hormonal therapy as the initial treatment and reserving surgical management for patients with tumor progression. Radiation therapy also can be used as “salvage” treatment after hormonal therapy fails, but large tumor masses, especially those greater than 3 cm and those with extensive skin involvement, frequently respond only partially. For patients treated with hormonal therapy because comorbidity precludes surgical therapy, radiation therapy should be considered when tumor shrinkage is maximal to try to prolong the duration of local tumor control. In the authors’ opinion, older women with localized breast cancer should be offered the same initial treatment options as offered to younger patients in most cases. The majority of patients treated initially with hormonal therapy do not achieve complete tumor regression and, over time, probably will need surgery or other treatments to control the primary lesion.

**Male Breast Cancer**

Male breast cancer is uncommon and accounts for less than 1% of all breast cancer incidence. The natural history of male and female breast cancer is similar, but males usually present at a later stage, probably because of a delay in diagnosis. Almost all cases are sporadic, except for males with Klinefelter syndrome (sex chromosomes XXY)—in which the prevalence of breast cancer ranges from 3% to 6%—or men with the BRCA-2 gene, which is associated with a 5% to 10% risk of male breast cancer. A careful family history is mandatory in all males with breast cancer. Mastectomy with axillary dissection is the standard approach to treatment but breast conserving surgery and irradiation is appropriate for males with small tumors. Histologically, most lesions are infiltrating ductal carcinomas, and the frequency of estrogen receptor–positive lesions is 70% to 80%. Because of the rarity of male breast cancer, there are few data on the role of adjuvant systemic therapy, and it is unlikely that large randomized trials will be undertaken. Many oncologists use the same guidelines for adjuvant therapy in men that are used in women with a similar stage and receptor status. Uncontrolled trials suggest that such treatment is similar in efficacy in men to that in women.

Males with metastatic breast cancer are incurable but frequently respond to endocrine therapy, including tamoxifen and orchiectomy. There is little experience with AIs in men with breast cancer. The results with systemic chemotherapy are similar to those in females.

**CONCLUSIONS**

Breast cancer is a major gerontologic problem. Both physician education and patient education concerning screening, early diagnosis, and management of breast cancer in this age group are required. Available data indicate that optimal treatment of breast cancer in older women results in outcomes similar to those from treatment of younger women. Although significant comorbid illness is encountered more frequently in older patients and may complicate breast cancer treatment, most patients can be managed with judicious “state-of-the-art” therapy. Barriers to the treatment of breast cancer in older women are generic to the treatment of all illnesses in this age group and include access to care, transportation, adequate family and social support, physician bias, and treatment costs.

Changes in health care policy, as well as focused research related to cancer in the geriatric population, will be needed to overcome these obstacles.

# Prostate Cancer

*Kenneth J. Pienta*

## EPIDEMIOLOGY AND RISK FACTORS

Prostate cancer remains the most common noncutaneous malignancy diagnosed in American men and is the second leading cause of cancer-related deaths in that group. In the year 2008, almost 187,000 will be diagnosed with prostate cancer and an estimated 29,000 men will die of the disease.

The only undisputed risk factors for prostate cancer are older age, African-American race, and positive family history. Prostate cancer is generally a disease of elderly men; risk increases exponentially with age, with a median age at presentation of 68 years. Eighty percent of prostate cancer diagnoses and 90% of prostate cancer deaths occur in men older than 65. The incidence rates of the disease among African-American men are higher than rates for men in *any* other racial or ethnic background. African-American men are more likely to be diagnosed with prostate cancer and to die from it than their Caucasian counterparts. The estimated lifetime risk of prostate cancer is 17.6% and 20.6% respectively for Caucasians and African-Americans, while the estimated lifetime risk of death is 2.8% and 4.7%. Studies suggest that early onset prostate cancer may be inherited in an autosomal dominant fashion, and it is estimated that approximately 10% of all prostate cancer cases are hereditary. A large twin study suggests that genetic factors may account for as much as 42% of prostate cancer risk, although the absence of clear, highly penetrant markers suggests that in the majority of men, prostate cancer risk involves a complex interaction of multiple genetic and environmental factors.

Additional factors such as diet, obesity, hormones, inflammation and sexually transmitted diseases, and occupational exposure have all been implicated in prostate carcinogenesis, but without consistent results. Dietary fat may be a risk factor for prostate cancer. Multiple epidemiological, case-control, and cohort studies have suggested a moderate to strong increased risk of developing prostate cancer, particularly advanced disease, associated with total dietary fat, saturated fat, alpha linolenic fatty acid, and cooked red meat.

Two large prospective studies and a smaller case-control study suggest that fish intake may be protective, possibly owing to marine omega-3 fatty acids—known antagonists of arachidonic acid, which suppress the production of proinflammatory cytokines. Evidence for the association with dietary fat is further correlated with worldwide incidence patterns; prostate cancer is more common in the United States and northern European countries and is relatively rare in Asia and Africa. When Asian men migrate to the West and change from a low-fat to a high-fat diet, their risk of prostate cancer increases. These studies, however, are complicated by the fact that many of the men migrating from low-fat diet areas also consume green tea and soy products, which contain isoflavones and estrogen that may act as antioxidants and chemoprotectants against prostate-specific carcinogenesis. Several epidemiologic studies have suggested an inverse relationship between soy intake and prostate cancer risk.

Most studies have not demonstrated an association between obesity and prostate cancer incidence, but there is growing evidence to support an association between obesity and aggressive prostate cancer, recurrence after primary therapy, and death from prostate cancer. Data from the Prostate Cancer Prevention Trial (PCPT) suggest that obesity increases the risk of higher-grade cancers, but decreases the risk of low-grade prostate cancer. While BMI  $\geq 30$  was associated with an 18% decrease in low-grade cancers (Gleason grade  $< 7$ ) there was a 29% increase in Gleason grade of 7 and above and a 78% increase in high-grade cancers (Gleason 8–10). These data suggest that obesity may differentially affect the development of aggressive and nonaggressive prostate cancer and may somehow play a role in the progression from latent to clinically significant prostate cancer. Although the specific role obesity plays in prostate cancer risk is unclear, it may be linked to other risk factors such as dietary fat and meat intake, hormone metabolism, and insulin metabolism. The prevalence of obesity also correlates with prostate cancer risk across populations and may provide a link between the increased risk of prostate cancer with westernization.

Although a diet rich in fruits and vegetables is associated with reduced risk in several cancers, their effect on prostate cancer risk is still unclear. Several studies have shown an inverse association with tomatoes and tomato products, presumably owing to the effects of lycopene, the most common carotenoid in the human body and one of the most potent carotenoid antioxidants. Data from the large Health Professionals Follow-Up Study (HPFS) suggest that frequent consumption of tomato products is associated with a decreased risk of prostate cancer, and in a meta-analysis of 21 case-control and cohort studies, a statistically significant 10% to 20% risk reduction was associated with high versus low intake of tomatoes. The majority of these studies also show a stronger effect for cooked versus raw tomatoes.

Although it seems intuitive that testosterone levels may influence the incidence of prostate cancer, no evidence exists to confirm this association. Dihydrotestosterone, the active hormone produced from the conversion of testosterone by the enzyme  $5\alpha$ -reductase, is associated in some studies with increased risk. A prospective, population-based study of 1156 men showed no correlation between 17 different hormones and prostate cancer development, with the possible exception of androstenediol glucuronide. Importantly, no dose-response relationships were seen, suggesting that serum hormonal levels may not be useful even in risk stratification.

There is some evidence that chronic inflammation may increase prostate cancer risk. One meta-analysis of 11 studies on prostatitis and prostate cancer showed an overall relative risk of 1.6, while another meta-analysis of aspirin and cancer showed that regular aspirin use was associated with an approximately 15% decrease in prostate cancer risk. Population based studies have suggested an increased risk of prostate cancer in patients with STDs, including syphilis, recurrent gonorrhea, HPV, and HIV. A meta-analysis of 17 studies of prostate cancer and sexual patterns suggested that an increased number of sexual partners was associated with an increased prostate cancer risk, possibly through an increased exposure to STDs. There are currently no strong data to suggest a link between benign prostate hypertrophy (BPH) and prostate cancer risk.

## PREVENTION

Chemoprevention is an area of ongoing research, and in many ways, prostate cancer is an ideal disease for this approach—relatively slow growing, centered in the elderly population, yet with devastating effects and difficult management after the onset of metastasis.

### Finasteride

Finasteride is a drug that blocks the actions of  $5\alpha$ -reductase, the enzyme that converts testosterone to dihydrotestosterone. The PCPT enrolled 18,000 men between January 1994 and May 1997 to study the efficacy of finasteride for decreasing the period prevalence of prostate cancer. The trial was based on two observations: androgens are required for prostate cancer development and men with congenital  $5\alpha$ -reductase deficiency develop neither BPH nor prostate cancer. This randomized, double-blind, placebo-controlled trial was closed early because of a perceived risk reduction with finasteride. After 7 years of treatment, prostate cancer was diagnosed in 18.4% of the men on finasteride and 24.4% of the men on placebo, a 6% absolute risk reduction and 24.8% relative risk reduction. The

risk reduction associated with finasteride was apparent across all risk groups defined by age, family history, race, and PSA. Finasteride use was also associated with increased sexual dysfunction, but decreased lower urinary tract symptoms.

Results from the trial, however, were tempered by an apparent increase in high-risk cancers in the finasteride group; 6.4% of the cancers in the finasteride group were Gleason grade 8 to 10 versus 5.1% in the controls. This represented a statistically significant 1.3% absolute increase in the risk of high-grade cancer associated with finasteride. Since high-grade cancers are associated with a poorer prognosis after definitive therapy, the role of finasteride in the prevention of prostate cancer remains controversial at this time. Several experts, however, have questioned whether the increase in high-grade cancers associated with finasteride in the PCPT is real or artifact. If finasteride induced higher-grade tumors, the incidence of prostate cancer in the finasteride arm should increase at a greater rate, particularly as the trial progressed and the duration of prostate exposure to finasteride increased. This was not the case however. Furthermore, ultrasound evaluation showed a 24.1% decrease in prostate volume in the treatment arm (median volume 25.5 cm<sup>3</sup> versus 33.6 cm<sup>3</sup>). There is evidence to suggest that the risk of missing high-grade cancers increases as prostatic volume increases; with a smaller volume, a larger proportion of the gland is biopsied and evaluated, increasing the chance of detecting cancer. Thus, some experts claim that the increased risk of high-grade cancer in the finasteride group could be because of increased sampling rather than a medication effect. Finally, there is new evidence to suggest that finasteride enhances the sensitivity of PSA for prostate cancer, by decreasing BPH and thus its effect on PSA levels.

Further evaluation of the role of  $5\alpha$ -reductase inhibitors in prostate cancer prevention will occur with The Reduction by Dutasteride of Prostate Cancer Events (REDUCE), a randomized, double-blind, placebo-controlled trial currently enrolling patients in Europe and the United States, randomizing men to Avodart, a new  $5\alpha$ -reductase inhibitor, versus placebo. Until these results are available, widespread use of finasteride for chemoprevention is currently not being advocated by most experts in the field. It remains, however, an effective treatment for BPH.

### Vitamin E and Selenium

In recent years, the role of oxidative stress in the development of prostate cancer has been investigated. The damage caused by reactive oxygen species is not limited to deoxyribonucleic acid (DNA); it can encompass lipids and proteins as well. The association of prostate cancer and a high-fat diet may be secondary to the generation of increased fatty acids, which can cause lipid peroxidation. The two most exciting agents in the area of chemoprevention are selenium and vitamin E.

Selenium is an essential trace nutrient, which enters the food chain via consumption of plants and plant eating animals. Since there is marked geographic variability in foods, linked to local soil content, selenium intake cannot be easily linked to dietary sources. Selenium was initially investigated in the prevention of recurrent basal and squamous cell skin cancers, and although it did not affect the incidence of recurrent skin cancer, an unexpected finding was a decrease in the risk of prostate, colorectal, and lung cancer. Remarkably, the incidence of prostate cancer decreased by 65%. Subsequently, both case-control and randomized placebo-controlled trials have

demonstrated a decrease in the risk of developing prostate cancer associated with selenium supplementation.

Alpha tocopherol is the most active and abundant source of vitamin E, and its antioxidant properties have been studied extensively in a variety of prostate cell lines and animal models. Results from human studies are conflicting. In one prospective study, there was no protective association between increased serum levels of vitamin E and the risk of prostate cancer, while other studies have shown a statistically significant positive effect. The Alpha-Tocopherol, Beta-Carotene Cancer Prevention Trial (ATBC) randomized 29,133 male smokers to either  $\alpha$ -tocopherol (50 mg daily), beta carotene (20 mg daily), both or placebo. Although the primary endpoint was lung cancer incidence and mortality, the trial demonstrated a statistically significant 32% decrease in prostate cancer incidence and a 41% decrease in prostate cancer mortality in the groups taking  $\alpha$ -tocopherol supplements. A recent meta-analysis of 19 randomized clinic trials, however, suggested that long-term supplemental vitamin E  $\geq$ 400 IU daily was associated with an increase in mortality from all causes. This has caused many to question the long-term use of this supplement as a chemoprotectant in the absence of data demonstrating clear benefit.

SELECT (Selenium and Vitamin E Cancer Prevention Trial) is an NCI sponsored, randomized, prospective, double-blind trial designed to determine whether selenium and vitamin E decrease the risk of prostate cancer in healthy men. It will enroll 32,400 healthy men with a normal digital rectal examination and a prostate-specific antigen (PSA)  $\leq$ 4 ng/mL. The 2  $\times$  2 factorial design includes four study arms: vitamin E + placebo, selenium + placebo, vitamin E + selenium, and placebo + placebo. The primary end point of the trial is the clinical incidence of prostate cancer; secondary endpoints include prostate cancer-free survival, mortality from any cause, and the incidence and mortality of other cancers or diseases affected by chronic supplementation with vitamin E and/or selenium. The planned duration of the study is 12 years with a minimum 7 years of treatment, and final results are expected by 2013. As prostate cancer incidence increases with age, it is important to enroll as many geriatric patients as possible, as the greatest risk reduction may be possible in this group.

## PRESENTATION

Most men who present with prostate cancer are asymptomatic, particularly in the era of PSA testing, which detects many cancers long before they are clinically apparent. Patients rarely have urinary symptoms, as the majority of cancers arise in the posterior aspect of the prostate. Most men undergo evaluation after routine screening reveals either an elevated PSA or abnormal digital rectal examination (DRE). Since the advent of PSA testing and regular screening, there has been a demonstrated risk migration, and presently in the United States, the majority of patients have clinically localized, intermediate-risk prostate cancer at diagnosis. A minority of patients are diagnosed when they present with symptomatic metastatic disease, usually manifested as bony pain; CapSure data demonstrate that while in 1988, 14% of new prostate cancer patients presented with metastatic disease, that number had fallen to 3.3% by 1998. Although screening has strongly influenced this downward stage migration, there are no data to suggest that it has significantly decreased prostate cancer-specific mortality; there is some concern that

screening may detect a significant number of clinically insignificant cancers. The wide discrepancy between incidence and mortality attributed to prostate cancer demonstrates that some slow growing cancers may never be life threatening. Published guidelines do exist, notably from the NCCN (National Comprehensive Cancer Network). Currently, there are two large scale, long-term, randomized clinical trials ongoing in the United States and Europe evaluating whether screening decreases mortality; these trials may ultimately provide evidence for the validity of wide-based screening.

A difficult task for primary physicians is thus deciding which patients should undergo screening for prostate cancer. In the absence of definitive data, a reasonable approach to screening should involve an active discussion between the physician and patient, taking into consideration the patient's overall health and treatment preferences. Men with a life expectancy of 10 to 15 years (owing to age or comorbidities) should be informed that screening may not be beneficial. Younger men with a family history of prostate cancer and African-American men should be encouraged to undergo screening, as the disease prevalence is high in these groups. Any patient with symptoms that may be referable to prostate cancer (bone pain, hypercalcemia, symptomatic pelvic lymphadenopathy) warrants a PSA evaluation as a part of his initial evaluation, since symptomatic patients can enjoy significant improvement with the institution of hormonal therapy. An ongoing challenge for the geriatrician is the need to remain current on the development of new treatments. In the future, as more targeted and less toxic therapies are identified, PSA screening may become a routine part of health maintenance for all men.

## EVALUATION

The appropriate screening examinations for prostate cancer include a serum PSA and DRE. PSA is a protein produced and secreted by both normal prostate and prostate cancer cells. It provides a sensitive but not highly specific screening test, as it is also elevated with BPH, inflammation, and infection of the prostate. The proposed cutoff is 4.0 ng/mL, but studies have shown that 15% of men with normal PSA levels will have prostate cancer and 2% will have high-grade prostate cancer. PSA is, however, more sensitive than DRE, detecting more cancers and earlier stage and smaller sized cancers than rectal examination alone. PSA-doubling time is also a significant factor in prostate assessment, and any patient with a rapid PSA-doubling time should be sent for further evaluation, even if the absolute value of the PSA is below the normal cutoff level. DRE yield alone is low; estimates are that only 3% to 6% of examinations yield suspicious results. On the basis of an elevated PSA or an abnormal DRE, the patient should be referred for a transrectal ultrasound-guided prostate biopsy. In general, six to twelve cores are taken for evaluation; areas that are abnormal on DRE may receive more biopsy attempts.

If the biopsy is positive, a Gleason score is assigned. This score is one of the most important determinants of prognosis. The pathologist assigns a numerical value (on a scale of 1 to 5) to the most prevalent and the second most prevalent grades of cancer seen in the specimens. The score is then reported on a scale of 2 to 10, with 10 being the most aggressive cancer. Gleason scores should be reported separately, for example, 3 + 4 = 7, as the primary pathology has prognostic implications.

Risk stratification plays an important role in both the selection and timing of treatment and is an important part of the initial evaluation. After diagnosis, the natural course of prostate cancer can be estimated from tumor volume, aggressiveness, PSA level, and extent of disease. Tumor volume assessment includes local stage, the number of positive biopsy cores, and the extent of cancer in affected cores. Gleason score is currently the standard measurement of aggressiveness with Gleason 5 to 6 cancers considered low grade, Gleason 7 intermediate grade, and Gleason 8 to 10 high grade. Taking all of these prognostic factors into effect, newly diagnosed patients are classified as having low-, intermediate-, or high-risk disease. In addition to these broad risk groups, multiple nomograms are available to help clinicians estimate an individual patient's probability of localized disease, risk of progression without intervention, and risk of recurrence after definitive therapy. Several of these tools are available online, and they can sometimes be more helpful than the broad categories in assessing an individual's risk, as they allow integration of discordant factors (e.g., high PSA with low Gleason score). PSA velocity prior to diagnosis may also provide valuable information in risk assessment; a PSA velocity  $\geq 2.0$  ng/mL in the year prior to radical prostatectomy is predictive of greater risk of biochemical recurrence, cancer-specific mortality, and overall mortality.

The staging evaluation for men with known prostate cancer or symptoms that could be attributable to metastatic prostate cancer includes serum chemistries, PSA, bone scan, and computed tomography (CT) scan of the abdomen and pelvis. These initial tests provide evaluation of the most likely sites of metastatic disease to avoid inappropriate surgical intervention or radiation therapy. The extent of evaluation for metastatic disease relates to the likelihood of finding disease. A recent prospective survey of 3690 men described the positive yield of bone scan, and CT was  $<5\%$  and  $12\%$ , respectively, for men with a PSA of 4 to 20 ng/mL. The yield decreased to  $2\%$  and  $9\%$  for those who also had a Gleason score of  $\leq 6$ . Only the combination of a Gleason score of 8 to 10 and a PSA  $>20$ , or a PSA  $>50$  alone, identified a group of men who had a  $>10\%$  yield on bone scan and a  $20\%$  yield on CT scan. To stage in an appropriate and cost-effective manner, patients with low PSAs and low to intermediate Gleason scores do not require evaluation. More risk factors increase the degree of preoperative evaluation. [Table 96-1](#) provides guidelines for preoperative staging. These studies also provide a baseline for follow-up. [Figure 96-1](#) illustrates a stepwise approach to evaluation, monitoring, and treatment.

## MANAGEMENT

After an initial diagnosis of prostate cancer, treatment decisions should take into consideration a number of factors including the individual patient's remaining life expectancy (which can be estimated using social security tables), comorbidities, baseline quality of life, treatment preferences, and disease characteristics/risk factors.

### Observation

The concept of observation or watchful waiting involves deferring treatment until patients develop symptomatic disease. It was first proposed in the 1970s after the results of the Veterans Administration Cooperative Urological Research Group (VACURG) trial suggested that delaying therapy until the onset of symptoms did not increase prostate cancer-specific mortality in patients with locally advanced or metastatic disease. To evaluate watchful waiting in the modern era, from 1985 until 1993 the Medical Research Council Trial randomized 938 men with locally advanced or asymptomatic metastatic prostate cancer to either immediate or deferred treatment with hormonal therapy. In this study,  $67\%$  of patients died secondary to prostate cancer, a substantial increase from the findings of the VACURG trial. Overall survival was significantly longer in the patients treated immediately, with the most pronounced difference in men who initially had no evidence of metastatic disease. The rate of complications, such as bone pain, pathological fractures, spinal cord compression, and ureteral obstruction was higher in the deferred group. Because PSA testing allows detection of cancers some 5 to 15 years earlier than DRE, men with T1c (PSA detected) tumors treated with watchful waiting may have better than 20-year disease-specific survival. Thus, watchful waiting, either at the time of initial diagnosis or at the time of progression, may still be applicable in a subset of elderly men without metastatic disease. However, if the patient is not a candidate for treatment and has no symptoms attributable to the disease, both the patient and the physician should reflect on why screening was undertaken.

### Active Surveillance

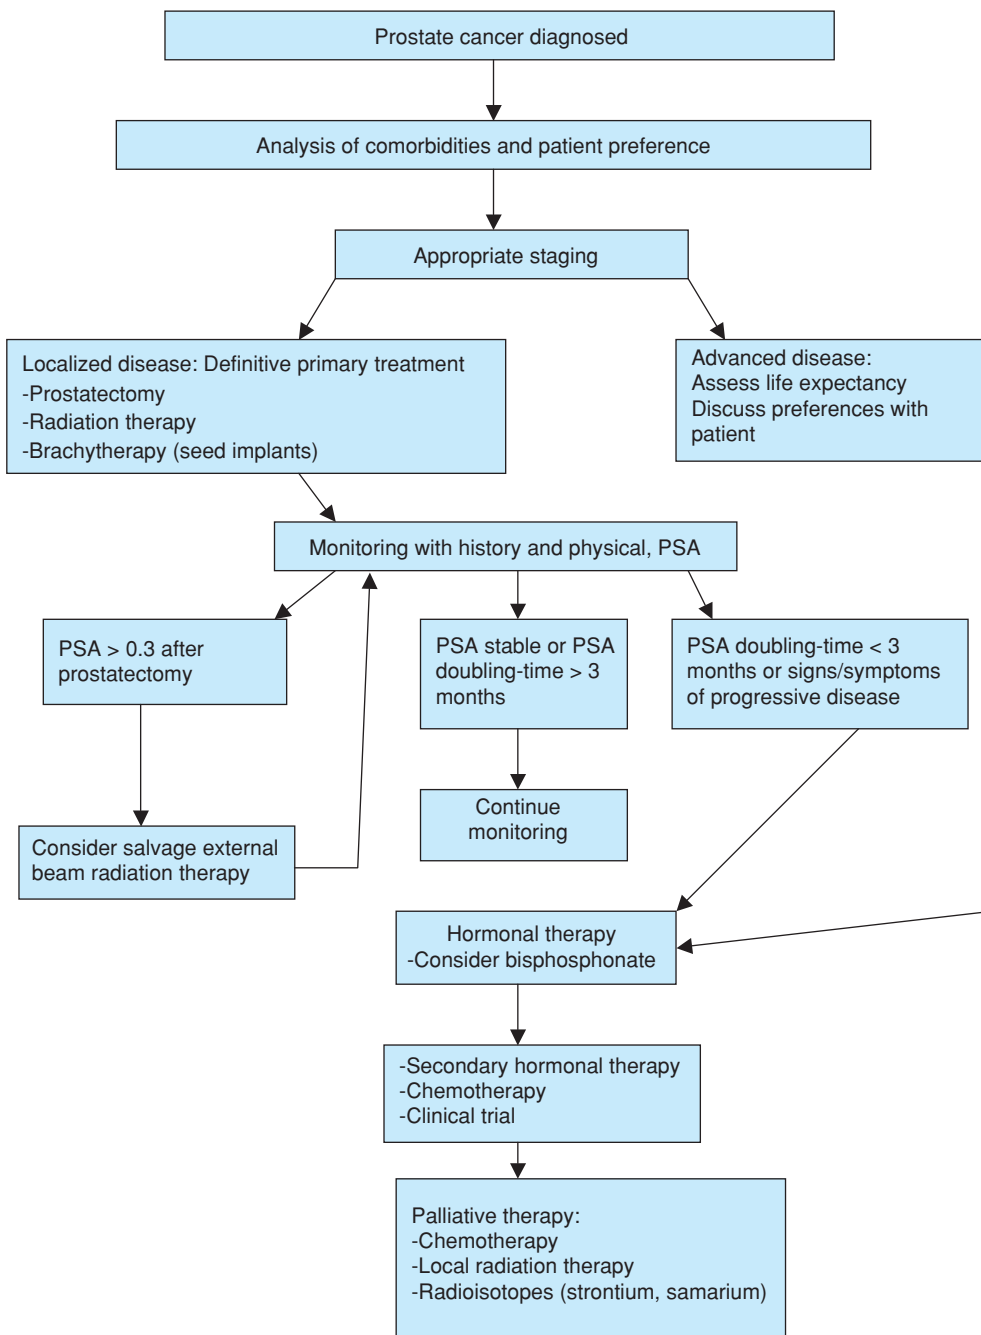

Active surveillance or expectant management differs from watchful waiting in the intensity of monitoring and the expectation of delayed but successful definitive, potentially curative therapy. This strategy is based on the observation that there is tremendous heterogeneity

**TABLE 96-1**

#### Guidelines for Staging Evaluation

PARAMETERS	RISK	METASTATIC EVALUATION	REFERENCES
PSA $< 15$ , Gleason 2–7, clinical stage $\leq$ T2b	Low	No screening	All 237 patients had negative bone scan and all 244 patients had negative CT scans in this category
PSA 15–50, Gleason 2–7, clinical stage $\leq$ T2b	Intermediate	Consider bone scan and perform CT scan of abdomen/pelvis	3 of 308 patients had positive bone scan and 8 of 174 patients had positive CT scan in this category
PSA $> 50$ , Gleason 8–10, clinical stage $\geq$ T2c	High	Perform bone scan and CT scan of abdomen/pelvis	OR for positive CT scan 6.17 for Gleason 8–10 vs. 2–6
Symptoms		Appropriate evaluation for symptoms noted	

CT, computed tomography; OR, odds ratio; PSA, prostate-specific antigen.

**FIGURE 96-1.** Prostate cancer evaluation and management flowchart. PSA, prostate specific antigen.

in the natural history of prostate cancer, and a significant number of men may be “overdiagnosed” in the sense that diagnosis and treatment may not improve either quality of life or survival. Active surveillance involves regular monitoring with PSA every 3 months, clinical examination with DRE every 6 months, and repeat biopsies as warranted by PSA and DRE (which can occur as frequently as once a year). An increase in PSA velocity (doubling time <3 years), primary Gleason pattern of 4 or 5 on repeat biopsy, or an increased number or extent of positive biopsy cores suggests progression of disease, and intervention with appropriately selected therapy should be initiated. Many experts feel that this is a reasonable approach for men with low-risk disease and may represent a practical compromise between radical treatment for all patients and watchful waiting with palliative treatment only (a strategy that undertreats aggressive disease). Although active surveillance may avoid overtreatment and

allow patients to maintain their baseline quality of life, the strategy carries with it a risk of local or metastatic progression before active treatment is initiated. It is important, therefore, that patients are made aware that even the most careful monitoring may miss the window for administering curative therapy.

### Local Therapy: Surgery, Radiation, or Brachytherapy

Surgery, radiation, or brachytherapy for early-stage disease is performed with curative intent.

#### Radical Prostatectomy

Radical prostatectomy (RP) involves removal of the prostate and seminal vesicles, and is an appropriate therapy for any patient with

disease confined to the prostate, a life expectancy >10 years, and no contraindications to surgery. Data have shown that outcomes are generally better with high-volume surgeons within high-volume medical centers. In the last decade, laparoscopic and robotic prostatectomies have been refined and moved into mainstream care. Outcome data to date suggest that in the hands of an experienced surgeon, these approaches are comparable to open surgery and may involve less morbidity. Randomized clinical trials have shown no benefit for neoadjuvant hormonal therapy with RP. There are, however, data demonstrating that patients with positive lymph nodes at the time of surgery have improved overall survival when immediate and continued androgen deprivation therapy is added to their initial treatment. Pathologic examination after surgery allows for verification of organ confinement and margin status as well as complete histological examination; several studies have reported that almost 50% of patients with biopsy Gleason 6 disease are upgraded to Gleason 7 or higher, once the entire gland is removed and evaluated.

### External Beam Radiation Therapy

External beam radiation therapy (EBRT) in most centers is now delivered using advanced CT planning or intensity-modulated radiation therapy. These newer techniques, collectively known as “3-dimensional conformal therapy,” have become standard of care. They allow for increased accuracy and thus the delivery of higher doses to the prostate while sparing normal tissues, ultimately decreasing both acute and delayed side effects. Often gold fiducial markers are implanted in the prostate prior to EBRT to provide landmarks for accurate daily dosing.

Radiation dosing is currently based on risk of recurrence. Patients with low-risk prostate cancer are generally treated with 70 to 75 Gy in 35 to 41 fractions. Higher doses of 75 to 80 Gy are recommended for patients with intermediate- and high-risk features. In addition, studies have shown that intermediate-risk patients benefit from 4 to 6 months of neoadjuvant and adjuvant androgen deprivation therapy (ADT), while high-risk patients should receive neoadjuvant and adjuvant ADT for a total of 2 to 3 years. Because the prostate is not removed with EBRT, there is no pathological confirmation of the extent of disease or adjustment of the biopsy Gleason score. Relative contraindications to EBRT include active collagen vascular disease, inflammatory bowel disease, and microvascular damage from hypertension or diabetes.

### Brachytherapy

Brachytherapy involves radioactive iodine ( $^{125}\text{I}$ ) or palladium ( $^{103}\text{Pd}$ ) implants, which are placed in the prostate under general anesthesia. They emit short-range radiation within the prostate, generally avoiding the bladder and rectum, and lose their radioactivity gradually. Prostate brachytherapy as monotherapy is indicated for patients with low-risk disease and small prostate volume (<60 g). For intermediate-risk patients, brachytherapy is frequently combined with external beam radiation (40–50 Gy). High-risk patients are generally considered poor candidates for this treatment modality.

Although there are no good randomized data comparing local treatment modalities, a review of 2991 patients treated at the Cleveland Clinic and Memorial Sloan-Kettering Cancer Center showed similar 5-year biochemical relapse-free survival rates for RP, EBRT, and brachytherapy, leading the authors to conclude that intrinsic

tumor characteristics rather than treatment modality play the larger role in determining progression after definitive therapy. Given similar outcomes between EBRT and prostatectomy, logistics and potential side effects may play a significant role in treatment decisions. Some men may not be candidates for major pelvic surgery, and therefore prostatectomy may not be an option. Others may find the 8 to 9 weeks of daily radiation treatments unacceptable and opt for prostatectomy or brachytherapy, which is completed in a single surgical procedure. Incontinence is the primary side effect noted after prostatectomy, though reported rates vary significantly from surgeon to surgeon. EBRT causes short-term irritative bladder symptoms; long-term incontinence is rare. Bowel dysfunction is a potential short and/or delayed side effect of radiation therapy. Impotence occurs in as many as 50% of patients treated with any of the three local approaches, though it tends to occur later with EBRT than with prostatectomy. Primary care providers may want to refer patients to both urology and radiation oncology in order to fully educate patients about their choices.

### Primary Androgen Deprivation

Patients with unfavorable prognostic factors, or those patients who are not interested in the risk:benefit ratio of local therapy, may choose primary hormonal therapy. Approximately 12.5% of the 3486 men in the Prostate Cancer Outcomes Study chose hormonal treatment as initial therapy, considered to be a surprisingly high number. Clearly, there is no chance of cure with this modality, but for some patients the risk of relapse may be too high to pursue aggressive local therapy. There is also scant evidence about the outcomes associated with this approach.

### Adjuvant Therapy

At this time, there is no standard adjuvant chemotherapy for patients at high-risk of recurrence, although there are several intergroup trials examining the role of adjuvant chemotherapy with both RP and EBRT. Adjuvant hormonal therapy, as noted above, is now standard of care with EBRT in patients with intermediate- and high-risk disease; after RP, it is recommended only for patients with node-positive disease.

## POSTTREATMENT SURVEILLANCE

The scheduled follow-up after definitive local therapy depends upon the risk of recurrence and the potential for curative salvage therapy. Patients at high risk of recurrence who would be good candidates for further intervention should have regular PSA testing (every 1–3 months) and DRE at least annually. Patients at low risk of recurrence or poor intervention candidates are more appropriately followed with evaluations every 4 to 6 months for the first 5 years and annually thereafter. Pound and colleagues found that 45% of patients who recur after prostatectomy do so within 2 years. Seventy-seven percent of recurrences occur within the first 5 years after prostatectomy and 96% within 9 years. Any patient with symptoms referable to local or systemic relapse (particularly new bone pain) should be evaluated with repeat serum and radiologic tests.

## Biochemical Recurrence

Biochemical recurrence after RP is defined as a PSA level greater than 0.3 ng/mL and rising on two or more determinations. Recurrence after EBRT has recently been redefined by ASTRO consensus as nadir PSA plus 2. The pattern of local recurrence is usually 1 to 3 years after primary therapy, with a slowly rising PSA or new finding on DRE; these patients should be followed closely and referred for local salvage therapy, if appropriate. The need for biopsy of radiologically proven disease in this setting is controversial. Patients who relapse quickly after local therapy (<6 months) are more likely to have metastatic disease that was not discovered prior to definitive local therapy and are therefore unlikely to respond to local salvage therapy.

Patients with a rising PSA and no clinical, symptomatic, or radiographic evidence of disease present a therapeutic dilemma, as there is no clear consensus as to the timing of further therapy. Some men with biochemical recurrence will eventually die of prostate cancer, while others will have indolent disease and ultimately die of other causes. Prognosis is best estimated by considering initial stage, Gleason grade, and PSA in addition to the absolute value of the PSA at the time of recurrence and the PSA-doubling time. PSA-doubling time has been shown to be a useful parameter for monitoring patients and deciding when to initiate treatment after biochemical recurrence. One analysis of 587 men who had undergone an RP for clinically localized disease analyzed the significance of PSA-doubling time as a predictor of clinical progression after biochemical (PSA) failure. In a multivariate model, PSA-doubling time was a significant risk factor ( $p < 0.001$ ) for both metastatic progression and local recurrence. The mean 5-year progression-free survival was 99% with a PSA-doubling time of > 10 years, 95% with a PSA-doubling time of 1 to 9.9 years, 93% with a PSA-doubling time of 6 to 11 months, and 64% with a PSA-doubling time of less than 6 months. As expected, patients with a PSA-doubling time of less than 6 months were far more likely to have metastatic disease than local recurrence. PSA-doubling time of  $\leq 3$  months has been shown in multiple studies to predict cancer-specific mortality among patients with biochemical recurrence after either RP or EBRT.

## Salvage Local Therapy

Patients whose PSA levels do not fall to an undetectable level after surgery should be evaluated for adjuvant or salvage therapy, including EBRT with or without ADT, or ADT alone. Approximately 20% to 25% of men with local recurrence postprostatectomy can be cured with early salvage EBRT. Several factors have been demonstrated to predict long-term response to salvage EBRT: Gleason score  $\leq 7$ ,

positive surgical margins at RP, negative nodal or seminal vesicle involvement, and post-RP PSA kinetics consistent with local failure (>3 year interval from RP to biochemical failure, PSA-doubling time >10 to 12 months, and an absolute PSA at salvage of  $\leq 1.0$ ). Patients who recur immediately after definitive radiation therapy are candidates for ADT, observation, or, in selected cases, salvage prostatectomy.

## ADVANCED DISEASE

A positive bone scan and pain in a weight-bearing area correlating to the scan should prompt an x-ray to assess for impending pathologic fractures. Patients should be made non-weight-bearing and immediately referred for both surgical and radiation consultation. The possibility of cord compression should be suspected in any man with a history of prostate cancer and new onset back pain. Pain from spinal cord compression is often severe and generally predates neurologic symptoms. A negative neurologic examination should not delay a definitive radiologic study (preferably magnetic resonance imaging [MRI] or CT myelogram), and patients with suspected cord compression should be initiated and maintained on steroids until compression is ruled out.

## Hormonal Therapy

### First-Line Hormonal Therapy

Patients with advanced disease at presentation, or patients who relapse after definitive local therapy are initially treated with some form of ADT. Timing of hormonal therapy should take into consideration the aggressiveness of the cancer as well as patient preferences. There is some evidence to suggest that starting ADT earlier rather than later improves outcomes, but the impact of early treatment on survival has yet to be defined.

The goal of ADT is to decrease the level of testosterone available to potentiate growth of the prostate cancer cells. A variety of treatments can achieve this goal; [Table 96-2](#) outlines the spectrum of drugs, which either alone or in combination are used as first-line hormonal therapy. Currently, the majority of men on ADT are treated with LHRH agonists alone (monotherapy) or in combination with an antiandrogen (combined androgen blockade). Although some physicians routinely use combination therapy, others prefer LHRH monotherapy, and there are no clear data showing benefit of one strategy over the other. Patients with known metastatic disease, however, need to be on an antiandrogen for at least 30 days, starting 7

**TABLE 96-2**

### Commonly Used First-Line Hormonal Therapy Options

TREATMENT	MECHANISM	EXAMPLE	ADMINISTRATION
Orchiectomy	Removal of major source of testosterone		Surgical
LHRH agonist	Stops the pulsatile secretion of LHRH from the pituitary and production of testosterone by the testes	Zoladex, Lupron	By depot injection, every 3–4 months
Antiandrogen	Androgen-receptor antagonist	Casodex, Eulexin, Nilandron	Daily pill

to 10 days prior to initiation of LHRH agonist therapy to avoid the initial testosterone flare associated with LHRH therapy.

Orchiectomy (surgical castration) may be an underused and underappreciated form of hormonal treatment. Clearly, with advances in surgical techniques, the morbidity associated with the procedure is minimal and barring unforeseen complications, it is an outpatient procedure. Data from the Prostate Cancer Outcomes Study provided an update on quality-of-life issues for patients receiving hormonal therapy. Men who chose LHRH agonist therapy reported greater problems than orchiectomy patients did with their overall sexual functioning, despite both groups having similar levels of function prior to beginning treatment. LHRH patients were also less likely to perceive themselves as free of cancer, likely because of the need for ongoing injections.

The duration of response to first-line ADT is typically 18 to 24 months, although patients who initiate therapy for biochemical relapse alone may show PSA responses for much longer. The continuation of ADT in the setting of hormone refractory disease is a subject of some controversy. A retrospective analysis by the Southwest Oncology Group (SWOG) showed no improvement in survival for patients remaining on LHRH therapy, while an Eastern Cooperative Oncology Group (ECOG) analysis showed a slight survival benefit. Given the potential for improved survival for patients remaining on testicular androgen suppression, many physicians continue to administer LHRH agonists for the duration of treatment with secondary hormonal therapies and chemotherapy.

Side effects from hormonal therapies include hot flashes, insomnia, decreased libido, erectile dysfunction, weight gain/fluid retention, diabetes, increased risk of cardiovascular events, and breast enlargement/nipple tenderness. Breast enlargement can be curtailed, although not reversed, by a few treatments of electron beam radiation directly to the breast stem cells underneath the areola. This low-risk treatment can provide significant physical and psychological benefit. Antiandrogen treatment can lead to hepatic dysfunction, requiring monitoring of liver function tests after the initial month of therapy, and every 3 months thereafter. Antiandrogens are also associated with gastrointestinal effects, including nausea, diarrhea, and constipation. Estrogens can predispose patients to thromboembolic complications, including deep vein thrombosis, pulmonary embolism, and myocardial infarction.

Patients with decreased testosterone caused by orchiectomy or ADT also have a significantly increased risk of bone loss. Most studies have demonstrated a 2% to 3% decrease per year in bone mineral density (BMD) of the hip and spine during initial testosterone suppressing therapy and BMD continues to decline during long-term therapy. Fracture rates are also higher in patients on ADT. Three large, claims-based studies have shown that LHRH treatment is independently associated with fracture risk. Patients on testosterone suppressing therapy should, therefore, be encouraged to take daily calcium (500 mg) and vitamin D (400 IU) supplements to prevent bone loss. In addition, patients may benefit from BMD testing to evaluate overall bone health. Men with osteopenia or osteoporosis should be considered for treatment with oral bisphosphonates (see section on "Supportive Care").

### Intermittent Androgen Deprivation

Intermittent androgen blockade has been advocated as a way to decrease side effects from ADT, and also to, potentially, increase the

time to androgen independence. With this strategy, patients are cycled on and off hormonal therapy based on PSA response. Once patients achieve an undetectable PSA in response to ADT, they are taken off therapy and monitored; treatment is reinitiated based on absolute PSA value and/or PSA-doubling time. Although intermittent ADT is now widely used and in most cases decreases the side effects attributable to ADT, its long-term efficacy is as yet unproven. A large intergroup trial is currently evaluating this strategy, randomizing patients to intermittent versus continuous ADT; primary endpoints are survival and quality of life.

### Second-Line Hormonal Therapy

There are several potential second- (and third-) line hormonal treatments for patients who fail first-line therapy. If the patient is receiving combined androgen blockade, the first treatment modality is antiandrogen withdrawal. The maximum duration of response is approximately 5 months. To date, there have been no identified predictors of androgen withdrawal response, although a longer duration of treatment with flutamide has been associated with response in two larger trials.

After withdrawal of one antiandrogen, some patients can derive benefit from the addition of a different antiandrogen, such as high-dose bicalutamide (150 mg daily). Ketoconazole, which decreases the production of adrenal androgens, has also been widely studied and has demonstrated transient response rates in patients with progression after ADT. Most ketoconazole trials, however, are confounded by the concomitant use of hydrocortisone (to prevent adrenal insufficiency); an evolving body of evidence suggests that steroids alone could be responsible for the PSA decline and improvement in quality of life. The first reported study of low-dose prednisone showed that 40% of patients had improved quality of life at 1 month, which was sustained for a median of 4 months in 20% of patients.

Estrogens, such as diethylstilbestrol, show promise both singly and in combination, although estrogen therapy is associated with side effects such as edema and increased incidence of thromboembolic complications. Judicious use of prophylactic agents, such as warfarin or low-dose aspirin, have been used in these trials, but not studied prospectively.

The decision to pursue secondary hormonal manipulations will likely depend on several factors. Available data suggest that patients with a significant and prolonged response to initial hormonal therapy, or a significant antiandrogen withdrawal response, may be good candidates for a trial of secondary hormonal therapy. Poor performance status and the presence of other medical problems may render attempts at further hormonal manipulation an attractive option as these patients are often intolerant of the side effects associated with chemotherapy. Patients with rapid PSA-doubling times are likely to have more aggressive disease and may receive more benefit from chemotherapy or a clinical trial with a novel agent.

### Chemotherapy

The use of chemotherapy in androgen-independent prostate cancer has undergone a revolution in the past decade. Although androgen-independent prostate cancer was once labeled "chemotherapy resistant," new agents show great promise in both palliative and response end points. Docetaxel is the first chemotherapeutic agent with demonstrated survival benefit in prostate cancer and has become standard of care for first-line therapy in hormone refractory

disease. In phase II and III clinical trials, docetaxel in combination with prednisone showed an increased median survival, PSA response, and quality of life compared with mitoxantrone. Mitoxantrone with prednisone has demonstrated palliative benefits in patients with bone metastases and is generally well tolerated; it may be used as a second-line option for symptomatic patients or as first-line for frailer patients who are poor candidates for docetaxel.

## SUPPORTIVE CARE

### Bisphosphonates

Bisphosphonates are synthetic analogues of inorganic pyrophosphates with high avidity for calcium and areas of bone mineralization. These compounds have been used for many years to treat disorders associated with bone resorption such as osteoporosis, Paget disease, and metastatic bone disease. Although various bisphosphonates have been tested in multiple clinical trials in the setting of advanced prostate cancer, only zoledronic acid—a potent, intravenous bisphosphonate—has a demonstrated effect on bone metastases in this population. In two placebo-controlled, randomized clinical trials, zoledronic acid decreased the incidence of skeletal events by 25% compared with placebo. Intravenous bisphosphonates are generally well tolerated, though patients should have regular creatinine assessment as renal toxicity is a known, but relatively uncommon, side effect. In addition, recent evidence has linked bisphosphonate use with osteonecrosis of the jaw—a rare but potentially devastating complication, which appears to be most prevalent in patients who have received these drugs over a period of several years. It may be prudent, therefore, for patients to have a dental examination prior to initiating therapy, and clinicians should ask patients regularly about their dental health.

As both increasing age and androgen ablation place men at higher risk of osteoporosis, bisphosphonates may also be useful in prevention of secondary fractures in this population. Even in a study of intermittent androgen blockade, evaluation of BMD in the lumbar spine revealed osteopenia in 46% and osteoporosis in 20% of patients, with similar values seen for the hip. A similar study found that 50% of men on androgen blockade for at least 12 months had asymptomatic vertebral fractures. A recent study of 47 men with hormone-sensitive prostate cancer compared BMD in men receiving the LHRH agonist leuprolide alone to BMD in men receiving the combination of pamidronate and leuprolide. Pamidronate showed significant protection of BMD in the lumbar spine, greater trochanter, and total hip. Although the study was only of 48 weeks duration, it underscored the startling amount of bone loss in patients on LHRH monotherapy for this period: 3.3% in the lumbar spine, 2.1% in the trochanter, and 1.8% in the total hip. As bone is a ready target for prostate cancer metastases as well, bone protection should be paramount, especially in the early stages of the disease. At this time, however, only oral bisphosphonates are FDA approved for the prevention and treatment of osteoporosis.

### Pain Control

The majority of men with advanced prostate cancer have bone metastases, which are frequently very painful. Pain control is thus a critical

issue in these patients and needs to be frequently monitored. Bone pain generally responds well to treatment with both nonsteroidal anti-inflammatory drugs and opioids, used alone or in combination. Although some elderly patients are very tolerant of narcotic analgesics, as a rule they should be started on low doses with careful dose titration and individualized treatment plans to achieve maximal analgesia and maintain quality of life. Constipation, the most common side effect of pain medications, should be aggressively addressed, but is generally well controlled with laxatives.

### Palliative Radiation and Systemic Radioisotopes

Palliative radiation therapy can provide significant pain relief for symptomatic bony metastases and is also used to prevent impending pathologic fracture, particularly in the femora. Thus, patients with one or two areas of severe bone pain, which is either inadequately controlled with narcotics or which requires unacceptably high doses of narcotics, should be referred to radiation oncology for consultation. Most palliative radiation is given in one to 10 dose fractions, and 80% to 90% of prostate cancer patients who receive palliative radiation for bone metastases experience significant and durable pain relief. The onset of pain relief may be as soon as 48 hours after the initiation of therapy, although some patients will not experience maximal relief for up to 2 weeks after therapy is complete. Systemic radioisotopes such as strontium-89 and samarium-153 deliver high-dose radiation to bone lesions without significantly affecting normal bone and can provide palliative benefit to patients with widespread, painful bone metastases, which are refractory to palliative chemotherapy or narcotic analgesia. These agents generally provide significant pain relief and can be re-administered if needed. They do, however, have the potential to cause significant myelosuppression and thrombocytopenia and should be used cautiously in patients with low baseline blood counts or patients receiving concomitant chemotherapy.

# Lung Cancer

*Daniel Morgensztern ■ Ramaswamy Govindan ■ Michael C. Perry*

## EPIDEMIOLOGY

According to American Cancer Society statistics, there will be 232,270 new cases of lung cancer in 2008, accounting for approximately 15% of cancer diagnoses. The likelihood of developing lung cancer is 1 in 2500 in men younger than 39 years of age and 1 in 15 in men between the ages of 60 and 79 years.

The vast majority of patients with lung cancer will still die of the disease. It is estimated that 166,280 patients will die of lung cancer in 2008, accounting for 31% of all cancer deaths in men and 26% of cancer deaths in women. Among women, the rate of deaths from lung cancer remains high. Since 1987, more women have died from lung cancer than from breast cancer. Despite an enormous effort to find effective therapies for lung cancer, the overall 5-year survival remains only 15%. The high mortality rate and low 5-year survival rate are largely the result of an inability to diagnose lung cancer at an early stage, when it is still potentially curable. Only 15% of lung cancers are diagnosed at this early stage. The uniformly poor results obtained with current therapies are a strong argument for the inclusion of all possible patients into clinical trials.

## ETIOLOGY

### Risk Factors

#### Tobacco Smoking

Smoking is by far the most common cause of lung cancer. Approximately 85% to 90% of lung cancer cases can be attributed directly to tobacco smoking. The risk of lung cancer is directly related to the length of time a person smokes, the number of cigarettes smoked per day, the age at which a person starts smoking, and the amount of tar contained in the cigarettes. The risk of developing lung cancer is

9- to 10-fold higher in an average smoker and up to 25-fold higher for a heavy smoker. However, not all tobacco smokers develop lung cancer. This may be attributable to differences in an individual's inherited predisposition to cancer development. There is also evidence that nonsmokers exposed to tobacco smoke (passive smokers) have an increased risk of developing lung cancer. It has been estimated that up to 25% of lung cancers in nonsmokers are caused by passive smoking. The risk of lung cancer declines steadily once a person stops smoking, but it takes up to 15 to 20 years for the risk to return to the level of nonsmokers. However, it never reaches this level if they had smoked two packs per day or more.

#### Other Risk Factors

Other factors reported to cause lung cancer include occupational exposure to arsenic, asbestos, nickel, uranium, chromium, silica, beryllium, and diesel exhaust. Dietary deficiency of vitamins A, C, and E, retinoids, carotenoids, and selenium, and air pollution, lung scars, and oncogenes have all been implicated in the causation of lung cancer. Asbestos is the most common occupational cause of lung cancer and increases the risk of lung cancer fivefold. Tobacco smoking and asbestos exposure act synergistically, and the risk of lung cancer in smokers who have been exposed to asbestos becomes as high as 80-fold to 90-fold higher than the risk in nonsmokers. Radon, produced by the decay of uranium, has a well-established association with lung cancer in underground miners. However, the association between lung cancer and residential exposure to radon is less well established.

## SCREENING

Most patients with lung cancer present with advanced-stage disease, when the outcome is dismal. Therefore, there has been an interest in screening high-risk people to detect lung cancers when they are smaller and presumably at earlier and more curable stages. Earlier

trials using chest radiography, cytologic examination of the sputum, or both, however, failed to decrease the disease-specific mortality. These trials have been criticized for their study design, statistical analysis, contamination, and older forms of technology. With the development of newer imaging technology, specifically low-dose spiral CT scans, there has been a new interest in screening for lung cancer. The International Early Lung Cancer Action Program screened 31,567 asymptomatic patients, with 27,456 repeat screenings and found lung cancer in 484 participants. Of these, 85% had stage I disease with an estimated 10-year survival rate of 88%. Although intriguing, this study has been criticized on methodological grounds. Another longitudinal study of 3246 asymptomatic patients from three centers found 144 lung cancers, compared to 44.5 expected cases. There was no evidence of a decline in the number of diagnoses of advanced lung cancers.

In addition to the overdiagnosis of small tumors detected during screening, which could otherwise remain silent until the patient dies from other causes, screening for lung cancer with spiral CT scan could potentially cause harm secondary to morbidity and mortality associated with thoracotomy, since lung tumors appear as noncalcified nodules and only a small fraction of those nodules actually represent lung cancer. The ongoing National Lung Cancer Screening Trial is carefully studying the role of CT scans in the screening of lung cancer in patients with a strong history of tobacco smoking. The issues of lead-time bias and additional morbidity and mortality are particularly relevant in the population of older adults in whom competing causes of death and multiple comorbidities are frequently encountered. At the present time, we do not believe there is enough evidence to recommend CT screening for lung cancer outside the context of clinical trial.

With better understanding of the molecular pathology of lung cancer, an interesting area of research is to examine the utility of molecular and genetic biomarkers in screening high-risk people. Because cancer is a multistep process, identification of these biomarkers in the sputum of high-risk individuals may help to identify the early clonal phase of progression of lung cancer. If this becomes reality, then it may enable detection of cancers earlier than with spiral CT. It could also be complementary to spiral CT screening.

## PATHOLOGY

Based on the light microscopic features, lung cancers are divided into two major groups: small-cell lung cancer (SCLC) and non-small-cell lung cancer (NSCLC). The later include squamous cell carcinoma, adenocarcinoma, and large-cell carcinoma (Table 97-1).

**TABLE 97-1**

### Most Common Histological Subtypes of Lung Cancer

Small-cell carcinoma
Adenocarcinoma
Squamous cell carcinoma
Large-cell carcinoma
Adenosquamous carcinoma
Undifferentiated carcinoma

Bronchoalveolar carcinoma is subclassified under adenocarcinoma. The distinction between small- and non-small-cell histology is important clinically, because small-cell histology is more aggressive and more responsive to chemotherapy and radiation.

In the past, the most common histology was squamous cell carcinoma, which accounted for 40% of lung cancers. However, now in the United States only 20% to 25% of lung cancers are squamous cell cancers. Squamous cell carcinoma is the classic lung cancer—central in location, endobronchial in nature, sometimes with central cavitation, and commonly associated with lobar collapse, obstructive pneumonia, or hemoptysis, with late development of distant metastases. On the other hand, adenocarcinomas, which in earlier times constituted 20% to 25% of all lung cancers, are now the most prevalent histology, accounting for almost 40% of all lung cancers. This increase in prevalence has been greater in North America than in Europe, where squamous cell cancer is still the most common type. Changes in smoking habits and other environmental factors are thought to account for this shift in histology.

Adenocarcinoma is not as strongly associated with smoking as other types of carcinomas and is the most common type in non-smokers. It is characterized by the early development of metastases, even when tumor still appears to be a solitary lesion. Adenocarcinoma is most frequently a peripheral lung lesion and is commonly accompanied by a malignant pleural effusion.

The incidence of squamous cell carcinoma rises with increasing age, while that of adenocarcinoma falls. This, in combination with the fact that elderly patients seem to have more localized disease at presentation, correlates with a greater likelihood that older patients will have resectable and thus potentially curable disease.

Bronchoalveolar carcinomas and large-cell carcinomas are less common. The former is either unifocal or multifocal, which can mimic pneumonia. It may be detected in the setting of prior fibrotic lung disease, such as idiopathic pulmonary fibrosis, scleroderma, or asbestosis. Large-cell carcinomas account for approximately 10% of all lung cancers. The lesions are usually peripheral and sometime cavitate because of necrosis. Small-cell carcinomas account for approximately 20% of all lung cancers. Among all the lung cancer types, they have the strongest association with smoking. These commonly form central masses and grow rapidly, with a tendency to early metastasis. Rarely, tumors contain two histologies.

## CLINICAL PRESENTATION

The initial clinical presentation of lung cancer patients is variable. Patients may seek medical attention for symptoms related to the primary tumor, mediastinal disease, distant metastases, or paraneoplastic syndromes (Table 97-2). In advanced cases, patients may present with systemic signs of anorexia, weight loss, fatigue, and weakness. Symptoms related to the primary tumor depend upon the location of the tumor: central or peripheral. Central tumors produce cough, dyspnea, hoarseness, stridor, hemoptysis, and postobstructive pneumonia. Superior sulcus tumors may produce shoulder pain, arm pain, or brachial plexopathy, or Horner syndrome. Peripheral lesions may cause pleuritic chest pain suggesting pleural involvement. Symptoms related to mediastinal disease include hoarseness caused by the involvement of left recurrent laryngeal nerve with left-sided tumors and obstruction of the superior vena cava with right-sided tumors

TABLE 97-2

## Clinical Presentation of Lung Cancer

LOCAL	INTRATHORACIC SPREAD	EXTRATHORACIC SPREAD	PARANEOPLASTIC
Cough	Chest wall pain	Abdominal pain	Clubbing
Chest pain	Dysphagia	Bone pain	Cushing syndrome
Dyspnea	Hoarseness	Headaches	Hypercalcemia
Hemoptysis	Pleural effusion	Jaundice	Hypertrophic osteoarthropathy
	SVC obstruction	Lymphadenopathy	Lambert-Eaton syndrome
		Paralysis	SIADH
		Seizures	

or associated lymphadenopathy. Less common features include dysphagia caused by esophageal obstruction and hypotension caused by pericardial tamponade. Direct involvement of the myocardium is rare, although pericardial effusions are sometimes seen and may produce severe dyspnea and refractory hypotension. Phrenic nerve involvement leads to paralysis of the ipsilateral diaphragm, most commonly seen as elevation of the affected diaphragm on a plain chest radiograph.

Metastases from lung cancer are common. Sites of spread include the brain, pleural cavity, bone, liver, adrenal glands, and contralateral lung. Because more than half of patients have metastases at presentation, initial symptoms related to a metastatic site are frequent, particularly in patients with adenocarcinoma or small-cell carcinoma.

## PARANEOPLASTIC SYNDROMES

Although lung cancer is associated with a variety of paraneoplastic syndromes, presentation with symptoms related to a paraneoplastic syndrome is uncommon. Apart from hypercalcemia and hypertrophic pulmonary osteoarthropathy that are associated with squamous cell carcinoma, all others are linked to SCLCs. These include the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), Cushing syndrome, and various neurological syndromes such as Eaton–Lambert reverse myasthenia syndrome, encephalitis, subacute sensory neuropathy, opsoclonus and myoclonus, cerebellar degeneration, and limbic degeneration. Hypercoagulability resulting in deep venous thrombosis is common in advanced lung cancers, particularly adenocarcinoma. Occasionally, lung cancers are diagnosed during work-up of patients with dermatomyositis or membranous glomerulonephritis.

## DIAGNOSIS

An accurate diagnosis with proper distinction between SCLC and the various non-small-cell types is essential before any further staging work-up can be performed. A change in the usual symptoms of cough and dyspnea in a chronic smoker is often an indication for a chest x-ray, which if abnormal, leads to further evaluation. Because benign and other malignant conditions can mimic lung cancer on radiologic studies, histological confirmation of the diagnosis is essential. Depending on the location of the tumor, this can be achieved through examination of sputum cytology, fiberoptic bronchoscopy, or transthoracic biopsy.

Sputum cytology is a cost-effective and easy way of reaching a diagnosis. The yield is high for endobronchial lesions such as small-cell tumors and squamous cell carcinomas, but it is low for peripheral lesions of adenocarcinoma and large-cell carcinoma. The false-positive rate for cytology is less than 1%, but the false-negative rate is 41% to 43%. A cytological specimen that is positive for malignancy is accurate in approximately 90% of cases, but the distinction between individual histologic types is not as accurate, and discordant results are often seen between cytology and histology bronchoscopy and needle-biopsy specimens.

In contrast, fiberoptic bronchoscopy provides direct visualization of the bronchial tree, and diagnostic material can be obtained with bronchial brushings, washings, and biopsy of the directly visualized tumor, or with a transbronchial biopsy. Fiberoptic bronchoscopy is well tolerated by elderly patients, and age alone should not exclude an appropriate diagnostic evaluation. For tumors not visualized, the yield for washing and brushing is approximately 75% in central lesions and 55% in peripheral lesions. Therefore, the yield in small-cell and squamous cell carcinomas is higher than in adenocarcinomas and large-cell carcinomas.

Percutaneous fine-needle aspiration of a lung lesion gives a high yield (more than 85%), with a high accuracy for histological subtype. This technique is very useful to establish a diagnosis for peripheral lesions and in patients who are not surgical candidates for an open thoracotomy. One deterrent for performing percutaneous fine-needle aspiration is the risk of inducing iatrogenic pneumothorax; however, chest tube placement is required only in approximately 5% of patients. The same technique is used in obtaining tissue from metastatic sites such as supraclavicular lymph nodes, adrenal glands, and liver. In patients with a classic solitary lesion that is surgically resectable, many times a diagnosis is made after a thoracotomy. This is because the management of the lesion is unlikely to be changed if a percutaneous biopsy is performed first. In patients with a pleural effusion, either cytological examination of the pleural fluid or, if that is inconclusive, thoracoscopic biopsy of pleural lesions is the method of obtaining a biopsy material. An additional method of obtaining a tissue is mediastinoscopy.

## Staging

Following the diagnosis of lung cancer, patients should be evaluated for the presence of spreading to regional lymph nodes or distant organs. Adequate staging of lung cancer provides important prognostic information and is one of the most important determinants of the optimal treatment for each individual patient. The staging system

for patients with NSCLC is the TNM staging, which takes into account the degree of involvement by the primary tumor (T), the extent of lymph node involvement (N), and the presence or absence of distant spread (metastasis, M). Although the TNM system can be used to stage SCLC, the high propensity for early metastasis led to the development of a more practical staging system, which divides these tumors into limited disease or extensive disease. Limited disease is defined as a tumor that can be encompassed within a single and tolerable radiation port and any spreading to sites beyond the definition of limited-stage disease is classified as extensive disease.

In the assessment of metastatic spread, the history and physical examination are the most helpful tests, supplemented by liver function tests. Chest CT provides information about the primary tumor as well as about the lymph node status of the mediastinum. The abdominal CT is used to examine the liver and adrenal glands. Magnetic resonance imaging (MRI) of the chest and abdomen does not appear to improve the accuracy of staging. Brain CT or MRI scan is indicated in all patients with SCLC and selected patients with NSCLC, including patients with stage III disease planned to receive chemoradiotherapy and those with neurological symptoms. Likewise, radionuclide bone scanning is only recommended in patients with symptoms of bone metastases, elevated alkaline phosphatase, or hypercalcemia. The yield of bone scans in asymptomatic patients is very low. Other invasive staging procedures employed in the staging of lung cancer include mediastinotomy and video-assisted thoracoscopy.

### Metabolic Staging

Noninvasive staging with CT scan is not very accurate in predicting the presence and absence of metastatic disease. This anatomic staging is dependent on the size of the underlying lymph nodes, which, when enlarged, could be reactive in pathology. On the other hand, CT scans can miss metastatic disease in a normal-sized lymph node. In a series of 102 patients, it was reported that CT scan has a sensitivity of 75% and a specificity of 66% for mediastinal staging for nodal disease. In a large meta-analysis, the overall sensitivity and specificity of CT scan were 60% and 77%, respectively. In these situations, the gold standard is to subject all potentially resectable patients to invasive procedures such as mediastinoscopy, mediastinotomy, and video-assisted thoracoscopy. With the advent of positron emission tomogram (PET) scanning, it is now possible to use metabolic staging whenever there is suspicion of occult metastases in the mediastinum or elsewhere. PET uses fluorodeoxyglucose (FDG) as a tracer with the underlying knowledge that there is increased glucose metabolism in tumor cells. FDG, a glucose analogue labeled with a positron emitter, concentrates in the tumor cells and is trapped because it does not proceed along the usual metabolic pathways. A PET scanner then picks up the tissue distribution. A higher concentration in the tumor could be easily observed on a computer-generated image. Despite some limitations, PET scan is more sensitive (91%) and specific (86%) than a CT scan.

The American Society of Clinical Oncology (ASCO) currently recommends the use of FDG-PET scan in patients without evidence of metastatic disease in the chest CT. Furthermore, owing to the high negative predictive value of FDG-PET scan, which is typically above 90%, patients without enlarged mediastinal lymph nodes in the CT scan and no increased uptake by FDG-PET may not require staging mediastinoscopy.

Sixty to seventy percent of patients with SCLC have extensive-stage disease at presentation.

### PROGNOSTIC FACTORS

For all lung cancers, the most consistent prognostic factor is the extent (stage) of disease and the performance status, measured by either the Zubrod or the Karnofsky scale. Simply stated, ambulatory patients (Zubrod scores of 0, 1, and 2, or Karnofsky scores of 70% or higher) survive longer than do nonambulatory patients. For patients with NSCLC, advanced disease stage and unintentional weight loss greater than 10% in the last 6 months are adverse prognostic indicators. For SCLC patients, extensive stage, male sex, increased age, elevated serum lactic acid dehydrogenase, elevated serum alkaline phosphatase, and hyponatremia are significant adverse prognostic indicators.

### TREATMENT OF NON-SMALL-CELL LUNG CANCER

#### Stage I (T1N0, T2N0)

Stage I patients are best treated by surgical resection with the aim of cure. The standard surgical procedure in fit patients consists of at least lobectomy. Despite undergoing surgery with curative intent, the 5-year overall survival is approximately 60% for clinical stage IA and 38% for stage IB. Current data do not support the use of chemotherapy in patients with resected stage I NSCLC.

In patients who are medically unfit for curative resection, primary radiotherapy offers a cure rate of approximately 25%. This option is commonly used in elderly patients who may have comorbid conditions making them high risk for surgery. In a single report of patients older than 70 years who had resectable lesions smaller than 4 cm but who were medically inoperable or who refused surgery, survival at 5 years following radiation therapy with curative intent was comparable to a historical control group of patients of similar age resected with curative intent. In the two largest retrospective radiation therapy series, patients with inoperable disease treated with definitive radiation therapy achieved 5-year survival rates of 10% and 27%. Both series found that patients with T1N0 tumors had better outcomes, with 5-year survival rates of 60% and 32% in this subgroup. Primary radiation therapy should consist of approximately 6000 cGy. Careful treatment planning with precise definition of target volume and avoidance of critical normal structures to the extent possible is needed for optimal results and requires the use of a simulator. Stereotactic radiosurgery is becoming increasingly popular for the treatment of appropriately located small lesions in patients who are not candidates for surgery owing to comorbid conditions. Another option for patients who cannot undergo proper cancer surgery is wedge resection; however, despite achieving negative margins, the local failure rate is very high.

#### Stage II (T1N1, T2N1, T3N0)

These patients are also treated by surgical resection with a curative intent. The types of surgical procedures considered standard care are lobectomy or pneumonectomy. However, the 5-year survival rate is

worse than stage I with 5-year survival ranging from 39% to 55%. Various attempts have been made to improve the cure rate with the use of postoperative radiation therapy or chemotherapy. In a large randomized trial of adjuvant radiation therapy in early-stage lung cancer, despite a decrease in local recurrence, there was no effect on the overall survival of the patients. A large meta-analysis of randomized clinical trials found that adjuvant radiation after curative resection was detrimental to patient survival. Cisplatin-based adjuvant chemotherapy improves survival in patients with resected stage II NSCLC.

Patients with inoperable stage II disease but with sufficient pulmonary reserve may be considered for radiation therapy with curative intent. Among patients with excellent performance status, up to a 20% 3-year survival rate may be expected if a course of radiation therapy with curative intent can be completed. In the largest retrospective series reported to date, 152 patients with medically inoperable NSCLC treated with definitive radiation therapy achieved a 5-year overall survival rate of 10%; however, the 44 patients with T1 tumors achieved an actuarial disease-free survival rate of 60%. This retrospective study also suggested that improved disease-free survival was obtained with radiation therapy doses greater than 6000 cGy.

### Stage IIIA (T3N1, T1–3N2)

Stage IIIA is a heterogeneous group of tumors that can be broadly classified into three distinct subgroups; incidental IIIA, potentially resectable IIIA, and bulky or unresectable IIIA. Patients with incidentally diagnosed stage IIIA at the time of thoracotomy should receive adjuvant chemotherapy. The role of adjuvant radiation in this setting is not clearly defined. A large intergroup study conducted in North America did not find any improvement in survival with the addition of surgery following chemotherapy and radiation in patients with resectable stage III NSCLC. However, patients with limited mediastinal lymph node involvement and excellent lung function who are likely to need only lobectomy (and not pneumonectomy) may be considered for neoadjuvant chemoradiotherapy followed by surgical resection. For those with bulky mediastinal adenopathy, the recommended treatment is the combination of chemotherapy and radiation, preferably given concurrently. Patients with poor performance status may be treated with sequential chemotherapy and radiotherapy or either modality alone.

### Stage IIIB (T4N0, any TN3)

While selected patients with stage IIIB because of T4 extension other than malignant pleural effusion may be treated surgically with curative intent, patients with contralateral mediastinal or supraclavicular involvement are not surgical candidates and should be treated with chemotherapy and radiation. Patients with stage IIIB NSCLC and malignant pleural effusion are incurable and should be treated as stage IV, with chemotherapy alone for palliation.

### Stage IV (any T, any N, M1)

Patients with stage IV NSCLC are treated with chemotherapy (Table 97-3), which improves survival compared with best supportive care. Typical results from randomized clinical trials of combination chemotherapy in this setting include response rates of approx-

Vinorelbine	

imately 30%, median survival times of 8 to 9 months, and 1-year survivals of 35%. Bevacizumab, a vascular endothelium growth factor inhibitor, recently demonstrated survival benefit when combined with standard chemotherapy in a randomized trial, with a median survival of greater than 12 months. Early studies, however, showed increased risk of fatal hemoptysis in patients with centrally located tumors, squamous cell carcinoma histology, and previous history of hemoptysis. Therefore, the addition of bevacizumab to chemotherapy represents the new standard of care in stage IV NSCLC in the patients without these risk factors. Since the disease is incurable, virtually every patient with metastatic NSCLC will develop progressive disease. Several randomized studies have already shown survival benefit from second-line therapy. Several molecularly targeted therapies are being studied in NSCLC. Epidermal growth factor receptor tyrosine kinase inhibitors such as gefitinib and erlotinib have been associated with striking response in patients who are lifelong never smokers with NSCLC. In a randomized study, erlotinib improved survival over best supportive care in unselected group of patients (smokers and nonsmokers) with advanced NSCLC who had progressive disease following initial therapy. Approved therapies in this setting include docetaxel, pemetrexed, and erlotinib.

Patients with solitary metastasis to the brain or adrenal gland may be candidates for curative resection.

Radiation therapy may be effective in palliating symptomatic local involvement from NSCLC such as tracheal, esophageal, or bronchial compression, bone or brain metastases, pain, vocal cord paralysis, or hemoptysis. In some cases, endobronchial laser therapy and/or brachytherapy have been used to alleviate proximal obstructing lesions. Such therapeutic intervention is important in maintaining the quality of life of the patient. In the rare patient with synchronous presentation of a resectable primary tumor in the lung and a single brain metastasis, surgical resection of the solitary brain lesion is indicated with resection of the primary tumor and appropriate postoperative chemotherapy and/or irradiation of the primary tumor site and with postoperative whole-brain irradiation delivered in daily fractions of 180 cGy to 200 cGy to avoid long-term toxic effects to normal brain tissue.

Aging is usually associated with decreased marrow reserve and renal function as well as the development of accumulative comorbidities. Consequently, elderly patients frequently undergo less aggressive therapy and are commonly excluded from clinical trials. Several retrospective studies, however, demonstrated benefit from chemotherapy over best supportive care in this patient population. Recent studies have demonstrated that age by itself should not be a

determinant to guide the therapeutic decision in patients with lung cancer. Elderly patients with good performance status and no significant comorbidities should be considered for aggressive therapy including surgical resection, chemoradiotherapy, and combination chemotherapy when appropriate.

## SMALL-CELL LUNG CANCER

SCLC is the most aggressive type of lung cancer, and without therapy, the median survival is only 6 to 12 weeks. Though initially very sensitive to chemotherapy and radiation, relapse of the disease is very common (Table 97-4). The combination of platinum and etoposide continues to be the standard therapy for now nearly three decades.

Patients with limited disease are typically treated with cisplatin, etoposide, and concurrent thoracic radiation. Because radiation is very effective in small-cell lung patients, earlier investigators wondered whether thoracic radiation could be combined with systemic chemotherapy. Randomized trials have shown improved survival with addition of radiation to chemotherapy in patients with limited-stage without the development of unacceptable toxicity. This benefit is usually greater, if the radiation is administered during the first several cycles of therapy. A meta-analysis of trials comparing chemotherapy alone with combined chemotherapy and thoracic radiotherapy found that combined treatment improved survival among patients with limited-stage SCLC. Cisplatin and etoposide have largely supplanted the older regimens of cyclophosphamide, doxorubicin, and vincristine because of the absence of toxic side effects on intrathoracic organs and the ability to use concurrent thoracic radiation. Surgery in limited-stage SCLC is only performed when a peripheral lung nodule is surgically resected for presumed NSCLC. Even these patients are further treated with systemic chemotherapy with or without thoracic radiation. On the other hand, patients with extensive-stage disease are usually treated with four cycles of etoposide with either cisplatin or carboplatin.

The response rates to combination chemotherapy are high, up to 75% to 80% in extensive-stage disease and 85% to 95% in limited-stage disease, with complete responses in 20% to 25% and 50% to 60%, respectively. The duration of chemotherapy treatment is typically four to six cycles. The median survival is 7 to 10 months in extensive-stage and 14 to 20 months for limited-stage patients. Patients with limited-stage disease have a 2-year survival of 20% to 30% and those with extensive-stage have 2-year survival rates of 5% to 10%.

SCLC has a high propensity for brain metastases. The actuarial risk of developing brain metastases in patients with limited-stage

lung cancer whose disease is controlled with combination therapy is 60% in the next 2 to 3 years. Many times the brain is the only site of metastases. Prophylactic cranial irradiation (PCI) decreases the risk of clinically apparent lesions in the brain by more than 50% with doses of 2400 cGy. A meta-analysis of seven randomized trials evaluating the value of PCI in patients in complete remission reported improvement in brain recurrence, disease-free survival, and overall survival with the addition of PCI. The 3-year overall survival was improved from 15% to 21% with PCI. PCI is now the standard therapy in patients with limited-stage disease who have a complete response to thoracic radiation and systemic chemotherapy. A European study recently demonstrated a near twofold increase in 1-year survival with the addition of PCI following chemotherapy in patients with extensive-stage disease who achieve a good response or stable disease.

The standard second-line therapy is topotecan, which was found to be as effective as CAV but with less toxicity. Patients with progression-free interval greater than 3 months are called chemotherapy sensitive and have better probability of response to second-line therapy. Patients with no initial response or progression within 3 months from the last cycle of first-line therapy are called chemotherapy refractory and have poor response to available chemotherapy agents.

Fear of increased toxicity from chemotherapy in elderly patients led some physicians to avoid combination therapy in these patients. Until recently, oral etoposide as a single agent was considered to be both well tolerated and effective in SCLC, with an overall response rate of 79% and a complete response rate of 17%. However, studies by the Medical Research Council Lung Cancer Working Party and the London Lung Cancer Study group compared single-agent etoposide with standard combination chemotherapy. Both trials found that oral etoposide was inferior to standard intravenous combination chemotherapy with fewer responses, a worse quality of life, and worse survival.

## SPECIAL PROBLEMS

### Pancoast (Superior Sulcus) Tumors

Pancoast tumors are carcinomas that develop peripherally in the apex of the lungs and invade the superior sulcus. They are a unique category of tumors that are locally invasive with a reduced tendency for distant metastases. Typically they cause symptoms of pain in the shoulder and along the vertebral border of the scapula and down the arm. As they extend into the thoracic inlet, they invade the sympathetic chain and stellate ganglion, causing Horner syndrome. If the tumor is relatively confined and there is no evidence of distant spread, the treatment is local with curative potential, especially for T3N0 disease. Radiation therapy alone, radiation therapy preceded or followed by surgery, or surgery alone (in highly selected cases) may be curative in some patients, with a 5-year survival rate of 20% or more in some studies. The best results have been achieved with a combination of chemotherapy and concurrent radiation therapy. Patients with more invasive tumors of this area, or true Pancoast tumors, have a worse prognosis and generally do not benefit from primary surgical management. Follow-up surgery may be used to

verify complete response in the radiation therapy field and to resect necrotic tissue.

### Chest Wall Tumors

Selected patients with bulky primary tumors that directly invade the chest wall can obtain long-term survival with surgical management provided that their tumor is completely resected. Standard treatment options include surgery, radiation, surgery and radiation, and chemotherapy combined with other modalities.

### Superior Vena Cava Syndrome

Approximately 80% of cases of the superior vena cava syndrome are caused by malignancy and carcinoma of the lung, particularly small-cell carcinoma, which accounts for the majority of these cases. The syndrome consists of edema of the face and neck with dilated veins in the neck and upper torso. Although considered by some to be a medical emergency, this is, in fact, only an urgency. If the patient's condition permits, a rapid search for histologic confirmation of the diagnosis should be sought (as above), followed by appropriate treatment. If the patient is clearly deteriorating, urgent radiation therapy is appropriate, followed by diagnostic evaluation at a subsequent time.

### Solitary Brain Metastases

Patients who present with a solitary cerebral metastasis after resection of a primary NSCLC lesion and who have no evidence of extracranial tumor can achieve prolonged disease-free survival with surgical excision of the brain metastasis and postoperative whole-brain irradiation. Unresectable brain metastases in this setting may be treated with radiosurgery. Because of the small potential for long-term survival, radiation therapy should be delivered by conventional methods in daily doses of 180 to 200 cGy, while higher daily doses over a shorter period of time (hypofractionated schemes) should be avoided because of the high risk of toxic effects observed with such treatments. Patients, including elderly ones, who are not suitable for surgical resection should receive conventional whole-brain radiation therapy. Selected patients with good performance status and small metastases can be considered for stereotactic radiosurgery. Approximately one-half of patients treated with resection and postoperative radiation therapy will develop recurrence in the brain; some of these patients will be suitable for additional treatment. In those selected patients with good performance status and without progressive metastases outside of the brain, treatment options include reoperation or stereotactic radiosurgery. For most patients, additional radiation therapy can be considered; however, the palliative benefit of this treatment is limited.

## SUPPORTIVE CARE

All lung cancer treatments produce some degree of adverse effects in every patient; therefore, supportive care has become an important aspect of cancer management. Irrespective of whether patients undergo surgery, radiation, or chemotherapy, they all will experience a decline in their nutritional status. This is more pronounced in patients who are elderly and those who are treated with combined

modality therapy. It is therefore imperative that all such patients receive proper nutritional support. There should be a low threshold for involving clinical dietitians in cancer management. Many patients have anorexia and weight loss because of their advanced cancer. These patients should be offered medroxyprogesterone or prednisone, which are beneficial in such circumstances.

Two of the major side effects of systemic chemotherapy are nausea and vomiting. Cisplatin, the most commonly used chemotherapeutic drug in lung cancer, is highly emetogenic. However, with prophylactic doses of dexamethasone and 5HT<sub>3</sub> antagonists (ondansetron and granisetron), severe nausea and vomiting are now seldom seen. Even delayed nausea and vomiting are now controlled with dexamethasone and lorazepam. All patients should be kept well hydrated while nausea and vomiting are being treated. Mucositis is frequently seen in patients receiving thoracic radiation with or without systemic chemotherapy. Amifostine is now used as an adjunctive drug in these situations, but it may not influence esophagitis.

Infections caused by the disease itself or by myelosuppression from chemotherapy should be treated aggressively with appropriate antibiotics. The use of colony-stimulating factors in selected patients may decrease the severity and shorten the duration of neutropenia. The American Society of Clinical Oncology now supports the use of colony stimulating factors in elderly patients who are high risk for the development of neutropenic fever.

Anemia is a major issue in patients on systemic chemotherapy. Those who receive radiation concurrently are at higher risk for developing symptomatic anemia. A number of studies have demonstrated that weakness and fatigue associated with chemotherapy negatively affect the quality of life and that such symptoms may improve with correction of anemia. Recombinant erythropoietin is now commonly used in this subset of patients and has made a significant impact on patients' well being.

Pain control is probably the most important aspect of supportive care in cancer patients (see Chapter 53). All patients experiencing pain should be on appropriate pain medications. The judicious use of long-acting narcotic analgesics with short-acting agents for breakthrough pain and adjuvant drugs such as nonsteroidal anti-inflammatory drugs and amitriptyline goes a long way toward promoting a sense of well being and improving performance status.

A cancer diagnosis has a major impact of the psychological state of patient and their family. Psychosocial issues, financial concerns, and family stress are all best managed by physicians, nurses, social workers, and dietitians working as a team. Thus, cancer is now a multidisciplinary disease, and coordination and communication between all members of the team are essential.

# Gastrointestinal Malignancies

*Nadine A. Jackson* ■ *Peter C. Enzinger*

## INTRODUCTION

Gastrointestinal cancers are primarily diseases of persons in their sixth, seventh, and eighth decade of life. Both incidence and mortality of gastrointestinal cancers increase with advancing age (Figures 98-1 and 98-2). Many elderly persons, however, have additional medical problems that almost certainly contribute to this inferior outcome. This chapter will explore the epidemiology, presentation, treatment options, and disparities in the care of older persons with gastrointestinal malignancies.

In general, the symptoms and presentation of gastrointestinal cancers in older individuals appear similar to those of persons of younger age. Although treatments for these cancers have been developed primarily in younger patients, greater expertise over time has permitted similarly safe and efficacious therapy to be extended to older age groups. Since the greatest percentage of gastrointestinal cancers are located in the colon and rectum, most of the information regarding older persons focuses on colorectal cancer. Unfortunately, there is a paucity of information concerning the treatment of elderly patients with other gastrointestinal malignancies. In this chapter, gastrointestinal malignancies are ordered by incidence in the U.S. population.

## COLORECTAL CANCER

Colorectal cancer accounts for approximately 10% of all new cancer cases and 10% of all cancer-related deaths in the United States. In fact, colorectal cancer causes more deaths than prostate cancer in men 60 to 79 years of age and more deaths than breast cancer in women 80 years or older. In 2008, 108,070 new cases of colon cancer and 40,740 new cases of rectal cancer will be diagnosed. The probability of developing colorectal cancer increases from 0.07% in the first four decades of life to 4.3% for females and to 4.8% for males in the

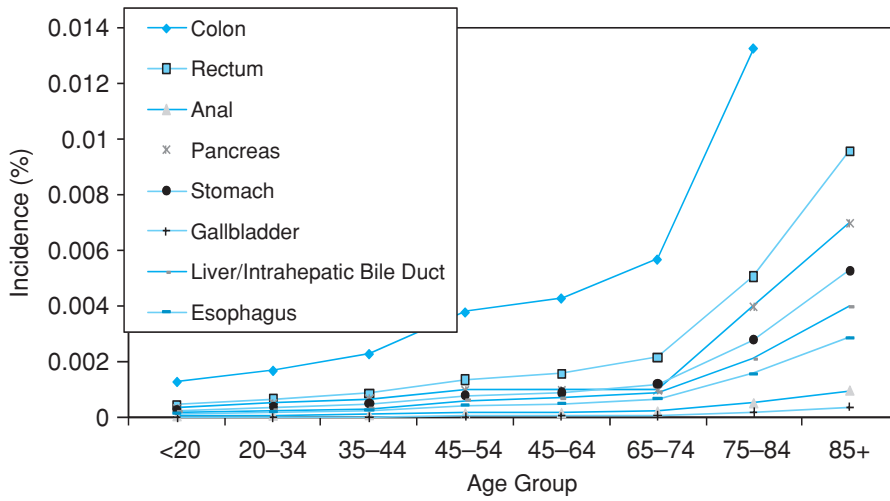

seventh decade of life. Although the 5-year relative survival (66%) with this cancer is identical for persons younger than 65 and for persons 65 to 74 years, it declines to 60% for individuals 75 years or older (Figure 98-3 and Figure 98-4).

Six out of seven studies suggest that elderly patients present at the time of diagnosis with the same probabilities of having localized and advanced colon cancer as younger patients. In randomized studies, elderly patients are reported to have the same performance status and incidence of tumor-related symptoms as younger patients, but tend to have more disease-related weight loss. Older patients also appear to have a greater incidence of right-sided (proximal) tumors and higher rates of obstruction and perforation. This in turn results in a greater likelihood of acute presentations, leading to a higher perioperative mortality rate in this older age group.

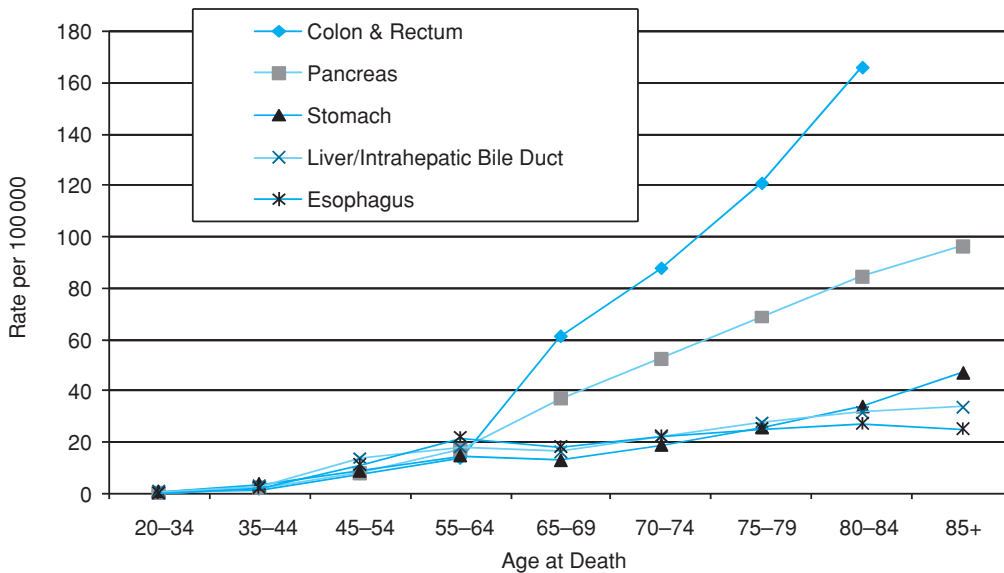

While some investigators have noted that overall survival is shorter in elderly patients, this difference is not significant if non-cancer deaths are excluded. In fact, comorbid illnesses account for a substantial number of deaths among older patients with colorectal cancer. In one study of 29,733 patients 67 years and older with localized colorectal cancer in the Surveillance, Epidemiology and End Results (SEER)/Medicare database, congestive heart failure, chronic obstructive pulmonary disease, and diabetes mellitus accounted for 9.4%, 5.3%, and 3.9% of deaths, respectively.

## Risk Factors of Colorectal Cancer

As in younger individuals, most older persons have no clearly defined risk factors for the development of their colorectal cancer. Hereditary syndromes, such as familial adenomatous polyposis or hereditary nonpolyposis colorectal cancer, have less impact in this older age group, since the majority of cases are diagnosed before the age of 65 years. There is one risk factor specific to men who were curatively treated with radiation for localized prostate cancer. These men have a 70% increased risk of developing cancer in previously

**FIGURE 98-1.** Percentage of incident cases by age group for GI malignancies (2000–2003), adjusted for 2003 U.S. census.

**FIGURE 98-2.** Mortality rates for GI malignancies (2000–2003) by age at death.

**FIGURE 98-4.** All-stage 5-yr survival by age group for colon and rectal cancer.

irradiated portions of the bowel and could potentially benefit from more frequent colorectal cancer screening.

### Chemoprevention of Colorectal Cancer

Various dietary supplements and drugs have been proposed as chemopreventive agents for colorectal neoplasia. Of these, aspirin has been the most widely studied; the regular use of this drug appears to confer a significant risk reduction (relative risk 0.56–0.68).

In at least two prospective cohort studies, the use of postmenopausal estrogens has been shown to reduce the risk of colorectal cancer by approximately 30%. Estrogen supplementation, however, has been associated with an increased risk for coronary heart disease, breast cancer, thromboembolic events, and early mortality in at least one large randomized study of postmenopausal women, thereby limiting its use as a chemopreventive agent in older women.

Most recently, it has been reported that cholesterol-lowering “statins” can significantly reduce the risk of colorectal cancer. As compared to individuals who did not use statins, individuals who used these agents for at least 5 years were able to reduce their relative risk of colorectal cancer by one-half.

### Screening of Colorectal Cancer

Approximately one in two persons will have an adenomatous polyp in their colon by the age of 70 years. The risk of sporadic colorectal cancer can be reduced by 50% to 90%, if adenomatous polyps are implicated by fecal occult blood testing or are visualized by barium enema, sigmoidoscopy, or colonoscopy and are then removed before they transform into a malignancy over a 5 to 10 year period. Three randomized trials have demonstrated that routine fecal occult blood testing can diminish colon cancer mortality by 15% to 20% during an 8 to 18 year follow-up period. The mortality benefit for older patients was slightly lower (10%–16%) than for younger patients (19%–23%).

Case-control studies suggest that lower endoscopy and removal of polyps may decrease the incidence and mortality of colorectal carcinoma by 50% to 80%. However, screening extends life to a lesser degree with advancing age. Although colonoscopy appears to be particularly beneficial in older patients who have a higher

incidence of proximal neoplasms, which are beyond the view of a flexible sigmoidoscopy, the risk of perforation from colonoscopy is higher than from sigmoidoscopy (OR 1.8). This risk increases with advancing age and number of comorbidities. Therefore, screening decisions must be individualized for every elderly patient.

Since only a small percentage of persons at risk for colorectal neoplasia undergo routine screening in the United States, Medicare now provides reimbursement for surveillance fecal occult blood testing plus sigmoidoscopy or barium enema or colonoscopy for all beneficiaries. This has increased the prevalence of “screening within 1 year” for fecal occult blood testing from 20% in persons younger than 65 years to 26% in persons 65 years and older and the prevalence of “endoscopy within 5 years” from 37% in persons younger than 65 years to 48% in persons 65 years or older.

Most older persons have a stated preference to continue colorectal cancer screening, feeling that their own life expectancy does not factor into this decision. Since the risk of advanced neoplasia and colorectal cancer is highest in the oldest individuals, it seems doubtful that screening should be arbitrarily discontinued after a certain age. In the United States, an individual who reaches the age of 80 years has an average life expectancy of an additional 8.6 years for women and 6.7 years for men. At age 85 years, average survival is 6.7 years for women and 4.7 years for men. This estimate must be adjusted for the number and severity of chronic diseases affecting the individual, as well as his or her functional status. It may be reasonable to discontinue screening when life expectancy is shorter than the time a polyp progresses to a cancer, that is, 5 to 10 years.

### Localized Colorectal Cancer

#### Surgery—Localized Colon Cancer

Cancers of the colon are typically resected with a hemicolectomy. Whether older age is an adverse prognostic factor in resection of localized colon cancer is controversial. Data on 20,862 patients undergoing surgery in 1997 for colon cancer from the Nationwide Inpatient Sample, a claims-based database, suggest that perioperative mortality increases gradually with advancing age until the age of 80 years, after which a substantial increase in mortality is seen (6.9% for patients older than 80 years). In Australia, patients 70 years

and older had a worse prognosis for early-stage colon cancer treated with surgery alone. A European study also showed increased 30-day morbidity and mortality rates for patients 80 years and older compared to their younger counterparts.

Older patients in the Nationwide Inpatient Sample from 1997 had lower mortality rates at high-volume hospitals than at low-volume institutions: 3.1% versus 4.5% for patients older than 65 years ( $p = 0.03$ ). This effect was even more pronounced for patients older than 80 years, where 4.6% of patients died at high-volume centers compared to 7.3% at smaller institutions ( $p = 0.04$ ). Therefore, it may be preferable to send the very oldest patients with colon cancer to high-volume hospitals for their resections.

A tendency to perform less aggressive surgery in older patients may be evident from a recent analysis of 116 995 adults with localized colorectal cancer in the SEER database (1988–2001). This retrospective study revealed that patients 71 years or older were half as likely to receive adequate lymph node evaluation (examination of at least 12 lymph nodes) as younger patients. Multiple studies have now demonstrated that inadequate lymph node evaluation correlates with inferior survival. These data would suggest that less aggressive surgical intervention predisposes elderly patients to a higher risk of recurrence and cancer-related death.

Increasingly, laparoscopy-assisted colectomies are being performed in the United States and elsewhere. Randomized studies indicate that patients undergoing this procedure have a similar outcome to patients undergoing an “open” colectomy, with slightly less postoperative pain and a one-day shorter hospital stay. Persons 75 years or older tolerate laparoscopic-assisted colectomy equally well as younger individuals. One study compared 51 patients 70 years or older who underwent laparoscopic colectomy to 102 age-matched patients who underwent open colectomy. Older patients had less overall morbidity with laparoscopic colectomy (17.6%) than with open surgery (37.3%), suggesting that laparoscopic surgery may lessen surgical morbidity for frail, elderly individuals ( $p = 0.01$ ).

### Surgery—Localized Rectal Cancer

A radical resection with anastomosis or ostomy is the standard surgical procedure for cancers of the rectum. A Veteran’s Administration study of 7243 patients who underwent surgery for their rectal cancer during the period of 1990 to 2000 revealed that 30-day mortality following resection for rectal cancer was 2.1% for patients younger than 65 years compared with 4.9% for patients 65 years or older ( $p < 0.0001$ ). Five-year survival was 60% versus 48%, respectively ( $p < 0.0001$ ). French investigators reviewed the records of 92 surgical patients who were 80 years or older and matched these to records of 276 younger patients who underwent resection during the same time interval. Although not statistically significant, older patients had a higher operative mortality than younger patients (8% vs. 4%, respectively). Among elective surgeries, the operative mortality was nearly identical (3%–4%). Although 5-year overall survival was greater for younger patients, 5-year cancer-specific survival was comparable for the two groups.

### Adjuvant Therapy—Localized Colon Cancer

Since the publication of a National Institutes of Health (NIH) consensus statement in 1990, 5-fluorouracil (5-FU)-based adjuvant therapy has represented the standard of care for patients in the United States following the complete resection of colon cancer

that has spread to regional lymph nodes (stage III disease). A benefit for postoperative chemotherapy has not been prospectively demonstrated in patients with fully resected, muscle-invasive, lymph node-negative (stage II) colon cancer. However, stage II cancers with high-risk features for recurrence (e.g., presentation with obstruction, perforation, or invasion into adjacent organs—stage IIb) are often treated by medical oncologists and are included in many randomized adjuvant trials.

Older patients receive adjuvant chemotherapy less often than their younger counterparts. A retrospective cohort study, utilizing the SEER database, identified 6262 patients 65 years or older with resected stage III colon cancer from 1991 to 1996. Overall, 55% of patients received adjuvant chemotherapy within 3 months of colon cancer resection. The likelihood of receiving treatment declined steeply with increasing age (Table 98-1). Similar results were noted in an Italian study of 1014 patients with resected stage II/III colon cancer.

The reason for this age-related disparity in management is not entirely clear. In one study utilizing the California Cancer Registry, oncologists cited patient refusal, comorbid illness, or advanced age as the most common reasons for not providing chemotherapy to elderly patients with resected colon cancer. Financial considerations and logistical problems may also prevent some elderly from seeking care. Additionally, treatment for older patients is more frequently discontinued, suggesting reluctance by physicians to treat older patients who have experienced some degree of side effects to chemotherapy.

A pooled analysis of 3351 patients in the United States, stratified by decade of life, from seven randomized trials evaluated the benefit of adjuvant chemotherapy in elderly persons with stage II or III colon cancer. The primary conclusion of this pooled analysis was that elderly patients derive the same clinical benefit from postoperative chemotherapy as younger patients. Treatment-related toxicity was somewhat higher for older patients, yet not statistically significant. Another U.S. study, however, could not extend this observation to patients 75 years and older, given limitations in the data.

Adjuvant chemotherapy also appeared to be slightly more toxic for elderly patients in a SEER-derived retrospective cohort study (Table 98-2). Hospitalization for various chemotherapy-related toxicities increased steadily with advancing age. Prospective data from the Royal Marsden Hospital in London confirmed this trend toward higher rates of severe toxicity in patients 70 years or older.

In conclusion, it appears that postoperative chemotherapy in stage III colon cancer is as beneficial in elderly patients, as it is in younger individuals. A slight increase in toxicity should not prevent the clinician from treating these older patients, although increased vigilance during chemotherapy is warranted.

### Adjuvant Therapy—Localized Rectal Cancer

Chemoradiation before or after surgery reduces the local recurrence rate and increases disease-free survival in patients with deeply invasive (T3–4) or lymph node–positive rectal cancer. Although there are few data to suggest that elderly patients respond any differently to chemoradiotherapy than younger patients, they are less frequently referred to oncologists for this treatment. Analysis of the SEER database identified patients 65 years or older with stage II or III rectal cancer who underwent surgical resection between 1992 and 1996. Increasing age corresponded inversely with the percentage of patients who received adjuvant therapy (Table 98-1). Overall,

**TABLE 98-1****Use of Chemotherapy for Colorectal Cancer by Age**

	AGE	TOTAL NUMBER OF PATIENTS	PERCENTAGE OF PATIENTS TREATED	HOSPITALIZATIONS FOR CHEMOTHERAPY-RELATED TOXICITY
Stage III colon cancer Schrag 2001	65–69	1261	78%	7%

\*Chemotherapy and radiation therapy.

chemoradiation therapy was associated with a 17% reduced risk of death among all cases, with a 29% reduced risk of death in stage III patients, but no statistically significant improvement in stage II cases, similar to the results reported in younger patients.

### Postoperative Surveillance—Localized Colorectal Cancer

There is general agreement that all patients with resected colorectal cancer should undergo regular surveillance screening with colonoscopy, CEA testing, and possibly an annual CT scan. Analysis of 52,283 Medicare beneficiaries treated for locoregional colorectal cancer between 1986 and 1996 suggests that younger patients are more likely to undergo periodic surveillance endoscopies, and that the median time to first follow-up endoscopy is significantly shorter ( $p < 0.0001$ ) for patients at younger ages.

### Advanced Colorectal Cancer

#### Surgery—Advanced Colorectal Cancer

Removal of the primary cancer is indicated in patients who have an (impending) obstruction, uncontrollable bleeding, or

oligometastatic disease that may potentially be cured with aggressive therapy. In spite of these restrictive criteria, a recent pattern of care study, utilizing the SEER database, revealed that the majority of patients 65 years or older with stage IV colorectal cancer undergo resection of their primary tumor. Overall, 72% of patients underwent this primary-cancer-directed surgery. The percentage of patients undergoing surgery declined gradually from 76% in patients 65 to 69 years old, to 70% in patients 80 to 84 years old, and then dropped to 62% in patients 85 years or older.

In this pattern of care study, the 30-day mortality was 10% for all patients. However, higher perioperative mortality rates for elderly patients with advanced colorectal cancer have been reported elsewhere; in patients 70 to 79 years of age, the mortality may be as high as 21% and in octogenarians it may reach 38%. Overall, improvements in surgical technique and postoperative care have led to a decrease in operative mortality particularly in older patients, so that current operative survival figures for elderly patients now approach those reported for younger patients a decade ago.

Elderly patients with oligometastatic disease or isolated recurrences of their colorectal cancer may be candidates for a “curative-intent” resection. In a series from the Memorial Sloan-Kettering

**TABLE 98-2****Severe Toxicity to 5-Fluorouracil-Based Therapy by Age in a Pooled Analysis of 1748 Patients with Advanced Colorectal Cancer Treated by the North Central Cancer Treatment Group**

SEVERE TOXICITY (NCI CTC GRADE $\geq 3$ )	AGE			P VALUE*
	<66 YR	66–70 YR	>70 YR

Stomatitis	13%	18%	17%	0.03
Infection	2%	5%	4%	0.02

\*The P value compares the rate of toxicity for the three age groups using  $\chi^2$  test with 2 degrees of freedom.

Cancer Center, 128 patients 70 years or older underwent liver resection for metastatic colorectal cancer between 1985 and 1994. While these patients experienced a 4% perioperative mortality rate and a 42% complication rate, their median survival was 40 months and 5-year survival rate was 35%. These older patients had a similar outcome to 449 patients younger than 70 years who underwent comparable liver resections during the same time period. In a retrospective analysis of patients 65 years and older in the SEER database, only 6.1% of the 13,599 patients identified with colorectal metastases limited to the liver underwent hepatic resection. The 30-day mortality rate was 4.3%. Five-year survival for resected patients was superior to those who did not undergo resection (32.8% vs. 10.5%;  $p < 0.0001$ ). Additionally, investigators have reported that appropriately selected elderly patients can tolerate resection of colorectal lung metastases with similar outcome as younger patients, with acceptable morbidity and mortality.

### Chemotherapy—Advanced Colorectal Cancer

**5-Fluorouracil.** Until the early 1990s, the only active treatment for advanced colorectal cancer was 5-FU, a thymidylate synthase inhibitor. Multiple studies have now demonstrated that this agent, given as a bolus with leucovorin or as an infusion with or without leucovorin, is effective and well tolerated in the elderly population, with similar response rates and overall survival compared to younger cohorts.

Folprecht and colleagues carried out a pooled analysis of 22 randomized European trials in which patients received palliative 5-FU-based therapy. In this retrospective analysis, overall survival (10.8 months for younger patients vs. 11.3 months for older patients,  $p = 0.31$ ) and response rate (20.8% for younger patients vs. 17.6% for older patients,  $p = 0.14$ ) were nearly identical in younger and older patients. Infusional 5-FU proved to be superior to bolus 5-FU in all age groups. Similar results were obtained in a meta-analysis of four large trials of 5-FU-based therapy to examine the efficacy and toxicity of 5-FU in patients 70 years and older ( $n = 303$ ) compared to younger individuals ( $n = 1181$ ). While severe neutropenia (40.4% vs. 33.6%) and stomatitis (10% vs. 4.6%) were significantly increased in older patients, overall response rate (39.5% vs. 33.1%) and overall survival (15.9 vs. 15.4 months) were similar to that of younger patients.

The North Central Cancer Treatment Group (NCCTG) conducted another pooled analysis of 1748 patients with advanced colorectal cancer treated with 5-FU-based therapy. No significant differences in response rate ( $p = 0.90$ ) or overall survival ( $p = 0.42$ ) were observed between patients younger than 56 years and older than 70 years. Patients 65 years or older had more overall severe toxicity than their younger counterparts (53% vs. 46%,  $p = 0.01$ ). Statistically significant differences in severe diarrhea and stomatitis were reported. Other studies have also noted higher rates of 5-FU-related palmar–plantar erythrodysesthesia in older patients.

**Capecitabine.** The oral 5-FU prodrug, capecitabine, has similar efficacy to monthly intravenous 5-FU and leucovorin (Mayo Clinic Regimen) in the metastatic and adjuvant setting. In patients 70 years or older with metastatic colorectal cancer, the overall response rate with capecitabine was 24% and the overall survival time was 11 months. In patients 70 years and older with resected colon cancer, capecitabine offered the same disease-free survival advantage as stan-

dard 5-FU and leucovorin. In this adjuvant trial, severe capecitabine-related toxicity was noted in only 12% of patients. Overall, the results with capecitabine in older patients appear similar to those seen in younger individuals.

**Irinotecan.** Irinotecan, a topoisomerase I inhibitor, is another active drug in metastatic colorectal cancer. A multi-institutional phase II study found similar rates of severe toxicity in patients 65 years or older and those younger than 65 years receiving a weekly schedule of this agent. In a trial comparing the weekly and the tri-weekly dosing regimens of this drug as second-line therapy for metastatic disease, more than one-third of 291 patients were at least 70 years of age. Age greater than 70 years did not affect survival or time to progression, but was associated with an increased risk of severe neutropenia and diarrhea compared to patients younger than 70 years of age.

Various trials have evaluated irinotecan-based chemotherapies in elderly patients with metastatic colorectal cancer. These have included combinations of irinotecan, bolus 5-FU, and leucovorin; irinotecan, infusional 5-FU, and leucovorin; irinotecan and capecitabine; and irinotecan and oxaliplatin. These trials uniformly revealed that response to chemotherapy, median survival times, and degree of toxicity in these elderly patients appear to be similar to those observed in younger patients.

**Oxaliplatin.** Oxaliplatin is a third-generation platinum analogue, which induces platinum–DNA adducts, inhibiting the replication of DNA. Although it has limited activity as a single agent in colorectal cancer, oxaliplatin has notable synergy with 5-FU and leucovorin (FOLFOX). In metastatic colorectal cancer, the toxicity following treatment with FOLFOX was evaluated for patients 70 years and older in a pooled analysis of four randomized clinical trials. Although severe hematologic toxicity was increased in older patients, there was no difference in other severe toxicities or 60-day mortality.

For patients with resected colon cancer, a randomized adjuvant trial, in which 35% of patients were 65 years or older, has suggested that disease-free survival can be enhanced if oxaliplatin is added to 5-FU and leucovorin. Subgroup analysis suggested a similar benefit for elderly patients as for the group as a whole. For those older patients with resectable liver metastases, preoperative FOLFOX therapy may be superior to 5-FU therapy. In this study, 2-year overall survival was prolonged in the “FOLFOX group” compared to the “5-FU group” or to the “no chemotherapy group” (84% vs. 60% vs. 23%).

The combination of capecitabine and oxaliplatin (CAPOX) has been evaluated in 76 patients 70 years and older with metastatic colorectal cancer. Overall response was 41%, median progression-free survival was 8.5 months and median overall survival was 14.4 months with little severe toxicity (3% peripheral neuropathy and 13% palmar–plantar erythrodysesthesia). A recent randomized study has suggested that the FOLFOX and CAPOX regimens have similar efficacy and rates of toxicity.

**Bevacizumab.** The humanized monoclonal antibody, bevacizumab, binds to the vascular epidermal growth factor, reducing the vascularity of tumors, leading to hypoxia and necrosis. It also appears to lower interstitial fluid pressure in cancer nodules, promoting diffusion of other chemotherapeutic agents into these tumors. Three pivotal studies in patients with advanced colorectal cancer

have established that this agent consistently enhances the efficacy of 5-FU-based therapy with either irinotecan or oxaliplatin for patients of all age groups. A fourth study compared bolus 5-FU and leucovorin alone or in combination with bevacizumab in patients 65 years and older or in patients of poor performance status. This study demonstrated that bevacizumab could significantly improve survival by 4 months in “suboptimal” patients without significantly increasing toxicity.

Bevacizumab may increase the risk of arterial thrombosis, i.e., myocardial infarction, stroke, or peripheral arterial thrombotic event. In a multivariate analysis, persons 65 years or older increased their risk of arterial thrombosis from 2.3% with chemotherapy alone to 7.1% with chemotherapy plus bevacizumab. This risk increased further to 17.9%, if the patient had a history of prior arterial thrombosis. However, progression-free and overall survival was better for those receiving the bevacizumab combination than for those receiving chemotherapy alone. Therefore, bevacizumab can still provide a benefit in carefully selected elderly patients with a history of atherosclerosis-related disease.

**Cetuximab/Panitumumab.** Cetuximab and panitumumab are monoclonal antibodies to the epidermal growth factor receptor. Blockade of this receptor in colorectal cancer cells induces apoptosis and cell death. In individuals with extensively treated metastatic colorectal cancer, these agents can induce significant tumor regressions in 8% to 11% of patients; cetuximab in combination with irinotecan has a response rate of 23%. The most common severe toxicities of these agents include dyspnea, asthenia, and an acneiform rash. Cetuximab may also cause a hypersensitivity reaction. In one phase II study of 114 patients 65 years and older with metastatic colorectal cancer refractory to irinotecan, oxaliplatin, and 5-FU, cetuximab achieved a response rate of 9.6% compared to a 12.5% response rate in 232 patients younger than 65 years ( $p =$  nonsignificant). In a randomized trial for patients with chemotherapy-refractory metastatic colorectal cancer, panitumumab resulted in partial response rate of 8% and a 46% reduction in risk of tumor progression compared to best supportive care. Similar to cetuximab, rash is the predominant adverse effect of panitumumab therapy. A severe rash early in the treatment course is predictive of enhanced response and survival with either agent.

## PANCREATIC CANCER

In the United States, the number of expected new cases and the number of anticipated deaths for pancreas cancer in 2008 are almost identical (37,680 and 34,290, respectively). Overall, the probability of 5-year survival for this cancer is less than 5%. The median age at presentation is 72 years, and thus a significant proportion of patients are elderly. A tissue confirmation of pancreas cancer is established less frequently in older individuals. Thus, a disproportionate number of elderly patients may be misdiagnosed with this malignancy and may be incorrectly given a poor prognosis in an attempt to spare them the discomfort of an accurate pathological diagnosis.

### Treatment—Localized Pancreas Cancer

Older patients are more likely than younger patients to present with early-stage pancreas cancer. Pancreaticoduodenectomy, the Whipple procedure, is the only potentially curative therapy for this malig-

nancy. There is ample evidence that this procedure can be performed safely in geriatric patients. For example, in 206 patients older than 70 years who underwent surgery at the Mayo Clinic between 1982 and 1987, operative morbidity and mortality rates were 28% and 9%, respectively. Overall median survival was 19 months and 5-year survival was 4%. Similarly, the operative mortality in 138 patients older than 70 years who underwent pancreatic resection at Memorial Sloan-Kettering Cancer Center was 6%, and the major complication rate was 45%. These results are virtually identical to those of younger patients. However, the probability of 5-year survival was slightly lower in this group of older patients (21% vs. 29%,  $p = 0.03$ ), possibly because of an enhanced risk from comorbid diseases.

Patients with grossly resected pancreas cancer or locally unresectable pancreas cancer may benefit from chemoradiation therapy. Alternatively, a recent prospective study evaluating the benefit of gemcitabine, a nucleoside analogue, after complete resection of pancreatic cancer demonstrated a disease-free but not an overall survival benefit in comparison to the observation arm. Although patients up to 82 years were included in this study, there was no specific evaluation of the effect of adjuvant gemcitabine in older patients.

### Treatment—Advanced Pancreas Cancer

Gemcitabine is considered the standard initial therapy for patients with metastatic pancreas cancer. Patients treated with gemcitabine have a median survival time of 5 to 7 months and a 1-year survival rate of 20%. In the pivotal trial of this agent, median age was 62 years and individuals as old as 79 years of age were enrolled, indicating tolerance of such treatment in the elderly. Although the addition of erlotinib, an epidermal growth factor receptor inhibitor, to gemcitabine demonstrated a small survival benefit in younger patients, no such advantage was demonstrated in the 268 patients 65 years or older.

## GASTRIC CANCER

Gastric cancer is the second leading cause of cancer death (after lung cancer) in the world. In the United States, the predicted number of new cases for 2008 is 21,500, with 10,880 deaths expected. The results of a German study have suggested that cancers with diffuse histology are more common in younger patients than in patients 70 years or older. In Japan, patients 80 years or older are found to have more advanced disease than younger patients, perhaps because of a later time to diagnosis.

### Treatment—Localized Gastric Cancer

Gastrectomy is the only curative treatment for gastric cancer. In patients who undergo the resection of all macroscopic and microscopic disease, the long-term survival is approximately 35%. A prospective review of 310 elderly patients with gastric cancer found that surgery in this group was reasonably well-tolerated and led to survival duration comparable to the results obtained in younger patients. Most, but not all, studies suggest a similar perioperative morbidity and mortality risk for gastrectomy in older and younger patients. For instance, a British multicenter prospective cohort study showed that surgical morbidity and mortality did not differ significantly by age. Of the 955 patients who underwent esophagectomy or gastrectomy, morbidity for patients younger than 70 years and older than 70 years

was 50% and 48%, respectively. Mortality was also similar at 10% and 14% for those two age groups. In Italy, age was found to be an independent predictor of recurrence in 536 patients following gastric cancer resection.

Although data specific to elderly patients are not currently available, it is generally recommended that patients with localized gastric cancer be considered for perioperative chemotherapy or postoperative chemoradiation. In a randomized controlled trial of perioperative chemotherapy for resectable esophageal, gastroesophageal junction, and gastric cancers, two cycles of combination chemotherapy administered before and after surgical resection provided a 4 month improvement in median survival compared with surgical resection alone. In another study of 556 patients with resected gastric or gastroesophageal junction cancer, individuals who received adjuvant chemoradiotherapy had a 9-month increase in overall survival compared to those who underwent surgery alone. It is currently uncertain which one of these two approaches is better tolerated and offers a superior survival advantage.

### Treatment—Advanced Gastric Cancer

The efficacy of chemotherapy programs for gastric cancer has not been specifically analyzed by patient age. Single-agent therapy generally results in less toxicity than is observed with platinum-based combinations and may be better suited for older individuals. Platinum analogues must be carefully dosed, since renal platinum clearance declines with increasing age. Single agents commonly used in gastric cancer include 5-fluorouracil, capecitabine, the taxanes, and irinotecan. Recent trials, including combinations of 5-FU, leucovorin, and oxaliplatin; capecitabine and oxaliplatin; irinotecan and cisplatin; 5-FU, leucovorin, and irinotecan, have included patients 65 years or older. However, subgroup analyses evaluating response and toxicity in these older patients have not been performed. Thus, it is unclear how older patients fare with more aggressive regimens. Small, single-institution trials have shown a benefit for combination therapy in selected, fit elderly patients. One such study of cisplatin, leucovorin, and fluorouracil in 58 patients 65 years and older with metastatic gastric cancer noted significant responses in 43% of patients. Investigators noted that the therapy was well tolerated.

### PRIMARY LIVER CANCER

Primary liver cancer—hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma—is the fourth most common cause of cancer death in the world, leading to almost half a million deaths annually. In contrast, the annual incidence in the United States has been relatively low, with 21 370 new cases and 18 410 deaths expected in 2008. In the United States, the incidence of HCC levels off at older age in males (70 years for Caucasian males and 55 years for African-American males), whereas the incidence of intrahepatic cholangiocarcinoma continues to climb with increasing age for both genders. The risk factors for primary liver cancer do not vary by age, but Japanese investigators suggest that the presence of portal vein thrombosis is a more important prognostic factor than tumor size or the number of tumors for patients 80 years and older.

### Treatment—Primary Liver Cancer

Treatment options for elderly patients with HCC restricted to the liver include operative resection, transarterial hepatic chemoem-

bolization, or nonsurgical tumor ablation. Surgery and chemoembolization in the geriatric population have been found to be tolerable in some but not all experiences. In one Italian study, the operative mortality was 8% in patients 65 years or older, with 1-year, 3-year, and 5-year survival probabilities of 89%, 61%, and 45%, respectively. These percentages were nearly identical to those of patients younger than 65 years of age. Localized tumor ablation with ethanol, cryotherapy, or radiofrequency has been increasingly utilized to eradicate small tumors and may be particularly appropriate for older patients, who are frequently considered poor candidates for surgery.

In a recent review of the 2696 Medicare patients with HCC between 1992 and 1999, 13% had procedures with curative intent (0.9% transplant, 8.2% resection, 4.1% local ablation), 4% underwent transarterial chemoembolization, 57% received palliative therapy, and 26% did not get treatment. Only 34% of patients with solitary lesions or lesions less than 3 cm in diameter received therapy with curative intent, suggesting underutilization of curative interventions in eligible elderly patients. Three-year survival for transarterial chemoembolization or local ablation was less than 10%.

Surgical resection of liver tumors is well tolerated in older patients. In a recent European study, cirrhotic patients with HCC aged 70 years and older were compared to patients younger than 70 years. The operative morbidity and liver failure rates were lower in the subset of older patients (23.4% vs. 42.4% and 1.6% vs. 12.9%, respectively). Operative mortality and 5-year survival rates were not significantly different between the two groups. Although smaller tumor size was predictive of better outcome for younger patients, this was not noted for older patients. Similar findings were reported by investigators in Taiwan.

### ESOPHAGEAL CANCER

Squamous cell carcinomas and adenocarcinomas of the esophagus are the sixth leading cause of cancer death worldwide. In the United States, esophageal cancer is less common, with 16 470 new cases and 14 280 deaths anticipated in 2008. Between 1974 and 1994, the appearance of adenocarcinomas of the esophagus has increased substantially, particularly in white men between 65 and 74 years of age, while the incidence of squamous cell carcinomas has declined slightly. The epidemiologic pattern of esophageal carcinoma does not appear different in elderly patients. Most studies report similar clinical symptoms at the time of presentation, as well as similar distribution of histology, stage, and location of tumors for patients older and younger than 70 years of age. In these series, approximately 50% to 75% of the older patients were found to have adenocarcinoma and 25% to 50% had squamous cell carcinoma.

It is unclear if the incidence of Barrett's associated adenocarcinoma increases with advanced age. Although one study has suggested a higher incidence in older patients, another study suggested this incidence is not age dependent. The location of tumors in the esophagus does not differ between older and younger patients—distal esophageal tumors predominate in all groups. A similar distribution in early- and late-stage cancers has also been reported.

### Treatment—Localized Esophageal Cancer

Most but not all studies suggest that age is not a limiting factor in surgery of the esophagus. Although elderly patients tend to have a higher incidence of respiratory and cardiovascular complications

than younger patients, this does not appear to have a significant effect on operative mortality or survival. In one series, 50 patients older than 70 years were compared to 89 patients younger than 70 years; postoperative complications and in-hospital mortality occurred in 38% and 3% of younger patients and in 44% and 0% of older patients. The mean duration of hospitalization was 17.9 days for younger patients and 18.6 days for older patients. The severity of postoperative dysphagia and weight loss were similar for both groups. The likelihood of survival after 8 years was identical at 20%.

In a second study of 60 patients 70 years and older, no difference was observed in the rate of resection with curative intent, surgical complications, or hospital mortality rate in comparison to a younger population. This was confirmed in another study, demonstrating equivalent surgical morbidity and mortality for older patients stratified by performance status and overall fitness in comparison to younger patients. A contradictory study suggested that age was predictive of morbidity and mortality following esophagectomy in multivariate analysis ( $p = 0.002$ ). Age and comorbidity were also noted to be significant predictors of outcome in a simple risk score developed to predict surgical mortality for esophageal cancer.

Although the rate of surgical complications may not be significantly increased in the elderly, the presence of such complications significantly worsens survival. This was the conclusion in a review of 510 patients who underwent resection of esophageal or gastroesophageal junction carcinoma at the Memorial Sloan-Kettering Cancer Center from 1996 to 2001. Surgical complications occurred in 31.8% of the 173 patients 65 to 74 years old and in 34.8% of the 66 patients 75 years and older. Although survival at 30 days did not differ significantly between patient groups who did and did not experience surgical complications, there was a notable decline in 1-year survival for patients 65 years and older who had suffered a perioperative complication. In a separate study at the same institution, octogenarians were noted to have more than a threefold higher mortality rate than patients 50 to 79 years old, although they experienced similar rates of operative complications (blood loss, cardiopulmonary complications, infection, and anastomotic leak).

A review of 945 patients in the Veteran's Administration National Surgical Quality Improvement Program found no difference in 30-day surgical mortality and morbidity between transthoracic and transhiatal esophagectomies. Age did significantly impact the overall mortality rate for both surgical techniques, with increasing age associated with an increased risk of surgical mortality. The same age-related surgical mortality risk was also noted in a French study of gastroesophageal junction adenocarcinomas.

Although age may not be a significant factor in the rate of curative resection, curative surgery is still underutilized in older racial minority patients. African-American patients 65 years and older were noted to have a lower rate of surgical consultation and half the rate of curative surgery as their elderly Caucasian counterparts (70% vs. 78%,  $p < 0.001$  and 25% vs. 46%,  $p < 0.001$ , respectively).

Chemoradiation therapy appears equally effective in patients 70 years of age and older as in younger individuals. Furthermore, there appears to be no association between age and toxicity in patients of good performance status. At Memorial Sloan-Kettering Cancer Center, 24 elderly patients (median age 77 years) with locally advanced esophageal cancer were treated with 5040 cGy of radiation and infusional 5-fluorouracil plus mitomycin C over a 6-week period of time. Nine of these individuals (38%) required hospitalization for toxicity and three required dose reductions. Sixteen patients achieved a clinical remission and 10 remained without evidence of

disease after a median follow-up of 1.2 years, suggesting that selected chemoradiation therapy is a feasible and well-tolerated alternative to esophagectomy in elderly patients.

### Treatment—Advanced Esophageal Cancer

Single agents, such as the taxanes, irinotecan, 5-fluorouracil, capecitabine, and vinorelbine, have some efficacy in palliating metastatic esophageal cancer and represent management options for elderly patients, particularly for those with lower performance status or significant comorbidities. Combination chemotherapy regimens tend to have more side effects and have not been systematically evaluated in older patients with esophageal cancer. Preliminary results of one study in patients 70 years or older suggested that the combination of weekly docetaxel and infusional 5-FU is well tolerated in this age group. Toxicities were primarily neutropenia and mucositis.

## GALLBLADDER CANCER

Cancers of the gallbladder occur infrequently in the United States. The incidence increases with age and reaches its peak in the seventh decade of life. In 2008, 9520 new cases and 3340 deaths are expected. The presentation and clinical features of this cancer do not appear to differ appreciably between older and younger patients. Endoscopic retrograde cholangiopancreatography (ERCP) is often used in the diagnosis of gallbladder cancer and is well tolerated in older patients—even the very old. In a study of 126 patients 90 years and older who underwent a total of 147 ERCP procedures, 9.5% were noted to have malignant stenosis. The overall morbidity and mortality rates were low at 2.5% and 0.7%, respectively.

### Treatment—Gallbladder Cancer

Surgery is the only potentially curative treatment for this disease. A retrospective single institution study from Japan reviewed the cases of 54 patients who were 75 years or older and compared them to 152 patients less than 75 years of age. Approximately 58% of patients in both age groups underwent a radical resection (rather than a simple cholecystectomy). Operative mortality and survival rates were similar between the two age groups. The investigators noted that the likelihood of 5-year survival was better for those elderly patients who had undergone a radical resection, compared to those who had undergone a simple cholecystectomy (61% vs. 14%,  $p = 0.01$ ). These uncontrolled results have not been validated through a randomized trial.

Although advanced gallbladder cancer is highly resistant to chemotherapy, single agents such as gemcitabine, 5-FU, and capecitabine are generally well tolerated in elderly patients and may offer some palliation in this disease. In a small study of advanced biliary tract cancers and gallbladder cancer, treated with the combination of gemcitabine and cisplatin, no difference in response rate was noted between 10 patients 60 years and older and 30 younger patients, although the older patients had higher rates of hematologic toxicity.

## ANAL CANCER

Squamous cell carcinoma of the anal canal is the least common but most treatable of the gastrointestinal malignancies. In 2008, 5070

new cases but only 680 deaths are expected for this malignancy. The risk factors for anal cancer and genital malignancies are similar. The risk of HPV-related anal cancer in men who have sex with men increases with age. Older age at first receptive intercourse was associated with increased prevalence of both low- and high-grade squamous dysplasia, the precursor lesions to anal cancer. The higher incidence of anal cancer is more pronounced in patients 65 years and older than in younger age groups. Five-year survival does not differ significantly by gender or age.

### Treatment—Anal Cancer

Since the 1970s, the standard treatment for anal cancer has been the combination of 5-FU, mitomycin, and radiation therapy. With this technique, 60% to 73% of patients will remain free of disease recurrence and a colostomy at 4 years. A small study evaluating this nonsurgical strategy in patients 75 years or older demonstrated similar complication rates to those seen in younger patients, suggesting that sphincter-conserving treatment is feasible in older patients with anal carcinoma. In an Australian study of 62 patients, treated with chemoradiation (mitomycin C and 5-FU) and anal sphincter preservation surgery, the local control rate was 86% and the colostomy-free survival at 2 years was 83%. This study included 38 patients 60 years and older.

Radiation used in the treatment of anal cancer in women 65 years or older can lead to a threefold increased risk of pelvic fracture. These women are at greater risk for fracture than women treated with radiation therapy for cervical or rectal cancer. Therefore, older women treated with chemotherapy and radiation therapy for anal cancer should undergo regular bone densitometry screening and bisphosphonate therapy.

### CLINICAL TRIALS

While 70% to 75% of colorectal cancers are diagnosed in patients older than 65 years, only 40% to 48% of patients enrolled in NCI-sponsored or cooperative group trials are drawn from this age group. This underrepresentation of elderly patients with colorectal cancer has not improved in the past several years. During the 2000 to 2002 time period, only 2% of colorectal cancer patients 65 to 74 years old and 0.5% of colorectal cancer patients 75 years or older enrolled in NCI-sponsored trials, substantially less than the 4% enrollment recorded for patients 30 to 64 years old. Similar data are not available for the less common gastrointestinal malignancies.

A possible explanation for this discrepancy may be financial, although a similarly low rate of enrollment for older patients has been documented in Canada, where the national health care program provides reimbursement for all health care costs. More plausible explanations for the lack of participation of elderly patients in clinical trials may include lack of social and home care support, physician reluctance to offer research protocols to older individuals, difficulties with access to clinics and hospitals, potential noncoverage of investigational treatments by Medicare, patient re-

fusal, increasing concomitant medication usage and co-morbidities with advancing age, and fewer trials specifically aimed at elderly patients.

# Intracranial Neoplasms

Noelle K. LoConte ■ Julie E. Chang ■ H. Ian Robins

Older patients with central nervous system (CNS) disease present a unique set of problems for the health care provider. Often their presentation can be atypical, potentially confounding or delaying the correct diagnosis. For example, older patients often present with cognitive dysfunction suggesting dementia, or personality changes suggesting depression rather than more typical symptoms such as headache. This population also has various comorbidities, which often complicate the potential for neurosurgery. Additionally, this group of patients may have a tendency to tolerate radiation, chemotherapy, or supportive agents (such as steroids or antiepileptics) poorly. Also, CNS tumors in general carry with them a significant risk of morbidity and mortality, independent of the patient's age, which may only further complicate the decision making process in the older adult patient. In this chapter, various intracranial neoplastic disease processes and their management in the older adult are considered.

## GLIOMAS

### Low-Grade Gliomas

Low-grade gliomas (i.e., astrocytomas and oligodendrogliomas) are relatively uncommon in patients older than 65 years. Therapy usually involves maximally feasible resection. Radiation therapy (RT) may be reserved for symptomatic patients, or patients with recurrent disease. In a randomized European trial, RT did not improve overall survival, but did improve progression free survival. Another indication for RT relates to a patient for whom minimal disease progression might result in significant neurological deterioration. It should be noted that low-grade oligodendrogliomas with chromosomal deletions in the 1p and 19q loci are very sensitive to both radiation and chemotherapy. This enhanced sensitivity to therapy is also true for anaplastic oligodendroglioma (discussed below).

### Anaplastic Gliomas

Grade 3 astrocytomas, as well as anaplastic oligodendroglioma, are also less common in older patients with a peak incidence in adults during the third decade of life. The mainstay of therapy is surgery and RT. The definitive role for chemotherapy is yet to be defined in these diseases. By extrapolation from the success of temozolomide chemotherapy (TMZ) in the treatment of newly diagnosed grade 4 astrocytoma (i.e., glioblastoma multiforme [GBM, discussed below]), some oncologists feel there is a role for TMZ chemotherapy in treating these patients at the time of diagnosis. There are, however, no level one data to support this therapeutic approach currently.

### Glioblastoma Multiforme

#### Background

Geriatric patients have an increasing incidence of GBM. This diagnosis in a geriatric patient population is typically associated with shorter survivals (than comparable patients who are younger) and may not be treated as aggressively (Table 99-2). Reasons for this may include the “biology” of primary GBM in these patients, comorbidities, and the inability to tolerate toxic therapies. Elderly patients with GBM appear to be less responsive to chemotherapy, and age appears to have a negative correlation with the tumor's response to treatment and time to disease progression, but a positive correlation with toxicity for patients older than 60 years (Table 99-1). Several studies have demonstrated that overall survival declines with increasing age and decreasing performance status, as measured by Karnofsky performance status (KPS).

Many studies have been performed in elderly patients in an attempt to determine the optimal management; the majority of these studies have used a “less is better” approach to treatment. This literature is summarized under two main points: what constitutes “elderly” is not well defined, and may be as low as 60 years of age, and studies have used different parameters for “good” versus “poor”

performance status, (e.g., KPS). Both of these factors impact outcome. Another confounder to interpreting outcome data in GBM is extent of surgery. Gross total resection surgery appears to have a modest benefit on survival, particularly in patients with good performance status. This is a surgery that removes all tumor visible to the naked eye. Relative to this, many older patients simply undergo a biopsy or partial resection, resulting in an incomplete surgical removal of tumor.

### Radiation Therapy

Most radiation studies in the geriatric patient population have focused on abbreviated courses of RT. Survivals obtained are similar or slightly less than the standard 6-week course, but require less time for treatment. The benefits of RT decrease with increasing age and are affected to some degree by extent of surgical resection. Villa et al. (1998) treated patients (median age 70) with 54 to 66 gray (Gy) of external beam radiation with a median survival of 18.1 weeks for all patients and 45 weeks for those who started RT. The median survival of patients younger than 70 years was 55 weeks, compared to 34 weeks for patients older than 70 years. Pierga et al. (1999) treated 30 patients (median age 73 and KPS 60–70) with 45 Gy for more than 5 weeks after maximal resection and found a median survival of 36 weeks. Philips et al. (2003) found that non-significant survival advantage for patients treated with 60 Gy (median survival of 41 weeks) versus 35 Gy (35 weeks). McAleese et al. (2003) compared patients treated with 30 Gy to a case matched control group of patients treated with 60 Gy and found an increase in survival of 2.5 to 4.5 months longer; the authors questioned whether the lesser survival was outweighed by an improved quality of life. Chang et al. (2003) treated 59 patients (median age 65) with 50 Gy in 4 weeks and found a median survival of 28 weeks, which was comparable to the Radiation Therapy Oncology Group (RTOG) database. Roa et al. (2004) randomized patients >60 (median was 72 years) to 60 Gy in 6 weeks or 40 Gy in 3 weeks. Median survival was similar at 20 weeks and 21 weeks with fewer patients in the lower dose group requiring an increase in steroids.

### Chemotherapy

The first glimpse of a therapeutic breakthrough in the treatment of GBM occurred in 2002 when Stupp and coworkers reported results

**TABLE 99-2**

#### General Characteristics of High-Grade Gliomas

CHARACTERISTIC	ANAPLASTIC ASTROCYTOMA	GLIOBLASTOMA MULTIFORME
Grade	3	4
Mean age of onset	40–50 yr	65 yr
Median survival	3–4 yr	12–14 mo with surgery and chemotherapy
Recurrence pattern	Often as grade 4	Rapid tumor growth and recurrence
Clinical challenge	Achieving gross total surgical resection	

of the use of daily TMZ (75 mg orally per square meter body surface area) during radiation (approximately 6–7 weeks), followed by 6 months of adjuvant therapy at 150 to 200 po mg/m<sup>2</sup> on days 1 through 5 of a 28-day cycle. The median survival in this phase II study was 16 months. The rationale for this approach included the possibility of radiosensitization. The concept of daily dosing was an attempt to overcome TMZ drug resistance. The background for this related to observations demonstrating that the repeated administration of TMZ depletes the DNA-repair enzyme O<sup>6</sup>-methylguanine-DNA methyltransferase (MGMT). MGMT is a resistance mechanism for TMZ. Thus, it is termed a “suicide enzyme.” After MGMT removes a methyl group from DNA (deposited by TMZ), it is no longer active. The use of adjuvant TMZ starting 1 month post-radiotherapy was predicated on the inherent antitumor activity of the drug. As the study by Stupp et al. demonstrated a promising 2-year survival rate of 31%, the European Organization for Research and Treatment of Cancer (EORTC) and the National Cancer Institute of Canada (NCIC) launched a phase III trial comparing this phase II regimen to radiotherapy alone. Recently, data presented from Stupp et al. in a randomized phase 3 study (2005) demonstrated that the combination of RT and TMZ followed by 6 months of TMZ was better than RT alone in terms of overall survival and disease control. This has become the new standard of care for GBM. Patients treated with chemotherapy and radiation had a progression free survival of 6.9 months compared to 5 months, a median survival of 14.6 months compared to 12.1 months, and a 2-year survival of 27% compared to 10%; all values were statistically significant. Importantly, in that study, patients older than 70 years were not eligible so the benefit in this group remains undefined. It is notable that the American Radiation Therapy Oncology Group (RTOG) in cooperation with the EORTC and the NCIC has launched a new phase 3 trial (RTOG 0525): one arm is the aforementioned Stupp regimen; the other is a dose dense TMZ treatment (75 mg/m<sup>2</sup> for 21 days on a 28-day schedule) postirradiation (in an attempt to overcome resistance). This study will have no age limitation, and therefore should provide important new data.

Despite the data available, the best approach for the elderly patient is not known with a variable approach depending on the biases of individual practitioners. For patients with a good performance status and no significant comorbidities, maximal resection followed by RT (60 Gy) + TMZ followed by TMZ for 6 months should probably be the approach to use. It has become a convention in the United States to treat patients with TMZ for 1 year post-RT, but there is no level one data to support this practice.

**TABLE 99-1**

#### Median Survival of Various Gliomas as a Function of Histology

GLIOMA TYPE	MEDIAN SURVIVAL (yr)	CHROMOSOMAL ABNORMALITY
Low-grade oligodendroglioma	4–10	
Low-grade astrocytoma	5	P53 gene, chromosome 22q
Anaplastic oligodendroglioma	3–5	Chromosomes 9p, 13q, 19q
Anaplastic astrocytoma	3	
Glioblastoma multiforme	~1	Chromosome 10

A geriatric patient population with newly diagnosed GBM is the ideal one for further study. One possible aim is the evaluation of the potential benefits of adjuvant TMZ. In a nongeriatric patient population, the benefit of concurrent and adjuvant chemotherapy as an overall treatment has been demonstrated, but the benefits of adjuvant chemotherapy (i.e., TMZ post-RT) as a portion of that approach has not been assessed. In a phase II ( $n = 55$ ) study done in Germany with a somewhat older patient population, TMZ was given with RT at a dose of only 50 mg/m<sup>2</sup> rather than the 75 mg/m<sup>2</sup> as in the Stupp study; no TMZ was given post-RT. The overall survival in this study approximated the Stupp trial. As many patients fail to complete the adjuvant treatment, it is possible that the concurrent therapy (TMZ/RT) is most important. In older patients, the decision to offer a trial comparing these options is justified by the greater uncertainty about the benefits of the overall treatment program with TMZ, as well as, the greater risk of toxicity of these regimens in older patients, and the poorer overall survival. The issue of survival is relevant as adjuvant therapy may occupy a period of time greater than the predicted median survival for the population.

A few studies have looked at the role of TMZ chemotherapy in the elderly post-RT only, or as sole treatment without RT. A small series of 23 GBM patients (mean age 68, all with good performance status) treated with surgery, TMZ and RT, with a median survival time of 15.38 months. Notable in this series was the development of leukoencephalopathy in 2 patients older than 70 years old. TMZ alone has been retrospectively compared to survival for RT alone, with no statistical difference between the two groups. Consistently, performance status was a predictor of survival. In prospective studies of TMG alone, neurologic improvement has been reported in 50% of patients with an overall survival of 6.4 months, and a median progression free survival of 5 months.

In spite of the advances described above, the overall prognosis for patients with GBM (in general, and particularly for the elderly) remains poor. Interestingly, the marked genetic heterogeneity of GBM may provide another opportunity for directed therapy. Recent elucidation of signaling pathways and evaluation of targeted agents has been an exciting approach in the treatment of cancer patients in general. For GBM, there are several promising targets. For example, GBM tends to overexpress epidermal growth factor receptor (EGFR). Additionally, research suggests that the status of the PTEN gene involved in the activity of the Akt signal transduction pathway (which is involved in resistance to apoptosis and acceleration of cell proliferation) may have implications for prognosis as well as response to EGFR tyrosine-kinase inhibitors for GBM. In a retrospective study, Mellingshoff et al. found that activated EGFR, (i.e., EGFR vIII) in combination with wild-type PTEN was associated with a very high response rate to the EGFR tyrosine kinase inhibitors erlotinib and gefitinib. Similarly, another group reported that EGFR amplification and low levels of protein kinase B/Akt phosphorylation was associated with response.

Taken collectively, such studies point the way for prospective trials, allowing for selection of patients based on the molecular characteristics of their tumors. In the now active RTOG study 0525, discussed above, such data will be collected prospectively, so that at the time of relapse such concepts can be clinically tested in specific cohorts of patients.

In conclusion, it is noteworthy that cooperative groups throughout the world have increasingly focused on age as a determinant in the outcome of geriatric GBM patients. This has resulted in recent

design of studies targeting geriatric studies, as well as open studies without age restrictions but with stratification for age. This awareness coupled with the increasing propagation of new agents, and biologic markers to allow for directed therapy will hopefully result in a significant improvement in outcome for these older patients.

## PRIMARY NERVOUS SYSTEM LYMPHOMAS

Primary central nervous system lymphoma (PCNSL) is a rare type of intracranial neoplasm, representing only 1% to 4% of all primary brain tumors. PCNSL is a subtype of extranodal non-Hodgkin's lymphoma that is confined to the brain, spinal cord, meninges, and eye. Patients may present with symptoms related to increased intracranial pressure, local mass effect, ocular involvement, or from focal involvement at cranial or spinal nerve roots. Diagnostic imaging of PCNSL is best achieved with magnetic resonance imaging (MRI), with PCNSL having the characteristic appearance of a periventricular homogenous, hypointense mass with indistinct borders.

Consideration of PCNSL in the differential diagnosis of an intracranial mass is important given the divergence in treatment modalities employed for PCNSL compared with other primary or metastatic brain tumors. In particular, PCNSL is frequently exquisitely sensitive to steroids, and initiation of high-dose steroids in cases of PCNSL may result in significant or complete regression of the mass prior to a diagnostic biopsy. Surgical resection should be avoided in cases where PCNSL is considered until a definitive tissue diagnosis is made, given the results of multiple retrospective series showing that gross total resection of PCNSL only results in increased morbidity without improving outcome. This is somewhat surprising given the important role of surgical resection in improving outcomes in other primary brain tumors and some metastatic brain tumors. Lastly, proper histologic diagnosis of PCNSL is important in order to adequately assess for other common sites of disease, including the eyes and leptomeninges. Failure to do so will result in inadequate treatment for occult or subclinical disease sites.

PCNSL may occur in immunocompromised or immunocompetent patients, although a discussion of treatment will be limited to the setting of immunocompetent patients. Whole-brain radiation therapy (WBRT) has been the mainstay of PCNSL treatment for more than a decade, with reported median survivals of 12 to 18 months. Ongoing efforts are underway to improve outcomes with the incorporation of chemotherapy. In contrast to other subtypes of non-Hodgkin's lymphoma, the most active agent in treatment of PCNSL is methotrexate, given at doses high enough to penetrate the blood-brain barrier (doses  $\geq 1$  g/m<sup>2</sup>). Previously, it has been reported that the best outcomes are observed with doses of methotrexate  $\geq 3.5$  g/m<sup>2</sup>. Combined modality therapy with methotrexate-based regimens and consolidation WBRT have been associated with improved median survival, but with high rates of neurotoxicity related to leukoencephalopathy. In patients older than age 60, the rates of severe neurocognitive dysfunction have approached as high as 60% to 80% in patients treated with high-dose methotrexate and WBRT. Recently, the long-term retrospective experience at Memorial Sloan-Kettering Cancer Center has suggested improved median survival in older patients treated with chemotherapy alone. In this series of patients with PCNSL treated with a methotrexate-based regimen with or without WBRT, age again emerged as an important prognostic variable in terms of overall survival and risk for neurotoxicity.

A median survival of 29 months was observed in the patients aging 60 years or older, which is significantly improved in comparison with historical data in older patients receiving WBRT alone (median survival 7–12 months).

Neurotoxicity was a significant problem in older patients receiving chemotherapy and WBRT, with rates of neurotoxicity of 75% compared with 12% in older patients treated with chemotherapy alone. Similarly, Abrey et al recently reported a prognostic scoring system in PCNSL in which age and KPS are significant predictors of outcome in terms of overall and failure-free survival in PCNSL.

Ongoing trials are investigating novel methotrexate-based regimens with the incorporation of agents known to cross the blood-brain barrier (e.g., temozolomide, procarbazine, cytarabine) as well as newer agents that have established activity in lymphoma (e.g., rituximab). Clearly, better means of assessing and detecting neurocognitive changes are needed as part of ongoing treatment of PCNSL, especially in older patients who are at highest risk for these complications. The recent description of a prognostic model based on age and performance status in PCNSL will aid in identifying patients who are candidates for more aggressive treatment strategies and will also serve as an important tool in clinical trial development. In older patients with a poor performance status at diagnosis, palliative WBRT remains a reasonable and effective treatment option.

## BRAIN METASTASES

Brain metastases represent the most common intracranial neoplasm in adults. Brain metastases may carry with them devastating functional impairments as well as generally carrying a poor prognosis. Several common solid tumors have a particular predilection to metastasize to the brain, including breast and lung cancer, as well as melanoma. The presenting signs and symptoms for a patient with brain metastases are similar to those with primary brain tumors; seizures, headaches, and focal neurological deficits tend to dominate the presentation. Conventional whole-brain RT remains the mainstay of treatment for brain metastases among patients of all ages. There is an emerging role for surgery, novel ways of delivering RT and chemotherapy.

### Radiation Therapy

The treatment typically given for intracranial metastases is whole-brain radiotherapy (treating the entire brain with equal amounts of radiation). The dose given ranges from 30 to 37.5 Gy of radiation, usually divided in 2 to 3 Gy fractions. A higher total dose is no more effective in increasing median survival, nor is shortening the duration of treatment to as little as one high-dose fraction. For patients whose overall survival is expected to be longer than 6 months, pursuing low per-fraction doses (i.e., 2 Gy per fraction) may reduce long-term complications of RT.

Reirradiation is generally not considered useful, except in usual circumstances, such as if a patient were to have a long disease-free period between initial radiation and reradiation. Of note, the risk of neurotoxicity and worsened cognitive function is higher with repeat radiation treatments.

Age and performance status do predict outcome. That is, the older or poorer the performance status, the worse the overall survival (2.3

vs. 7.1 months). Controlling the primary disease outside of the brain is also an important consideration.

Newer techniques for delivering radiation, including stereotactic radiosurgery, have a role in the management of brain metastases as well. Stereotactic radiosurgery delivers one to a few fractions of high-dose radiation to a well-circumscribed area. This treatment is more targeted than whole-brain RT, involves less fractions of treatment, and is typically delivered as an outpatient. This modality can be particularly useful for patients who, for whatever reason, cannot have surgical resection, and in patients with up to 3 metastatic deposits of disease without mass effect. There have been no randomized trials comparing radiosurgery versus conventional resection.

### Surgery

The role of surgery is largely in patients with oligometastatic disease, normally with only one or two metastatic deposit in the brain, and in whom their systemic disease is either resolved or well controlled. Surgery to remove the tumors, given in conjunction with postoperative whole-brain RT, improves local control as well as median survival when compared to surgery alone. Notably RT was started within 14 days of surgery, and the majority of the studies included patients with only one metastasis. A retrospective review, however, suggested that there is also a benefit for patients with multiple metastases if all sites of disease can be removed.

### Prognosis

Prognosis is best for patients with a solitary brain metastasis, excellent performance status, and little or no disease outside of the brain. Even in this good prognosis category, median survival is still only approximately 12 months. In patients with a low performance status and a high extracranial burden of disease, survival is only weeks to months and consideration should be given to palliative care alone.

## MENINGIOMAS

Meningiomas are normally benign, slowly growing intracranial neoplasms, though they can rarely be found to be malignant. The management of benign meningiomas is discussed below. These tumors are normally seen attached to the dura mater, and are a common incidental finding on imaging pursued for other reasons than a suspected intracranial neoplasm. On neuroimaging, meningiomas are frequently calcified and extraxial in location, and may be accompanied by edema, occasionally in significant amounts. The histologic variant of a meningioma is generally not helpful in defining prognosis or optimal treatment. The peak age for meningiomas to be diagnosed is in mid-40s, and there is a female to male predominance. Meningiomas are also more common in African-Americans than whites. Surgical resection is the treatment of choice, though radiosurgery may also be a reasonable option. Importantly, if a meningioma is discovered incidentally, observation or a plan for expectant reimaging may also be a reasonable consideration, particularly if the patient has no symptoms or has other life-limiting comorbidities. Surgery in the older adult should be approached cautiously, as older age is associated with worse outcomes, including higher in-hospital mortality, longer mean hospital stay, and higher likelihood of discharge to a nursing facility. In the event of a positive margin or a recurrence in the bed of a prior resection, radiation may be used as

a salvage therapy. The prognosis for meningiomas is excellent with a 5 years survival of more than 90%; the issue of greatest concern is the neurological deficit that remains after resection. Meningiomas also can recur as late as 20 years after the original resection, so a long period of follow-up may be necessary, as appropriate.

## NEUROMAS

The most common neuromas in the older adult patient are acoustic neuromas, which are benign schwannomas of the vestibular nerve. These represent only 5% to 7% of intracranial neoplasms. They are slightly more common in women, and are also seen in association with neurofibromatosis type 2. These tumors arise from a mutation in the *NF2* gene, resulting in lack of production of the merlin protein. There are several approaches to this tumor depending on symptoms and patient's health condition. Although they are benign tumors, they may cause many symptoms depending on their location and proximity to the cranial nerves and brainstem. Presenting symptoms may include hearing loss, ringing in the ears and balance difficulties. Treatment options include surgery, expectant observation, or radiosurgery. The treatment plan for most acoustic neuromas is made by a multidisciplinary team of practitioners, as all approaches bring with them potential serious morbidity given the tumor's location.

## GENERAL CONSIDERATIONS

### Clinical Presentation

The older adult can present in different way clinically than the younger patient, perhaps owing to brain changes with age, which allow tumors to grow without much in the way of mass effect or elevated intracranial pressure, such as headaches, seizures, or papilledema. Conversely, older adults are more likely to present with mental status changes, memory problems, and confusion. On examination, a focal neurologic finding should be strongly suggestive of a possible brain tumor. Importantly, frontal brain tumors are more likely to present without focal findings, but instead personality change. Slowly growing tumors, such as meningiomas may present with a long history of symptoms.

### Diagnostic Evaluation and Imaging

Where possible, initial imaging for an intracranial neoplasm should include MRI with and without gadolinium contrast, as this provides a superior sensitivity for tumors when compared to computed tomography (CT), and also provides multiplanar imaging, useful in treatment planning. CT has a role in defining extent of bony invasion, or for a rapid clinical deterioration where the delay in acquiring an MRI may be too long. Positron emission tomography (PET) can be used to differentiate residual or recurrent tumor from necrosis after treatment, particularly RT. A brain biopsy may be useful in determining the World Health Association grade of a tumor (Table 99-3).

### Non-Chemotherapy Medication Considerations

Corticosteroids (most commonly dexamethasone) are commonly used in the setting of CNS neoplasms to reduce or prevent edema.

**TABLE 99-3**

### WHO Classification of Common Brain Tumors

TUMOR TYPE	WHO PATHOLOGICAL GRADE
Glioblastoma multiforme	4
Anaplastic astrocytoma	3
Meningioma	1
Primary CNS lymphoma	3–4
Astrocytoma	1–2
Atypical meningioma	2–3

The dose of steroid may be tapered after several weeks of treatment if symptoms have stabilized. The lowest possible dose to control symptoms should be used. Common or serious side effects with this medication include oral thrush, hyperglycemia and steroid induced diabetes mellitus, insomnia, weight gain, agitation and delirium, all of which may complicate use in the older patient. It is our practice to start empiric antithrush prophylaxis at the time of starting corticosteroids. We also check blood glucoses while on higher doses of steroids. Patients and their caregivers should be counseled about the side effects of corticosteroids prior to administration.

Antiepileptics are commonly used to treat seizures associated with brain tumors or the accompanying edema. They are not required without a history of seizures except perhaps for prophylaxis around the time of surgery. The provider should recall that most antiepileptics agents interact with many medications by hepatic interactions, including dexamethasone, some chemotherapies, and anticoagulants, such as warfarin. There are a few antiepileptics (such as gabapentin and levetiracetam) that are not hepatically processed, and so may have fewer of these drug interactions. Antiepileptic drugs also carry the risk of the serious dermatological side effect of Stevens-Johnson syndrome. Any rash that develops in a patient with a brain tumor and concurrent antiepileptic use must be watched carefully.

The majority of patients with CNS neoplasms have some degree of a reactive depression, which should be treated in all but the minority of cases. This depression appears to be more severe in the older patients. Although the discussion regarding which antidepressant should be used is beyond the scope of this chapter, it is notable that the tricyclic and monoamine oxidase inhibitors should be avoided in patients on procarbazine chemotherapy.

## CONCLUSIONS

Taken collectively, CNS disease in the older adult patient presents unique therapeutic challenges. Continued laboratory and clinical investigation should provide development of new less toxic and more efficacious approaches to therapy. Relative to this, the continued elucidation of resistance mechanisms, which may be modified by specific clinical strategies, should prove beneficial. Further, in the past year, laboratory correlative studies have opened the potential for the therapeutic application of signal transduction modifiers. Finally, the continued exploration of approaches to minimize toxicity in this fragile patient population is an ongoing research aim, which is now receiving significant interest by various acknowledged investigative groups.

# Skin Cancer

*Mathew W. Ludgate* ■ *Timothy M. Johnson* ■ *Timothy S. Wang*

## INTRODUCTION

Nearly 1.5 million new skin cancers are diagnosed in the United States each year, which represents more than half of all new U.S. cancer diagnoses. Approximately 10 000 people die annually of skin cancer in the United States; one an hour from melanoma and one every 4 hours from nonmelanoma skin cancer. There are three main types of skin cancer: basal cell carcinoma (79% of skin cancers), squamous cell carcinoma (14%), and melanoma (5%). Other skin cancer types comprise the remaining 2%. While melanoma accounts for only 5% of skin cancer diagnoses, it accounts for 75% of skin cancer deaths. Basal and squamous cell carcinomas are considerably less lethal, but these tumors are associated with significant morbidity. As with most malignancies, the incidence of skin cancer increases with age. Owing to their sheer numbers, the public health burden from skin cancer is great.

One in five people in the United States and one in three Caucasians will develop skin cancer during their lifetime. Since 1960, the incidence of skin cancer has risen by 4% to 8% per year. It continues to rise faster than any other cancer, and skin cancer has been labeled as “today’s epidemic” in the lay press. It is likely that much of the data on the incidence and prevalence of skin cancer are an underestimation, as many biopsies of nonmelanoma skin cancer are interpreted in physicians’ offices, and thus go unreported to hospital-based registries.

## ETIOLOGY

Both genetic and environmental risk factors are implicated in the development of skin cancer. The most common known environmental risk factor is chronic and/or acute intense intermittent ultraviolet light exposure in the form of sunlight, artificial tanning devices (tanning booths), and sunburns. The Centers for Disease Control

Behavior Risk Factor Surveillance System data report that nearly 32% of all adults (57% of those aged 18–29) and more than 40% of children in the United States develop at least one sunburn annually. Ultraviolet B (UVB), at wavelengths between 290 to 320 nm, causes most of what we see as sun tanning and sun burns and is responsible for much of the actinic skin damage caused by sunlight. Ultraviolet A (UVA), 320 to 400 nm penetrates more deeply into the skin and is also an important factor in photoaging and skin cancers. UVB radiation induces skin cancer by a variety of mechanisms including direct DNA damage, damage to DNA repair systems, and alteration of the local cutaneous immune system. Some of the strongest evidence that implicates ultraviolet light as being important in the etiology of skin cancer comes from epidemiologic and experimental data correlating the incidence of tumors with the degree of pigmentary protection. Fair-skinned individuals with blue or green eyes and red, blonde, or light brown hair are at highest risk. These patients also typically tan poorly and sunburn and freckle easily. The risk of skin cancer varies with race and ethnic group with Caucasians of Celtic ancestry having the highest incidence rates. Skin cancer is less common in African-Americans, Asians, and Hispanics, but a rise in the Hispanic and Asian population is occurring. Other strong epidemiologic data correlate an increased incidence of skin cancer with residence at lower latitudes where there are higher levels of ambient UVB radiation.

The changes that most persons equate with aging of the skin are a result of chronic solar damage. Prolonged exposure to ultraviolet light leads to cutaneous atrophy, alterations in pigmentation, wrinkling, dryness, telangiectasia, and solar elastosis. Ultraviolet light from the sun or artificial tanning devices is believed to be the most common cause of nonmelanoma skin cancer (NMSC) and may account for some melanomas. Most NMSCs occur on sun-exposed sites such as the face, head, neck, or extensor arms and hands. Understandably, skin cancer is a significant occupational hazard for people who work outdoors. Although NMSCs usually occur on sun-exposed sites, they also rarely occur in sun-protected sites such as the anogenital area, mucous membranes, palms, and soles.

Other environmental/exposure factors associated primarily with squamous cell carcinoma (SCC) include chronic exposure to chemicals such as hydrocarbons (coal tars, soot, cutting oils, and asphalt). Chronic exposure to arsenic is associated with NMSC on both sun-exposed and sun-protected sites. PUVA (psoralen in combination with UVA) used in the treatment of psoriasis and other inflammatory dermatoses produces a dose-dependent increase in SCC and melanoma. Cigarette smoking is linked to SCC of the lip and mouth. The human papilloma virus has been associated with cutaneous SCC in the genital and acral/periungual areas. The carcinogenic effect of ionizing radiation inducing NMSC is documented in human and animal models. Other conditions associated with NMSC include burn and vaccination scars, chronic inflammatory processes and ulcers, and immunosuppression.

A number of genetic syndromes are associated with an increased risk of developing NMSC. Nevoid basal cell carcinoma syndrome (Gorlin syndrome) is an autosomal dominant or mosaic disorder associated with the occurrence of hundreds to thousands of lifetime basal cell carcinomas beginning in childhood or young adulthood. Jaw cysts, palmoplantar pits, abnormal ribs and vertebrae, frontal bossing, and hypertelorism are also found. Albinism, which can occur owing to one of several causal genetic defects, is associated with an increased risk of all skin cancer types. It is characterized by partial or complete failure to produce or distribute ocular, hair, and/or cutaneous UV protective melanin pigment. Xeroderma pigmentosum is a rare autosomal recessive disorder that results in the inability to repair UV-induced DNA damage. It is characterized by hypersensitivity to UV light and the relentless development of skin cancer, especially SCC and melanoma. Individuals with xeroderma pigmentosum are usually diagnosed with their first cancer prior to the age of 10.

A genetic component is also implicated in the pathogenesis of melanoma. Currently, a small percentage of melanomas are known to be associated with chromosomal mutations in *CDKN2A* (p16), *MC1R*, or *BRAF*. The hereditary nature of melanoma is also noted in families with >100 normal nevi or any number of atypical appearing (dysplastic) nevi. Atypical nevi are not “premelanoma” *per se* but represent a phenotypic marker for an increased risk of melanoma. A positive family history of melanoma is present in 5% to 15% of melanoma patients. Five to ten percent of individuals with a prior melanoma develop a second melanoma. The genetic etiology of melanoma represents an area of future discovery.

Congenital nevi (CN) are present at birth or appear within the first 6 months of life. The risk of melanoma developing in CN <20 cm in diameter is similar to that of any other area of skin. Melanoma in CN usually occurs after childhood and arises at the dermoepidermal junction making early detection possible. Thus, in the absence of warning signs or symptoms, routine prophylactic removal of CN <20 cm in diameter is rarely indicated. Large ( $\geq 20$  cm) CN are at increased risk for developing melanoma (5% to 20%), tend to progress to melanoma prior to age 10 (70%), and may originate deep in the lesion resulting in later detection.

## NONMELANOMA SKIN CANCER

### Basal Cell Carcinoma

Basal cell carcinoma (BCC) is the most common type of skin cancer and has no known precursor lesion. Approximately 80% of BCCs

occur on the head and neck. BCCs are classified by clinical appearance and histologic pattern and include nodular, superficial, aggressive growth, and pigmented subtypes. BCCs rarely metastasize and grow slowly for years prior to sometimes developing a more rapid growth rate. Although they can appear quite indolent, BCCs grow relentlessly and if left untreated can cause extensive local destruction. Occult invasion can also occur and may be deep and asymmetric with root-like extensions sometimes several centimeters beyond their apparent borders. Metastatic BCC is a rare event (0.03% of all BCCs), most often spreading to the regional lymph nodes followed by the lungs, bones, and skin. The 5-year survival rate for patients with metastatic BCC is poor and patients with distant disease have a median survival of only 10 and 14 months.

The most common BCC subtype is the well circumscribed nodular or noduloulcerative variant. This typically begins as a small, translucent or waxy flesh-colored or pink, pearly papule or nodule with small telangiectasias on the surface and a translucent, rolled border (Figure 100-1) (Color Plate 14). They may be pruritic or bleed. With time, the nodule increases in size and undergoes central ulceration. Most nodular BCCs present as small (< 1 cm) papules, however, patients still occasionally present with large, disfiguring lesions that have been neglected for many years. Classic histologic features of the nodular BCC include the presence of well circumscribed, basaloid tumor lobules of various sizes in the dermis. The basal cells at the tumor periphery appear to line up, a phenomenon known as peripheral palisading. Areas of separation or retraction artifact between tumor nodules and the adjacent connective tissue embedded in a pale mucinous stroma are also seen.

Superficial BCCs occur predominantly on the trunk and usually present as a pink to red, flat scaly lesion, sometimes with a fine, thread-like translucent border with central areas of hypopigmentation or atrophy (Figure 100-2) (Color Plate 15). They are sometimes confused with scaly skin conditions such as psoriasis or other eczematous dermatoses, and may closely resemble actinic keratosis or Bowen disease. Significant and sometimes extensive superficial subclinical involvement is common as they grow by peripheral extension. Histological features of the superficial BCC include numerous, multifocal small buds of basaloid tumor cells that arise in the epidermis and extend into the superficial dermis and down and around hair follicles.

**FIGURE 100-1.** Nodular BCC on the lower eyelid. Small pearly papule with telangiectatic blood vessel visible at superior aspect of lesion.

**FIGURE 100-2.** Superficial BCC occurring on the chest. Pink, flat lesion with slightly raised scaly borders.

The aggressive BCC subtype usually presents as a flat, firm, indurated, pale, white-to-yellow papule or plaque with harder to detect clinical borders and a “scar like” appearance. This subtype is also known as infiltrating, morpheaform, sclerosing, sclerotic, and fibrotic BCC. Clinically, aggressive BCCs can exhibit subclinical extension widely beyond (> 1 cm) their apparent borders, and can also ulcerate (Figure 100-3) (Color Plate 16). They have a higher rate of recurrence following standard treatment modalities because of distant, small finger-like projections of tumor cells that may deeply invade into the dermis, subcutis, and muscle and skate along fascial planes, cartilage, and bone. These small, finger-like islands are often missed with standard histologic margin control. Histological features of aggressive-growth BCC include small islands and spiky finger-like linear strands and cords of basaloid tumor cells embedded in a dense, fibrous sometimes sclerotic connective tissue stroma. Peripheral palisading and stromal retraction is often subtle or absent and perineural invasion is more common. Micronodular BCC similar to aggressive

**FIGURE 100-3.** Aggressive BCC. Note the very subtle clinical features with an indurated plaque with telangiectasia present. This lesion is likely to have wide subclinical extension present.

BCC often has significant subclinical extension through the dermis or subcutis. Histologically, smaller tumor islands similar in size to hair bulbs, characterize micronodular BCC. In some cases, a BCC has histologic features of squamous metaplasia and keratinization. These tumors have basosquamous differentiation and may become more aggressive and develop regional lymphatic spread. It is important for the pathologist to convey the BCC histologic subtype pattern to the clinician, especially for aggressive-growth BCC. Multiple histologic patterns may be present in up to 35% to 50% of BCC with the most aggressive pattern correlating with biologic behavior.

Pigmentation from melanin can be seen in all BCC subtypes, but is most commonly seen in nodular BCCs. Some lesions categorized as pigmented BCC are heavily pigmented and can bear a striking resemblance to melanoma or pigmented seborrheic keratoses.

BCC is thought to originate from immature pluripotential epidermal cells. The cytokeratin pattern in BCC resembles that found in the outer root sheath of the hair follicle below the isthmus in the bulge area rather than that of the epidermis, supporting a follicular origin for the tumor. These cells can mature and differentiate in a pattern resembling any of the epithelial structures. BCC can develop in both a hereditary and sporadic fashion. Mutations in the patched (PTCH) gene have been identified in nevoid BCC syndrome and in sporadic BCC. PTCH is a cell membrane receptor for a family of proteins called hedgehog (Hh). The PTCH protein binds and inhibits a transmembrane protein known as smoothened (SMO). Mutations in either PTCH or SMO lead to increased SMO signaling and growth promotion with subsequent cancer formation. The activation of the SMO pathway leads to induction of a number of proteins via the Gli1 transcription factor, including transforming growth factor (TGF- $\beta$ ), platelet-derived growth factor receptor- $\alpha$ , PTCH, and Gli1 and are relevant to cancer development. Mutations that inactivate the tumor suppressor gene p53 have also been identified in more than half of BCCs, but a causal role for p53 mutations in BCC development or progression has not been demonstrated. Patients with Li-Fraumeni syndrome, characterized by an inherited mutation in the p53 gene, have an increased incidence of a number of malignancies, but an increase in NMSC has not been reported.

### Squamous Cell Carcinoma

SCC is the second most common skin cancer type. It possesses the potential to metastasize, the risk of which depends on various risk factors. The most common site of metastasis is the regional lymph nodes, which occurs in 85% of metastatic cases. Approximately 15% of metastases involve distant sites such as the lungs, liver, brain, bone, and skin. The prognosis for patients with metastatic SCC is poor with 10-year survival rates of <20% for patients with advanced regional lymph node involvement and <10% for patients with distant metastases. Fortunately, the majority of cutaneous SCCs are low-risk lesions that are treated with high cure rates.

SCC has a precursor “pre-malignant” lesion termed actinic keratosis (AK). AKs are extremely common in fair-skinned elderly Caucasian individuals who have had significant chronic sun exposure. AKs usually occur in areas damaged by sun exposure, such as the bald scalp, face, and extensor forearms/hands. AKs occur as well-demarcated, scaly, rough patches or plaques on chronic sun-exposed skin surfaces. Their color can vary from skin colored, erythematous, pink, or to brown, and they are often more easily palpated than seen. The majority of cutaneous SCCs arise in AKs. However, the incidence of progression of an individual lesion from AK to SCC in

situ (Bowen disease) and then to invasive SCC remains low, ranging from 0.025% to 20% and occurs slowly over years in immunocompetent individuals. The cumulative risk depends on the number of lesions and the length of time they persist. AKs are easily treatable with cryotherapy or topical agents such as 5-fluorouracil for more numerous lesions. Other conditions predisposing to SCC include radiation exposure; scarring from a previous injury such as a burn, chronic inflammatory processes such as chronic wounds or ulcers, osteomyelitis, sinuses, or discoid lupus; human papilloma virus particularly in acral and genital sites; and chronic arsenic or hydrocarbon exposure.

Patients who are immunosuppressed following organ transplant deserve special consideration and attention. SCC is the most common skin cancer in immunosuppressed organ transplant recipients, occurring 65 to 250 times more frequently than in the general population. Large numbers of premalignant AKs can rapidly develop and progress in fair-skinned, immunosuppressed individuals with a history of significant sun exposure. Moreover, these AKs behave more aggressively and tend to transform into invasive, rapidly growing SCCs with a more aggressive behavior and increased risk of metastasis. Frequent clinical surveillance and early intervention and prevention are thus essential in these patients. Almost half of the malignancies that arise in patients with impaired immune surveillance occur in the skin. The great majority of these are squamous cell cancers, occur in sun-exposed areas, and almost 50% of patients have multiple tumors.

Ultraviolet-induced mutations of the p53 tumor-suppressor gene interfere with apoptosis of the damaged cells, permitting damaged cells to proliferate. More than half of cutaneous SCCs and AKs have p53 gene mutations. Nucleotide sequence analysis demonstrates that these mutations are specifically associated with exposure to UVB light.

Clinically, cutaneous SCCs most commonly develop (80%) on chronically sun-exposed areas on the head and neck and extremities, followed by the trunk. Clinical presentation varies, but most commonly occurs as a 0.5 to 1.5 cm firm, sometimes tender, hyperkeratotic pink to red papule, nodule, or plaque (Figures 100-4 and 100-5) (Color Plates 17 and 18). Ulceration and easy bleed-

**FIGURE 100-4.** Invasive SCC on the cheek. Large ulcerated nodule with central core filled with hyperkeratotic material.

**FIGURE 100-5.** Invasive SCC on the ear. Ulcerated crusted lesion on the ear associated with a high risk of regional metastasis.

ing is a relatively common finding. Rapid and deep local invasion may occur. In darker skinned patients, SCC may present in non sun-exposed areas and is most commonly associated with chronic inflammatory or scarring processes.

Histologically, several subtypes of SCC exist, but the conventional subtype is the most common. Other subtypes include adenoid/acantholytic, bowenoid, spindle/pleomorphic, small cell, verrucous, and keratoacanthoma. The conventional subtype is associated with irregular masses of epidermal cells proliferating downward and invading the dermis. The invading tumor masses are composed of varying proportions of normal squamous cells and atypical cells. These atypical cells demonstrate variations in the size and shape of the cells, hyperchromasia and hyperplasia of the nuclei, absence of intracellular bridges, keratinization of individual cells, and the presence of atypical mitotic figures. In SCC, differentiation is toward keratinization. Horn pearls, which are concentric layers of squamous cells with gradually increasing keratinization toward the center, can also be seen. The dermis often shows a marked inflammatory reaction. Histologic grading of SCC depends on the percentage of keratinizing cells, percentage of atypical cells, number of mitotic figures, and depth of invasion. The Broders classification system is based on the degree of de-differentiation of the cells: in grade 1, <25%; in grade 2, <50%; in grade 3, <75%; and in grade 4, >75% of the cells are undifferentiated (poorly differentiated).

### Treatment for BCC and SCC

Prior to any treatment, a biopsy confirming the diagnosis is mandatory. Numerous surgical and nonsurgical modalities are effective in treating BCC and SCC. Despite the enormous amount of literature pertaining to the treatment of BCC and SCC, there is relatively little high-level evidence-based research on the efficacy of the treatment modalities used. Most of the reported literature is retrospective, not randomized, and suffers from selection bias, such as allowing treatment modality to be influenced by whether the lesion is low- or high-risk. Based on the best available cumulative evidence, the selection of therapy is based upon several clinical and histologic risk factors noted in Table 100-1. The majority of lesions are relatively low risk and can be treated effectively with standard techniques such

**TABLE 100-1****Basal Cell Carcinoma (BCC) and Squamous Cell Carcinoma (SCC) Risk Factors for Occult Subclinical Invasion and Recurrence**

Recurrent tumor
Location
High-risk: mask areas of face (eyelid, eyebrow, periorbital, nose, lip, chin, mandible, temple, ear, in front or behind the ear), genitalia, hands, and feet
Medium-risk: cheeks, forehead, scalp, and neck
Low-risk: trunk, extremities
Size
Lesions > 5 mm on high-risk area: mask areas of face, genitalia, hands, and feet
Lesions > 9 mm on medium-risk area: cheeks, forehead, scalp, and neck
Lesions > 19 mm on low-risk area: trunk and extremities
Histology
BCC: aggressive growth (morpheaform, fibrosing, sclerosing, infiltrating, micronodular)
SCC: poorly differentiated, invades deep reticular dermis or adipose
Ill-defined clinical borders
Perineural invasion
Immunosuppression
Etiology: development in site of prior radiation, scar, chronic inflammatory process
SCC-depth of invasion
SCC-rapid growth

as electrodesiccation and curettage, curettage alone, standard surgical excision, radiation, or ablative cryosurgery with 92% to 98% local control rates for low-risk tumors. As the lesions develop additional risk factors noted in [Table 100-1](#), the control (cure) rate begins to drop precipitously. For higher risk lesions, Mohs surgery or surgical excision with comprehensive margin control or wide margins still results in 95% to 99% local control rates in the majority of cases.

### Electrodesiccation and Curettage

Electrodesiccation and curettage (ED&C) is a common, effective, operator-dependent treatment option. ED&C causes local tissue destruction and is quickly performed with local anesthesia in the office. First, a curette is used to remove the gross tumor, which is soft and friable. This is followed by electrodesiccation of the periphery and base of the wound to destroy residual tumor cells. This process is repeated with both a large and small curettes and electrodesiccated for 2 to 4 cycles depending upon the size and feel of the lesion. The experienced operator can provide similar high cure rates with curettage alone, omitting electrodesiccation. The resulting wound heals by granulation with a hypopigmented, atrophic, and sometimes a depressed scar. If the curette extends into the subcutis or a sclerotic “feel” is noted, ED&C should be discontinued and excision of the site should be performed. The major disadvantage of ED&C is the lack of a surgical specimen to examine for margin control.

### Cryosurgery

Ablative cryosurgery is another treatment option, but less frequently used. It is also quickly performed using local anesthesia in the office.

Liquid nitrogen is delivered to the tumor and a margin of normal appearing skin, which causes deep-freezing to  $-50^{\circ}$  to  $-60^{\circ}$ C and significant local destruction and tissue necrosis. Common side effects include edema, pain, extensive blister formation, and erythema. Chondritis and cartilage necrosis may occur for auricular lesions. The drawbacks of poorer cosmetic result, time to heal, and lack of a tissue specimen are similar to those seen with ED&C. Cryosurgery is an effective treatment for low-risk BCCs as well as for some SCCs.

### Topical Chemotherapy

Topical chemotherapy can be an effective treatment modality for AKs and has been used for select low-risk BCC. The two main agents available are topical 5-fluorouracil (5-FU) and the imidazoquinoline, imiquimod. Topical 5-FU is usually used in a 5% cream formulation, applied twice daily for 2 to 4 weeks. Topical 5-FU is particularly useful for treating larger areas of AKs, when more localized treatment such as cryosurgery becomes impractical. It has also been used for low-risk superficial BCC. Local inflammation and irritation are the main complications of therapy. Topical imiquimod 5% cream is also an effective treatment for AKs and is also used for select low-risk superficial BCC. Imiquimod is an immune response modifier and exerts its effect via toll-like receptors to increase inflammatory cytokine production. Similar to topical 5-FU, local inflammatory reactions are common, and some patients can also develop systemic flu-like symptoms.

### Radiotherapy

Fractionated radiation therapy (RT), usually performed in 15 to 25 daily treatments over 3 to 5 weeks, is an effective therapy for lower risk NMSC especially in patients who are poor surgical candidates. Experience and a clinical understanding of NMSC are vitally important to achieve good results. While early cosmetic results are better than destructive techniques, long-term results are not. Contraindications for RT include genodermatoses predisposing to skin cancer (nevroid BCC syndrome and xeroderma pigmentosum) and connective tissue disease (lupus and scleroderma). Local recurrences following RT are more aggressive and as with destructive techniques, a surgical specimen to examine for margins is lacking.

### Surgical Excision

Surgical excision is an effective treatment modality for all types of NMSC and possesses the advantage of a tissue specimen for histologic assessment of margins. Excisions heal more rapidly often with superior cosmetic results when compared with destructive techniques. Recommended margins for excision of NMSC generally range from 4 to 10 mm. Surgical excision is more invasive, more expensive for low-risk lesions, and requires training and experience. Many cases can be performed in a treatment room with local anesthesia, but larger cases may require general anesthesia or intravenous sedation in the operating room. High-risk lesions require more comprehensive histological processing and evaluation or widely clear margins with standard tissue processing to achieve high control rates. Standard histopathologic (bread loaf) processing of standard surgical excision specimens examines <1% of the true surgical margin. This may be problematic for higher risk NMSC such as those with greater subclinical extension. Following an incompletely

excised NMSC by observation is not appropriate therapy. Rather, re-excision by either Mohs surgery, or additional therapeutic intervention should be performed. The cure rate of low-risk lesions by excisional surgery is similar to those of destructive techniques and RT.

### Mohs Micrographic Surgery

Mohs surgery is a highly effective treatment for NMSC when done by experienced, appropriately trained Mohs surgeons and results in the highest local control (cure) rates with maximal sparing of normal tissue. Mohs surgery avoids many of the problems associated with the aforementioned treatments for skin cancer. Originally developed in the 1930s using a zinc chloride chemical paste to fix the tissue *in vivo*, the procedure is named after its inventor Dr. Frederic E. Mohs. The technique was refined in the 1970s to its current “fresh tissue” technique, which essentially involves serially excising cancerous tissue with 1 to 3 mm margins per stage, and examining the entire undersurface and edges of the specimen. When done properly, nearly total (theoretical 100%) margin control can be obtained. Of all NMSC treatments, Mohs surgery offers the highest cure rate (often >99%), lowest likelihood of recurrence, potential for minimal scarring and disfigurement, and unmatched precision. By definition, the Mohs surgeon performs a dual role as both surgeon and pathologist, and through advanced 1 to 2 year postgraduate fellowship training, the Mohs surgeon is adept at microscopic interpretation of horizontally cut frozen sections as well as local flap and graft soft tissue reconstruction techniques to repair the resulting wounds.

Mohs surgery is performed under local anesthesia in an office-based setting. Briefly, the visible portion of the tumor is outlined and anesthetized, then all gross tumor is removed by curettage. With the scalpel blade held at a 45-degree angle to the skin to facilitate tissue processing of the deep and peripheral margins, the surgeon excises a layer of tissue in the shape of a saucer with 1 to 3 mm deep and peripheral margins around and under the curettage defect. The specimen is divided into sections, color coded with dyes, and a schematic map is made for precise anatomic orientation. The specimen is then turned over and flattened into one plane so that the beveled skin edge is placed in the same horizontal plane as the deep margin. The Mohs histotechnician processes horizontal frozen sections that incorporate the entire deep and peripheral margin for interpretation.

The undersurface and edges of each section are examined by the Mohs surgeon under the microscope for evidence of remaining cancer. If cancer cells are noted, the surgeon marks their precise location on the map and returns to the patient to remove another layer of skin at the corresponding site of residual tumor. This layer is again examined microscopically for additional cancer cells. The process continues layer by layer in stages until no detectable cancer cells remain. Maximal normal tissue conservation is preserved, and nearly 100% of the margin is examined resulting in exceedingly high local control rates. Reconstruction is performed without delay after margins are free. In cases involving extensive defects or very large or complex tumors, a collaborative multidisciplinary team approach is important. Adjunctive RT may be indicated in cases of extensive perineural spread and in cases of SCC with a significant risk of lymphatic spread.

Mohs surgery is a labor-intensive technique and requires an experienced team. Surgical training is often highly variable with practice ranging from no postgraduate training; weekend courses to postgraduate Mohs College approved fellowship training, and ACGME

approved postgraduate training. To achieve high cure rates, the Mohs surgeon must be provided high quality Mohs frozen section slides. This requires specialized histotechnician training and experience. Mohs surgery is considered the “gold standard” for removal of higher risk NMSC. However, for small lower risk lesions, the cure rates for the treatment of NMSC with Mohs versus standard therapies are comparable.

## MELANOMA

Melanoma results from the malignant transformation of melanocytes usually located at the dermal–epidermal junction. Melanoma confined to the epidermis is termed melanoma *in situ*, which is theoretically 100% curable. With time, the melanoma invades vertically into the dermis where it can metastasize to the regional lymph nodes and/or other distant visceral organ systems via the lymphatic or vascular systems. The deeper melanoma invades, the greater the risk for metastasis and advanced systemic disease, which is by and large fatal.

Melanoma occurs in a younger age group than many cancers with approximately 25% occurring in patients <45 years of age, including children. Melanoma is one of the leading cancer types in terms of average years of potential life lost because of cancer-related death. In the United States, melanoma is the most common cancer type in Caucasian women aged 25 to 29, is second only to breast cancer in women 30 to 34 years of age, and is the most common type of cancer in Caucasian men in Michigan aged 25 to 44. The incidence in Caucasians has more than tripled since 1980. Encouragingly, the 5-year survival rate has increased from 50% in 1954 to 85% to 90% in 2006. This is largely a reflection of earlier detection. The annual direct cost of treating melanoma in 1997 was estimated at \$563 million with projections exceeding \$5 billion by 2010 for Medicare alone. Approximately 90% of this cost is attributable to the less than 20% of patients with more advanced disease, highlighting the importance of early detection, diagnosis, and treatment.

Primary care practitioners are often the patient’s first contact with the health care system, and therefore they play a vital role in the early detection of melanoma. Primary care practitioners knowledgeable about persons at risk and who have a heightened awareness of melanoma have a “golden” opportunity for early melanoma detection and education. Lives can be saved and health care costs reduced by early detection of this potentially fatal skin cancer. Although fewer than 20% of melanomas are detected by physicians and health care providers, provider-detected melanomas are significantly thinner, resulting in a better prognosis and lowered costs for treatment. Patients taught to examine their skin and the importance of bringing suspicious skin lesions to the attention of their providers also detect earlier lesions.

Melanoma can arise anywhere on the skin surface. One-third occur within a preexisting pigmented lesion and two-thirds occur with no precursor lesion or nevus on clinically normal appearing skin. The most frequent site for melanoma in men is the trunk, particularly upper back and shoulders. The most frequent sites for melanoma in women are the legs followed by the trunk. Melanoma can also rarely occur in mucosal, genital, nail bed, and ocular sites. In the African-American population, the hands and feet are common sites for melanoma. Risk factors for the development of melanoma include blue or green eyes, blonde or red hair, fair complexion with a tendency to freckle, sunburn and to tan poorly, the presence of

dysplastic nevi or >100 normal appearing nevi, a personal or family history of melanoma, and a history of significant UV exposure or sunburns.

The earliest clinical features of melanoma include a change in the size, shape, or color and occasionally persistent itching in a lesion. Later features include ulceration, bleeding, and/or tenderness. Classically an ABCD rule has been used to help recognize lesions suspicious for melanoma. “A” stands for asymmetry—one half of the lesion does not match the other half as a mirror image when drawing an imaginary line through the center of the lesion. “B” stands for irregularity of the borders—the edges of the lesion are ragged, notched, jagged, scalloped, or fuzzy. “C” stands for color—the color is not homogeneous throughout the lesion. Varying and mottled shades of tan, dark brown to jet-black, or shades of red, white, and/or blue may be present. Historically, “D” stands for diameter >6 mm, which has proven to be relatively insensitive as an independent factor. At our melanoma center and in many in the United States, “D” now stands for difference whose meaning is two-fold. The first application of “difference” describes any change or difference in an individual lesion, especially with respect to size, shape, color, or persistent itching. The second applies more to the evaluation of multiple nevi. In patients with multiple normal or slightly abnormal appearing nevi, those nevi when viewed as a group should grossly appear similar to one another. That is that they should have a “family” resemblance. Any members of the family that look “different”, like they do not belong to the family, should be examined. This has also been called the “ugly duckling” sign. The presence of atypical nevi represents a risk factor for the development of melanoma anywhere on the skin. The ABCD rule and other diagnostic aids enhance early detection, but do not provide the ability to differentiate between benign and malignant in every setting. Some advocate adding an “E” to denote evolution and change.

Early melanomas often lack all of these classic ABCD features. Therefore, any changing pigmented lesion or new atypical lesion should be evaluated and considered for biopsy especially in a patient with risk factors for melanoma. Melanomas can completely lack pigmentation (amelanotic melanoma) in 3% to 4% of cases. Understandably, these are often associated with later detection. As previously mentioned, melanoma arises within a preexisting nevus in only 33% of cases, and therefore it occurs *de novo* on clinically normal appearing skin in 66% of cases. Although one’s threshold for biopsy should be low and suspicion for melanoma high, prophylactic removal of preexisting nevi is therefore rarely indicated.

Historically, melanomas are classified by histological patterns and clinical characteristics into four major subtypes: superficial spreading melanoma, lentigo maligna melanoma, nodular melanoma, and acral lentiginous melanoma. These classifications are of little prognostic value as the biological behavior and risk of metastasis today are based mainly on the thickness of the primary tumor (Breslow depth).

Superficial spreading melanoma comprises approximately 60% to 70% of melanomas and represents the most common melanoma subtype. They often arise in a preexisting nevus and typically develop as a spreading pigmented plaque with irregular borders and variation in color and surface contour. They often exhibit the classic clinical features of melanoma (Figures 100-6 to 100-8) (Color Plates 19, 20, 21). Areas of regression may result in pink to white areas within the black or brown tumor. They may progress to a vertical growth phase faster than lentigo maligna.

**FIGURE 100-6.** Early superficial spreading melanoma. Note asymmetry and irregular border.

**FIGURE 100-7.** Superficial spreading melanoma showing all of the ABCD features. Breslow depth 3.5 mm.

**FIGURE 100-8.** Superficial spreading melanoma. Breslow depth 1.1 mm.

**FIGURE 100-9.** Lentigo melanoma (melanoma in situ) on the dorsum of the nose. Irregularly pigmented flat macule that had been slowly enlarging over a number of years.

The lentigo maligna melanoma subtype comprises approximately 10% to 15% of all melanomas and usually begins as a pigmented macular lesion with variation in black and brown color (Figure 100-9) (Color Plate 22). They are most common on the chronically sun-exposed areas of the head and neck, most often in older individuals. Lentigo maligna represents the in situ phase and with time, progresses to the invasive phase then termed lentigo maligna melanoma. These lesions have irregular outlines and may slowly enlarge over many years with progression to black and development of other classic melanoma features. The malignant cells may extend asymmetrically several centimeters beyond the clinical lesion and extend down hair follicles and other skin appendages. These characteristics can make lentigo maligna and lentigo maligna melanoma difficult to cure by superficial treatments and result in higher recurrence rates with standard surgical margins. Amelanotic and desmoplastic melanoma with neurotropism may occur more frequently in the setting of lentigo maligna melanoma.

Nodular melanoma often arises without evidence of a preexisting lesion. They constitute approximately 15% to 30% of melanomas and have a minimal radial-lateral growth phase. These tumors are more aggressive because they are often thicker when detected, stressing the importance of lesion change and difference for early detection. Nodular melanomas usually appear as a raised, nodular, or polypoid lesion with more uniform color and regular borders. They often present as <6 mm, may become ulcerated with rapid growth, and can lack the classic melanoma features (Figure 100-10) (Color Plate 23).

Acral lentiginous melanoma represents approximately 2% to 8% of melanomas in Caucasians, but 35% to 60% in people of color. They usually occur on acral sites, i.e., the hands, feet, fingers, toes, and under the nails. Subungual melanomas can present as an irregular, tan-brown longitudinal streak in the nail. Approximately 75% of subungual melanomas involve the great toe or thumb and are often confused with subungual hematoma.

### Staging and Prognosis

Accurate staging is necessary for counseling, treatment recommendations, and survival. Additionally, stage grouping better defines

**FIGURE 100-10.** Large nodular melanoma. Breslow depth 11.5 mm with ulceration associated with 45% 5-yr survival (stage IIc).

homogeneous populations for clinical trials. The guidelines for management of melanoma continue to rapidly evolve owing to a wealth of new knowledge and research. Tumor thickness as measured in millimeters is termed the Breslow depth and is the single most important independent factor of the primary lesion that determines treatment, follow-up, and prognosis. The presence or absence of ulceration in the primary lesion is also an independent prognostic and staging factor. The American Joint Committee on Cancer (AJCC) uses a five-stage system that is based on classifying melanoma according to tumor thickness (T), nodal status (N), and metastatic disease (M). Five stages exist, which correlate with prognosis: stage 0 (in situ melanoma), stage I (local disease), stage II (local disease), stage III (regional nodal disease, satellitosis or in-transit metastases), and stage IV (distant metastases). Distant metastasis portends a poorer prognosis. Melanoma metastasizes most frequently to the skin, subcutaneous tissue, and lymph nodes. Visceral metastases manifest most commonly in the lungs, liver, brain, bone, and intestines but may occur in any organ. A thorough description of the current TNM classification and melanoma staging system is found in a seminal article referenced: Balch M, Buzaid AC, Soong SJ, et al. Final version of the American Joint Committee on Cancer Staging System for Cutaneous Melanoma. *J Clin Oncol.* 2001;19:3635–3648.

### Microstaging

The most important histologic prognostic factor of melanoma is the Breslow depth of the primary tumor. Breslow depth is the measured thickness (in millimeters) of the primary tumor from the top of the granular layer (the uppermost layer of the epidermis) to the base of the tumor. As above, the presence of ulceration is also an independent prognostic factor. Breslow depth and the presence or absence of ulceration often determines work-up, treatment, and prognosis. Poorer prognosis generally correlates with deeper Breslow depth and the presence of ulceration. Five-year survival rate range from greater than 95% for those diagnosed with melanoma less than 1.00 mm thick with no ulceration to 45% for those with melanoma greater than 4.00 mm thick with ulceration.

The status of the regional lymph node basin is the most powerful predictor of overall survival. For those with nodal metastasis, the tumor burden (both microscopic vs. macroscopic disease and the

number of involved lymph nodes) has an inverse correlation with survival. The 5-year survival rate for patients with involved lymph nodes ranges from 25% to 70% based primarily on tumor burden and ulceration status of the primary lesion. The use of sentinel lymph node biopsy (SLNB) for melanoma deeper than 1.0 mm in Breslow depth or 0.75 to 1.0 mm with other adverse features can identify patients with micrometastatic nodal disease who have a favorable prognosis compared to those with macroscopic nodal involvement. The lymph node status and tumor burden based on SLNB is incorporated into the current AJCC staging system. A thorough description of prognosis based on Breslow depth and other prognostic factors is found in a seminal article referenced: Balch M, Soong SJ, Gershenwald JE, et al. Prognostic factors analysis of 17600 melanoma patients: validation of the American Joint Committee on Cancer Melanoma Staging System. *J Clin Oncol.* 2001;19:3622–3634.

## Treatment of Melanoma

### Biopsy

The primary lesion of melanoma can vary in depth, and prognosis is based on the deepest measured area of invasion. Therefore, a full-thickness excision with narrow margins oriented parallel to the lines of lymphatic drainage is the preferred method to evaluate a suspicious pigmented lesion with the goal being to provide the pathologist a complete specimen for histologic interpretation and accurate microstaging. A superficial shave biopsy is never recommended for a lesion suspicious for melanoma, because if the melanoma is transected, the ability to obtain an accurate measurement of tumor thickness may be lost. Performing a wide excision with 0.5 cm margins or greater as the initial step is similarly discouraged as it may result in the inability to accurately perform a subsequent SLNB. For suspicious lesions too large for complete excision, a full-thickness incisional biopsy deep enough to avoid transecting the lesion at the deep margin may be performed using an ellipse, deep saucerization shave, or punch. Incisional biopsies of melanoma do not increase the risk of metastasis. Formalin-fixed, paraffin-embedded, permanent sections are required for accurate microstaging and diagnosis of the primary lesion. The biopsy should be interpreted by a dermatopathologist with experience in melanocytic lesions. Frozen sections and fine-needle aspiration have no role in the diagnosis of primary cutaneous melanoma, but can be useful in the diagnosis of metastatic disease in palpable nodules found in the nodal basin or soft tissues.

In the case of recently diagnosed melanoma and in the presence of an unremarkable history and physical examination, the National Comprehensive Cancer Network (<http://www.nccn.org/>) in 2007 recommends (1) no routine tests for local disease <1 mm Breslow depth, (2) no routine tests versus optional CXR and serum LDH plus SLNB (if indicated to follow) for local disease  $\geq 1$  mm, and (3) CXR, LDH, pelvic CT if groin nodes involved versus CT chest/abdomen/pelvis and MRI head for regional disease. Work-up for stage IV disseminated melanoma is often dictated by clinical trial protocols. Significant emotional distress of many patients with melanoma occurs, regardless of disease stage. Thus, access to psychoncology services is an important aspect of the overall management in the patient with melanoma.

### Surgical Excision of the Primary Tumor

Surgical excision of the primary tumor is the standard therapy for melanoma to prevent local recurrence caused by persistent disease.

For melanoma in situ, excision margins of 0.5 to 1 cm are indicated. For invasive melanoma, excision with margins of 1 cm for melanoma  $\leq 1$  mm thick, 1 to 2 cm for those 1 to 2 mm thick, and 2 cm for those  $>2$  mm thick is indicated for local control. For the clinically ill-defined lentigo maligna melanoma, these standard margin recommendations may be inadequate because of potentially extensive (up to several centimeters) subclinical extension. Histological confirmation of negative margins is necessary for complete surgical resection of lentigo maligna melanoma, preferably using permanent section processing.

## Regional Node Management

**Sentinel Lymph Node Biopsy.** The concept of SLNB is based on the hypothesis that in some patients melanoma involvement of a nodal basin develops in an orderly fashion with metastasis to the SLN as the first step in the metastatic process. With the intradermal injection of lymphatic tracers such as blue dye (Lymphazurin) and/or a radiolabeled colloid solution, the first draining node from the primary lesion site, the sentinel lymph node, can be identified and used to accurately stage the entire nodal basin. The technique of SLNB is most often performed in conjunction with the wide excision of the primary tumor and is routinely performed as an outpatient procedure. If the SLN is negative for melanoma, the remaining lymph nodes are free of involvement in  $>96\%$  of cases, the prognosis is more favorable and observation is indicated. If the SLNB is positive for melanoma, regional therapeutic lymphadenectomy is indicated based on potential survival and clinical benefit.

Patients without clinical evidence of metastasis with primary melanoma  $\geq 1$  mm in thickness should be counselled for SLNB. For some subgroups with melanoma Breslow depth 0.75 to 1.0 mm including young patients, evidence of ulceration, extensive dermal regression to 1.0 mm, or  $\geq 1.0$  mitosis/mm<sup>2</sup> in young patients, SLNB may also be considered. The rate of SLNB positivity in patients with melanoma  $>1$  mm is approximately 15% with the rate positivity increasing with Breslow depth. Reasons not to perform SLNB include a low risk of regional nodal metastasis, significant medical comorbidities, wide excision already performed in ambiguous draining areas, or the patient does not desire SLNB after an informed discussion.

SLN status is the most powerful independent factor predicting survival and provides the highest sensitivity and specificity of any nodal staging test available in 2007. Additionally, SLNB followed by immediate complete lymphadenectomy may result in improved regional control compared to delayed complete lymphadenectomy after clinical evidence of nodal disease occurs. No definitive evidence exists that a positive SLNB followed by immediate complete lymph node dissection improves overall survival in patients with melanoma. However, interim evidence suggests a potential subset survival benefit of approximately 20% at 7 years. This interim evidence suggests that in a subset of patients with occult SLN metastasis, immediate complete lymphadenectomy prolongs disease-free survival compared with delayed complete lymphadenectomy when nodal metastasis becomes clinically evident.

**Lymphadenectomy Indications.** Therapeutic complete lymphadenectomy of metastases to regional lymph nodes is potentially curative. The 5-year survival rate for patients who undergo therapeutic lymphadenectomy for nodal disease ranges from 25% to 70% and correlates with tumor burden. In addition, for those patients

not cured by lymphadenectomy, complete lymphadenectomy can still be beneficial by preventing potential painful uncontrolled nodal disease. After surgical resection of regional nodal disease in the absence of known distant metastasis, high-dose protocol interferon- $\alpha$ 2b (IFN- $\alpha$ ) is the only adjuvant treatment that has demonstrated a modest benefit in disease-free survival. IFN- $\alpha$  is associated with significant side effects, and many patients are thus not good candidates. Clinical trials involving investigational drugs, often versus IFN- $\alpha$  are available.

### Treatment of Disseminated Melanoma (Stage IV)

Cure for Stage IV melanoma is rare. Dacarbazine is the main, single-agent chemotherapeutic drug for treatment of disseminated melanoma with response rates in the range of 10% to 20%. Complete responses are rare and usually brief, often less than 6 months. Combination chemotherapy with multiple agents has been used, but unfortunately with results not significantly better than single-agent dacarbazine. Systemic interleukin-2 (IL-2) may result in a 15% to 20% response rate, but is associated with high toxicity and is thus often used in otherwise relatively young and healthy patients with advanced melanoma. Approximately 5% of patients have a complete response, which may be durable for a prolonged period of time. Several immunotherapeutic trials exist for disseminated metastatic melanoma in select patients. Trials with adoptive immunotherapy, dendritic cells, and vaccines with and without the concomitant use of IL-2 and chemotherapeutic agents, gene therapy, and combinations of IL-2 and/or IFN- $\alpha$  with chemotherapy (biochemotherapy) are ongoing. RT may be used for palliation of bone pain secondary to metastatic disease or brain metastasis but has little role in the treatment of primary melanoma. Surgical resection of metastatic melanoma may be useful for palliation in patients with isolated recurrences in the skin, brain, lung, and gastrointestinal tract. Isolated hyperthermic limb perfusion of chemotherapeutic agents may be considered in a small subgroup of patients with nonresectable subcutaneous or skin metastases confined to a lower limb.

## OTHER CUTANEOUS TUMORS

There are a number of less-common cutaneous tumors that are beyond the scope of this chapter. The reader is referred to a standard dermatology text for discussion of the following:

- Merkel cell carcinoma
- Cutaneous T-cell and B-cell lymphoma
- Histiocytic tumors
- Mast cell tumors
- Malignant adnexal tumors (hair follicle origin—malignant proliferating tricholemmal tumor, tricholemmoma carcinoma, malignant pilomatrixoma; eccrine gland origin—malignant eccrine poroma, hidradenocarcinoma, malignant chondroid syringoma, malignant spiradenoma, malignant cylindroma, eccrine ductal

carcinoma, mucoepidermoid carcinoma, microcystic adnexal carcinoma, eccrine epithelioma, adenoid cystic carcinoma, mucinous carcinoma, aggressive digital papillary adenocarcinoma; apocrine gland origin—extramammary Paget disease, apocrine adenocarcinoma; sebaceous gland origin—sebaceous epithelioma, sebaceous carcinoma)

- Cutaneous sarcoma—fibrosarcoma, malignant fibrous histiocytoma, dermatofibrosarcoma protuberans, liposarcoma, synovial sarcoma, leiomyosarcoma, rhabdomyosarcoma, malignant nerve sheath tumor, angiosarcoma, lymphangiosarcoma, malignant hemangiopericytoma, Kaposi sarcoma, alveolar soft part sarcoma, epithelioid sarcoma of Enzinger, clear cell sarcoma of tendons and aponeuroses, extraskeletal osteosarcoma, extraskeletal chondrosarcoma
- Metastatic cancer to the skin

# Aging of the Hematopoietic System

*Gurkamal S. Chatta* ■ *David A. Lipschitz*

## INTRODUCTION

Aging of the lymphohematopoietic system often manifests as a blunted response to hematopoietic stress and is thought to be associated with an increased incidence of neoplasia, autoimmune diseases, and infections in elderly people. Although the physiological basis of this suboptimal response remains unclear, our understanding of human hematopoiesis has increased exponentially over the last two decades. However, most of the initial breakthroughs, as well as the seminal findings in the biology of hematopoiesis, have occurred in murine models. This review will discuss (1) the biology of hematopoiesis, (2) age-related changes in lymphohematopoiesis, and (3) indications for the use of hematopoietic growth factors in elderly patients.

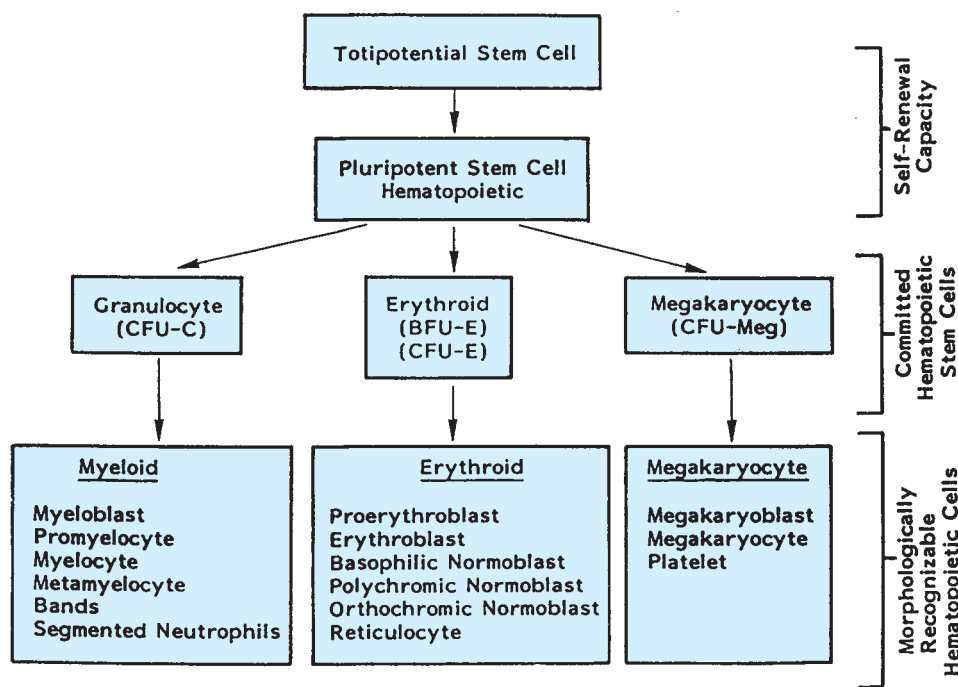

## BIOLOGY OF HEMATOPOIESIS

The hematopoietic system derives from a small pool of hematopoietic stem cells (HSCs), which can either self-renew or differentiate along one of several lineages to form mature leukocytes, erythrocytes, or platelets. HSCs differentiate into mature cells through an intermediate set of committed progenitors and precursors, each with decreasing self-renewal potential and increasing lineage commitment. Hematopoiesis is tightly regulated by a complex series of interactions between HSCs, their stromal microenvironment, and diffusible regulatory molecules (hematopoietic growth factors) that effect cellular proliferation. The orderly development of the hematopoietic system *in vivo* and the maintenance of homeostasis require that a strict balance be maintained between self-renewal, differentiation, maturation, and cell loss.

## Murine Hematopoiesis

HSCs cannot be directly observed, but are defined and identified by their ability to reconstitute and maintain hematopoiesis. The earliest morphologically recognizable cells of the myeloid and erythroid series are the myeloblasts and proerythroblasts (Figure 101-1). These cells are derived from morphologically unrecognizable progenitors that were first identified by *in vitro* culture techniques. There are two forms of erythroid progenitors: a more primitive precursor referred to as a burst-forming unit–erythroid (BFU-E), and a more mature progenitor referred to as the colony-forming unit–erythroid (CFU-E). A committed myeloid progenitor, also known as colony-forming unit–granulocyte/macrophage (CFU-GM), is the immediate precursor of the myeloblast. The committed progenitor cell compartments are supplied, in turn, by a common pluripotent stem cell, which has the capacity to differentiate into either hematopoietic or lymphoid cells. Figure 101-1 shows the hierarchy of cellular proliferation and differentiation in this pathway. The pluripotent HSC is called a colony-forming unit–spleen (CFU-S) by virtue of its ability (1) to produce colonies in spleens of lethally irradiated mice and (2) to repopulate the marrow of lethally irradiated recipients. There is evidence that the number of CFU-S in cell cycle is minimal, but that cycling can be greatly increased if demands for regeneration are increased. The CFU-S has a heterogeneous self-renewal capacity whereby an uncommitted CFU-S with high self-renewal capacity produces more committed CFU-S with decreasing self-renewal capacity and increasing differentiation potential.

Modern multichannel flow cytometry together with the availability of antibodies for different progenitor cell surface markers has validated the above findings, by allowing the identification of distinct progenitor cell populations with variable potential for hematopoietic reconstitution in lethally irradiated recipients. All HSC activity

**FIGURE 101-1.** The hierarchy and production of hematopoietic precursors from primitive pluripotent stem cells.

in many strains of mice is contained within a minor bone marrow population with a cell surface phenotype of *c-kit* positive (K), lineage negative (L), and Sca-1 positive (S), also known as the KLS cell fraction. However, only 1 in 30 KLS cells have true stem cell function. Two additional murine bone marrow markers, *flk 2* and murine CD34, have also been identified. Thus, the KLS, *flk2*<sup>-</sup>, CD34<sup>-</sup> cells are the only cells within the KLS fraction, which possess long-term multilineage reconstituting HSC ability and are also known as the long-term repopulating stem cells or the LT-HSC. The KLS, *flk2*<sup>+</sup>, CD34<sup>+</sup> cell fraction has limited repopulation potential and is known as the ST-HSC.

### Effect of Age on CFU-S and LT-HSC

A major question with regard to the aging hematopoietic system is whether or not the pluripotent HSC has a finite replicative capacity. Studies of long-term bone marrow culture show that maintenance of hematopoiesis varies inversely with the age of the donor from which the culture was initiated. Additional studies using serial transplantation, whereby HSCs are subjected to *in vivo* serial transfer into recipient animals in which hematopoiesis has been ablated, also reveal a gradual loss in the ability to self-replicate. Thus, CFU-S from young donors is better able to repopulate the marrow of irradiated mice than CFU-S from old donors. A finite replicative capacity of the HSC was also found in an *in vivo* mouse model. Although finite, the lifespan of HSCs is thought to be well in excess of the potential lifespan of a species.

With the ability to detect stage-specific membrane markers, it is now possible to distinguish between long-term (LT) and short-term (ST) HSCs, and thus more accurately dissect the changes in the subtypes of CFU-S with age. Isolated bone marrow cells bearing the phenotype of LT-HSC and ST-HSC demonstrate a fivefold increase in the frequency of cells with the stem cell phenotype from older mice. However, their functional capacity was only a quarter of that seen with these cells from younger mice. The impact of aging on the

lineage potential of stem cells has now been studied by transplanting limited numbers of purified LT-HSC from young and old mice into young congenic recipients, followed by analysis of donor cell contribution to B-cell, T-cell, and myeloid cell lineages at multiple time points posttransplant. These studies demonstrated that total donor reconstitution was consistently diminished in mice transplanted with old HSC. Furthermore, it was also noted that LT-HSCs from old mice had an increased propensity for myeloid differentiation and were deficient in generating mature lymphocytes. This skewed pattern of myeloid-lymphoid differentiation was not influenced by the aging marrow microenvironment, and was primarily thought to be an inherent attribute of the aging LT-HSC. Furthermore, in a murine model of chronic myeloid leukemia (CML), older animals with CML primarily developed a myeloid disorder with rare lymphoid involvement, as opposed to involvement of both myeloid and lymphoid lineages in younger animals with CML. Thus, it has been postulated that the myeloid dominance of adult leukemia may in part be driven by age-related deficient lymphopoiesis. Gene expression analysis of aging LT-HSCs supports this hypothesis by revealing (1) a 2- to 12-fold down-regulation of lymphoid lineage genes, (2) a two- to sixfold up-regulation of myeloid genes, and (3) a two- to fivefold up-regulation of leukemic proto-oncogenes like *Aml 1*, *Pml*, and *Eto*. In all, more than 700 genes were found to be differentially regulated with aging in the LT-HSCs, with genes involved in inflammatory and stress responses being up-regulated, and genes regulating chromatin remodelling and DNA repair being down-regulated.

### Effect of Aging on Bone Marrow Function

The effect of age on committed HSC number and on the number of differentiated hematopoietic bone marrow cells has also been examined. In mice, no age-related reduction in the number of erythroid (BFU-E, CFU-E) or myeloid/macrophage (CFU-GM) progenitor cells occurs. Red blood cell survival is unchanged with aging, the plasma iron turnover and erythron iron turnover are unchanged,

and the red blood cell mass is normal. The apparent anemia frequently observed in aged mice appears to be caused by an expansion of plasma volume. These findings and those of others indicate that no change in basal hematopoiesis occurs with aging. However, the ability of the aged hematopoietic system to respond to increased demands appears to be compromised. For example, older mice recover their hemoglobin values more slowly after phlebotomy than do young mice. Furthermore, when aged animals are placed in a high-altitude chamber, the expected increase in hemoglobin level is more variable and tends to be lower in older, as compared with younger, animals. Similar observations have also been made for the myeloid lineage, whereby bacterially challenged older mice undergo myeloid exhaustion earlier than younger mice.

The fragility of the aged hematopoietic system is further highlighted by studies on mice approaching their maximal life expectancy. When 48-month-old C57 BL/6 mice were housed in individual cages (one animal per cage), no change in hematopoiesis was seen. If, however, they were housed in groups of five animals per cage, the animals became more anemic and the number of stem cells in their bone marrow decreased. Thus, a suboptimal response in the face of stimulus-driven hematopoiesis and a failure to maintain homeostasis is a central characteristic of the aging hematopoietic system.

The mechanism/s responsible for the decline in HSC function remain unclear. Recently, accumulated DNA damage has been proposed as the principal and unifying mechanism underlying age-dependent HSC decline. HSC reserves and function with age in mice deficient in several genomic maintenance pathways including nucleotide excision repair (XPD<sup>TTD</sup> mice), telomere maintenance (mTR<sup>-/-</sup> mice) and nonhomologous end-joining (Ku80<sup>-/-</sup> mice) have been studied. None of the knock-out mice had a diminution either in HSC number or stem cell frequency. However, HSC functional capacity was severely affected under conditions of stress, leading to loss of reconstitution and proliferative potential, diminished self-renewal, increased apoptosis and, ultimately, functional exhaustion. Furthermore, endogenous DNA damage was noted to accumulate with age in wild-type HSCs. These data were thought to be consistent with DNA damage accrual being a physiological mechanism of stem cell aging that may contribute to the diminished capacity of aged tissues to return to homeostasis after exposure to acute stress or injury. Efforts are also underway to dissect the molecular mechanisms of HSC senescence. Analyses of cell cycle genes have implicated reciprocal roles for the cycle-dependent kinase inhibitors p21 and p18 in HSC function, with a deletion of p21 accelerating hematopoietic exhaustion and a deletion of p18 improving the engraftment potential of LT-HSC in serial transplantation experiments in mice.

## THE EFFECT OF AGE ON HEMATOPOIESIS IN HUMANS

### Normal Hematopoiesis

The human hematopoietic system derives from a small pool of stem cells that can either self-renew or differentiate along one of several lineages to form mature leukocytes, erythrocytes, or platelets. Marrow progenitors can be enriched on the basis of surface markers expressed at sequential stages of maturation. With respect to the myeloid lin-

age, the relevant surface markers are CD33 and CD34. CD33 is found on most cells of the myeloid lineage in the marrow, and CD34 is expressed only by more primitive progenitors (1% to 4% of the marrow cells). Thus, precursors of myeloid colony-forming cells (pre-CFC) express CD34 and lack expression of CD33 and other antigens expressed by mature lymphoid and myeloid cells. Since CD34<sup>+</sup> marrow cells can engraft and reconstitute hematopoiesis in lethally irradiated baboons and humans, surface expression of CD34 on marrow and circulating cells serves as a surrogate for stem cell function.

Proliferation and differentiation of progenitor cells to become mature blood cells requires intimate contact between stem cells, stromal cells, and the extracellular matrix, and is thought to be mediated by the hematopoietic growth factors (HGFs). The HGFs are produced by multiple cell types and, on the basis of their actions, are characterized either as multilineage hematopoietins, e.g., stem cell factor (SCF), or mast cell growth factor (MGF), interleukin-3 (IL-3), and granulocyte-macrophage colony-stimulating factor (GM-CSF); or as lineage restricted hematopoietins, for example, granulocyte colony-stimulating factor (G-CSF), macrophage colony-stimulating factor (M-CSF), erythropoietin (EPO), thrombopoietin (TPO), and T-cell growth factor (IL-2). In addition to the above growth factors, lymphohematopoiesis is also modulated by an ever-expanding list of other cytokines (Table 101-1). These are produced by diverse cell types, have wide-ranging biological effects, and participate in a variety of cellular responses. Currently, G-CSF, GM-CSF, EPO, and IL-2 are in common clinical use.

G-CSF is a 24kD glycoprotein promoting the growth and maturation of myeloid cells and in particular, the proliferation and differentiation of neutrophil progenitors both in vitro and in vivo. There are two recombinant forms of G-CSF currently available.

**TABLE 101-1**

### Cytokines Modulating Hematopoiesis

LYMPHOKINE	MAJOR BIOLOGICAL PROPERTIES
IL-1	Activates resting T-cells; induces fever; activates endothelial cells and macrophages
IL-2	Growth factor for activated T-cells; synthesis of other lymphokines
IL-3	Supports growth of multilineage bone marrow stem cells
IL-6	B-cell growth factor
IL-7	B-cell and T-cell growth factor
IL-12	Differentiation of naive CD4 T cells to the Th1 subset
Stem cell factor (SCF)	Promotes proliferation of primitive progenitors
Granulocyte-macrophage colony-stimulating factor (GM-CSF)	Promotes growth of neutrophilic, eosinophilic and macrophage cell lineages
Granulocyte CSF (G-CSF)	Promotes growth of neutrophilic cells
Macrophage CSF (M-CSF)	Promotes growth of monocytes and macrophage
Erythropoietin (EPO)	Promotes growth of erythroid cells
Thrombopoietin (TPO)	Stimulates megakaryocyte and platelet production

CSF, colony-stimulating factor; IL, interleukin.

Filgrastim (Neupogen<sup>®</sup>) is a nonglycosylated, smaller molecule than its endogenous counterpart, but has the same biological activity. Pegfilgrastim (Neulasta<sup>®</sup>) is pegylated formulation of G-CSF, allowing for an increased plasma half-life permitting once a chemotherapy cycle (every 14 to 21 days) administration as opposed to daily administration with nonpegylated G-CSF. Pegfilgrastim has shown a comparable safety and efficacy profile to filgrastim in three randomized clinical trials. Phase III studies established the safety and efficacy of recombinant human (rh) G-CSF in ameliorating chemotherapy-related neutropenia in cancer patients and for the treatment of severe chronic neutropenia. G-CSF is also routinely used for the purposes of mobilizing peripheral blood stem cells (PBSCs). Its role in the treatment of acute leukemia and myelodysplasia is controversial. It is usually administered subcutaneously, is well tolerated, and other than medullary bone pain and a skin rash at the site of injection, no significant side effects have been reported.

*GM-CSF* is a glycosylated 22-kDa peptide that has a broader range of cellular targets than G-CSF. The two forms of recombinant human GM-CSF currently in use are sargramostim (Leukine<sup>®</sup>), and molgramostim (nonglycosylated or *E coli*-derived). The effects of GM-CSF both in causing neutrophilia and in mobilizing PBSC are very similar to those of G-CSF. GM-CSF was first reported to enhance marrow recovery in the setting of autologous marrow transplantation for lymphoid malignancies. Currently, GM-CSF is approved for use in AML in elderly patients. The use of GM-CSF as a vaccine adjuvant, in particular its ability to recruit dendritic cells to the site of injection, is under investigation. Because of its wider spectrum of biological effects, GM-CSF has more systemic toxicity and at high dosage levels, the capillary leak syndrome is a particular concern.

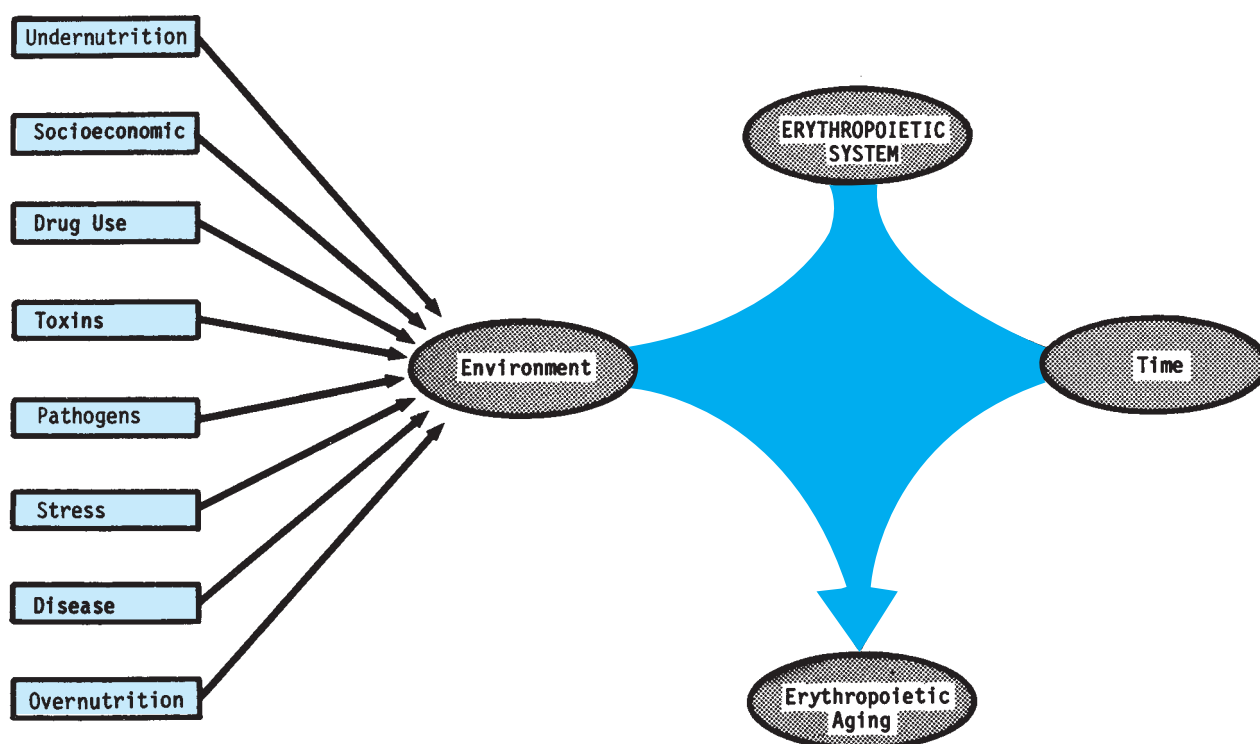

*EPO* is a 34- to 39-kDa glycoprotein that selectively acts on the erythroid lineage. *EPO* has been in clinical use since 1985 for pa-

tients with end-stage renal disease. Erythropoiesis can be stimulated by the exogenous administration of two FDA approved agents: the recombinant human erythropoietin (Epogen<sup>®</sup> or Procrit<sup>®</sup>), and darbepoetin alfa (Aranesp<sup>®</sup>). The latter is more heavily glycosylated and longer acting than the former. *EPO* is also widely used for the treatment of cancer-related anemia. The target hemoglobin is typically 11 g%, with there being continued controversy as to whether higher levels are desirable or detrimental. *EPO* is well tolerated and most of its side effects, that is, thromboembolic phenomena, have been described in the setting of dialysis.

### Age-Related Changes in Lymphohematopoiesis

The evaluation of hematopoiesis in older humans is made exceedingly difficult by the complex interaction of environmental variables with the host over extended periods of time. Figure 101-2 illustrates the large number of factors that may modulate erythropoietic function in elderly subjects.

An extensive study performed on a group of carefully selected, hematologically normal (Table 101-2) healthy young and elderly subjects revealed no significant differences in peripheral blood or ferrokinetic data. Furthermore, quantitation of marrow progenitors and differentiated precursors demonstrated no significant differences between the young and the elderly group. A series of longitudinal studies of hematological parameters on a group of affluent subjects in New Mexico also demonstrated no obvious hematologic problem, and no abnormalities developed during a 3-year follow-up. Based upon these observations and the animal studies described above, the aging process is thought to primarily affect stimulus-driven hematopoiesis, with little or no impact on the basal state. The blunted hematopoietic response to stress has been ascribed to age-related deficits in marrow progenitor cell numbers, changes in

**FIGURE 101-2.** External variables likely to modify age-related decrements in erythropoiesis.

TABLE 101-2

## Hematological Profile in Young and Elderly Hematologically Normal Subjects

	YOUNG	ELDERLY
Age (yrs)	34 ± 2.0*	78 ± 2.0
Hemoglobin (g/dL)	15 ± 0.3	15 ± 0.2
Mean corpuscular volume (fl)	89 ± 0.9	91 ± 1.8
Serum iron (μg/dL)	107 ± 8.1	93 ± 5.0
TIBC (μg/dL)	297 ± 10	307 ± 13
Saturation (%)	36 ± 3.0	30 ± 2.2
Serum ferritin (ng/mL)	126 ± 17	219 ± 26
Proto:heme (μmol/mol)	24 ± 1.4	22 ± 1.8
Vitamin B-12 (μg/mL)	476 ± 34	451 ± 34
Serum folate (ng/mL)	5.6 ± 0.8	4.8 ± 0.5
Retic index	1.1 ± 0.3	1.0 ± 0.2
Leukocyte (× 10 <sup>3</sup> /μL)	8.8 ± 0.4	7.6 ± 0.5
Neutrophils (× 10 <sup>3</sup> /μL)	5.9 ± 0.3	4.5 ± 0.6
Lymphocyte (× 10 <sup>3</sup> /μL)	1.9 ± 0.8	1.9 ± 0.3
Platelet (× 10 <sup>3</sup> /μL)	361 ± 38	277 ± 2.1
EIT <sup>†</sup>	0.5 ± 0.1	0.5 ± 0.1
Total myeloid precursors (× 10 <sup>9</sup> cells/kg)	38 ± 16	40 ± 15
CFU-C (× 10 <sup>6</sup> /kg)	0.9 ± 0.3	0.7 ± 0.2

\*Mean ± SE.

†Erythron iron turnover (ng/dL whole blood per day).

Data from Lipschitz DA, Nutrition, aging, and the immunohematopoietic system. *Clin Geriatr Med.* 1987;3(2):p319–28.

the marrow microenvironment, decreased production of regulatory growth factors, or a combination of these mechanisms. However, in a number of areas, the data are conflicting. This is partly a result of the tremendous heterogeneity of the aging process and partly a result of the difficulty in separating the effects of age per se from the effects of occult diseases. The effects of age on lymphohematopoiesis are summarized in the following sections.

## Myeloid Lineage

### Hematopoietic Progenitors

Studies on marrow hematopoietic progenitors report increased, decreased, and no change in colony numbers in aging humans. When isolated marrow CD34+ cells from the young and elderly persons were assayed in culture, similar proportions of committed marrow progenitors, that is, CD34+ marrow cells, were found in the two groups. However, “in vitro” colony formation by marrow CD34+ cells from elderly individuals required a twofold higher concentration of G-CSF to induce equivalent levels of colony formation as cells from young people. The number of subjects evaluated in all these studies was relatively small, and at present, in humans there are no reports on the effects of age on the very primitive marrow progenitors, that is, CD34+Lin− cells. There is also little information on circulating progenitors in human aging. However, it has been reported that at least in response to G-CSF, the ability of elderly persons to mobilize peripheral blood colony-forming cells is reduced. This is of potential clinical significance, given the increasing use

of cytokine-mobilized PBSC as a part of high-dose chemotherapy protocols.

Telomere length, which is known to correlate with the replication history of somatic cells, has also been investigated in hematopoietic cells: adult CD34+ CD38<sup>lo</sup> stem cells have shorter telomeres than their counterparts from fetal liver and umbilical cord blood; blood cell telomeres of marrow transplant recipients were on average 0.4 kilobase (kb) shorter than those of their respective donors, equivalent to that seen with around 15 years of aging. This suggests that stem cells in humans probably have a finite replicative capacity, which is further attenuated in the presence of replicative stress.

**Polymorphonuclear Neutrophils.** Polymorphonuclear neutrophils (PMNs) phagocytose and kill bacteria by the generation of a series of toxic radicals and by the release of enzymes located in neutrophil granules. The process of bacterial killing is associated with a 100-fold increase in neutrophil metabolism and oxygen uptake in a reaction referred to as the respiratory burst. Thus, PMN function can be assessed by exposing PMNs to a series of chemotactic peptides or other reagents, which stimulate the respiratory burst, and evaluating oxygen metabolism in the cells. The respiratory burst activity of neutrophils from elderly individuals has been found to be decreased and the level of various neutrophil enzymes secreted during degranulation reduced. The prime defect with age appears to be a decline in the concentration of the metabolically active phosphoinositide precursors of inositol triphosphate and diacylglycerol. This defect in PMN function is not large enough to interfere with the ability of neutrophils from elderly people to phagocytose or to kill bacteria. However, this diminution in PMN reserve capacity may have clinical relevance when patients are protein-deficient. This observation maybe a partial explanation for the high prevalence of serious bacterial infections in hospitalized older individuals who are also frequently malnourished. Other studies evaluating different aspects of PMN function in aging, such as adherence, chemotaxis, phagocytosis, microbicidal capability, and response to cytokines, report that neither PMN counts nor PMN function at the level of the individual cell are altered with aging. Thus, at least in healthy elderly people, both neutrophil production and function can be upregulated to levels comparable to young adults with the exogenous administration of G-CSF.

**Monocytes and Macrophages.** Circulating monocytes are transformed into tissue macrophages and are the principal cells for processing antigens. Their number and function are not affected by the aging process. There is little information on age-related changes (if any) in the ability of dendritic cells to process and present antigens.

**Red Cells.** Although unexplained anemia is often seen in healthy elderly people, it is unclear whether baseline counts are affected with aging. However, the erythroid response to hematopoietic stress is known to be blunted in aged animals and thought to be suboptimal in elderly persons.

### Hematopoietic Growth Factors

The blunted hematopoietic response to stress has been attributed to age-related decrements in growth factor secretion, particularly by marrow stromal cells. However, in humans, available data indicate that at least with severe infections, G-CSF levels can rise to

a comparable degree in young and elderly patients. Erythropoietin levels in the anemic elderly patient are also not significantly different from young controls, but altered responsiveness of erythroid precursors has been invoked as a possible cause for the unexplained anemia in healthy elderly people. Animal data are more compelling for age-associated defects in stimulus-driven hematopoiesis—bacterially challenged, aged mice had blunted myelopoiesis when compared to younger animals challenged in a similar fashion. The production of the growth factor IL-6 has also been reported to go up with the aging process. Hence, according to one view, aging is associated with inappropriate underproduction and overproduction of different cytokines leading to a dysregulated hematopoietic state.

## Lymphoid Lineage

Most components of the immune system undergo age-related restructuring, leading to both enhanced as well as reduced function in different components. The effect of aging on cell-mediated and humoral immunity is reviewed in detail in Chapter 3 and is not included in this chapter.

## HEMATOPOIETIC GROWTH FACTORS IN ELDERLY PERSONS

There is emerging consensus that aging per se has no appreciable effect on steady state hematopoiesis. Age-related deficits tend to be subtle and are of clinical import either when present cumulatively or under conditions of hematopoietic stress. Relatively few studies have specifically addressed the use of growth factors in the elderly population. The effects of administration of growth factors in the context of cancer chemotherapy, aplastic anemia, myelodysplasia, chronic neutropenia, and anemia, and involving the use of either recombinant GM-CSF, G-CSF, or erythropoietin have been studied. When the hemoglobin level and the total neutrophil count were the end points, there was no age-related difference either in the mean time to response or in the level of absolute hematopoietic response at different doses of the growth factors.

In one prospective randomized study, the effects of rhG-CSF on the blood and marrow were evaluated in 19 young and 19 healthy elderly volunteers. When rhG-CSF was administered subcutaneously to young and healthy elderly volunteers over a 2-week period, rhG-CSF was well tolerated in both age groups, with an equivalent increase in PMN response in both groups. The increase in PMNs in blood was dose dependent, being fivefold at 30  $\mu\text{g}$  and 15-fold at 300  $\mu\text{g}$ . No age-related compromise, either in the magnitude or in the timing of the PMN response to rhG-CSF, was found. In the marrow, rhG-CSF caused expansion of the mitotic pool primarily at the promyelocyte and myelocyte stage, with no significant change in marrow myeloblasts. This finding suggests that G-CSF expands the marrow myeloid pool at or distal to the CFU-GM stage and that this portion of the myeloid pathway is well preserved in healthy elderly people. The only age-related change observed was the reduced ability of elderly people to mobilize peripheral blood CFU-GM in response to rhG-CSF. The doses of G-CSF used in this study were relatively modest (5  $\mu\text{g}/\text{kg}$ ). Hence, it is unclear whether routinely used mobilization dosages of G-CSF, that is, 10 to 30  $\mu\text{g}/\text{kg}/\text{d}$  would further accentuate or blunt differences between young and the elderly people.

**TABLE 101-3**

### Use of Growth Factors in Elderly Patients

GROWTH FACTOR	MOLECULAR WEIGHT	INDICATIONS
Granulocyte colony-stimulating factor	24 kD	Chemotherapy-related neutropenia Chronic and drug-induced neutropenia Peripheral blood stem cell transplantation ?Myelodysplasia
Erythropoietin	34–39 kD	Renal disease with anemia Anemia in cancer patients ?Myelodysplasia
Granulocyte-macrophage colony-stimulating factor	22 kD	As for G-CSF

Thus, on the basis of the available data, the indications for the use of hematopoietic growth factors in the elderly population are no different from the general population. Table 101-3 summarizes the growth factors that have special relevance for use in elderly people. Given the increased susceptibility of the elderly cancer patients to treatment-related morbidity and mortality, there may be even more compelling reason for the use of growth factors to obviate complications like bleeding and infections.

## SUMMARY

Evaluation of the effect of age on hematopoiesis at the organ or cellular level demonstrates evidence of a diminished reserve capacity. In addition to being lower, the aged response tends to be more variable. Given a comparable stress, hematological abnormalities are likely to occur earlier and to be of greater severity in elderly people as compared to the young. Age-related changes in the early stages of hematopoiesis in humans remain to be elucidated, with most of the breakthroughs in HSC biology coming from murine models. Given the inability to conduct gene knockouts or do serial transplantation experiments in larger animals, much effort has been expended on alternate experimental strategies. HSC kinetics and replication rates have been studied in small and large animals using the tracking of transgene expression after retroviral-mediated gene transfer and quantitation of the average telomere length of granulocytes. This work suggests that baboon and macaque HSCs replicate more slowly than both cat and mouse HSCs. However, the mean number of times that an HSC will replicate during a mammal's lifespan is reasonably constant across species.

There is increasing recognition that genomic instability, impaired DNA repair, and consequent genetic and epigenetic changes impact many aspects of the aging hematopoietic system. This is further underscored by the link between premature aging syndromes, defective DNA repair, and impaired HSC function. Thus, accumulated DNA damage may be a common unifying mechanism responsible for age-related declines. The availability of several new animal models of the different DNA repair pathways provides the opportunity for linking specific DNA repair pathways with either preserving or impairing stem cell function. Dissection of these pathways may also provide

targets for manipulating stem cell function to reverse age-related hematopoietic decline.

# Anemia

*Paulo H. M. Chaves*

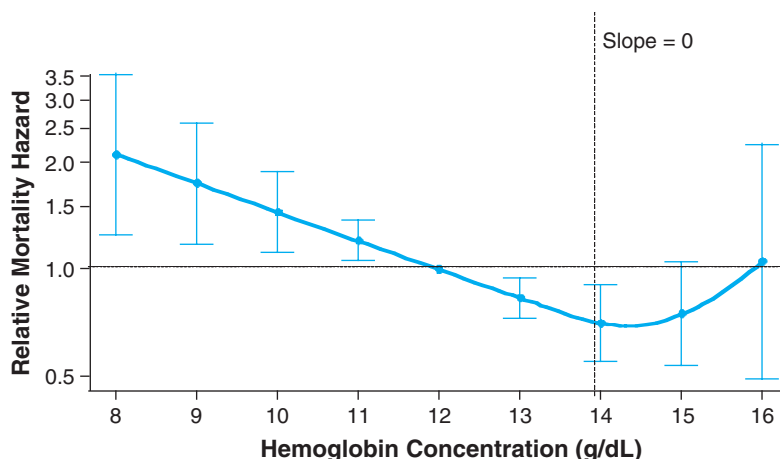

Anemia, a common clinical syndrome in older adults, has been the focus of renewed attention over the last decade, as attested by the increasing number of publications addressing its clinical epidemiology. Anemia in older persons tends to be multifactorial in origin, and is often associated with a combination of chronic medical conditions. The clinical presentation of anemia in older adults is complex, and symptoms are often insidious and nonspecific. Unless severe, anemia it is often perceived as a relatively benign condition that is either a normal accompaniment to aging and/or merely a marker of prevalent chronic diseases. However, data gathered to date have established that this may be an incorrect perception. Consistently, several studies have shown that anemia, even if mild, is a strong, independent, risk factor for major adverse outcomes in older adults, including decline in physical and cognitive function, frailty, disability, and mortality. Aside from its prognostic implication, it has been hypothesized that even nonsevere anemia could causally contribute to the occurrence of these adverse outcomes, and that anemia correction could potentially lead to improved outcomes in older adults. These hypotheses remain to be proven. Future studies, including large randomized clinical trials (RCTs), are expected to contribute key insight as to whether correction of anemia that is nonsevere in the broad older population could prevent additional morbidity and/or mortality. In this context, aiming to summarize valuable information for the health professional involved with the care of older adults, this chapter presents basic information on a number of relevant issues related to the topic of anemia in older adults, including insight regarding prevalence, associations with major adverse clinical outcomes, and potential intervention opportunities.

## DEFINITION OF ANEMIA IN OLDER ADULTS

Conceptually, anemia is a clinical syndrome caused by a reduced mass of circulating red blood cells (RBCs). In practice, anemia is often operationally defined as a decreased level in any of the following

parameters: the concentration of hemoglobin (Hb) in the whole blood; the proportion occupied by RBCs in a sample of whole blood—that is, hematocrit (Hct); and/or the number of RBCs in a standardized volume of whole blood. Often, Hb is expressed as g/dL, Hct as %, and RBC count as the number of RBCs in millions per microliter. Consistent with the literature, we will use Hb as the key parameter to define anemia in this chapter.

A widely used standard to define anemia in older adults is the one usually referred to as the World Health Organization (WHO) criteria, published in the 1968 WHO report on nutritional anemias. According to this criteria, anemia is defined as a Hb less than 12 g/dL in older women, and less than 13 g/dL in older men. This gender difference is primarily because of the differences in the distributions of Hb in older men and women. These criteria are the same as proposed earlier (1933) by Wintrobe. Lower Hb cutoffs have also been proposed for anemia definition in older adults, under the nonempirical argument that the concentration of Hb is “normally” lower in older populations. Important limitations of the methods used to define anemia in older adults should be acknowledged, however. Current criteria used to select the Hb cutoff for anemia have been derived primarily on the basis of statistical distribution considerations; i.e., the Hb cutoff used to separate subjects with and without anemia being the one corresponding to minus 2 standard deviations ( $-2$  SD) below the mean calculated in an apparently healthy, standard population. Although this constitutes a useful and traditional method for defining the lower limit of the “normal range” of a biological parameter in general, it has limitations. Apparently healthy older populations, which are often defined in terms of self-reported clinical diseases, are likely to include older adults with subclinical diseases and health status changes (e.g., inflammation, decline in kidney function, etc.). These subclinical factors may shift the Hb distribution in the whole older population to the left (toward lower values). Thus, the use of  $-2$  SD as the key criterion may result in biased, lower-than-optimal Hb cutoffs for a definition. Additionally, this statistical distribution method, which assumes a meaningful threshold difference between

**FIGURE 102-1.** Relationship between hemoglobin (Hb) concentration and 5-yr all-cause mortality in community-dwelling disabled older women (Women’s Health and Aging Study I, 1992–2000). The figure shows a graphical display of relative risk estimates for the mortality linked to specific Hb concentrations compared with the risk linked to Hb of 12 g/dL. The curve represents smoothed relative mortality hazards across Hb concentrations, and the bars indicate their 95% confidence intervals. Also indicated is the 13.9 g/dL Hb threshold at which the slope of mortality risk decline was no longer statistically significant (i.e., the 95% confidence interval for the slope of the tangent included 0). The y-axis was transformed so that, for example, the graphical display of an increase in risk of the magnitude of two (hazard ratio (HR) = 2) would be equivalent to that of a decrease in risk of the same magnitude (HR = 0.5) in terms of scale size. Risk estimates are adjusted for age, race, congestive heart failure, coronary heart disease, peripheral artery disease, stroke, pulmonary disease, cancer, estimated creatinine clearance, ankle–arm index, depression, body mass index, smoking status, education, disability performing basic activities of daily living, and number of domains with difficulty. (Chaves PHM, Xue QL, Guralnik JM, et al. What does constitute normal hemoglobin concentration in community-dwelling disabled older women? *J Am Geriatr Soc.* 2004;52(11):1811–1816. Modified, reprinted with permission.)

subjects with Hb levels below  $-2$  SD (abnormally low) versus those with Hb levels between  $-2$  SD and  $+2$  SD (“normal” range), does not take into account the direct relationship between Hb and the risk of clinically relevant outcomes. In fact, recent observational epidemiologic studies have demonstrated that Hb is related to the risk of major adverse clinical outcomes in a rather continuous, curvilinear pattern (see “Outcomes Associated with Anemia”). The observed pattern was marked by an association of highest risk of outcomes with lowest Hb levels, and a monotonically risk decrement with increasing Hb levels up to mid-normal Hb levels (Figure 102-1). Even within the “normal range,” a risk gradient was observed, with Hb levels considered per current standards as low-normal being associated with a higher risk of outcomes such as frailty, disability, and mortality, as compared to levels currently perceived as mid-normal Hb. Consistently, analysis of the relationship between Hb and serum erythropoietin in older women revealed that that serum erythropoietin levels were significantly higher at low-normal Hb, as compared to mid-normal Hb, where serum erythropoietin levels were lowest (Figure 102-2). Collectively, current evidence suggests that while the WHO criteria constitute a valid approach to define data in older adults, it may not be optimal, at least from the risk prediction perspective.

Arguments have been made in favor of the use race-specific criteria for anemia definition. This perspective is supported by a recent observational study conducted in the Health, Aging, and Body Composition Study. In that study, although concerns with residual confounding by comorbidity burden as well as with selection bias at least partially explaining study findings cannot be discarded, race was shown to be an effect modifier of the associations of WHO-defined anemia with all-cause mortality (over 6 years) as well as incident mobility disability (over 4 years); that is, anemia was associated with an increased risk of mortality and disability in white, but not in black older adults.

Finally, it should be acknowledged that what may constitute best naturally occurring levels of Hb in observational studies of older

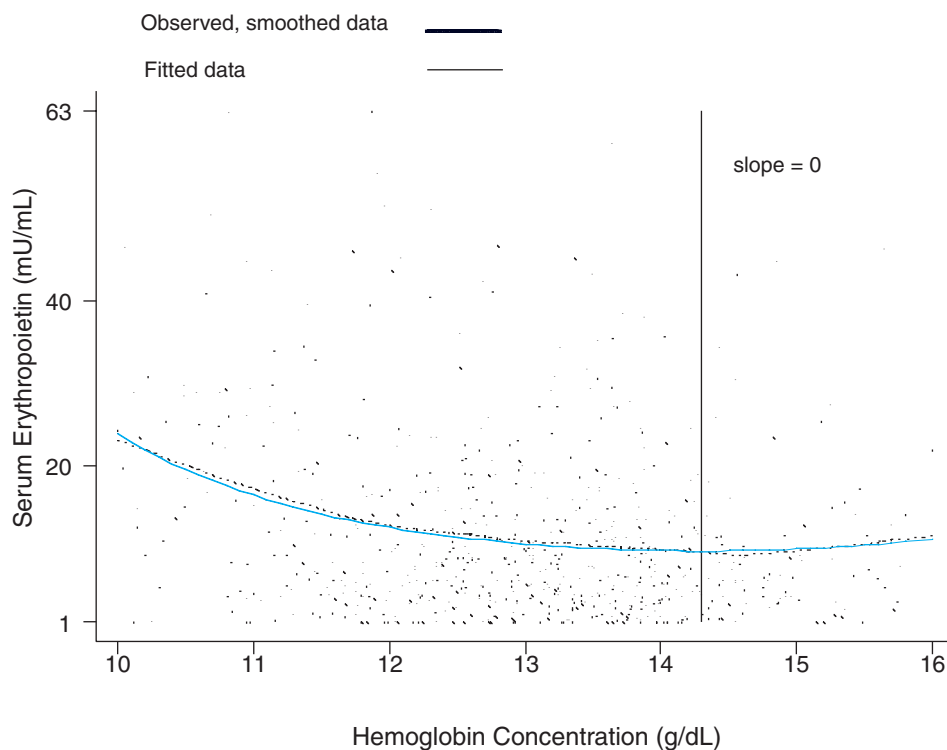

adults from a risk prediction perspective does necessarily constitute optimal levels from other clinical decision-making perspectives. In fact, major discrepancies have been reported between Hb levels linked to lowest risk of adverse outcomes in observational studies with “optimal” target Hb of recombinant erythropoietin in RCTs (see “Therapeutic Considerations”).

## PREVALENCE AND TYPES OF ANEMIA

### Prevalence

The prevalence of anemia in older adults varies according to the setting in which it is estimated. Higher prevalence estimates have been reported in long-term care facilities such as nursing homes than in the general community-dwelling older population. This difference maybe explained by the fact that, in general, anemia is associated with poorer health status. Differences in prevalence estimates within similar settings have also been reported, and maybe primarily attributed to methodological differences, such as variations in background characteristics of targeted populations, response rates, and the way anemia was defined.

A recent study reported on the prevalence of anemia in the large U.S.-representative sample of noninstitutionalized older adults who participated in the Third National Health and Nutrition Examination Survey (NHANES III, 1988–1994). In that study, the prevalence of anemia was 11% in older men and 10.2% in older women. Overall, the prevalence in the population of community-dwelling subjects 65 years and older was 10.6%. There were, nonetheless, significant differences according to age groups (Figure 102-3). In both men and women 65 years and older, the prevalence of anemia steadily increased with advancing age, being highest in the 85+ year age group. In subjects who were 65 to 74 years old, the prevalence

**FIGURE 102-2.** Graphical display of the curvilinear relationship between serum erythropoietin and hemoglobin (Hb) concentration in community-dwelling disabled older women (Women's Health and Aging Study I, 1992–1995). The slope of the tangent line to the EPO versus the Hb curve was equal to zero at the Hb threshold point of 14.3 (95% CI = 13.2–15.4). EPO at a Hb concentration of 12 g/dL was 28% greater than EPO at a Hb concentration of 13.9 g/dL (95% CI = 15–44%). Adjustment for age, race, and creatinine clearance did not change this difference estimate. Similarity between observed (smoothed) and fitted curves indicated proper model fit. (Chaves PHM, Xue QL, Guralnik JM, et al. What does constitute normal hemoglobin concentration in community-dwelling disable older women? *J Am Geriatr Soc.* 2004;52(11):1811–1816. Modified, reprinted with permission.)

of anemia was slightly higher in women than in men; however, in the age groups 75 to 84 years and 85+ years old, the prevalence of anemia was substantially higher in men than in women.

As compared to the distribution of Hb in older men, anemia in older women was shifted to the left; that is, toward lower values (Figure 102-4). Only a very small minority of anemia in community-dwelling older adults is severe, with less than 1% of the total sample having Hb levels lower than 10 g/dL (see Figure 102-4). Additionally, in that study, significant differences in the prevalence of anemia according to race and ethnicity were reported (Figure 102-5). The prevalence of anemia was lowest in non-Hispanic whites, and highest in non-Hispanic blacks. Anemia prevalence in Mexican Americans was only slightly higher than that of non-Hispanic whites.

## Types of Anemia

Anemia maybe classified in a number of different ways. A practical scheme used in the geriatrics literature involves the classification of

anemia in the following major categories: (a) nutrient deficiency, (b) anemia of chronic kidney disease (CKD), (c) anemia of chronic inflammation (ACI; previously referred to as anemia of chronic disease), and (d) unclassified (also called “unexplained” anemia). These broad categories should not be seen as exclusive, as more than one type of anemia maybe present. For example, in patients with anemia of CKD, nutrient absolute or functional nutrient deficiency, and/or chronic inflammation may also contribute to impaired erythropoiesis and anemia. Other schemes for classification of anemia exist, including ones appropriately more refined for the investigation of causes of anemia in the clinical setting (see below).

## Nutrient-deficiency Anemia

Anemia with nutrient deficiency is common. In a recent study that analyzed NHANES III data from community-dwelling adults 65 years and older, approximately one third of all causes of anemia met the study criteria for iron, folate, and/or vitamin B-12 deficiency.

**FIGURE 102-3.** Percentage of persons with anemia according to age and sex (National Health and Nutrition Examination Survey (NHANES) III, phases 1 and 2, 1988–1994). (Guralnik JM, Eisenstaedt RS, Ferrucci L, et al. Prevalence of anemia in persons 65 yrs and older in the United States: evidence for a high rate of unexplained anemia. *Blood.* 2004;104:2263–2268.)

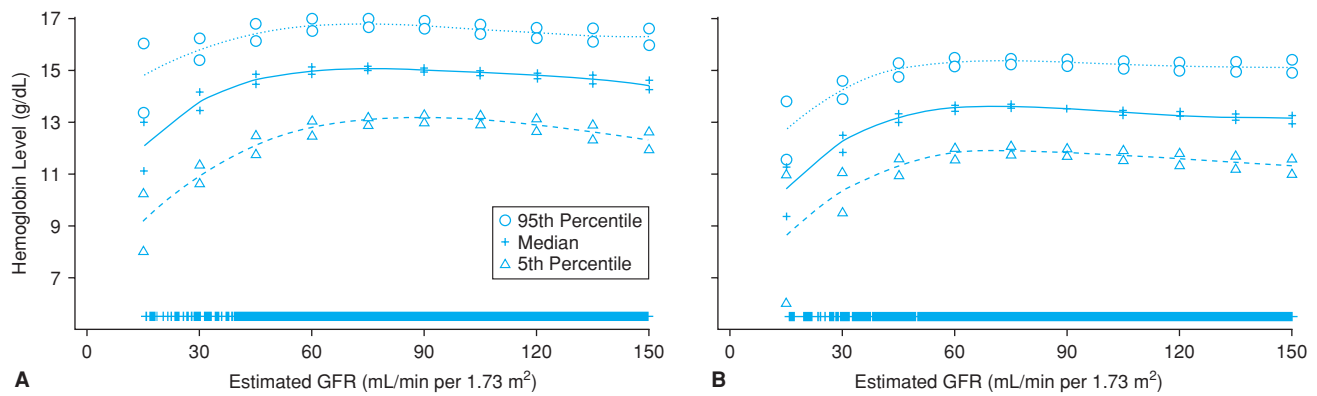

**FIGURE 102-4.** Distribution of hemoglobin in community-dwelling persons 65 yrs and older according to sex (National Health and Nutrition Examination Survey (NHANES) III, phases 1 and 2, 1988–1994). (Guralnik JM, Eisenstaedt RS, Ferrucci L, et al. Prevalence of anemia in persons 65 yrs and older in the United States: evidence for a high rate of unexplained anemia. *Blood*. 2004;104:2263–2268.)

**Anemia with Iron Deficiency** Iron deficiency is by far the most common cause of nutrient-deficient anemia. Along with protoporphyrin IX, iron is a key component of the heme complex, the nonprotein pigment of the hemoglobin molecule in RBCs that is directly involved with oxygen binding and transport. Reduced availability of iron may cause anemia through impaired Hb synthesis. Iron-deficiency anemia is usually the endpoint of a negative overall iron balance disorder that gradually progresses over time. While decreased oral iron intake as well as reduced absorption may be important contributing factors, it is believed that iron-deficiency anemia in older adults is primarily caused by chronic blood loss, in particular from the gastrointestinal (GI) tract. Iron-deficiency anemia constitutes an advanced stage of iron deficiency. The earlier stages of iron deficiency are marked by progressive depletion of iron stores. With exhaustion of iron stores, Hb synthesis becomes compromised, and results in erythropoiesis impairment. Eventu-

ally, Hb drops below specific thresholds, and anemia is diagnosed. Early in iron-deficiency anemia, anemia may be normochromic and normocytic. Increased variation in RBC size may be observed, as assessed by an increase in red cell distribution width (RDW) in automated analysis of RBCs. As the duration and severity of iron deficiency increases, overt iron-deficiency anemia ensues. At this more advanced stage, the production of microcytic (small-sized), hypochromic (with decreased Hb content) erythrocytes is characteristic. Other typical laboratory abnormalities of advanced, overt iron-deficiency anemia include low serum ferritin concentration, low serum iron concentration, increased total iron-binding capacity (TIBC), low transferrin saturation ratio (serum iron divided by TIBC), and increased levels of soluble transferrin receptor (sTfR) (see below). Complementary laboratory tests may be useful to further characterize the different stages of iron deficiency and iron-deficiency anemia.

**FIGURE 102-5.** Distribution of types of anemia in community-dwelling persons 65 yrs and older (National Health and Nutrition Examination Survey (NHANES) III, phases 1 and 2, 1988–1994). (Guralnik JM, Eisenstaedt RS, Ferrucci L, et al. Prevalence of anemia in persons 65 yrs and older in the United States: evidence for a high rate of unexplained anemia. *Blood*. 2004;104:2263–2268.)

**FIGURE 102-6.** Median and 5th and 95th percentiles of hemoglobin levels among men (A) and women (B) 20 yrs and older who participated in the Third National Health and Nutrition Examination Survey (1988–1994). All values are adjusted to the age of 60 yrs. Estimates and 95% confidence intervals are demarcated at selected levels of estimated glomerular filtration rate (GFR). Marks near the abscissa indicate the estimated GFRs of individual data points. (Astor BC, Muntner P, Levin A, et al. Association of kidney function with anemia: the Third National Health and Nutrition Examination Survey (1988–1994). *Arch Intern Med.* 2002;162(12):1401–1408, reprinted with permission.)

### Anemia with Vitamin B-12 (Cobalamin) and/or Folate Deficiency

The remaining cases of nutrient-deficiency anemia are largely caused by deficiency of folate and/or vitamin B-12. These deficiencies may impair erythrocyte maturation and proliferation through their adverse effect on DNA synthesis and result in macrocytic anemia, i.e., anemia with oversized RBCs, usually quantified as a mean corpuscular volume (MCV) greater than 100 femtoliters (fL). Analogously to iron deficiency, vitamin B-12 deficiency usually progresses across stages of severity. In its earlier stages, one is able to maintain erythropoiesis using vitamin B-12 from body stores. After, stores become depleted, erythropoiesis becomes impaired, and megaloblastic anemia ensues. Often, vitamin B-12 deficiency, as assessed by low serum vitamin B-12 levels, as well as macrocytic changes may be noted before the drop of Hb below the level in which anemia is diagnosed. Typically, other laboratory abnormalities that accompany the macrocytic anemia of vitamin B-12 deficiency include the presence of hypersegmented granulocytes on blood smears; giant platelets may also be observed. Thrombocytopenia, as well as leucopenia may also occur. Presence of iron deficiency concomitant to vitamin B-12 deficiency anemia may mask typical abnormalities of the latter. Often, vitamin B-12 deficiency anemia is caused by gastric and intestinal disorders that prevent the proper digestion of vitamin B-12, involving either impaired release of cobalamin from the ingested food and/or the absorption of free cobalamin in the GI tract. Examples of these disorders include hypochlorhydria, surgical procedures involving the stomach, atrophic gastritis (involving a deficiency in the production of intrinsic factor by parietal cells of the gastric mucosa), pancreatic insufficiency, and small bowel bacterial overgrowth. Vitamin B-12 deficiency, resulting from dietary deficiency is not common, but may occur in subjects with severe long-term avoidance to meat products, as maybe found in strict vegetarians. Folate deficiency, on the other hand, is often caused by poor nutritional intake. GI disorders result in decreased absorption of folate (e.g., hypochlorhydria associated with atrophic gastritis or acid-suppressive therapy, celiac disease) and adverse effects of drugs (e.g., alcohol, methotrexate, anticonvulsants). Like vitamin B-12 deficiency, folate deficiency typically presents as a macrocytic anemia. Laboratory tests are useful to distinguish folate- versus vitamin B-12 deficiency. The distinction is

important vis-à-vis therapeutic implications (see below). Other vitamins and trace minerals have also been hypothesized to impair erythropoiesis, and potentially contribute to the development of anemia, when other mechanisms are also present, including deficiencies in vitamins A, C, E, and pyridoxine and riboflavin (vitamin B group), as well as copper, selenium, and zinc.

**Anemia of CKD** With increasing age, the prevalence of CKD increases, kidney function declines, and the prevalence of anemia—a common complication of CKD, particularly when the latter is advanced—increases. Figure 102-6 displays data on the age-adjusted, cross-sectional relationship between renal function, as assessed by estimated glomerular filtration rate (eGFR) levels, and the continuous distribution of Hb observed in a nationally representative sample of 15 625 noninstitutionalized Americans 20 years and older. Stable Hb levels were observed across eGFR levels greater than 60 mL/min per 1.73 m<sup>2</sup>; below this threshold, lower eGFR levels were associated with progressively lower Hb levels. In another study that analyzed NHANES III data and used a strict definition for anemia of CKD, 8.2% of all cases of anemia were attributed to anemia of CKD only, and an additional 4.3% to anemia of CKD in combination with ACI (see below). The definition of anemia of CKD in that study was the following: Hb <12 g/dL in women and <13 g/dL in men, an eGFR less than 30 mL/min per 1.73 m<sup>2</sup> and no evidence of iron, folate, or vitamin B-12 deficiency. Had more sensitive eGFR cutoffs (e.g., eGFR <45 or <60 mL/min per 1.73 m<sup>2</sup>) been used to define anemia of CKD, higher prevalence estimates of this type of anemia would have been yielded. Typically, anemia of CKD is normocytic and normochromic. The primary mechanism through which CKD causes anemia is a deficiency in the production of erythropoietin, a naturally occurring erythropoiesis-stimulating hormone mainly produced by the kidneys in adults, which is secreted in response to hypoxia. The diminished renal production of erythropoietin is most noticeable in the most advanced stages of renal failure. In the failing kidney, in addition to the absolute deficiency in erythropoietin, the decline in the renal excretory function also plays a part in the pathogenesis of anemia, as it may contribute to a shortened life span of RBCs and bone marrow suppression. Other concomitant factors may also inhibit erythropoiesis in anemic subjects with CKD,

including nutrient deficiency, subsequent to blood loss, decreased oral intake, and dialysis removal, as well as increased iron utilization during therapy with erythropoiesis stimulating agents (see below). Increasing attention has been paid to the role of inflammation as a mechanistic factor in the pathogenesis of anemia in CKD patients (see below).

**Anemia of Chronic Inflammation** Traditionally, this type of anemia has been referred to as anemia of chronic disease. Recently, to more properly capture the inflammatory nature of this condition, the term anemia of chronic inflammation (ACI) started to be used. In a recent study that analyzed data from a large population-based sample of community-dwelling adults 65 years and older (NHANES III), more than 20% of all cases of anemia met the criteria for ACI. In that study, the overall prevalence of ACI (24%) was slightly higher than that attributed to anemia with iron deficiency (20%). ACI is associated with a wide variety of inflammatory conditions, including chronic infection, cancer, diabetes, rheumatoid arthritis, and congestive heart failure, and trauma. It is said that the severity of ACI and that of the underlying disease(s) are positively correlated.

Several mechanisms mediated by inflammatory cytokines have been proposed to explain ACI. The key one involves unavailability of iron for erythropoiesis despite adequate, if not elevated total iron stores, mediated by inflammation. This dysregulation of iron homeostasis results from sequestration of iron in the cells of the reticuloendothelial system, with consequent inadequate availability of iron for erythropoiesis. Interleukin-6 (IL-6), a proinflammatory cytokine, has been shown to stimulate the hepatic production of hepcidin, a polypeptide that is a major regulator of iron homeostasis. Hepcidin inhibits the release of iron from the reticuloendothelial and macrophage systems, as well as iron intestinal absorption. High levels of IL-6 have been shown to induce an increased production of hepcidin, which in turn can lead to sequestration of iron by reticuloendothelial cells, reduced amount of iron available for erythropoiesis, and, ultimately anemia. Additional mechanisms maybe involved in the pathogenesis of ACI, including the inhibition of the proliferation and differentiation of erythroid progenitor cells, which may result from inflammation-mediated induction of apoptosis of progenitor cells, and/or through a direct toxic effect of inflammation on progenitor cells. Another mechanism involves a blunted erythropoietin response, i.e., an attenuated compensatory response in erythropoietin production in relation to the degree of anemia, resulting in a relative erythropoietin deficiency. Support for this explanation include in vitro evidence of inhibition of erythropoietin production by proinflammatory cytokines, such as tumor necrosis factor alpha (TNF- $\alpha$ ) and interleukin-1, as well as evidence of lower levels of serum erythropoietin in patients with ACI as compared to patients with iron-deficiency anemia for the same level of anemia. Controversy exists though as to whether the iron-deficiency group is a proper control group, given its exacerbating impact on hypoxia homeostatic mechanisms. Shortened RBC life span may also contribute to the pathogenesis of ACI.

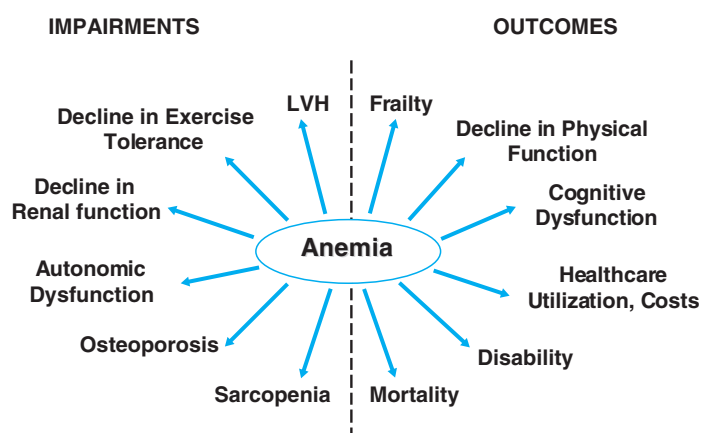

Characteristically, laboratory evaluation of ACI reveals a normochromic, normocytic anemia. As ACI progresses over time, anemia may become macrocytic. Reflecting its pathogenesis, the hallmark ACI is the presence of low serum iron along with evidence of adequate iron stores, as indicated by normal or increased levels of serum ferritin. Typically, serum transferrin levels are low, and so is the TBIC. Serum levels of sTfR, which reflects bone marrow

erythropoiesis, are usually normal or low. Concomitant presence of iron deficiency may confound the typical laboratorial findings identified above. The index calculated as the ratio of sTfR by the log of serum ferritin maybe useful for distinguishing ACI without iron deficiency, from ACI with iron deficiency, as well as iron-deficiency anemia without ACI (see below). Reflecting an improved knowledge about the pathogenesis and measurement of ACI, diagnosis of ACI is no longer a diagnosis of exclusion, but rather it is established on the basis of specific laboratory findings. The exclusion of other diagnoses now results in “unclassified” or “unexplained” anemia.

**“Unclassified” or “Unexplained” Anemia** Often, older adults have anemia that does not meet specific classification criteria. In these cases, anemia is said to be unclassified or unexplained. This occurs commonly in community-dwelling subjects. Investigators analyzing NHANES III data reported that, after excluding other possible causes of anemia according to study criteria (which used laboratory tests for classification of the type of anemia consistent with that commonly used in the clinical setting by geriatricians), about one third of all cases of anemia in community-dwelling men and women 65 years and older were “unclassified.” It is possible that a more comprehensive and repeated assessment, particularly in the case of long-duration and more severe anemia, may increase the likelihood of detection of a specific etiology. The “unclassified” group of anemia is likely a heterogeneous one; reflecting this, it has been speculated that all mechanisms listed above could play a role in the pathogenesis of “unclassified” anemia. More recently, it has been demonstrated that, as a group, unclassified anemia is marked by low levels of serum erythropoietin, and low levels of circulating proinflammatory markers.

## OUTCOMES ASSOCIATED WITH ANEMIA

Observational findings from epidemiological studies have documented that anemia is a strong and independent risk factor for major adverse clinical and public health outcomes in older adults, including mortality, frailty, decline in physical function, disability, and cognitive impairment (Figure 102-7). Additionally, studies have

**FIGURE 102-7.** Anemia, physiological impairments, and clinical outcomes. Anemia has been linked to a number of physiological impairments and clinical outcomes in community-dwelling older populations, including the ones highlighted.

shown that presence of both anemia and prevalent comorbidities are associated with a synergistically increased risk of adverse outcomes. These findings have been consistently replicated in different settings, including population- and patient-based studies involving older adults with specific diseases (e.g., CKD, cardiovascular disease, and diabetes), as well as subjects representative of the broad population of older adults living in the community. In this section, we review data on selected outcomes and discuss the nature of the documented associations.

## Mortality

The association between prevalent anemia and increased risk of mortality has been well documented by a number of large epidemiological studies of noninstitutionalized older adults. For example, in a large ( $n = 755$ ) community-based study of adults aged 85 years and older in Leiden the Netherlands, it was estimated that 5-year all-cause mortality risk was 1.84 (95% confidence interval [CI]: 1.50–2.25) times higher in those with prevalent anemia (as defined according to the WHO criteria; that is, Hb <12 g/dL in women and Hb <13 g/dL in men) as compared to those without it, after adjustment for age and gender. Additional insight was provided by a subsequent study that examined the relationship between the continuous Hb distribution and all-cause mortality risk over a median follow-up period of 5 years in 686 community-dwelling women 65 years and older with moderate-to-severe physical disability (see Figure 102-1). In the latter study, there was evidence of a reversed J-shape curve characterized by highest mortality risk at lowest Hb levels, and lowest mortality risk at mid-normal Hb levels around 13.9 g/dL; above this Hb threshold, mortality risk increased with higher Hb levels. The highest mortality risk associated with mild anemia persisted even after comprehensive adjustment for major confounders, such as demographics, comorbidity, and disease severity indicators; e.g., as compared to a Hb level of 12 g/dL, a Hb of 11 g/dL was associated with a 20% (95%CI: 10–40%) higher mortality risk in adjusted analysis. Additionally, this study also showed that a Hb of 12 g/dL, a level that is considered low-normal by WHO and current clinical practice standards, is independently associated with a significantly higher mortality risk, as well as increased serum

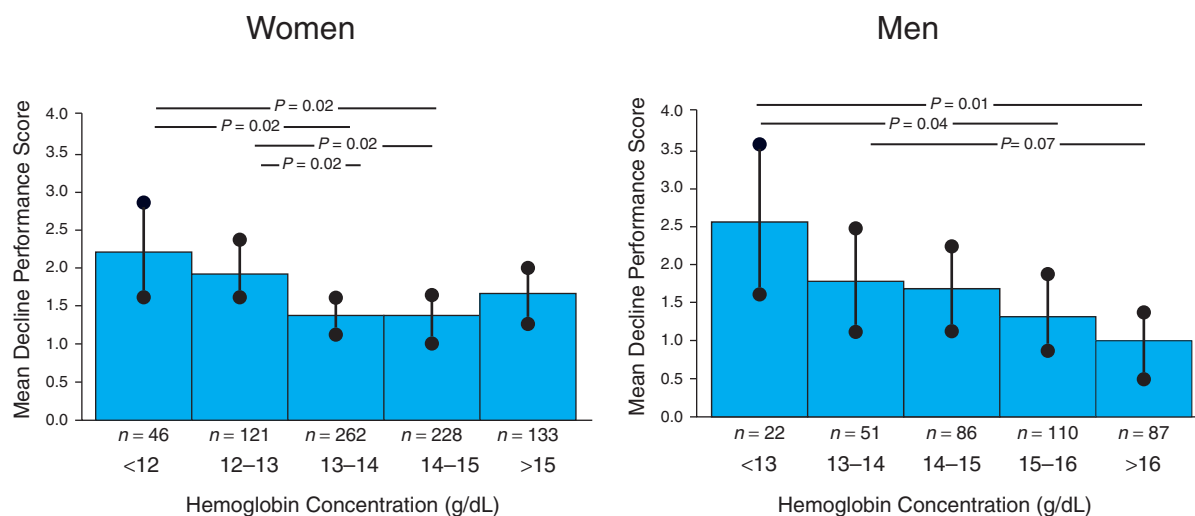

erythropoietin levels, as compared to mid-normal Hb levels such as 14 g/dL. Collectively, recently published data have consistently demonstrated that, in community-dwelling older adults, (a) WHO-defined anemia, which primarily corresponds to mild anemia, is an independent risk factor for 5-year all-cause mortality; (b) there is a dose–response in mortality risk associated with increasing anemia severity; and (c) there is a meaningful mortality risk gradient even within the Hb range currently perceived as normal. Also relevant were findings of interactions of anemia with other comorbidities—including CKD, left ventricular hypertrophy (LVH), and CVD—in regard to increased mortality risk in older patients.

## Decline in Physical Function

Aside from mortality, anemia has also been related to decline in physical function, as well as physical disability. A recent cross-sectional study evaluated the association of prevalent anemia with self-reported and objectively measured mobility function in 633 community-dwelling women aged 70 to 80 years with Hb higher than 10 g/dL (mean  $\pm$ ) participating in the Women's Health and Aging Studies (WHAS) I and II. As compared to mid-normal Hb levels such as 14 g/dL, where the likelihood of mobility disability was lowest and mobility performance was best, Hb levels corresponding to mild anemia and even low-normal Hb were associated with increased likelihood of mobility disability (defined as difficulty in walking one-quarter mile or climbing 10 steps) (Figure 102-8) and worse mobility performance (objectively assessed by the Short Physical Performance Battery (SPPB) scores, based on tests that the assessed ability to hold balance on different standing positions, the time to walk a few meters at usual pace, and the time to raise from a chair as quickly as possible five times), even after adjustment for demographics, disease, and other major health indicators. Subsequently, a prospective study conducted in 1146 older subjects (mean age  $77 \pm 5$  years; 70% female) participating in the Established Populations for Epidemiologic Study of the Elderly (EPESE) provided further insight by documenting an independent association of WHO-defined anemia with subsequent, meaningful decline in objectively measured mobility performance (as assessed by SPPB scores) over a 4 year-period both in women as well as in men

**FIGURE 102-8.** Relationship between mobility disability and hemoglobin concentration (Women's Health and Aging Studies I and II, 1992–1996). The figure shows graphical display of the probability of having mobility disability (difficulty walking one-quarter mile or climbing up 10 steps) as a function of hemoglobin concentration levels. Shown are observed, smoothed (straight line) and fitted curves (line with “+” signs). A nonlinear relationship pattern was documented, with the probability of mobility difficulty being lowest at mid-normal Hb levels around 14.0 g/dL, and highest at Hb extremes. Hypothesis testing confirmed that the likelihood of mobility difficulty was not constant between 12.0 and 16.0 g/dL of Hb ( $p < .01$ ). (Chaves PHM, Ashar B, Guralnik JM, Fried LP. Looking at the relationship between hemoglobin concentration and prevalent mobility difficulty in older women. Should the criteria currently used to define anemia in older people be reevaluated? *J Am Geriatr Soc.* 2002;50:1257–1264. Modified, reprinted with permission.)

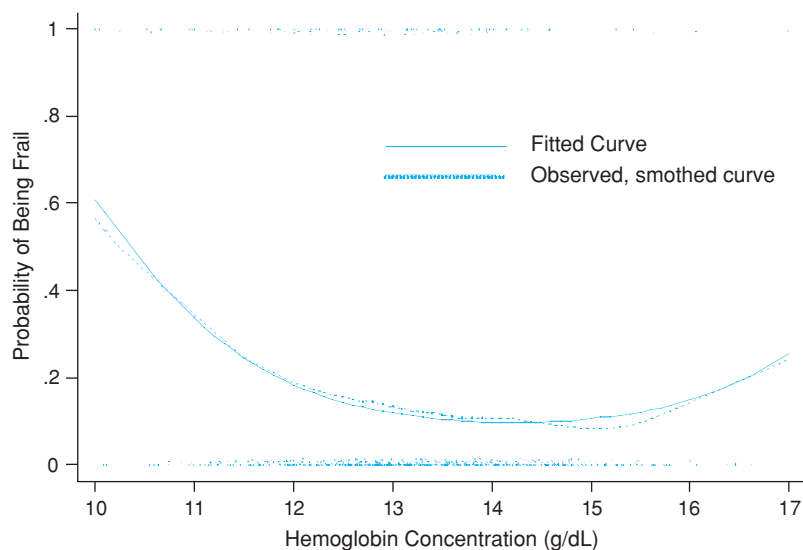

**FIGURE 102-9.** Adjusted mean decline in mobility performance, as assessed by Short Physical Performance Battery (SPBB) scores, as a function of hemoglobin concentration in community-dwelling older women and men (Established Populations for Epidemiologic Study of the Elderly, 1988–1992). Decline in performance corresponds to a negative change in score. Decline is adjusted for baseline performance score, age, education, smoking, blood pressure, body mass index, coronary heart disease, heart failure, stroke, diabetes, cancer, lung disease, infectious disease, and renal disease. *P* values indicate significant differences between categories. (Penninx BW, Guralnik JM, Onder G, et al. Anemia and decline in physical performance among older adults. *Am J Med.* 2003;115:105–110.)

(Figure 102-9). Consistently, several studies have reported associations of anemia with a number of intermediate endpoints—for example, reduced aerobic capacity, exercise tolerance symptoms such as fatigue, and decreased muscle strength—and distal outcomes of the disablement process, such as difficulty and dependency carrying out basic activities of daily living (ADLs), a more severe types of physical disability than mobility disability.

### Frailty Status

Frailty has been conceptualized as a clinical syndrome whose hallmark is increased clinical vulnerability to stressors caused by loss of physiological reserve. While related to aging and disability, frailty has been conceptually regarded as being a separate entity. In fact, many have proposed frailty as a risk factor for disability in older adults (see

Chapter 52). The relationship between anemia and frailty status was examined in a study that analyzed data from WHAS I and II. In that study, frailty was defined according to a validated set of criteria as the presence of at least three out of the following five manifestations: shrinkage, slowness, weakness, exhaustion, and low energy expenditure. The relationship between frailty and anemia was best described by a reversed J-shaped curve that was consistent with that reported for mortality and physical disability (Figure 102-10). As compared to mid-normal Hb levels such as 13.5 g/dL, the likelihood of being classified as frail was significantly higher for lowest and highest Hb levels, even after adjustment for major confounders. Another major finding of that study was evidence of a synergistic interaction between anemia and cardiovascular disease in regard to the likelihood of frailty. Clinically, such an interaction could be thought of as follows. In older adults, the likelihood of frailty might be minimized

**FIGURE 102-10.** Probability of prevalent frailty as a function of current hemoglobin concentration levels in community-dwelling older women aged 70–80 yrs (Women’s Health and Aging Studies I and II, 1992–1996). (Chaves PHM, Semba RD, Leng S, et al. Impact of anemia and cardiovascular disease on frailty status of community-dwelling older women: The Women’s Health and Aging Studies I and II. *J Gerontol A Biol Sci Med Sci.* 2005;60:729–735.)

**FIGURE 102-11.** Performance in cognitive tests that reflect executive function according to hemoglobin levels in high physically functioning women 70–80 yrs of age free of dementia (Women’s Health and Aging Studies II, 1994–1996). Shown are distributions of performance as assessed by two measures: (A) time to complete the Trail Making Test Part B (TMT-B) and (B) time to complete TMT-B minus the time to complete the Trail Making Test Part A (TMT-A) stratified by hemoglobin categories. Anemia was associated with worst performance. The sum of percentages in each column may not add exactly to 100% because of rounding. (Chaves PHM, Carlson M, Ferrucci L, et al. Association of mild anemia with executive function impairment in community-dwelling older women: The Women’s Health and Aging Study II. *J Am Geriatr Soc.* 2006;54:1429–1435. Modified, reprinted with permission.)

in subjects without anemia or CVD, and increased, to a certain extent, when CVD is present. If anemia is present, but key physiologic cardiovascular system-mediated compensatory capacity is compromised because of prevalent CVD, the likelihood of frailty or clinical vulnerability to adverse events might be substantially increased. Such an enhancement in the risk of adverse outcomes in older adults with prevalent comorbidities in the presence of anemia, which has been documented for other outcomes in a number of studies, highlights the clinical importance underlying interactions across comorbidities in older adults and is of particular relevance for professionals caring for the health of older adults.

### Cognitive Function

The relationship between anemia and cognitive function, which has been less studied than the relationships of anemia with mortality or physical disability, has been the focus of recent observational studies. In a study of 364 high-functioning women aged 70 to 80 years who had Mini-Mental Status Examination (MMSE) scores  $\geq 24$  and were living in the community, subjects with mild anemia (Hb between 10 and 12 g/dL) were four to five times more likely to perform worst on tests reflective of executive function (Trail Making Test Parts A and B) compared with those without anemia, even after

controlling for age, education, race, prevalent diseases, and relevant physiological and functional parameters (Figure 102-11). Executive function refers to a set of high-order cognitive abilities including planning, monitoring, and problem solving of goal-oriented tasks. Executive function impairment, which occurs commonly even in nondemented older adults, has been linked to subsequent functional decline and disability in instrumental activities of daily living. Associations of mild anemia with prevalent impaired cognition, assessed by a MMSE  $<24$ , as well as with incident dementia have also been documented in community-dwelling older adults. Consistently, associations of severe anemia with cognitive impairment in patients with CKD, as well as cancer have also been reported.

### Other Selected Outcomes

Anemia is a well-recognized independent risk factor for LVH, an intermediate CVD endpoint, as well as incident CVD outcomes such as coronary heart disease events. This has been well documented in studies involving middle-aged subjects and/or subjects with CKD (including both middle-aged and older adults). Presence of anemia has also been associated with accelerated CKD progression. Additionally, it has been demonstrated that, in subjects with CKD or LVH, the risk of CVD-related outcomes is synergistically increased

in the presence of anemia. Not surprisingly, given the strong association of anemia with increased comorbidity and disability, studies have consistently documented associations of anemia with increased hospitalization, health care utilization, and health care costs.

### Nature of Associations: Anemia as a Causal or Noncausal (Marker) Risk Factor?

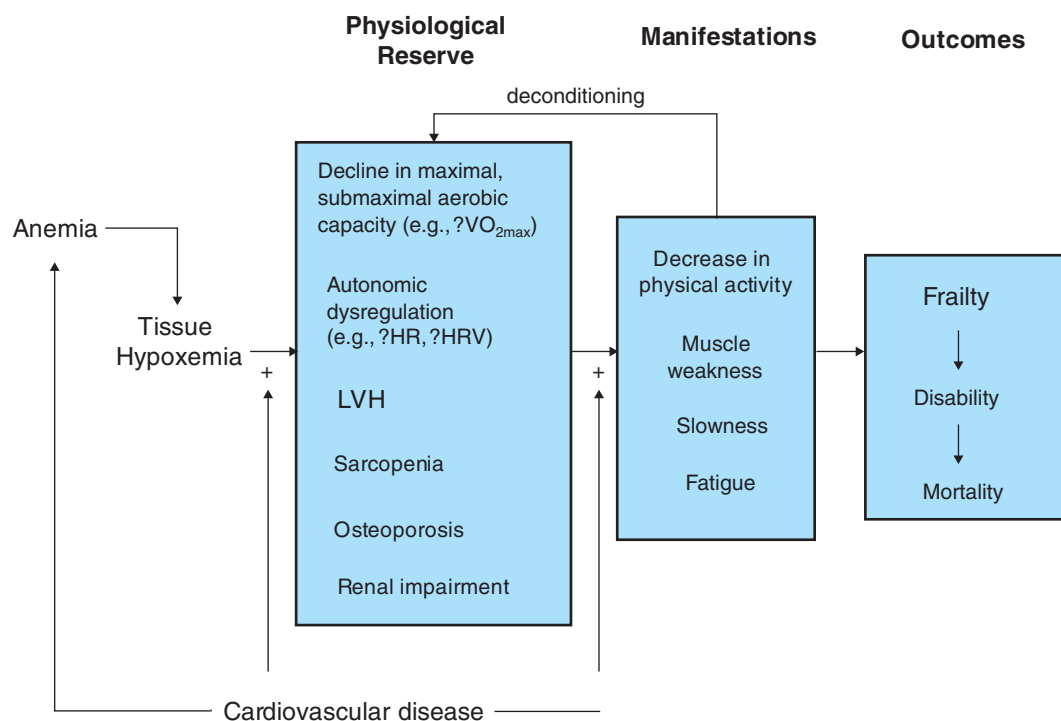

A clear understanding about the nature of the associations of anemia with adverse outcomes described above is critical for clinical decision-making. Both causal and noncausal associations may be useful for prognostic screening. However, only causal associations may offer a potential opportunity for direct therapeutic intervention. To make inferences about causality, a number of considerations are evaluated.

Biological plausibility refers to whether the observed association may be potentially explained in light of current biological and physiological knowledge. In this regard, several hypotheses in support of the notion that associations of anemia with clinical adverse outcomes might be biologically plausible have been proposed. Chronic anemia, particularly if severe, promote a series of hemodynamic adaptations—including, for example, increase in cardiac preload, and decrease in cardiac afterload—that may lead to increased cardiac output, and ultimately to LVH, which in turn has been linked to in-

creased risk of CVD outcomes and mortality. Anemia-related reduction of oxygen delivery to heart tissue could further aggravate maladaptive LV remodeling changes and contribute to subendocardial ischemia, which could potentially explain, at least partly, observed interactions of anemia with CKD in regard to CVD-related outcomes.

Secondary to decreased oxygen-carrying capacity of the blood linked to anemia, it has also been hypothesized that persistent anemia over time, even if nonsevere, could result in chronic hypoxemia in a number of tissues, which in turn could lead to physiological impairments (e.g., decreased aerobic capacity, decline in kidney function, sarcopenia, osteoporosis, cardiac autonomic dysfunction, executive dysfunction, etc.), and decreased overall physiologic reserve. The latter is a key feature of the syndrome of frailty in older adults (Figure 102-12). In this scenario, anemia could potentially contribute in a causal manner to the clinical manifestations of frailty, such as occurrence of exercise-tolerance symptoms, as well as decreased physical activity, strength, and mobility speed. Anemia may also promote further physical deconditioning, which could lead to the onset and progression of physical disability and its complications, such as increased health care utilization and costs and mortality.

It has also been speculated that anemia could potentially have an adverse effect on cognitive function. Potential mechanisms might involve chronic reduction of cerebral oxygenation; physical

**FIGURE 102-12.** Proposed mechanisms through which anemia could contribute to the development of frailty. Anemia, particularly when severe, decreases the oxygen-carrying capacity of the blood, and thus may lead to tissue hypoxemia. It has been hypothesized that milder forms of anemia could also promote physiologically relevant chronic tissue hypoxemia, which would result in a number of impairments, including reduction in maximal and submaximal aerobic capacity, sarcopenia, osteoporosis, and progression of renal impairment. Chronic anemia also promotes a series of hemodynamic adaptations, which may result in autonomic dysregulation and left ventricular hypertrophy (LVH). Cardiovascular disease (CVD), an outcome that has been linked to anemia-related physiological impairments, including decreased physical activity, LVH, and autonomic dysregulation, might synergistically enhance the adverse impact of anemia on tissue oxygenation through perfusion impairment. Anemia-related physiological impairments may lead to a number of manifestations typical of frailty that reflect limitation in exercise tolerance, including decreased physical activity and/or fatigue, as well as muscle weakness, and slowness. Behavioral modifications such as excessive reduction in physical activity may in turn promote further physical deconditioning, which can contribute to further physiological decline. Presence of chronic diseases such as CVD or pulmonary diseases precluding optimal cardiorespiratory physiologic adaptive responses to anemia may contribute to the development of frailty-related manifestations. Reduction in physiologic reserve beyond a certain threshold may compromise physiologic resilience, thus increasing vulnerability to stressors—the clinical hallmark of frailty—and ultimately contributing to major frailty outcomes, including disability and mortality. HR, heart rate; HRV, heart rate variability; LVH, left ventricular hypertrophy.

deconditioning, leading to a decrease in brain-derived neurotrophin factor or a parasympathetic-related efficiency of prefrontal neural function; autonomic dysfunction; and incident CVD outcomes.

Other considerations for inferences about causality include temporal relationship, strength of association, dose–response relationship, and replication. In this regard, review of the literature reveals a clear, consistent documentation of coherent, independent, strong, dose–response associations of anemia with a number of clinical adverse outcomes in older adults by observational studies in different settings. While promising, current evidence is *not* conclusive that anemia is, in fact, a causal risk factor for these outcomes. This is a reflection of a number of important limitations inherent to observational studies of anemia in older adults. One major limitation has to do with the possibility of residual confounding by chronic disease burden, of which anemia is a well-established marker. Chronic disease burden is a causal risk factor for outcomes including physical disability, frailty, cognitive impairment, and mortality. Thus, it is theoretically possible that associations of anemia with outcomes such as the ones listed above could be not be a direct consequence of anemia, but rather indirectly, as a consequence of the fact that anemia is a marker of prevalent chronic disease burden. While epidemiologic design approaches and statistical techniques used in the analysis of observational studies (e.g., adjustment by regression models) may help minimizing confounding effects, they may not eliminate it.

Another important causality criterion refers to the documentation of change, i.e., reduction, in the risk of outcome resulting from correction of the risk factor hypothesized to be causal. In this context, intervention studies are pivotal. Observational studies unfortunately do not constitute an adequate setting for assessment of the ability of anemia correction in improving major clinical outcomes in the broad population of older adults, as treatment is currently available for only the minority of anemia cases (see below) and because of potential selection biases. Preliminary clinical trials examining the potential efficacy of therapy with erythropoiesis-stimulating agents (ESAs) in improving outcomes of anemia, including LVH, kidney function decline, and mortality in CKD patients with severe anemia did show initial promising evidence. However, generalization of these findings to milder and/or other types of anemia that are often present in the population of older adults at large should not be made automatically. Additionally, larger RCTs more recently completed have failed to document improvement in key outcomes associated with correction of milder anemia in CKD patients (see below). In summary, future large RCTs are expected to provide key insight into the causality, as well as potential clinical impact, of observed association of anemia with major adverse outcomes.

## DIAGNOSTIC CONSIDERATIONS

Current published evidence supports the notion that anemia is not a “normal,” clinically appropriate finding in older adults, whether in community or institutionalized settings. As outlined above, the presence of anemia is associated with a variety of adverse outcomes, but it should also be recognized that anemia may be a manifestation of major underlying disorders such as occult malignancy. A long-time clinical axiom is that anemia is often, if not always, secondary to an underlying disorder. In this context, evaluation of anemia is warranted, and may help clinicians in understanding potential

opportunities for anemia treatment, as well as in diagnosing major potentially treatable underlying diseases.

An initial important consideration is that the clinical presentation of anemia in older adults may differ from that in other age groups. Clinical symptoms of anemia depend on the severity and onset of anemia. Mild, chronic, and gradually developing anemia occurs commonly in older adults. Additionally, the number of prevalent comorbidities is significant in this segment of the population, which may confound the presentation of anemia. These factors, along with possible physiologic changes secondary to age- and/or disease-related changes, and behavioral modifications (e.g., older subjects may have cut down on the frequency and/or intensity of task performance to avoid exercise tolerance symptoms) may contribute to the fact that anemia symptoms are often nonspecific, insidious in older adults. This is analogous to the increased occurrence of subclinical presentation of diseases (e.g., CVD) in this segment of the population.

The clinical investigation of anemia in older adults involves the determination of its presence, classification, as well as identification of its underlying causes. While the overall classification scheme discussed earlier in this chapter is useful for the classification of anemia in the research setting, other more refined approaches are used in the clinical setting in clinical decision-making. These approaches are based on comprehensive evaluation of the patient’s medical history—including detailed assessment of prevalent comorbidities and use of medications, which are often overlooked—and physical examination as well as laboratory tests. This information serves as the basis for the classification of anemia according to kinetic and/or morphologic considerations. Kinetic considerations involve the classification of anemia in three overall mechanistic groups that are primarily marked by (a) decreased production, (b) increased destruction, or (c) loss of RBCs. Each group has further subdivisions. Morphological considerations refer to the classification of anemia on the basis of the size of RBC, as usually determined by the RBC MCV index, in combination with the reticulocyte count. Based on the MCV index, anemia can be classified as microcytic, macrocytic, or normocytic. Both MCV and reticulocyte count can be obtained by automated cell counting methods. Review of peripheral blood smear may contribute to the evaluation of anemia by allowing direct evaluation of morphological features of blood cells.

Several clinical algorithms have been developed to assist in the clinical investigation of anemia. They are readily accessible elsewhere. Results from a number of laboratory tests are incorporated in these algorithms. Tests that are commonly used in the preliminary steps of the evaluation of anemia include assessment of a complete blood count (CBC), which quantitatively estimates (either directly measured or calculated from measured parameters) a number of key parameters, including RBC count; white blood cell (WBC) count, including total and differential WBC; hemoglobin concentration (Hb); hematocrit (Hct); RBC indices, including MCV, mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), RDW; and platelet count. Absolute reticulocyte count and the reticulocyte production index are routinely assessed. The peripheral blood smear is often reviewed.

Additional tests that are always useful in the evaluation of anemia include the following:

- (a) Tests to assess iron deficiency, including serum iron, TIBC, serum ferritin, transferrin saturation, and serum sTfR. The latter reflects the product of proteolytic cleavage of transferrin

receptors that are predominantly expressed on the surface of cells with high iron requirements, such as erythroid progenitor cells. In situations of iron deficiency, there is increased expression of transferrin receptors on the cellular membrane, and, concomitantly, increased sTfR levels. Serum levels of sTfR are positively correlated with bone marrow erythropoietic activity and negatively with the amount of iron stores. Serum levels of sTfR, and in particular, the index calculated as the ratio between sTfR serum transferrin receptor and the log of serum ferritin have been proposed as a particularly useful, sensitive method for differential diagnosis between iron-deficiency anemia and ACI with and without iron deficiency. Increased serum levels of sTfR and the ratio of sTfR by the log of serum ferritin are found in iron-deficiency anemia, but not in ACI. Whether measurement of sTfR levels could help improving current approaches used for monitoring of functional iron deficiency during therapy with ESAs remains to be established.

- (b) Tests to assess vitamin B-12 deficiency, including serum vitamin B-12, serum methylmalonic acid (MMA), and serum total homocysteine. Measurements of serum MMA and/or total homocysteine provide a more sensitive approach to assess tissue vitamin B-12 deficiency than measurement of serum vitamin B-12 levels. This is because elevation of serum MMA and homocysteine levels tends to occur before serum vitamin B-12 falls below normal levels.
- (c) Tests to assess folate deficiency, including serum folate, and RBC folate
- (d) Tests to assess renal function, aiming at calculation of eGFR
- (e) Tests of liver function
- (f) Tests for evaluation of hemolysis, including serum lactate dehydrogenase (LDH), indirect bilirubin concentrations, and serum haptoglobin concentration
- (g) Tests to evaluate occult GI bleeding, including fecal occult blood detection and endoscopy
- (h) Tests to directly evaluate bone marrow, including aspiration and biopsy
- (i) Tests to evaluate selected endocrine disorders, including thyroid dysfunction, and hypogonadism. Assessment of testosterone-related measures, for example, are currently recommended only if male hypogonadism is suspected, and not specifically for anemia evaluation.

There are also a number of additional measurements that, while not systematically used in the current evaluation of anemia in older adults, may eventually become part of anemia algorithms. Further clinical epidemiologic characterization of these measurements are warranted. They include serum erythropoietin, proinflammatory markers, and hepcidin. Serum erythropoietin increases as severity of anemia increases. The increase in serum erythropoietin, a key stimulator of erythropoiesis, reflects a compensatory physiologic response to tissue hypoxemia promoted by complex hypoxia-sensing homeostatic mechanisms. However, serum erythropoietin levels are not presently measured routinely in patients with anemia because the level is abnormally increased only when severe anemia is present. Another contributing factor is that serum erythropoietin levels may be inaccurately low for the degree of anemia as a result of the blunted erythropoietin response discussed above (Figure 102-13). Recent

**FIGURE 102-13.** Scatterplot of the relationship between hemoglobin and log(erythropoietin), according to level of inflammation expressed by the number of proinflammatory markers (C-reactive protein, IL-6, IL-1 $\beta$ , TNF- $\alpha$ ) in the upper tertile. The lines were obtained from a linear regression model predicting log(erythropoietin) including age, sex, hemoglobin, squared hemoglobin, inflammatory index (dummy variables), and appropriate terms for the interactions of the inflammatory index with hemoglobin and squared hemoglobin. (Ferrucci L, Guralnik JM, Woodman RC, et al. Proinflammatory state and circulating erythropoietin in persons with and without anemia. *Am J Med.* 2005;118(11):1288.)

data have suggested, nonetheless, that even within its normal range, serum erythropoietin levels may reflect significant differences across Hb levels in the mid-normal to moderately reduced range (see Figure 102-2). High-sensitivity C-reactive protein, high-sensitivity IL-6, and TNF- $\alpha$ , among others, are well established proinflammatory markers. Given the role of inflammation on the pathogenesis of anemia, particularly of ACI, one may expect that measurement of proinflammatory markers may become useful in the evaluation of anemia in older adults the future. Major methodological progress has been recently made in regard to the measurement of hepcidin in the blood and the urine. Given that hepcidin is an important modulator of iron metabolism and may play a major role in the pathogenesis of ACI, it may be that measurement of hepcidin will prove useful in anemia-related clinical decision-making in the future.

## THERAPEUTIC CONSIDERATIONS

### Nutrient-deficiency Anemia

Intervention involves two critical components: replacement of the nutrient that is deficient and treatment of the underlying disorder that is causing the deficiency. Available interventions for this type of anemia are effective, safe, and relatively inexpensive. Iron-deficiency anemia is traditionally treated with oral iron replacement. This is usually accomplished through the use of oral iron supplements,

though recommendation of ingestion for high-iron-content foods should not be forgotten. Usually, initial hematological response is rapid, as assessed by a marked increase in the number of reticulocytes within 7 to 10 days of therapy. Continued iron replacement, however, is important for repletion of total body iron stores. Often, adverse GI symptoms may occur, threatening treatment compliance and requiring adjustments. If the underlying condition has not been corrected (e.g., blood loss), effectiveness of treatment maybe delayed or even precluded. In community-dwelling older adults with mild-to-moderate anemia, parenteral iron replacement is rarely pursued. Several studies have shown that IV iron therapy maybe particularly useful in patients with cancer or CKD undergoing treatment with ESAs.

Folate deficiency is primarily treated with oral folate replacement. Vitamin B-12 typically is replaced through parenteral therapy, for example, intramuscular, monthly doses of vitamin B-12. Alternative routes of administration, including oral vitamin B-12 therapy, have also been proposed. In patients lacking intrinsic factor, high oral doses of vitamin B-12 maybe considered. In patients with deficient food digestion resulting in impaired release of vitamin B-12 from ingested foods leading to poor absorption of free vitamin B-12, oral doses of vitamin B-12 not as high as that for patients with pernicious anemia maybe effective. Initial hematopoietic response to vitamin B-12 replacement in vitamin B-12-deficiency and to folate in folate-deficiency anemia is also rapidly observed, as assessed by a substantial increase in the reticulocyte count within 1 week of therapy. Folate replacement may produce a transient, suboptimal hematological improvement in anemia as a result of vitamin B-12 deficiency; however, vitamin B-12 neurologic complications may appear and progress without vitamin B-12 replacement.

### Anemia of CKD

The use of ESAs is the keystone of management of anemia in older adults with CKD. Several studies have been shown that ESA therapy constitutes an effective, safe therapy to treat anemia and lead to improvement in quality of life parameters in CKD patients. At the time this chapter is being written, there are two ESAs licensed for the treatment of anemia of CKD in the United States: epoetin alfa and darbopoetin alfa. Both are glycoproteins that are manufactured using recombinant DNA technology. They stimulate erythropoiesis through the same mechanism of action as endogenous erythropoietin. Epoetin alfa is a recombinant human erythropoietin (rHuEPO) that has the same amino acid sequence of naturally occurring erythropoietin. It was originally licensed in 1989 for the treatment of anemia in patients with anemia of CKD. Subsequently, epoetin alfa therapy was approved for additional indications, including the treatment of anemia in cancer patients on chemotherapy, and anemia in zidovudine-treated patients infected with the human immunodeficiency virus (HIV). Darbopoetin alfa is a rHuEPO analog that contains extra carbohydrate chains, which increases the molecular weight of the glycoprotein. As compared to epoetin alfa, darbopoetin alfa has a longer half-life. Additional ESAs are currently being investigated.

Detailed guidelines exist to guide ESA therapy in patients with CKD. Varying administration schemes provide therapy flexibility. Traditional outpatient regimens involve the subcutaneous administration of ESA once per week or every 2 weeks. More recently, extended-dosing regimens involving ESA administration every

3 weeks and even once monthly have been proposed. To avoid impaired erythropoiesis caused by true iron deficiency or functional iron deficiency, iron stores should be fully replenished before and during ESA therapy. This may initially be attempted through oral iron replacement, though often IV iron therapy is required. ESA therapy is considered safe. However, major adverse effects should be acknowledged, including an increased risk of death, thromboembolic complications, stroke, heart attack, aplastic anemia, tumor progression, and others. To minimize risks of these adverse events, careful monitoring of hemoglobin levels, along with adjustment of ESA dosing, to maintain the lowest hemoglobin level clinically needed is recommended. The target Hb level that should be pursued in patients with anemia of CKD remains a subject of controversy (see below). Current clinical recommendations at the time this chapter is being written suggest a target Hb range between 11 and 12 g/dL.

Before the advent of recombinant erythropoietin, androgens were regularly used for treatment of anemia in patients with end-stage CKD. Hypothesized mechanisms included stimulation of erythropoietin production, a direct effect on the bone marrow enhancing the response of erythroid progenitors to erythropoietin, and increase in RBC survival. However, adverse effects of androgen therapy, along with availability of recombinant erythropoietin, obviate the use of androgen therapy for anemia of CKD. Current guidelines recommend against use of androgens as adjuvant therapy to ESA treatment.

### Anemia of Chronic Inflammation

Treatment of underlying chronic inflammatory diseases constitutes the cornerstone therapy for ACI. This axiom remains valid to this date. Cases exist though of refractory ACI despite proper treatment for underlying diseases, including, for example, rheumatoid arthritis, inflammatory bowel disease, and congestive heart failure. At this time, there is no approved specific treatment for ACI. Preliminary small pilot studies of short duration have suggested that the use of ESAs along with iron replacement may result in hematological response and anemia correction. Further large RCT studies will be necessary to establish whether pharmacologic correction of anemia with ESAs could ultimately lead to improved hard outcomes, for example, increased survival, in older adults with specific diseases survival and/or in the broad older population.

### “Unclassified” or “Unexplained” Anemia

Reflecting the limited knowledge about pathogenic mechanisms involved with this heterogeneous anemia group, no specific anemia treatment is currently recommended. Considering the axiom that anemia is always secondary to a specific cause, i.e., not simply caused by aging per se, it is possible that a specific etiology may eventually become apparent as a consequence of continued clinical investigation over time.

### Impact of Anemia Correction with Recombinant Erythropoietin on Clinical Outcomes

Over the last decade, data from several intervention studies that included older adults in different settings helped establishing the efficacy of recombinant erythropoietin therapy in safely increasing Hb levels in older adults. More important, increasing Hb levels through recombinant erythropoietin therapy has been consistently

shown to improve health-related quality of life in patients with severe and/or moderate anemia and specific diseases, including CKD and cancer. However, discrepancy of evidence from observational studies and small preliminary trials with that from recent major RCTs have been documented in regard to the ability to improve hard outcomes, as a result of anemia correction via ESA therapy. For example, recent RCTs conducted in CKD patients have shown that recombinant erythropoietin targeting Hb levels currently considered in the “normal” range (“full correction of anemia”) as opposed to below “normal” levels (“partial anemia correction”) did not show hypothesized results in terms of improving mortality, left ventricular mass changes, CVD events, and slowing of renal function decline. In fact, recent RCT data have, in fact, raised concerns that increase in Hb levels with recombinant erythropoietin up to levels until recently thought of as normal may in fact increase the risk of serious adverse events. These concerns even have motivated the United States Food and Drug Administration’s (FDA) to recently (March 2007) issue a warning to health care professionals in regard to the in regard to the risk of these serious adverse complications associated with ESA therapy complications.

## CONCLUSION

Anemia is a major clinical syndrome in older adults. Recent advances have been made in the characterization of important mechanisms underlying the pathogenesis of this syndrome and of the relationship of anemia with major outcomes in older populations. Treatment data that have become recently available have contributed novel insight not only on the ability to correct anemia with ESA therapy, but more importantly, on the potential impact of this therapy on major clinical outcomes. Despite these advances, many questions remain to be answered at this time, including the selected topics regarding the clinical epidemiology of anemia in older adults identified below:

- (a) In older adults with anemia and specific diseases for which ESA therapy is currently approved, can anemia correction with ESA therapy slow declines in physical and cognitive function, prevent frailty and disability, and/or improve survival? If so, what should the target Hb be to optimally improve clinical outcomes?
- (b) Can correction of mild ACI with ESA therapy improve major outcomes such as the ones listed in (a) in the broad population of community-dwelling older adults?
- (c) How should health status heterogeneity impact anemia-related clinical decision-making in older adults? For example, how should screening and treatment considerations differ for community-dwelling older adults without advanced disability versus nursing home residents?

- (d) In regard to the definition of anemia in older adults, should criteria differ according to race?
- (e) What are the major mechanisms underlying unclassified/unexplained anemia? Does ESA therapy constitute a therapeutic approach in this type of anemia?

# White Cell Disorders

Heidi D. Klepin ■ Bayard L. Powell

White blood cells (WBC) provide major host defense mechanisms against invading pathogens through phagocytosis and the immune response. In addition, lymphocytes provide immune surveillance against the development of cancer and are important mediators of disorders of the immune system. White cell disorders are usually the result of overproduction or underproduction of one or more of the WBC series, which include the granulocytes—neutrophils, basophils, and eosinophils—and/or mononuclear cells—lymphocytes and monocytes. Less frequently, WBC disorders result from WBC dysfunction despite normal number of cells. The acuity and severity of these disorders are related to the number of white cells, the subset(s) of WBC involved, their degree of maturity, and their functional capacity.

Initial clinical manifestations of WBC disorders can vary widely but often include signs and symptoms of infection. Disorders of WBC, benign or malignant, frequently also involve abnormalities of the red blood cells (RBCs) and platelets. In these situations, the signs and symptoms of disease at presentation may include those related to anemia (i.e., weakness and easy fatigability) and/or thrombocytopenia (i.e., easy bruisability, mucosal or gastrointestinal bleeding, and hematuria). A careful history and physical examination with evaluation of the peripheral blood, and bone marrow when needed, will establish a diagnosis in many cases.

Aging is not associated with significant changes in the peripheral WBC count or WBC differential (Table 103-1). Therefore, abnormalities in white cell numbers should be evaluated as a probable sign of an active disease process. Most white cell disorders are more common with increased age and the most common WBC disorders in the elderly are neoplastic diseases. Table 103-2 lists the spectrum of white cell disorders encountered in clinical practice. Full descriptions of these processes are available in textbooks of hematology and oncology. This chapter focuses on these disorders as related to geriatric medicine.

The most common assessment of white cells is quantitative evaluation of their numbers. Careful attention should also be paid to the

distribution of the different types of white cells (WBC differential). Equally important is the microscopic examination of the peripheral blood smear (and bone marrow when needed) for morphologic changes in the WBC as well as the red cells and platelets. Specific quantitation of WBC subsets by immunophenotyping techniques can aid in the diagnosis of many neoplastic WBC disorders. Qualitative or functional defects are more difficult to establish with laboratory techniques and are usually strongly suggested by the medical history.

## DECREASED WHITE BLOOD CELLS

Leukopenia may occur with a broad array of medical problems. Leukopenia can range from a mild suppression of the WBC to clinically significant neutropenia (Table 103-3). Most intrinsic (hereditary/familial) disorders and syndromes are detected during infancy or childhood. Leukopenia in older adults is generally the result of acquired or secondary disorders, either reactive (drugs, nutritional, infections, immune) or malignant. Table 103-4 presents key components in the clinical workup of neutropenia.

### Drug/Toxin Effects

Elderly patients commonly consume many prescribed and over-the-counter medications and are at higher risk for developing drug-related neutropenia or pancytopenia. The bone marrow is one of the more rapidly proliferating organs of the body; therefore, it is not surprising that exposure to noxious agents may temporarily or permanently inhibit production of one or more elements of the blood. The list of possible offenders is extensive and constantly evolving with new drug development. Table 103-5 lists some of the more commonly reported offenders. In a situation of neutropenia, leukopenia, or pancytopenia, the physician should thoroughly review the patient's medications and the duration of the medication

**TABLE 103-1****Normal WBC Counts for Adults**

TEST	RANGE ( $\times 10^3/\mu\text{L}$ )
WBC	4.5–11.0
Segmental neutrophils	1.6–7.3
Band neutrophils	0.0–0.2
Lymphocytes	1.0–5.1
Monocytes	0.1–0.9
Eosinophils	0.0–0.5
Basophils	0.0–0.5

exposure. In the absence of alternative explanations, medications administered within 4 weeks of onset of neutropenia should be evaluated. Short duration of exposure does not remove the possibility of a drug-induced cytopenia; it could be an idiosyncratic reaction. Diagnosis involves identification of a possible offending agent and exclusion of alternative etiologies for the leukopenia. A bone marrow

**TABLE 103-2****Disorders of White Blood Cells**

- I. Lack of production
  - A. Drug or toxin suppression, which may be temporary or permanent
  - B. Ineffective myelopoiesis secondary to B-12 or folate deficiency
  - C. Bone marrow failure (aplastic anemia)
  - D. Neoplastic causes of decreased WBC (e.g., MDS, acute leukemia, LGL leukemia)
- II. Increased destruction
 

Immune neutropenia secondary to rheumatologic disorders, Felty's syndrome, and lymphoproliferative malignancies
- III. Increased splenic sequestration
 

Congestive splenomegaly with cirrhosis, Gaucher's disease, etc.
- IV. Nonneoplastic increases in WBC
  - A. Response to stress (e.g., infection)
  - B. Response to drug (e.g., corticosteroids, granulocyte colony-stimulating factor)
  - C. Other reactive increases (e.g., inflammation)
- V. Neoplastic diseases
  - A. Primary hematologic
    1. Myelodysplastic syndromes (MDS)
    2. Acute leukemias
      - a. Acute myelogenous leukemia (AML)
      - b. Acute lymphocytic leukemia (ALL)
    3. Chronic leukemias
      - a. Chronic lymphocytic leukemia (CLL)
      - b. Chronic myelogenous leukemia (CML)
      - c. Hairy-cell leukemia
      - d. Large Granular Lymphocytic Leukemia (LGL leukemia)
    4. Other myeloproliferative diseases
    5. Non-Hodgkin's lymphoma (with circulating lymphoma cells)
  - B. Cancers metastatic to bone marrow
 

Most commonly breast, lung, prostate, and lymphomas
- VI. Normal count with impaired function
  - A. Diabetes mellitus: impaired polymorphonuclear neutrophil function
  - B. Chronic renal failure: Impaired polymorphonuclear neutrophil and lymphocyte function
  - C. Drugs (e.g., corticosteroids)

**TABLE 103-3****Neutropenia**

ANC*	INFECTION RISK
$\geq 1000$	Essentially normal
500–1000	Slight $\uparrow$ risk
<500	"Significant" risk
<100	Severe risk

\*Absolute neutrophil count (ANC) = WBC  $\times$  % (seg + bands).

biopsy is often indicated as part of the workup if the leukopenia is severe.

Drug effects on the bone marrow range from mild neutropenias (more common) to agranulocytosis; lymphocytopenia occurs less frequently. The RBC and platelets may or may not be affected. Drug-induced reduction of the granulocytic series may be a direct toxic effect, as with many cancer chemotherapeutic drugs or may be the result of an immunologic phenomenon wherein a drug–antibody complex reacts with mature neutrophils and/or their precursors in the peripheral blood or bone marrow. Treatment usually consists of supportive care, with administration of antibiotics for febrile patients. Upon withdrawal of the offending agent, there may be a relatively brisk marrow recovery within 14 to 21 days. A bone marrow examination during this recovery period may reveal an increased number of immature elements, which can be confused with a malignant process such as an acute leukemia or myelodysplasia. If this is a possibility, close follow-up for an additional 2 to 3 weeks will usually provide the answer. The recovering marrow will go on to differentiate, but the malignant marrow will either stay the same

**TABLE 103-4****Key Components in the Evaluation of Neutropenia**

**TABLE 103-5****Drugs Associated with Agranulocytosis/Neutropenia**

1. Cancer chemotherapeutic agents
2. Psychotropic drugs:
  - Clozapine
  - Risperidone
  - Olanzapine
  - Haloperidol
  - Phenothiazine
  - Tricyclic antidepressants
  - Meprobamate
3. Anti-inflammatory/antiarthritic drugs:
  - Sulfasalazine
  - Nonsteroidal anti-inflammatory agents
  - Colchicine
  - Immunosuppressive agents
  - Penicillamine
  - Gold salts
  - Allopurinol
  - Immunosuppressants
4. Thyroid suppressants:
  - Propylthiouracil
5. Cardiovascular drugs:
  - Antiarrhythmic agents (procainamide, quinidine, amiodarone)
  - ACE inhibitors (captopril, enalapril)
  - Nifedipine
  - Hydralazine
  - Propranolol
  - Methyldopa
  - Ticlopidine
  - Dipyridamole
  - Digoxin
6. Antibiotics:
  - Sulfa drugs
  - Semisynthetic penicillins
  - Cephalosporins
  - Macrolides
  - Vancomycin
  - Rifampin
  - Clindamycin
  - Gentamicin
  - Linezolid
7. Anticonvulsants:
  - Phenytoin and derivatives
  - Carbamazepine
8. Thiazide diuretics
9. Antihistamines- H<sub>2</sub> blockers
10. Oral hypoglycemia drugs

or worsen. Other marrow toxins include a variety of household and industrial chemicals, especially organic solvents, naphthalenes, insecticides, and herbicides. Inquiries about chemical exposure from hobbies or occupations must therefore be part of history taking. While the hematologic effects of drug and chemical exposure are frequently reversible, some may result in myelodysplastic syndromes (MDS) or aplastic anemia which, in turn, may evolve into acute myelogenous leukemia (AML).

### Nutritional Deficiency

Mild neutropenia may be associated with nutritional anemias secondary to folate or B-12 deficiency. Older individuals, especially

those living alone, may not be attentive to their diet for various socioeconomic, psychological, or medical reasons. The main sources of folates are fresh green vegetables, many fruits, and beans. Cooking and canning destroys folates. The body's folate stores can be depleted after 4 to 5 months of poor dietary intake. Thus, a dietary history may provide an important clue to the diagnosis of the hematologic problem. Dietary folate deficiency may be aggravated by alcoholism and chronic hemolysis. Additional hematologic findings of folate deficiency include macrocytic anemia and hypersegmented neutrophils. Potential folate deficiency is best evaluated by measuring RBC folate.

In contrast, body stores of vitamin B-12 are not readily depleted by poor dietary habits alone. It takes 3 to 5 years to deplete the body stores of vitamin B-12. However, gastric atrophy is more common with increasing age, and this may lead to failure of gastric secretion of intrinsic factor, which binds to dietary cobalamin—a necessary step in the absorption of vitamin B-12 in the ileum. Other conditions that cause a B-12 deficiency include gastrectomy or subtotal small-bowel (ileal) resection. It should be noted that neurologic signs and symptoms of B-12 deficiency may be confused with other neurologic problems in the elderly patient. These include peripheral paresthesias (peripheral neuritis), loss of balance (posterior column damage), spasticity (lateral column damage), and impaired cognitive function. Any of these neurological signs and symptoms may be mistakenly attributed to “old age,” but if caused by B-12 deficiency may be corrected with vitamin B-12 replacement therapy. Low serum cobalamin levels (<200 ng/L) are diagnostic of deficiency and will be found in the majority of patients who are symptomatic. Subclinical cobalamin deficiency can be detected by measuring serum methylmalonic acid. Subclinical cobalamin deficiency is characterized by low normal serum cobalamin level (200–350 ng/L) and an elevated methylmalonic acid level. It should be noted that homocysteine will be elevated in both folate and cobalamin deficiency.

Copper deficiency is a more recently reported but uncommon cause of neutropenia. Neutropenia is typically associated with anemia and may be confused with early MDS, particularly in an older adult. Copper deficiency is most commonly associated with malabsorption, malnutrition, use of total parenteral nutrition, or excess oral zinc supplementation. The diagnosis is suggested by the appropriate clinical setting and a low serum copper level. Hematological changes are potentially reversible with oral copper supplementation.

### Infections

A number of infections can be associated with neutropenia and/or leukopenia in older adults. These infections include viral (e.g., influenza, varicella, hepatitis A, B, or C, cytomegalovirus, human immunodeficiency virus, parvovirus B19), and bacterial (e.g., *Staphylococcus aureus*, brucellosis, tularemia, rickettsia, and tuberculosis). Neutropenia associated with most viral illnesses is self-limited and of minimal clinical consequence. A few viruses (hepatitis B, Epstein-Barr, and human immunodeficiency virus) can cause protracted, clinically significant neutropenia. Bacterial septicemia, particularly with Gram-negative organisms, is a serious cause of acquired neutropenia and confers a poor prognosis. The mechanism of leukopenia is usually bone marrow suppression, but in the case of overwhelming bacterial sepsis, can result from exhaustion of bone marrow reserves. Treatment focuses on supportive care including use of antibiotics for infection; the role of myeloid growth factors in this setting is unproven.

## Bone Marrow Failure

Severe and prolonged bone marrow failure may occur in association with drugs, toxins, or infections, but is frequently idiopathic. Aplastic anemia is characterized by severe pancytopenia and bone marrow hypoplasia. Clinical signs and symptoms reflect the cytopenias: infection, bleeding, and/or the signs/symptoms of anemia. Pure white cell aplasia occurs rarely. Treatments for this life-threatening disease include supportive care (transfusion, antibiotics), immunosuppression (antithymocyte globulin, cyclosporine, steroids), and stem cell transplant (limited application in the elderly population).

## Increased Destruction

Immune neutropenia may be associated with various rheumatologic conditions such as systemic lupus erythematosus, rheumatoid arthritis, polyserositis, and lymphoproliferative malignancies. In these situations, neutropenia is caused by the elimination of immunoglobulin-coated granulocytes by the reticuloendothelial system. Immune-mediated neutropenia is often clinically significant with absolute neutrophil count (ANC)  $<500$  cells/mm<sup>3</sup>, predisposing to increased infection risk. In general, the bone marrow is hypercellular or normocellular and lacking in mature neutrophils. Neutropenia of Felty's syndrome (rheumatoid arthritis, splenomegaly, and neutropenia) has a complex etiology that includes immune destruction and suppression as well as splenic sequestration. These neutropenias frequently respond to granulocyte colony-stimulating factors (G-CSF) or granulocyte-macrophage colony-stimulating factors (GM-CSF).

## Splenic Sequestration

Any condition causing splenomegaly (e.g., hepatic cirrhosis) may lead to sequestration of sufficient neutrophils to cause mild-to-moderate neutropenia as a component of the pancytopenia of hypersplenism. The mild-to-moderate neutropenia usually does not predispose to increased infections and often occurs in association with anemia and/or thrombocytopenia.

## Neoplastic Causes of Decreased WBC

Malignancies (hematological and nonhematological) can present with neutropenia and need to be considered in the evaluation of this finding. Details of the presentation and workup of many of these disorders will be presented later in this chapter.

## INCREASED WBC

### Benign Causes of Leukocytosis

The most common causes of sustained increases in WBC are neoplastic diseases. However, there are a number of nonneoplastic etiologies for increases in one or more white cell forms. The most common among these is a leukocytosis, specifically neutrophilia, in response to infection. This is associated with a "left shift" in the differential, with increases in bands and other less-mature granulocytes, including metamyelocytes and myelocytes. Such a normal granulocytosis

can also be seen in response to an exogenous steroid. Increases in specific subsets of white cells (e.g., eosinophils or basophils) can occur in response to a number of exposures or illnesses. Hereditary and familial (e.g., Down syndrome) causes of leukocytosis are rare and usually detected early in life.

## Infection

Infection stimulates the acute release of neutrophils from the marginated storage pools of the bone marrow. Neutrophilia commonly occurs with acute bacterial infections, and is less predictably seen with viruses. An increase in band neutrophils and metamyelocytes is most common. Toxic granules in those cells are frequently present on review of the peripheral blood smear. A dramatic "leukemoid reaction," characterized by a WBC  $>50,000/\mu\text{L}$ , a marked left shift with increased immature granulocytes including myelocytes, promyelocytes, and even blasts, may be confused with malignant disorders, especially chronic myelogenous leukemia (CML). Leukemoid reactions are characterized by a high-leukocyte alkaline phosphatase (LAP [low in CML]) and absence of the Philadelphia chromosome. Leukemoid reactions are uncommon and the probability of an underlying bone marrow disorder should always be suspected in this setting.

## Drug-Induced Leukocytosis

Corticosteroids are the most common medications associated with increases in WBC, primarily neutrophilia. The mechanism includes reduced neutrophil adhesion and release from marrow stores. The hematopoietic colony-stimulating factors (e.g., G-CSF, GM-CSF) are designed to stimulate neutrophilia, and lithium can induce neutrophilia through similar CSF pathways. Beta-adrenergic agonists also frequently stimulate acute release of neutrophils from marginated pools.

## Other Reactive Leukocytosis

Mild neutrophilia (WBC 12,000–20,000/ $\mu\text{L}$ ) can occur after a stress, resulting from release of neutrophils from marginated pools into the bloodstream. Stressful stimuli include exercise, seizures, anesthesia, and surgery. Acute inflammation and tissue necrosis are also associated with neutrophilia. Examples include burns, electric shock, trauma, and infarction. Asplenia can be associated with moderate leukocytosis. Chronic inflammatory conditions such as colitis, rheumatoid arthritis, and vasculitis may stimulate a modest increase in bone marrow production and release of neutrophils. Mild to moderate leukocytosis (WBC  $<30,000/\mu\text{L}$ ) may also occur in association with a variety of malignancies without bone marrow involvement.

Isolated increases in WBC subsets occur with or without increase in total WBC. Monocytosis may be associated with inflammatory diseases, specifically infections, autoimmune and granulomatous diseases, and numerous malignancies. Eosinophilia ( $>600/\mu\text{L}$ ) usually represents a reaction to drugs, infection (e.g., fungi, parasites), allergic disorders, vasculitis, or malignancies. Lymphocytosis, though frequently representing malignancy, may occur in response to infection.

## MALIGNANT DISEASE OF THE HEMATOPOIETIC SYSTEM

Hematologic malignancies, although most frequently characterized by elevated WBC, can be associated with low, normal, or high WBC. The WBC differential, as well as the red cell and platelet counts, are usually abnormal.

Malignant diseases of the WBCs include the four major subtypes of leukemia—AML, acute lymphocytic leukemia (ALL), CML, and chronic lymphocytic leukemia (CLL); as well as the MDS (preleukemias); the myeloproliferative disorders other than CML; hairy cell leukemia; large granular lymphocytic leukemia; metastatic cancers to the bone marrow; and circulating non-Hodgkin's lymphoma cells. Older adults make up a large proportion of incident and prevalent cases of these diseases. In fact, the age-specific incidence rates of all leukemias increase in the elderly population (Figure 103-1). As the population ages, the burden of these diseases is nearly certain to rise, with the elderly population being most affected.

The effectiveness of treatments has improved substantially over recent decades for most hematologic malignancies. Unfortunately, the response rates and cure rates in elderly patients have lagged behind for a number of reasons, including the more common occurrence of chronic leukemias, MDS, and myeloproliferative disease in the elderly person, limited ability of the elderly person to tolerate the more aggressive curative approaches for acute leukemia, underrepresentation of older adults in clinical trials, and the more common occurrence of multiple poor prognostic factors in elderly patients. With the increased focus on elderly specific clinical trials and the ongoing development of less toxic, targeted therapies, opportunities for effective treatment of older adults with malignant WBC disorders should improve.

### Myelodysplastic (Preleukemia) Syndromes

The myelodysplastic syndromes, frequently referred to as preleukemia, encompass a heterogeneous group of clonal hematopoietic disorders characterized by ineffective hematopoiesis, peripheral blood cytopenias, and hypercellularity of the bone marrow. In these diseases, cells of the affected lineage are unable to undergo maturation and differentiation, resulting in cytopenias. The major clinical significance of these disorders is the morbidity associated with profound cytopenias and the potential to evolve into AML.

The true incidence of myelodysplastic syndromes is not known, but currently estimated at 15,000 to 20,000 new cases per year in the United States. About two thirds of patients with MDS are elderly males. MDS are clearly diseases of aging patients, with a median age at diagnosis of 65 to 70 years. The nomenclature associated with myelodysplastic syndromes is confusing. Terms found in the literature include odoleukemia (threshold of leukemia), subacute myeloid leukemia, smoldering leukemia, dysmyelopoietic syndrome, and preleukemia.

Diagnosis of MDS relies mainly on peripheral blood and bone marrow findings. The diagnosis should be suspected in individuals presenting with cytopenia. In clinical studies, the majority of patients have a hemoglobin of less than 11, platelet count <100,000, and an ANC <1000 at the time of diagnosis. However, careful attention should be paid to consistent decreases in blood counts over time in an older adult, which may signify early developing MDS. Many patients are asymptomatic at the time of diagnosis. However, careful

history taking should include questions regarding recurrent infections, bruising, and bleeding. The differential diagnosis for suspected MDS includes AML, aplastic anemia, megaloblastic anemia (B-12 and folate deficiency), copper deficiency, viral infections (HIV), large granular lymphocytic leukemia, and heavy metal poisoning.

The initial serologic workup includes a complete blood count (CBC) with differential, reticulocyte count, RBC folate, serum B-12, iron studies, and review of the peripheral smear. Classic peripheral blood findings associated with MDS include macrocytosis and hypogranular, hypolobated (dysplastic) neutrophils. A bone marrow biopsy with cytogenetic analysis is required to confirm the diagnosis. The bone marrow is typically hypercellular and demonstrates evidence of dysplasia. Cytogenetic abnormalities play a critical role in the diagnosis and natural history of MDS. Common cytogenetic abnormalities involve chromosomes 5, 7, 8, 17, or 20.

The classification of MDS has evolved over the past 10 years. In 1982, the French-American-British (FAB) Cooperative Group established a classification system with five diagnostic categories based on peripheral blood and bone marrow characteristics. These include refractory anemia (RA), RA with ring sideroblasts (RARS), RA with excess blasts (RAEB), RAEB in transformation (RAEBT), and chronic myelomonocytic leukemia (CMML). Details of this classification system are presented in Table 103-6.

A more recent classification scheme was proposed by the World Health Organization (WHO), which incorporates evolving knowledge of the biology of disease including the significance of cytogenetic abnormalities. This classification scheme is presented in Table 103-7 and better reflects the heterogeneity of MDS. There are several important differences between the FAB and WHO classifications. The WHO classification defines  $\geq 20\%$  blasts (RAEBT) as AML; defines CMML as a myelodysplastic/myeloproliferative disease; and adds new categories of MDS such as the 5q-syndrome.

The natural history of patients with MDS syndromes is quite variable and can range from a chronic relatively indolent disease to an acute fulminant and progressive process. It is well established that mutagen-induced MDS is associated with a poor prognosis and that increased age is also a negative prognostic factor. However, the heterogeneity of this disease has complicated accurate prognostication in de novo MDS. The International Prognostic Scoring System (IPSS) (Table 103-8) was developed to risk stratify patients at the time of diagnosis based on cytogenetic, morphologic, and clinical data. The IPSS for MDS was developed based on an analysis of 816 patients, which demonstrated that specific cytogenetic abnormalities, the percentage of marrow blasts in the bone marrow, and the number of hematopoietic lineages involved in the cytopenia were the most important variables in disease outcome. Risk scores are determined based on these variables, and a categorization of low risk, intermediate-1, intermediate-2, and high risk is assigned (Table 103-9). The IPSS has demonstrated improved prognostic discrimination over earlier classification schemes and has been incorporated into clinical practice and subsequent trial design.

There are few effective therapies for MDS. However, treatment strategies have been evolving in recent years to target higher risk MDS and subgroups defined by specific cytogenetic abnormalities. Current treatment recommendations involve a risk-adapted therapeutic approach. In general, the National Comprehensive Cancer Center guidelines recommend classifying patients into relatively low risk (IPSS Low or Intermediate-1 categories) and higher risk (IPSS Intermediate-2 and High categories). Supportive care aimed

### Age-Specific (Crude) SEER Incidence Rates by Sex for Leukemias, All Races SEER 17 Registries for 2000–2003

at controlling symptoms related to cytopenias is the mainstay of treatment for lower risk patients. Supportive care with red cell and platelet transfusions and antibiotics for infection has long been considered standard therapy for most patients with MDS. Hematopoietic growth factors such as erythropoietin are used to try to minimize transfusion requirements in responding patients. Over time, most

patients become transfusion-dependent, increasing the risk of iron overload. Iron chelation therapy should be initiated after 20 to 30 units of red cells have been transfused or the serum ferritin is >2500 mcg/L. Supportive care is also recommended for adults with higher risk disease who have poor performance status and are more likely to suffer complications from aggressive therapies.

TABLE 103-6

## Characteristics and Prognosis of Myelodysplastic Syndromes

FAB SUBGROUP	PERIPHERAL BLOOD BLASTS (%)	BONE MARROW BLASTS (%)	PROGRESSION TO AML (%)	MEDIAN SURVIVAL (MONTHS)
Refractory anemia	<1	<5	10	70
Refractory anemia with ring sideroblasts	<1	<5	15	65
Chronic myelomonocytic leukemia	<5	≤20	30	10
Refractory anemia with excess blasts	<5	5–20	40	10
Refractory anemia with excess blasts in transformation	≥5	21–30	60	5

Patients in the higher risk IPSS categories are more likely to experience morbidity related to cytopenias and to progress to acute leukemia in a shorter time interval from diagnosis. Publications by Silverman and Kornblith described improvements in survival, quality of life, and a longer time to progression to acute leukemia, in patients with MDS who received 5-azacytidine (vs. observation) in a randomized trial of the national cooperative group Cancer and Leukemia Group B (CALGB). The strongly positive results of this large randomized study support 5-azacytidine as a standard of care for treatment of MDS. The FDA also recently approved decitabine, a second pyrimidine nucleoside analog of cytidine, which inhibits

DNA methylation for the treatment of higher risk MDS. While these medications are associated with toxicity, they represent the mainstay of treatment for good performance status older adults with higher risk MDS. Higher intensity therapy such as allogeneic transplantation, to date the only curative therapy for MDS, is restricted to younger adults with acceptable donors because of the high morbidity and mortality associated with the therapy itself.

Treatment options have expanded for patients with the 5q-syndrome. This subset of MDS is defined by a deletion of the long arm of chromosome 5 as the sole abnormality. The 5q-syndrome typically manifests as refractory anemia and is considered a more

TABLE 103-7

## WHO Classification of Peripheral Blood and Bone Marrow Findings in Myelodysplastic Syndromes

DISEASE	BLOOD FINDINGS	BONE MARROW FINDINGS
Refractory anemia	Anemia No or rare blasts	Erythroid dysplasia only <5% blasts <15% ringed sideroblasts
Refractory anemia with ringed sideroblasts	Anemia No blasts	≥15% ringed sideroblasts Erythroid dysplasia only <5% blasts
Refractory cytopenia with multilineage dysplasia (RCMD)	Cytopenias (bicytopenia or pancytopenia) No or rare blasts No Auer rods <1 × 10 <sup>9</sup> /L monocytes	Dysplasia in ≥10% of the cells of two or more myeloid cell lines <5% blasts in marrow No Auer rods <15% ringed sideroblasts
Refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-RS)	Cytopenias (bicytopenia or pancytopenia) No or rare blasts No Auer rods <1 × 10 <sup>9</sup> /L monocytes	Dysplasia in ≥10% of the cells in two or more myeloid cell lines ≥15% ringed sideroblasts <5% blasts No Auer rods
Refractory anemia with excess blasts-1 (RAEB-1)	Cytopenias <5% blasts No Auer rods <1 × 10 <sup>9</sup> /L monocytes	Unilineage or multilineage dysplasia 5–9% blasts No Auer rods
Refractory anemia with excess blasts-2 (RAEB-2)	Cytopenias 5–19% blasts Auer rods ± <1 × 10 <sup>9</sup> /L monocytes	Unilineage or multilineage dysplasia 10–19% blasts Auer rods ±

\*Karyotype definitions:

Good risk: Normal; -Y, del(5q), del(20q). Poor risk:  $\geq 3$  abnormalities; abnormal chromosome 7. Intermediate risk: All other abnormalities.Data from Greenberg P, et al. International scoring system for evaluating prognosis in myelodysplastic syndrome. *Blood*. 89:2079, 1997.

favorable MDS subset because a large percentage of patients do not progress to acute leukemia. In a recent clinical study, lenalidomide, an oral immunomodulatory drug, significantly decreased transfusion requirements and demonstrated reversal of cytogenetic abnormalities in patients with 5q-syndrome. This drug has become the standard of care for treatment of transfusion-dependent, lower risk patients with 5q-syndrome and reinforces the clinical and therapeutic importance of cytogenetic evaluation in MDS.

### Acute Myelogenous Leukemia

AML refers to a group of clonal hematopoietic disorders that are characterized by proliferation of immature myeloid cells in the bone marrow. Accumulation of leukemic cells impairs the normal hematopoietic function of the bone marrow, resulting in cytopenias with or without leukocytosis.

AML is a disease of older adults, with a median age at diagnosis of 67 years. The American Cancer Society estimated that 11 930 patients would be diagnosed with AML in 2006 with an anticipated 9040 dying of disease. The incidence increases with age (see Figure 103-1). According to the Surveillance Epidemiologic and End Results (SEER) statistics from 2000 to 2003, over 55% of incident cases of AML were diagnosed in adults aged 65 years and older.

Risk factors for the development of AML include a history of preceding MDS, exposure to certain chemotherapy drugs (alkylating agents, topoisomerase 2 inhibitors, and nitrosoureas), radiation or benzene exposure, and a history of Down's syndrome. The majority of diagnosed cases of AML, however, are not linked to any known risk factor.

The clinical signs and symptoms of AML can be varied and non-specific. Patients usually present with evidence of bone marrow failure: anemia, thrombocytopenia, granulocytopenia. Fatigue, dyspnea, bleeding, fever, and infection are common upon presentation. Leukemic infiltration of tissues outside the bone marrow such as

liver, spleen, skin, lymph nodes, and central nervous system (CNS) can produce a variety of other symptoms specific to the site of involvement. Some patients present with severe leukocytosis, which can produce symptoms of leukostasis as a result of a large blast fraction in the peripheral blood. Peripheral blood findings range from pancytopenia with or without circulating blasts cells to severe leukocytosis with circulating blasts typically with anemia and thrombocytopenia.

The diagnosis of AML depends primarily upon detection of leukemic blasts of myeloid lineage ( $\geq 20\%$ ) in the bone marrow. Morphologic evaluation can be aided by immunohistochemical and flow cytometry techniques to confirm myeloid versus lymphoid origin. The traditional international classification system (FAB) details subtypes of AML (M1 through M7) based on morphology, histochemical characteristics, and immunophenotyping. The more recently proposed WHO classification of AML (Table 103-10)

**TABLE 103-10****Classification of Acute Myeloid Leukemia**

Acute myeloid leukemia with recurrent genetic abnormalities
Acute myeloid leukemia with t(8;21)(q22;q22); (AML1/ETO)
Acute myeloid leukemia with abnormal bone marrow eosinophils inv(16)(p13q22) or t(16;16)(p13;q22); (CBF $\beta$ /MYH11)
Acute promyelocytic leukemia (AML with t[15;17][q22;q12] [PML/RAR $\alpha$ ] and variants)
Acute myeloid leukemia with 11q23 (MLL) abnormalities
Acute myeloid leukemia with multilineage dysplasia
Following a myelodysplastic syndrome or myelodysplastic syndrome/myeloproliferative disorder
Without antecedent myelodysplastic syndrome
Acute myeloid leukemia and myelodysplastic syndromes, therapy-related
Alkylating agent-related
Topoisomerase type II inhibitor-related (some may be lymphoid)
Other types
Acute myeloid leukemia not otherwise categorized
Acute myeloid leukemia minimally differentiated
Acute myeloid leukemia without maturation
Acute myeloid leukemia with maturation
Acute myelomonocytic leukemia
Acute monoblastic and monocytic leukemia
Acute erythroid leukemia
Acute megakaryoblastic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis

incorporates morphologic, immunophenotypic, genetic, and clinical features. There are four major categories, each with two or more subtypes described by Brunning et al. The WHO classification highlights the importance of a cytogenetic classification for prognosis and treatment. In recent years, subsets of AML defined by specific cytogenetic abnormalities have been shown to be associated with improved prognosis such as the core binding factor leukemias (inv 16, t(8;21), t(16;16)), and acute promyelocytic leukemia (t(15;17)). Risk-adapted treatment strategies have been developed to maximize clinical outcomes and minimize toxicity based upon cytogenetic classification.

If untreated or unresponsive to chemotherapy, AML may be rapidly fatal (median survival < 2 months). The major causes of death are overwhelming infection and hemorrhage related to the disease-associated cytopenias.

Standard induction therapy for AML is combination chemotherapy that includes cytosine arabinoside (ara-C) and an anthracycline such as daunorubicin. These drugs yield complete remissions (CRs) in 50% to 80% of patients, depending upon various prognostic factors. Increased age is an important negative prognostic factor. The poorer prognosis associated with increased age is related to both a higher frequency of fatal infections and hemorrhage during the period of disease and treatment-related marrow hypoplasia (induction deaths) and to chemotherapy failure (residual or resistant leukemia). While CR rates have usually been 60% to 80% in younger patients with AML, the CR rate in patients aged 60 years and older has generally been  $\leq 50\%$  (with induction death rates of 20% to 40%).

Tumor biology contributes to worse prognosis in older adults with AML. As a group, older patients with AML have a higher percentage of unfavorable cytogenetic abnormalities and a lower percentage of favorable cytogenetic abnormalities compared to younger patients. Unfavorable cytogenetic abnormalities are associated with decreased rates of remission and shortened overall survival. Expression of MDR1, which confers resistance to chemotherapeutic agents, is more common in older AML patients. Older patients are more likely to have a secondary AML arising from underlying myelodysplastic syndrome, which is less responsive to standard therapy. Clinical characteristics including increased comorbidity, age-associated physiologic changes, polypharmacy, and functional and cognitive impairment complicate therapy in older adults and likely also contribute to outcome disparities.

To date, the optimal treatment strategy for older adults remains controversial with recommendations ranging from supportive care alone to standard aggressive therapies. A landmark randomized study by Lowenberg et al. demonstrated improved survival in selected patients aged 65 years and older treated with induction chemotherapy versus supportive care alone. This study demonstrated a potential benefit to aggressive treatment for selected older adults. However, outcomes remain suboptimal in this population. Attempts to improve response rates in older patients with AML have included attenuated doses of standard therapy; these treatments have resulted in decreased induction death rates but without improved CR rates. The roles of gemtuzumab ozogamicin (Mylotarg), a monoclonal antibody directed at CD33, and other directed therapies are yet to be determined. Patients in the subgroup with acute promyelocyte leukemia (APL; AML-M3) are now treated very effectively with oral all-*trans*-retinoic acid (ATRA) plus chemotherapy; AML-M3, however, occurs uncommonly in older patients. The role of more aggressive therapies, including stem cell transplantation (high-dose therapy with stem cell rescue), has been limited in elderly patients

by the high rates of complications and prohibitive toxicity. However, improvements in supportive care have allowed for increased investigation of dose-intensive therapies in older patients.

The median duration of CR is approximately 1 year, and a small percentage ( $\leq 15\%$ ) of older (60 years of age and older) patients will be cured of their leukemia. Patients who achieve CRs should be considered for therapy after remission in an attempt to prevent or delay relapse. However, the exact role and optimal type of such postremission therapy in older patients remain poorly defined.

Treatment decisions for older adults with AML should be individualized. Decisions should include risk stratification based on tumor biology (cytogenetic risk groups) and an estimate of physiologic reserve based on clinical characteristics such as comorbidity and functional status. Older adults with favorable cytogenetics and good functional status should be considered for aggressive curative treatment. Poor-risk patients based on tumor biology or clinical characteristics could be considered for novel treatments on clinical trials or supportive care in an effort to maximize quality of life.

### Acute Lymphoblastic Leukemia

ALL is primarily a disease of children, but in adults, age-adjusted incidence increases in the elderly. There are approximately 3900 new cases of adult ALL in the United States annually, with a slight male predominance (1.2:1). With available therapy today, childhood ALL is curable in the majority of patients. ALL in adults is not the same as the childhood disease. First, the frequency of complete response is lower—70% to 75% in adults as opposed to more than 90% in children. Second, the remission duration and curability using the same therapy is considerably less. Important prognostic features for outcome in the treatment of ALL include age, cytogenetics, and immunophenotype. Poor prognosis is especially associated with the presence of chromosomal translocations such as Philadelphia (Ph) chromosome t(9;22), t(4;11), t(8;14), t(2;8), or t(8;22), and with a phenotype indicating mixed lymphoid–myeloid leukemia (also called biphenotypic leukemia).

The initial goal of therapy for adult ALL is to correct problems secondary to bone marrow failure; that is, to treat anemia with blood transfusions, treat documented or suspected infection, and control bleeding. Specific antileukemia treatment is then directed toward the achievement of a CR. Induction chemotherapy therapy for ALL, very different from that for AML, usually includes the use of prednisone, vincristine, daunorubicin, and asparaginase. While these drugs are well-tolerated in children, increasing age is associated with poorer drug tolerance. Mortality, usually from infection and/or bleeding during the induction process, may occur in 10% to 20% of elderly patients.

In contrast to the treatment of AML, it is widely accepted that patients with ALL require therapy after CR. These phases of treatment once the patient is in CR have been referred to as intensification therapy and maintenance therapy. The optimal therapy after remission and the duration of such therapy in older patients are not clearly defined. Most programs use multiple drugs administered in a cyclic fashion over a 2-year period; the more intensive therapy is given over about 6 months after CR is achieved (intensification or consolidation), followed by a less-intensive outpatient maintenance regimen for approximately 18 months.

Directed treatment to the craniospinal axis (CNS prophylaxis) is standard practice in the treatment of childhood ALL. While the incidence of CNS leukemia is lower in adults than in children,

TABLE 103-11

\*Surface immunoglobulin.

treatment to the CNS is also part of ALL therapy in adults. This usually consists of intrathecal methotrexate in conjunction with high-dose systemic therapy such as high-dose methotrexate and ara-C, or cranial radiation.

With the above intensive treatment plan, the median duration of remission is approximately 2 years, with 35% to 45% of adult patients disease-free at 5 years; however, prognosis is poorer for older adults. One contributing feature to this poorer response duration in adults as opposed to children is the inability to deliver optimal chemotherapy at maximal doses caused by comorbid diseases and increased susceptibility to toxicity.

### Chronic Lymphocytic Leukemia

CLL is the most common leukemia in the western hemisphere and may be commonly encountered in a geriatric practice. CLL is a disorder of clonal proliferation of mature lymphoid cells in the peripheral blood, bone marrow, and lymphoid organs. CLL occurs predominantly in older adults, with median age at diagnosis of approximately 70 years. The reported incidence of 3.8 per 100,000 population in western countries (about 10,000 new cases per year in the United States) may be an underestimate because many patients are asymptomatic for years; incidence in persons older than age 60 years is about 20 per 100,000 population. There is no racial difference in the United States between blacks and whites, but there are very few cases in the Far East and among persons of Oriental descent; the male:female ratio is approximately 2:1. Current diagnostic studies, especially immunophenotyping, allow for differentiation of the chronic lymphoid malignancies: B-cell CLL, T-cell CLL, prolymphocytic, circulating non-Hodgkin's lymphomas, and hairy cell leukemia.

#### B-cell CLL

B-cell CLL accounts for over 95% of all CLL. Twenty-five percent of such patients are identified with asymptomatic lymphocytosis during evaluation for other medical problems. Symptomatic patients may present with weight loss, fatigue, recurrent infections, fevers, or pain associated with hepatosplenomegaly or bulky lymphadenopathy. In most patients, the disease has a gradual progression spanning several years and the extent of the lymphoid burden at diagnosis correlates well with length of preexisting disease. In some patients, the disease has a more aggressive course and progression to advanced clinical stages may occur within a few months of diagnosis. Identification of molecular and protein markers are beginning to explain the heterogenous natural history observed in this disease.

The diagnosis of CLL is based on peripheral blood lymphocytosis  $>10,000$  lymphocytes/ $\mu\text{L}$  and a specific immunophenotyping pattern (coexpression of CD5 and CD20/23 with weak expression of surface immunoglobulin) showing a clonal proliferation of lymphocytes. Diagnosis and staging of CLL can usually be established by history, physical examination (careful evaluation for lymphadenopathy and splenomegaly), CBC with review of the blood smear, and immunophenotyping of the peripheral blood using flow cytometry. Classic findings on the peripheral smear include increased mature appearing lymphocytes and smudge cells (peripheral smear artifact reflecting the fragility of the B-CLL cells to mechanical manipulation). Bone marrow studies are usually not needed for diagnosis.

The differential diagnosis for B-CLL includes other mature B-lymphoproliferative disorders such as mantle cell lymphoma, prolymphocytic leukemia, hairy cell leukemia, and splenic lymphoma with villous lymphocytes. The clinical course and treatments differ widely for these disorders, particularly mantle cell lymphoma. Evaluation of clinical presentation, morphology, and immunophenotype are necessary to arrive at the correct diagnosis (Table 103-11).

The original Rai classification (Table 103-12) implied an orderly progression from lymphocytosis alone to the successive development of adenopathy, organomegaly, and, eventually, anemia and thrombocytopenia. The prognostic importance of these variables has been confirmed. Specific cytogenetic abnormalities correlate with

TABLE 103-12

## CLL Rai Clinical Classification

STAGE	RISK*	CLINICAL FINDINGS	SURVIVAL (yr)
0	Low	Lymphocytosis only	$\geq 12$
1	Intermediate	$\uparrow$ Lymphs plus $\uparrow$ nodes	7-10
2	Intermediate	$\uparrow$ Lymphs plus $\uparrow$ spleen and/or liver $\pm \uparrow$ Nodes	4-9
3	High	$\uparrow$ Lymphs plus $\downarrow$ Hgb ( $<11$ g/dl) $\pm \uparrow$ Nodes, $\uparrow$ liver, $\uparrow$ spleen	1.5-2
4	High	$\uparrow$ Lymphs plus $\downarrow$ platelets ( $<100,000/\text{ul}$ ) $\pm \uparrow$ Nodes, $\uparrow$ liver, $\uparrow$ spleen, $\downarrow$ Hgb	1.5-2

\*Data from Rai classification.

prognosis. A 13q deletion is associated with a better prognosis, compared to deletions of 11q and 17p, which confer a worse prognosis. Additional molecular markers of prognostic significance include presence of CD38 and ZAP-70.

Therapy for B-cell CLL has been considered palliative and therefore has been reserved for patients who are symptomatic or who progress to develop cytopenias (Rai stages 3 or 4). The mainstay of therapy has been oral alkylating agents (chlorambucil or cyclophosphamide) for control of lymphoid proliferation and steroids for autoimmune complications. Leukocytosis alone (stage 0) does not require therapy, because the prognosis of these patients is excellent in the absence of the other poor prognostic factors. The rate of increase of leukocytosis is a better indicator of disease activity than the absolute count. Leukostasis associated with high circulating blast counts in acute leukemias does not generally occur in this condition because most of the lymphocytes are mature, small cells.

Treatment with chemotherapy or local radiation can be used to control symptoms in patients with stage I or II disease; however, symptomatic improvement does not appear to prolong survival. In contrast, when treated with combination chemotherapy, patients with stage III or IV CLL have an improved median survival, which ranges from 1.5 years to more than 4 years. The development of more effective initial therapies for CLL such as nucleoside analogs (e.g., fludarabine) have resulted in an increased number of patients achieving CR. It is not yet clear that these remissions result in prolonged survival, although data from recent clinical trials are encouraging. These promising results have encouraged many hematologists and oncologists to institute therapy at an earlier stage. A monoclonal antibody against CD-52, alemtuzumab, has been approved as second line therapy for patients previously treated with alkylating agents and fludarabine. The best way to integrate newer agents such as fludarabine and monoclonal antibodies (e.g., rituximab and alemtuzumab) with each other and/or with more traditional therapies (alkylators and steroids) are not yet well-defined. There are multiple clinical trials currently evaluating different combinations of these medications (concurrent or sequential). Unfortunately, each of these agents has been associated with increased risk of opportunistic infections, particularly in the older adult.

Autoimmune manifestations of CLL are common and include development of antibodies to platelets and red cells (IgG and C3 on direct antiglobulin test) and to erythroid precursors, resulting in red cell aplasia. For anemic patients, reticulocyte counts and direct Coomb's testing should be obtained to help differentiate hemolysis from decreased bone marrow production. All of the autoimmune complications are indications for therapy with steroids or intravenous gamma globulin for refractory cases of red cell aplasia.

Recurrent infections are the most common complications leading to death in CLL. Patients with stage 0 CLL have minimal increased risk of infection. In anticipation of gradual deterioration in immune response, however, pneumococcal vaccine and boosters should be administered while the potential for response is still intact. All other patients have higher risks for infection. As the disease advances clinically, immune function becomes progressively compromised, with increased susceptibility to viral, bacterial, and fungal infection. Patients should avoid direct contact with the body fluids of children who have received live-virus vaccines (oral polio, measles-mumps-rubella) for the duration of viral shedding. The subset of patients presenting with recurrent bacterial infections may benefit from administration of intravenous gamma globulin.

### B-Cell Prolymphocytic Leukemia

This rare subtype of lymphoid leukemia is characterized by marked lymphocytosis (often  $>100,000$  lymphocytes/ $\mu\text{L}$ ), extensive bone marrow infiltration, massive splenomegaly, and minimal to absent adenopathy. Prolymphocytes comprise the majority of circulating WBC ( $>55\%$ ; often  $>90\%$ ). The prolymphocyte is about twice the size of a normal lymphocyte, with a characteristic dense border outlining a prominent nucleolus. B-cell prolymphocytic leukemia (B-PLL) cells usually express CD19, CD20, CD22, CD79a, FMC7, and strong surface IgM; CD23 is usually negative.

Most patients with B-PLL have advanced clinical disease at presentation, with a prognosis similar to that of patients with stage III and IV B-cell CLL. Therapy for these patients has included multi-agent chemotherapy to control the splenomegaly and leukocytosis, and radiation therapy to palliate splenic engorgement. Patients become increasingly refractory to therapy, with an expected survival of 1.5 years and death caused by uncontrolled disease. Recent data suggest that more aggressive newer agents such as alemtuzumab (CAMPATH-1H) are more effective than previous therapies for PLL, with improved response rates and survival.

### T-Cell PLL/CLL

T-cell PLL/CLL is a rare subtype that accounts for 2% to 3% of all small lymphocytic leukemia ("CLL") cases. Clinical manifestations include lymphocytosis, hepatosplenomegaly, generalized lymphadenopathy, skin infiltration (20%), and bone marrow involvement. Immunophenotyping in the peripheral blood shows a clonal proliferation of the malignant T cells—CD2, CD3, CD7 positive with weak CD3; in approximately 60% of patients, the cells are CD4+/CD8-, 25% are CD4+/CD8+, and 15% are CD4-/CD8+. Prognosis is generally poor, with limited responsiveness to therapy though newer agents (e.g., alemtuzumab) appear to be active.

### Hairy Cell Leukemia

Hairy cell leukemia is rare and almost exclusively seen in men older than age 60 years. The clinical features include massive splenomegaly, absence of adenopathy, and peripheral pancytopenia. The diagnosis is made by the morphologic characteristics of the circulating lymphocytes, which are small and have cytoplasmic projections ("hairs"). Diagnosis, previously made histochemically with the tartrate-resistant acid phosphatase (TRAP) stain, is now made with immunophenotyping that shows positive sIgM, CD19, CD20, CD22, CD79a, CD11c, CD25, and CD103; negative CD5, CD10, and CD23. Bone marrow aspiration usually yields little material (dry tap) and bone marrow biopsy shows increased cellularity with diffuse infiltration by the hairy cells. The spleen is infiltrated with the same clone of cells. Infections with Gram-negative and staphylococcal species is the predominant complication.

Splenectomy was the treatment of choice in the past with improvement of neutropenia in about 50% of patients for 8 to 10 years. Interferon (IFN)- $\alpha$  produced partial and CRs in more than 50% of patients, sparing many patients a surgical procedure and the effects of the splenectomy on the immune system. Interferon has now been replaced by the nucleoside analogs, especially cladribine (2-CdA), which is very well tolerated. This 5-day treatment yields high remission rates, frequently after only one course of therapy.

## T-cell Large Granular Lymphocytic Leukemia

T-cell large granular lymphocytic (T-LGL) leukemia is a rare clonal disorder of cytotoxic T lymphocytes, which typically presents with chronic neutropenia. T-LGL leukemia represents approximately 4% of lymphoproliferative disorders. Patients tend to be older, with a median age of 60 years. Many patients are asymptomatic and will have chronic neutropenia, mild lymphocytosis with or without anemia. Symptoms are typically related to recurrent infections particularly of the skin, oropharynx, and perirectal regions. Splenomegaly is common but lymphadenopathy is uncharacteristic. The peripheral blood demonstrates a proliferation of large granular lymphocytes. These can also be seen in reactive disorders such as viral infections. The diagnosis depends upon establishing a clonal T-cell receptor gene rearrangement within the population of large granular lymphocytes using polymerase chain reaction (PCR) or flow cytometry techniques on the peripheral blood. The diagnosis is supported by the characteristic immunophenotype of CD3+, CD8+, CD16+, and CD57+. T-LGL leukemia is a relatively indolent disease with median survival >10 years. Indications for treatment include severe neutropenia (ANC < 500), recurrent infections, and transfusion-dependent anemia. Treatment involves immunosuppression with agents such as methotrexate, cyclosporine, or steroids.

## Chronic Myelogenous Leukemia

CML is a myeloproliferative disorder characterized by excess production of mature granulocytes that eventually progresses to a clinical picture similar to acute leukemia with an overgrowth of immature cells (blast crisis). It accounts for 15% to 20% of all leukemias, with an age-adjusted incidence rate of 1.5 per 100,000 population without geographic, sex, or racial differences. The incidence increases with age and the median age at diagnosis is 67 years.

Diagnosis is suspected by the demonstration of granulocytosis in the peripheral blood with a predominance of segmented neutrophils and myelocytes, increased basophils and eosinophils, increased bone marrow cellularity, a low LAP score. The presence of the Philadelphia chromosome t(9;22) and or its products (*BCR/ABL* fusion mRNA, *Bcr/Abl* protein) are required to confirm the diagnosis. Diagnosis can be made on peripheral blood using PCR or fluorescence in situ hybridization (FISH) techniques. Bone marrow biopsy is still required for complete cytogenetic evaluation.

The disease characteristically proceeds through three phases: chronic, accelerated, and terminal (blastic) phase (Table 103-13). The length of the chronic phase is highly variable, from 1.5 years to 14 years (median duration of 3 years). In the chronic phase, the disease is easily controlled without aggressive therapy. The accelerated phase begins with gradual increases in white cells, platelets, and spleen size. Initially good maturation persists, but eventually more blasts are seen in the peripheral blood, and higher doses of medication are required to maintain control. This phase generally lasts a few months but may extend over 1 year. The terminal phase of the disease is indistinguishable from acute leukemia. The blasts have myeloid surface markers in 85% of the patients and lymphoid markers in the remaining 15%.

Treatment for CML has changed dramatically in recent years, altering the natural history of this disease. IFN- $\alpha$  was the first drug to change the natural history of CML, decreasing the percentage of cells exhibiting the Ph chromosome and prolonging the chronic

**TABLE 103-13**

### CML Classification

CHRONIC PHASE	ACCELERATED PHASE	BLAST PHASE
<10% blasts	Any of the following: 10–19% blasts Thrombocytopenia <100,000/cmm Peripheral basophilia >20% Appearance of additional cytogenetic abnormality Increasing spleen size or WBC on therapy	Any of the following: >20% blasts Extramedullary blasts

From Brunning R, et al. *Tumors of Hematopoietic and Lymphoid Tissues*. Geneva: World Health Organization; 2001.

phase by 1 to 2 years. Imatinib mesylate (Gleevec; STI-571), a targeted tyrosine kinase inhibitor designed specifically for the treatment of CML (in oral formulation), proved to have significant activity in the blast phase and accelerated phase of CML. In chronic phase CML, imatinib mesylate yielded marked improvements in clinical and cytogenetic responses, rates of disease progression, and treatment related toxicity compared to IFN- $\alpha$  plus low-dose ara-C in a randomized clinical trial. Based on these results, imatinib mesylate has replaced interferon regimens as the standard of care for patients with chronic phase CML. Imatinib is very well tolerated, which is particularly relevant for the elderly population. Many patients who would not have been good candidates for cytotoxic therapy or interferon can be effectively treated with imatinib. It is too early to determine the duration of remissions for elderly patients treated with this medication. However, second line therapy with newer tyrosine kinase inhibitors (dasatinib, nilotinib) have demonstrated activity in patients who have progressed on imatinib providing additional treatment options for older adults.

Allogeneic stem cell transplantation in the chronic phase, a promising intervention in younger patients, has limited benefit in the elderly patient because of the morbidity and mortality of this treatment. Imatinib mesylate should be the initial treatment for both the accelerated and blastic phases of CML if not already used during the chronic phase of the disease. Treatment of the blastic transformation (after imatinib) depends on the cell origin of the blasts. Myeloid blastic states respond poorly to standard AML therapies, and no standard therapy is available. Lymphoid blastic states can be controlled for 6 to 12 months, with standard combination regimens as used for de novo ALL.

## Myeloproliferative Diseases

Myeloproliferative diseases include CML (described above), polycythemia vera, myelofibrosis, and essential thrombocytosis. Both polycythemia vera and myelofibrosis can be associated with increased WBC. Polycythemia vera is usually associated with mild increases in white count with a relatively normal differential, while myelofibrosis is frequently associated with immature WBCs in addition to nucleated RBCs. The leukocytosis associated with polycythemia vera is usually of little consequence and treatment is directed towards the control of the increased red cells. Myelofibrosis can be associated

with variable abnormalities in WBC numbers, either increased WBC with circulating immature precursors or decreased WBCs, especially in the present of massive splenomegaly.

### Cancers Metastatic to Bone Marrow

Many of the common malignancies have a propensity for metastasis to the bone and bone marrow. These include carcinomas of the breast, lung, prostate, and the lymphomas. Space-occupying lesions in the bone marrow, which crowd out normal hematopoietic elements, are termed myelophthisis. Manifestations of myelophthisis in the peripheral blood include pancytopenia and leukoerythroblastosis. Pancytopenias may be aggravated by nutritional deficiencies, especially folate deficiency.

# Non-Hodgkin's and Hodgkin's Lymphomas and Myeloma

William B. Ershler ■ Dan L. Longo

Lymphoid malignancies include nearly 40 named entities; however, they can be divided into roughly five large categories based on the clinical syndrome they cause: acute lymphoid leukemias, chronic lymphoid leukemias, non-Hodgkin's lymphomas, Hodgkin's disease, and plasma cell disorders (chiefly multiple myeloma). In 2007, 111,820 people were diagnosed with a lymphoid malignancy and 36,440 patients died from a lymphoid malignancy. [Figure 104-1](#) shows a distribution of the annual incidence in a pie chart. Acute and chronic lymphoid leukemias are covered in a separate chapter. We shall discuss non-Hodgkin's lymphomas, Hodgkin's disease, and plasma cell disorders in this chapter.

## NON-HODGKIN'S LYMPHOMA

The non-Hodgkin's lymphomas (NHLs), the most common lymphoid malignancies, are a heterogeneous group of cancers that have in common the clonal expansion of cells of lymphoid origin. The heterogeneity stems from the very large number of distinct lymphocyte subsets and diverse molecular and genetic pathways to neoplasia. Mutations, chromosome translocations, or other alterations in certain genes (e.g., *BCL2*, *c-MYC*, *FAS*, *BCL6*) contribute to the pathogenesis in many cases and gene expression profiling has identified subsets of NHL with varying aggressiveness and response to chemotherapy. About 88% of all NHLs are derived from B cells. Despite insights into the alterations associated with specific NHL types, the mainstay of current therapy remains empiric and typically includes cytotoxic chemotherapy combined with monoclonal antibody directed at the CD20 molecule, which is expressed on nearly all B cells. Clinical trials suggest that elderly patients may safely receive these agents with expectations similar to their younger counterparts.

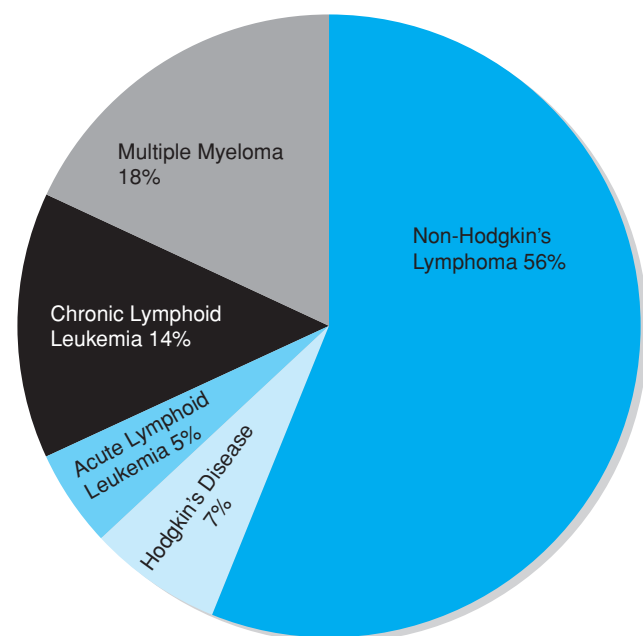

### Epidemiology

In 2007, 63,190 new cases of NHL were diagnosed and about half occurred in persons aged 60 years or older. National Cancer Insti-

tute data indicates an approximate 25% increase in NHL incidence since 1950, although there is some evidence that the rate of rise has declined somewhat since 1990. Although some of the increase can be related to the acquired immunodeficiency syndrome (AIDS) epidemic, particularly in young and middle-aged persons, the bulk of the cause of the increase is undefined, particularly in the aged population. With more effective human immunodeficiency virus (HIV) treatment, HIV-associated lymphoma is becoming less frequent. However, NHL affects older patients (one third are 70 years or older) and is the fifth leading cause of cancer deaths in women aged 80 years and older. Furthermore, current cancer surveillance statistics indicate that despite the fact that incidence is declining for the population as a whole, for those aged older than 65 years, there is a net increase of 1.3% compared to a rate of -1.5% for the younger population.

### Classification

Lymphoma classification was a contentious field until 1999 when the World Health Organization Classification was developed by an international panel of hematopathologists and clinicians based on consensus criteria including histology, immunology, genetics, and clinical features of diseases ([Table 104-1](#)). The classification includes nearly 40 named entities; however, the 10 most frequent diagnoses are printed in bold type. Fortunately, about 75% of patients have one of two histological types, diffuse large B-cell lymphoma (DLBL) (~40% to 45% of lymphomas in the United States) and follicular lymphoma (FL) (~30% of lymphomas in the United States). These two prototypical forms of lymphoma highlight an intriguing paradox. In general, FLs, which have a more indolent natural history, frequently present with few symptoms but with widespread disease and are generally considered incurable with the current modalities. The more aggressive DLBLs present with more constitutional symptoms and more often at earlier stages and are in most cases curable, even at an advanced stage. The challenge for those treating lymphomas in elderly patients is to balance the likelihood of a meaningful treatment response against the potentially enhanced rate and severity of

**FIGURE 104-1.** Distribution of lymphoid malignancies in the United States.

treatment toxicity in the setting of an individualized assessment of the patient's functional status and projected longevity.

Given that most lymphomas are either follicular or DLBL, most of the discussion will deal with management of these two entities.

Less detailed discussion will be provided for a handful of more unusual lymphomas. The approach to the patient with lymphoma is similar regardless of the specific diagnosis. One first seeks to establish the extent of the disease and establish the clinical stage (see later). A variety of specialized tools have been applied to the diagnosis of lymphomas including cytogenetics and flow cytometry to define the expression of certain cell surface markers, and immunohistochemistry and molecular biology techniques. These tests can sometimes be helpful in making a difficult diagnosis, but often the results are not available in a clinically useful time frame. Similarly, the development of microarray technology and the demonstration that various patterns of gene expression correlate with clinical outcomes is of interest; however, it is not clear that these techniques are suitable for clinical application to a particular patient.

## Etiology

For most lymphomas, the cause is unknown. Lymphomas are increased in the setting of primary and secondary immunodeficiency disease and certain autoimmune diseases (Sjogren's syndrome, celiac disease, rheumatoid arthritis, systemic lupus erythematosus). A number of lymphoma types are associated with infectious agents. For example, gastric mucosa-associated lymphatic tissue (MALT) lymphoma is associated with *Helicobacter pylori* infection. Exposure to agricultural chemicals seems to be associated with an increased risk of lymphoma. However, the factors that produced an increasing incidence between 1950 and 1990, which has leveled off in recent years, is unexplained. Many types of lymphomas have characteristic

**TABLE 104-1**

### WHO Classification of Lymphoid Malignancies

B CELL	T CELL	HODGKIN'S DISEASE
<b>Precursor B cell neoplasm</b> Precursor B lymphoblastic leukemia/lymphoma (precursor B cell acute lymphoblastic leukemia)	<b>Precursor T cell neoplasm</b> Precursor T cell lymphoblastic lymphoma/leukemia (precursor T cell acute lymphoblastic leukemia)	Nodular lymphocyte-predominant Hodgkin's disease
<b>Mature (peripheral) B cell neoplasms</b> B cell chronic lymphocytic leukemia/small lymphocytic lymphoma B cell prolymphocytic leukemia  Lymphoplasmacytic lymphoma Splenic marginal zone B cell lymphoma ( $\pm$ villous lymphocytes) Hairy cell leukemia	<b>Mature (peripheral) T cell neoplasms</b> T cell prolymphocytic leukemia  T cell granular lymphocytic leukemia  Aggressive NK cell leukemia Adult T cell lymphoma/ leukemia (HTLV-I +)  Extranodal NK/T cell lymphoma, nasal type	Classic Hodgkin's disease Nodular sclerosis Hodgkin's disease Lymphocyte-rich classic Hodgkin's disease Mixed-cellularity Hodgkin's disease Lymphocyte-depletion Hodgkin's disease
<b>Plasma cell myeloma/plasmacytoma</b>	Enteropathy-type T cell lymphoma	
<b>Extranodal marginal zone</b> B cell lymphoma of MALT type	Hepatosplenic $\gamma\delta$ T cell lymphoma	
<b>Mantle cell lymphoma</b>	Subcutaneous panniculitis-like T cell lymphoma	
<b>Follicular lymphoma</b> Nodal marginal zone B cell lymphoma ( $\pm$ monocytoid B cells)	<b>Mycosis fungoides/Sézary syndrome</b> Anaplastic large cell lymphoma, primary cutaneous type	
<b>Diffuse large B cell lymphoma</b>	<b>Peripheral T cell lymphoma, not otherwise specified (NOS)</b>	
<b>Burkitt's lymphoma/Burkitt cell leukemia</b>	Angioimmunoblastic T cell lymphoma Anaplastic large cell lymphoma, primary systemic type	

HTLV, human T cell lymphotropic virus; MALT, mucosa-associated lymphoid tissue; NK, natural killer; WHO, World Health Organization.

**TABLE 104-2****Staging for Lymphoma—Ann Arbor Classification, Cotswolds Modifications**

I	Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer's ring)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (the mediastinum is a single site; hilar lymph nodes should be considered "lateralized" and, when involved on both sides, constitute stage II disease)
III	Involvement of lymph node regions or lymphoid structures on both sides of the diaphragm
III1	Subdiaphragmatic involvement limited to spleen, splenic hilar nodes, celiac nodes, or portal nodes
III2	Subdiaphragmatic involvement includes paraaortic, iliac or mesenteric nodes plus structures in III1
IV	Involvement of extranodal site(s) beyond that designated as "E"; more than one extranodal deposit at any location; any involvement of liver or bone marrow
A	No symptoms
B	Unexplained weight loss of > 10% of body weight during the 6 months before staging Unexplained, persistent, or recurrent fever ( $T > 38$ degrees C) in the previous month Recurrent drenching night sweats in the previous month
E	Localized, solitary involvement of extralymphatic tissue, excluding liver and bone marrow

chromosomal translocations that are thought to play a role in their origin. However, lymphomagenesis remains largely undefined. Only the *c-myc* translocations in Burkitt's lymphoma are sufficient to produce the lymphoma they are associated with. Other characteristic translocations seem to be one of several molecular alterations required to produce disease.

## Evaluation and Staging

The Ann Arbor staging system that was developed for Hodgkin's disease is also applied to patients with NHL, but often the system applies to NHL patients poorly. With the widespread use of systemic therapy to treat all stages of NHL and Hodgkin's disease (see later), precise pathological staging (Table 104-2) is less critical than it was when eligible patients were treated with localized therapies (e.g., radiation therapy). For example, in the low-grade lymphomas, the disease may be stage IV without much change in prognosis compared with earlier stages, and in the higher-grade aggressive lymphomas, systemic treatment is necessary even when disease is confined to one anatomical region. A patient with stage II DLBL could have small-volume disease involving two lymph node groups and an outstanding prognosis with a shortened course of chemotherapy or could instead have a football size mass in the abdomen with a poorer prognosis. Because anatomical staging does not define prognosis well in NHL, other supplementary systems have been developed. The International Prognostic Index (IPI) was developed for DLBL based on outcome of treating patients with CHOP (cyclophosphamide, hydroxydaunorubicin [doxorubicin], vincristine, prednisone) or CHOP-like regimens. The addition of rituximab to CHOP improved prognosis substantially and altered the prognostic significance of the IPI factors; these alterations have been incorporated into a new revised IPI (Table 104-3). A similar prognostic index has been developed for FL

**TABLE 104-3****Revised International Prognostic Index (IPI) for Diffuse Large B-Cell Lymphoma Treated with R-CHOP**

Five clinical prognostic factors:

1. Age  $\geq$  60 yrs
2. Serum lactate dehydrogenase levels elevated
3. Performance status  $\geq$  2 (ECOG) or  $\leq$  70 (Karnofsky)
4. Ann Arbor stage III or IV
5. More than one site of extranodal involvement

0 factors = very good risk, 10% of patients, 94% 4-yr survival.

1,2 factors = good risk, 45% of patients, 79% 4-yr survival.

3,4, to 5 factors = poor risk, 45% of patients, 55% 4-yr survival.

in which hemoglobin level and number of sites of nodal involvement replace Ann Arbor stage III or IV and > 1 extranodal site of disease in the IPI (Table 104-4). The staging workup for lymphomas (NHL and Hodgkin's) is shown in Table 104-5. Aggressive histology lymphomas, such as diffuse large B cell, Burkitt's and lymphoblastic, may require evaluation of the central nervous system (CNS) with a head computed tomogram (CT) and lumbar puncture, especially in patients with diffuse histology, bulky abdominal lymphadenopathy, or bone or bone marrow involvement. Keep in mind that older patients are more likely to present with more advanced disease. This may reflect a delay in diagnosis, as has been demonstrated for older people with solid tumors.

Overall, it does not appear that lymphomas in older patients have distinct clinical or pathological features from those same lymphomas occurring in younger people, though the confidence in that conclusion is undermined by the general underrepresentation of older patients on clinical trials. However, in certain series, it has been reported that older patients are more likely to have diffuse histology and present with extranodal disease involving gastric or bone marrow sites.

## Clinical Features and Therapy

### Diffuse Large B-Cell Lymphoma

DLBL is the most common form of lymphoma in the United States accounting for 40% to 45% of cases. DLBL often presents with diffuse adenopathy or an abdominal mass, and extranodal sites are involved in about 45% of cases. Factors influencing prognosis have been incorporated into a prognostic index (Table 104-3). The median age is about 64 years. The male-to-female ratio is 55:45. About one third of patients have B symptoms and about 50% present

**TABLE 104-4****International Prognostic Index for Follicular Lymphoma (FLIPI)**

Five clinical prognostic factors:

1. Age  $\geq$  60 yrs
2. Serum lactate dehydrogenase levels elevated
3. Performance status  $\geq$  2 (ECOG) or  $\leq$  70 (Karnofsky)
4. Hemoglobin level < 12 g/dL
5. Number of nodal groups involved > 4

0,1 factor = low risk, 36% of patients, 83% 8-yr survival.

2 factors = intermediate risk, 37% of patients, 62% 8-yr survival.

$\geq$  3 factors = poor risk, 27% of patients, 51% 8-yr survival.

**TABLE 104-5****Staging Recommendations for Lymphoma**

History, with special attention to “B” symptoms, including fevers, night sweats, and >10% loss in body weight
Physical examination with special attention to node-bearing areas, liver, and spleen
Initial blood work to include a complete blood count with white cell differential and platelet count, serum chemistries including liver function tests, creatinine, albumin, total protein, and erythrocyte sedimentation rate
Radiologic studies to include chest x-ray, positron emission tomography (PET), superimposed upon chest, abdomen and pelvis CT
Bilateral iliac crest bone marrow biopsies
(Selected cases) Bipedal lymphangiogram
(Selected cases) Laparotomy with exploration of lymph node-bearing areas, liver biopsies, and splenectomy; if laparotomy is not to be performed, consider percutaneous or laparoscopic-guided liver biopsies

with advanced stage disease. A small subset of patients has disease restricted largely to the mediastinum and the tumor is encased in dense fibrotic tissue. This mediastinal DLBL predominantly affects younger patients (median age 37 years) and women are affected twice as commonly as men. The approach to the patient is not influenced by the differences in presentation.

Most DLBL occurs *de novo* in the absence of known underlying disease. However, DLBL can also occur in the setting of immunosuppression, either from primary immunodeficiency diseases or AIDS or from iatrogenic immunosuppression in the setting of organ transplant. Often the Epstein–Barr virus (EBV) is an etiological agent of lymphomas occurring in immunosuppressed patients. EBV is also associated with primary CNS lymphoma and some cases of Hodgkin’s disease, particularly cases of mixed cellularity histology. DLBL frequently manifest mutations in p53 and alterations in the *Bcl-6* gene on chromosome 3q27. Distinct subsets have been defined by gene expression profiling, but such data are not usually relevant to the management of patients.

The treatment of choice for DLBL is a five-drug regimen called CHOP-R (cyclophosphamide, doxorubicin, vincristine, prednisone and rituximab). Patients with early stage disease may receive four to six cycles and those with advanced disease six to eight cycles. Overall survival at 4 years ranges from 94% for those with no poor prognostic factors to 55% for those with three or more poor prognostic factors. Patients who do not relapse within the first 2 years of achieving a complete response are very unlikely to do so. Overall, complete response rates are 70% to 100% with less than one third of complete responders relapsing. Untreated patients survive only 4 to 6 months. About 40% of patients who relapse are curable with high-dose therapy and autologous hematopoietic stem cell transplantation. Overall, more than two thirds of patients with DLBL are cured.

The curability of the disease makes it essential that the treating physician carefully inform the patient of the options available to them. CHOP-R is generally well-tolerated with predictable dose-related toxicities. Even very old patients can be successfully treated. In addition, infusional regimens like R-EPOCH (rituximab, etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin) are also safe and highly effective in older patients.

The new standard treatment represents a true advance in therapy. In an earlier study, the Nebraska Lymphoma Study Group used the CAP/BOP regimen (cyclophosphamide, doxorubicin, procarbazine, bleomycin, vincristine, and prednisone) to treat all patients with DLBL. They found a similar overall complete remission (CR) rate of 65% in patients older and younger than 60 years of age; however, patients younger than 60 years had a 62% 5-year survival, whereas those older than 60 years had a 35% 5-year survival. They found that treatment toxicity was similar and that deaths from apparently unrelated causes accounted for most of the survival difference. However, as therapy has improved, the contribution of age to prognosis has decreased.

### Follicular Lymphoma

FL is the second most common form of lymphoma in the United States accounting for about 33% of cases. Thus, FL and DLBL together account for about 75% of lymphomas. FL is predominantly a disease of lymph nodes. New painless adenopathy is the predominant presenting symptom. Some patients give a history of adenopathy that has waxed and waned in the past. B symptoms occur in less than 25% of patients and the disease is often widely disseminated at presentation with involvement of bone marrow noted in over 40%. Females are affected slightly more commonly than males and the median age is 59 years.

FL is associated with a characteristic genetic lesion, a t(14;18) that results in the expression of *bcl-2*, an antiapoptotic protein. How *bcl-2* expression is related to lymphomagenesis is undefined. An important biologic feature of FL is its genetic instability. Normal follicle center B cells undergo extensive somatic hypermutation to increase the ability of the antibody it produces to bind to antigens. In neoplastic follicular center cells, the mutation process is not restricted to the immunoglobulin genes. As mutations in other genes accumulate, the disease has a tendency to undergo transformation to DLBL with an acceleration in natural history and often an increased resistance to therapy. Histologic progression occurs at a rate of 5% to 7% per year and is not increased by therapy. The vast majority of patients with FL who die have DLBL as the cause of death. Median survival appears to have been increasing in the last 20 years from a median of 8 years to a median of 13 years. The basis for the improvement is not defined.

Patients in whom FL is restricted to lymph nodes may be cured by involved-field radiation therapy. Early studies of radiation therapy in early stage disease documented long-term disease-free survival in 90% of patients. The relegation of a patient to a watch-and-wait approach without staging the disease is indefensible. Many patients with localized disease have experienced disease progression while under “observation” and are thereby denied the potential for cure of early stage disease.

Management of patients with advanced stage disease is controversial. Because of the indolent course of disease, an initial period of “watchful waiting” is very appealing, especially in the elderly. In prospective trials, no overall survival difference has been demonstrated between observation and early chemotherapy. However, it should be noted that the CR rates and duration of the remissions are longer in the group treated initially compared with the observation groups. If one withholds treatment until a clinical indication emerges, the median time to initiation of chemotherapy is between 2 and 3 years. In one study, about one-fifth of the patients

in the observation protocol remained free from an indication to begin chemotherapy at 10 years. In a large prospective British trial, which had a 19-year follow-up, the actuarial survival without needing treatment in elderly patients was 40% (out of 51 patients). If one is to choose the watchful waiting approach, careful patient selection is essential. The presence of B symptoms, peripheral blood cytopenia, kidney or liver involvement, and any life-endangering organ involvement suggest a more aggressive disease requiring immediate treatment.

A single agent oral alkylating agent like chlorambucil or cyclophosphamide may be an attractive choice in the elderly because of ease of administration and relatively low toxicity. When used alone, this therapy results in response rates of 60% to 80% with about half of all patients achieving a complete response. Combination chemotherapy with cyclophosphamide, vincristine, and prednisone (CVP) is also effective and may result in slightly higher CR of 60% to 70%. Fludarabine, a purine nucleotide analog, is also an active agent used in the treatment of indolent lymphoma. Used alone, it can induce remissions in about 60% to 80% of all treatment naive patients.

The use of interferon for treatment of indolent lymphoma remains controversial. A meta-analysis demonstrated usefulness as a maintenance therapy in patients treated with aggressive combination chemotherapy who had responded to the therapy. It was shown that the DFS was increased with addition of interferon alfa as a maintenance agent. However, many patients on interferon have symptoms of fatigue and depression that affect their quality of life.

When used as a single agent in previously untreated patients, rituximab produces response in 47% to 73% of patients with up to 37% achieving a CR. Moreover, when combined with combination chemotherapy such as CHOP, rituximab has shown an excellent overall response rate (100%) and CR (87%). When combined with CVP (cyclophosphamide, vincristine, prednisone), R-CVP yields better overall survival (81% vs. 50%), CR (57% vs. 10%), and time to progression (median 27 months vs. 7 months) than CVP alone.

Patients with advanced stage disease including involvement of extranodal sites should be informed that recent advances in treatment appear to be associated with longer remissions and longer survival, but definitive evidence of disease curability is still scarce. Formerly, CRs could be achieved with a wide range of interventions including radiation therapy, single agent and combination chemotherapy, antibodies, interferon, and various combinations. However, the CRs tended to be short-lived, with a median duration of 2 years. More active regimens and agents are changing this picture. Combination chemotherapy programs including CHOP (see earlier in the chapter) or fludarabine with rituximab produce complete responses in 90% or more of patients with median durations of complete responses exceeding 8 years. Because patients with FL can survive for many years with lymphoma, treatment-induced improvement in overall survival has been more difficult to demonstrate. However, some evidence of treatment benefit is beginning to emerge from studies that use effective drugs with rituximab during induction therapy and some sort of maintenance therapy (either rituximab or interferon). It is not clear if maintenance therapy is merely keeping disease at a subclinical level or is eradicating disease. Another benefit from aggressive treatment approaches seems to be a reduction in the rate of histologic progression.

Once a relapse occurs, the disease is likely to respond to treatment again, but the response rates and duration decrease with each

relapse. Some data support the use of high-dose therapy with autologous stem cell transplant in selected (usually younger) patients. Two radionuclides have been approved by the FDA in the treatment of rituximab refractory indolent NHL. Yttrium-90-conjugated ibritumomab tiuxetan and iodine-131-conjugated tositumomab produce responses in two-thirds to three-fourths of rituximab-resistant patients. <sup>131</sup>I tositumomab is also effective as a single agent in previously untreated patients with over 90% OR and 75% CR. However, use of these agents as a primary therapy requires further randomized studies.

The confusion in the field is evident when expert recommendations range from watch and wait to high-dose therapy with transplant. However, a reasonable approach is to treat all patients with stage I or II disease with curative intent with radiation therapy. Patients with advanced disease should be assessed for intercurrent illness and life expectancy. Patients whose life expectancy is greater than 10 years may be candidates for an initial attempt at inducing durable remission with R-CHOP. Those with a shorter life expectancy with intercurrent illness can be observed and treated palliatively with single agent oral chlorambucil with or without prednisone when needed to control symptoms.

### Small Lymphocytic Lymphoma/Chronic Lymphocytic Leukemia

Small lymphocytic lymphoma (SLL) is the tissue counterpart of chronic lymphocytic leukemia (CLL) and occurs in patients with a median age of 65 years. CLL is the most common form of leukemia in the United States (Figure 104-1; ~15 500 cases/year) while SLL accounts for only 6% to 7% of lymphomas (~4160 new cases/year). Initially, there are few symptoms of SLL/CLL and many patients are diagnosed incidentally based on abnormal lymphocytes on the peripheral blood smear. Fevers, sweats, and weight loss (the typical "B" symptoms) are uncommon and should prompt evaluation for other potential causes, such as infection, histologic conversion (see later), or second malignancy. The disease is nearly always in advanced stage at diagnosis.

The malignant cell in SLL/CLL is a CD5+ B cell. The difference between SLL and CLL is thought to depend on the expression of adhesion molecules that either favor lymph node-based growth or not.

Immunologic abnormalities are not demonstrable in most histologic types of lymphoma except SLL, which is similar in nature to CLL. In this disorder, hypogammaglobulinemia is common and is associated with a propensity to infection, primarily with encapsulated bacterial organisms but also with common viruses. Monoclonal gammopathy may be noted, particularly if examined by sensitive techniques. Circulating tumor cells can be detected by immunoglobulin gene-rearrangement studies even when peripheral lymphocyte counts are not elevated. Hemolytic anemias, especially cold-agglutinin disease (1.7%), and immune thrombocytopenia (0.4%) are uncommon but well-known complications.

Occasionally (in ~5% of patients), and less commonly than FL, SLL/CLL may convert to a more aggressive large cell lymphoma after 5 to 8 years of clinically indolent disease (Richter's conversion). These aggressive tumors demonstrate more rapid growth, are more resistant to treatment, and are associated with a median survival of less than 6 months. Suspicion for such a conversion is raised when a single node or group of nodes is found to be growing disproportionately

to nodes at other sites, and biopsy reveals the large cell lymphoma, with SLL still being present in other nodes or in the bone marrow.

Treatment for SLL/CLL is generally based on fludarabine-containing combination chemotherapy. Cyclophosphamide plus fludarabine plus rituximab is an active regimen that obtains excellent responses in the majority of treated patients. When used in CLL, 70% of patients have complete responses that may last many years. Large series of SLL have not been reported, but the disease generally responds identically to CLL. Even though nodal masses predominate in SLL, 80% of patients have marrow involvement and it is marrow compromise that is the main life-threatening feature of the disease. In the face of progressive anemia or thrombocytopenia, it is important to assess whether the cause is immune destruction or marrow replacement. Immune destruction can be managed with prednisone while marrow replacement requires antitumor therapy.

### Marginal Zone Lymphoma

The marginal zone lymphomas (MZL) are considered indolent in natural history. Various subtypes of MZL exist, including nodal MZL, splenic MZL, and extranodal MZL. Extranodal MZL, which may involve mucosa-associated lymphoid tissue (MALT), is the most common form. The nodal MZL behaves very similar to FL. Splenic MZL is rare and is managed successfully by splenectomy. Extranodal MZL of the MALT type appears to begin as a consequence of chronic antigenic stimulation and where it is possible, removing the stimulus may cause tumor regression.

MALT lymphoma accounts for about 7.6% of lymphomas in the United States. Median age is 60 years. It commonly presents in the stomach, although it may involve other extranodal sites including orbit, intestine, thyroid, lung, breast, salivary gland, urinary bladder, kidney, and CNS. Gastric MALT lymphoma is a consequence of infection by *Helicobacter pylori*. Thyroid lymphomas of MALT type are usually associated with Hashimoto's thyroiditis. MALT lymphomas of the salivary glands are usually associated with Sjogren's syndrome. Orbital MALT lymphomas have been linked to *Chlamydia psittaci* infection. Gastric MALT lymphoma is the most common form of extranodal MZL. The disease often presents with symptoms of ulcer and is discovered at the time of upper endoscopy. Treatment of *H. pylori* may result in gradual tumor regression and even CR. If the tumor does not regress completely within a year of eradicating the bacterium, chemotherapy is usually required. Two distinct genetic forms of gastric MALT lymphoma have been defined: about half the cases have t(11;18), which creates an API/MALT1 fusion product and is genetically stable; the other form is characterized by genetic instability and may show trisomies of chromosomes 3, 7, 12, or 18. The latter form has the propensity to evolve into DLBL of the stomach and requires R-CHOP therapy. The patients who achieve CR with just antibiotics (~50% of patients) almost always have a very superficial form of the disease. For those not responding completely to antibiotics, chemotherapy or radiation therapy is generally required. Treatment with combination chemotherapy using CVP (cyclophosphamide, vincristine, prednisone) with or without involved field radiation leads to cure in most patients. Five-year survival is 72%.

Splenic MZL is responsible for about one fourth of low-grade B cell tumors affecting the spleen. Hepatitis C infection may be associated with this lymphoma. Splenectomy is effective therapy as is treatment of the underlying hepatitis C infection. However, a poor response to alkylating agents is often seen with this subgroup. Both

nodal MZL and splenic MZL can transform to aggressive DLBL, conferring a poor prognosis.

### Mantle Cell Lymphoma

Mantle cell lymphoma (MCL), first described as an independent entity in 1992, is a lymphoid malignancy in which the malignant cells are usually CD5+ and overexpress cyclin D1, usually as a result of a t(11:14) chromosomal translocation. It comprises ~6% of all lymphomas and with a median age of 63 years. It is commonly seen in the elderly. The male-to-female ratio is 3:1. MCL commonly involves lymph nodes, spleen, bone marrow, Waldeyer's ring, and gastrointestinal tract and has been associated with lymphomatous polyposis. It tends to be clinically aggressive though a wide range of natural histories have been seen. Five-year survival is only 27%. Aggressive chemotherapy regimens such as Hyper C-VAD plus rituximab are improving complete response rates and remission durations, but convincing evidence for improved overall survival has not yet been generated. Bortezomib, a proteasome inhibitor, also has some antitumor activity.

### Highly Aggressive Lymphomas

The highly aggressive lymphomas are the precursor B and T cell malignancies and Burkitt's lymphoma. These entities can either cause a leukemia clinical picture or have a dominant pattern of tissue involvement that spares the peripheral blood and looks like a lymphoma. However, their rapid natural history usually manifests in a short prodrome (less than 2 weeks between symptoms appearing and diagnosis) and an untreated natural history of a few weeks. When the precursor B and T cell malignancies produce lymphoma, they are generally called lymphoblastic lymphoma. Since lymphoblastic lymphoma is almost completely a disease of adolescence and young adulthood, it will not be discussed here except to note that, unlike other lymphomas, lymphoblastic lymphomas are most commonly of T cell origin. Burkitt's lymphoma too has a median age of onset of 31 years, but rare older persons may have this disease and it may occur in people with AIDS.

In the United States, the Burkitt lymphomas usually present with rapidly expanding abdominal masses, high LDH and uric acid levels, and systemic symptoms. The growth fraction of the tumor is nearly 100%; thus, the evaluation and workup of patients with Burkitt's lymphoma should be geared toward the rapid institution of combination chemotherapy with appropriate prophylaxis for tumor lysis syndrome. Although Epstein-Barr virus is associated with the endemic (African) form, its role in the pathogenesis of sporadic Burkitt's lymphoma in the United States is unclear. These tumors arise from mature B cells of follicular center phenotype, as evidenced by the expression of surface immunoglobulin (SIg), CD19, CD20, and CD22, and the presence of mutated immunoglobulin genes. The tumor can be identified karyotypically by one of three characteristic chromosomal translocations [t(8:14), t(8:22), and t(2:8)], all of which result in juxtaposition of the *c-myc* proto-oncogene (chromosome 8) to one of the three immunoglobulin genes, heavy chain on chromosome 14, or lambda or kappa light chain genes on chromosomes 8 and 22, respectively.

The prognosis is poor in older patients because of the need for extremely aggressive and specialized leukemia-like treatment. Often the bone marrow is involved. Treatment requires prophylaxis against tumor lysis syndrome (intravenous fluids, alkalinization of

the urine, and allopurinol), intensive doses of chemotherapy for several months, and CNS prophylaxis with intrathecal chemotherapy and whole brain irradiation.

## HODGKIN'S LYMPHOMA

Hodgkin's lymphoma (HL) in the United States has a bimodal age incidence. The early peak occurs between the ages of 20 and 30 years, and the later peak occurs between ages 70 and 80 years, with the incidence starting to increase around the age of 50 years. Men far outnumber women in the later peak. HL is one cancer in which the disease may differ in older patients. Age >50 years is a prognostic factor and a decreasing ability to tolerate treatment does not appear to influence outcome. HL was diagnosed in 8190 people in the United States in 2007; its incidence has been stable for many years. Only 1070 people died from the disease, indicating the widespread implementation of effective treatment programs.

There has been a curious association of Epstein–Barr virus and HL. The risk of HL is increased in patients with a history of infectious mononucleosis, and the Epstein–Barr virus has been demonstrated directly in some cases. However, this association is not found in HL developing in older patients. The contribution of age-associated immune dysregulation to the pathogenesis in late-life HL has theoretical appeal, but there are no supporting data.

### Presentation

Adenopathy, usually in the neck, is the most common presenting sign of HL in all age groups. However, as a presenting complaint, adenopathy is less frequent and systemic symptoms (fever, night sweats, weight loss) are more frequent in older patients. Abdominal disease is also more common in older patients. In a study from Stanford University, unexplained adenopathy was still the most common presentation in patients aged older than 60 years (65%) and “B” symptoms were the presenting complaint in 29%. Because nearly every patient (except those with peripheral IA disease) receive combination chemotherapy as a component of their treatment, pathological staging with staging laparotomy is only rarely performed and is restricted to patients in whom it will influence choice of treatment (radiation therapy vs. chemotherapy). The staging schema is shown in [Table 104-2](#).

### Histologies

The diagnosis of HL depends on detecting the characteristic malignant cell, the Reed-Sternberg (RS) cell, in a setting of a pleiomorphic

inflammatory infiltrate that includes lymphocytes, macrophages, and eosinophils with a variable degree of fibrosis. The infiltrate effaces the nodal architecture. The RS cell is a large binucleated cell with at least two prominent nucleoli. The cell is often said to display an “owl's eyes” appearance, particularly in mixed cellularity HL. In nodular sclerosis HL, it takes the form of a so-called “lacunar cell” because of cytoplasmic retraction during fixation and in lymphocyte predominant HL, it may have a convoluted nucleus that looks like popcorn and is called a “popcorn cell.” Although there has been controversy on the cell of origin of HL for many years and at least some heterogeneity exists, the vast majority of cases originate from a B cell of follicular center phenotype that have rearranged and mutated their immunoglobulin genes but do not transcribe them.

HL is divided into two categories in the WHO classification ([Table 104-1](#)): classical Hodgkin's disease accounts for 95% of HL and nodular lymphocyte predominant Hodgkin's disease accounts for about 5%. Classical Hodgkin's disease has four histologic subsets: lymphocyte-predominant, nodular sclerosis, mixed cellularity, and lymphocyte-depleted. Of these types, nodular sclerosis is by far the most common in the United States accounting for 65% to 75%. Mixed cellularity is next most common (20%) and most of the rest are lymphocyte-predominant. Lymphocyte-depleted histology is rare and can be confused with DLBL. Mixed cellularity is more common in South American and in HIV-infected patients. In addition, mixed cellularity appears to increase in frequency with age ([Table 104-6](#)).

The Finsen Institute study involved 506 unselected patients who were studied for the age distribution of histology. In the younger groups, nodular sclerosis was the most common histological type and this type was also most common in patients older than 60 years, but to a lesser extent. Mixed cellularity histology, uncommon in the younger groups, appeared almost as frequently as nodular sclerosis in the older group. Lymphocyte-predominant and lymphocyte-depleted histologies were notably uncommon in the elderly.

### Staging

Anatomical staging has been an important factor in HL management. The disease tends to originate in nodes (particularly the cervical nodes) and march to adjacent nodal groups in a stepwise fashion. The first site of intraabdominal involvement is often the spleen and the liver, though rarely involved, is never involved unless the spleen is involved. A suggested staging workup is found in [Table 104-5](#). A careful medical history and thorough physical examination are essential. Clinical staging also includes CT of the chest, abdomen and pelvis, and positron emission tomography (PET). The

**TABLE 104-6**

#### Influence of Age on Histological Patterns of Hodgkin's Lymphoma

Histology	SPECHT AND NISSEN		PETERSON ET AL.		WEDELIN ET AL.	
	Age <40 (%)	Age >60 (%)	Age <40 (%)	Age >60 (%)	Age <50 (%)	Age >50 (%)
Lymphocyte predominant	12	12	7	11	12	17
Nodular sclerosing	61	44	30	7	49	21
Mixed cellularity	25	37	42	52	29	46
Lymphocyte depleted	<1	2	14	20	7	13
Unclassified	2	4	7	11	4	4

lymphangiogram provides unique information about the involvement of paraaortic nodes and can also allow the physician to follow the response monthly with a plain abdominal film as involved nodes shrink under therapy, but the expertise to conduct this test is vanishing and it is rarely employed today. Bilateral bone marrow biopsies will indicate the presence of marrow involvement in a subset of patients (perhaps 10%) for whom staging to that point did not indicate any suspicion of extranodal disease. In older individuals, the marrow cellularity and evidence for adequate hematopoiesis are of additional value for planning therapy.

In general, management of all stages of HL involves combination chemotherapy plus or minus radiation therapy. Therefore, most patients do not require a staging laparotomy. However, for patients who have clinical early stage disease and who have intercurrent illness that would make the use of combination chemotherapy particularly hazardous, a staging laparotomy should be considered. This involves careful abdominal exploration with routine biopsies of paraaortic, celiac, splenic hilar, mesenteric, portal, and iliac nodes; wedge and core biopsies of the liver; and splenectomy. Staging laparotomy will demonstrate more advanced disease (upstage) about 35% of the time, but in some cases (10% to 15%) radiographically suspicious lesions are shown to be not Hodgkin's and downstaging is the result. An enlarged spleen on CT scan is involved with Hodgkin's disease only two thirds of the time. If the staging laparotomy is negative, one could consider the use of radiation therapy alone to treat a patient too ill to receive systemic therapy. Before taking a patient to splenectomy, pneumococcal vaccine should be given, preferably at least 2 weeks in advance of splenectomy.

A staging laparotomy is a major surgery and may not be well tolerated in elderly patients. The benefits of more accurate assessment and more precise therapy have to be weighed against the operative risks. Alternative staging approaches, including new visualizing techniques, are being explored. However, for patients in whom radiation therapy alone is being considered, staging laparotomy remains the standard evaluative approach.

## Therapy

The therapy for HL has become better defined as a result of clinical trials (Table 104-7). The main debate centers on whether to add radiation therapy to chemotherapy versus relying on chemotherapy

alone. Nearly every patient received chemotherapy. The source of the controversy is the very high rate of late, fatal complications from the use of radiation therapy. Long-term follow-up studies demonstrate a threefold increased rate of *fatal* myocardial infarctions in patients who received mantle-field radiation therapy. In addition, the risk of strokes is increased. Furthermore, patients who received radiation therapy begin developing second malignancies about 5 to 7 years after completing treatment and by 25 years after treatment, 25% to 30% of patients have a second cancer. These cancers are mainly in or adjacent to treatment fields and include lung cancer, breast cancer, head and neck cancer, melanoma, and sarcomas. Chemotherapy-treated patients have not demonstrated this increased risk of second cancers, heart disease, or stroke.

In older patients, the intervention should be based on the life expectancy in the absence of HL. If a patient with HL is expected to live more than 20 years if the HL is cured, it would be best to avoid radiation therapy as a component of treatment. On the other hand, older patients with intercurrent illnesses and a life expectancy independent of HL of less than 10 years could be treated with radiation therapy alone to avoid the acute and chronic toxicities of combination chemotherapy. The main acute side effect of the active chemotherapy programs is myelosuppression. ABVD (doxorubicin, bleomycin, vinblastine, dacarbazine) is the most widely used regimen and involves intravenous therapy every 2 weeks for 24 weeks. Doxorubicin can compromise cardiac function in a patient with preexisting heart failure, while more cardiac-sparing anthracyclines can be substituted (e.g., mitoxantrone, liposomal doxorubicin), an alkylating agent-based regimen may be preferable. Bleomycin can induce pulmonary fibrosis and should not be given to patients with preexisting compromise of their diffusing capacity.

MOPP (nitrogen mustard, vincristine, procarbazine, prednisone) and ChIVPP (chlorambucil, vinblastine, procarbazine, prednisone) are effective alternatives to ABVD in those with contraindications. They are myelotoxic acutely in a dose-related fashion. The main late toxicity is infertility, which is rarely a consideration in the elderly. When combined with radiation therapy, the alkylating agent-based regimens produce acute leukemia in about 3% of treated patients and older patients may be more susceptible to this late effect. However, the window of risk seems to be 3 to 10 years following treatment, after which the risk declines sharply. If given without radiation therapy, the leukemia risk is decreased about 90%.

Other regimens used to treat HL include Stanford V and BEACOPP. Stanford V uses a short course of chemotherapy together with radiation therapy in every patient. It has been hoped that the use of a lower total dose of radiation therapy will reduce the incidence of late fatal complications but this hope has not yet been validated by actual data. BEACOPP employs higher doses and more agents than either ABVD or MOPP and is more difficult to administer to older patients. It is not clearly superior to six cycles of ABVD. Studies combining MOPP and ABVD have not shown an improvement over ABVD alone.

In light of the controversies, consensus treatment recommendations have not been developed. However, it is rational to assess every patient and make individualized treatment programs. For most patients, clinical staging followed by six cycles of ABVD chemotherapy will be an effective approach to patients of all stages. In those with cardiac or pulmonary problems, MOPP or ChIVPP are equally active alternatives to ABVD. For patients with localized (stage I or II) disease in whom chemotherapy is attempted, but toxicities prevent

**TABLE 104-7**

### Recommended Therapy for Hodgkin's Lymphoma

STAGE	THERAPY
I, II (A or B, negative laparotomy)	Subtotal lymphoid irradiation or combination chemotherapy
Clinical stage I, II (no laparotomy)	Combination chemotherapy
I, II (A or B with mediastinal mass >1/3 diameter of chest wall)	Combination chemotherapy followed by irradiation to involved field
IIA <sub>1</sub> (minimal abdominal disease)	Combination chemotherapy
IIIA <sub>2</sub> (extensive abdominal disease)	Combination chemotherapy alone or with irradiation to persistent PET-positive sites
IIIB	Combination chemotherapy
IV (A or B)	Combination chemotherapy

the administration of more than 50% of the doses or lead to treatment delays, it is reasonable to use radiation therapy. Involved-field radiation therapy may eradicate the disease.

Radiation therapy is appropriate in two other settings. In patients who respond well to chemotherapy but still have PET positive sites after four or six cycles of chemotherapy, radiation therapy to the positive site can convert many patients into durable complete responders. Often the residual positivity is in the mediastinum. In addition, patients who have massive mediastinal disease at presentation may benefit from involved-field radiation therapy after chemotherapy.

Toxicity from both radiotherapy and chemotherapy increases with age. The typical side effects of radiation therapy for HL include acute and transient anorexia with occasional nausea, vomiting, diarrhea, transient and occasionally permanent drying of salivary secretions, transient pharyngitis and esophagitis, fatigue, and cytopenias. The long-term side effects include hypothyroidism (common), pneumonitis, constrictive pericarditis, rare endocardial or myocardial fibrosis, skin pigmentation and breakdown, and second malignancies. Long-term follow-up of patients who have received radiation therapy to upper mantle areas should include periodic thyroid evaluations.

The side effects of chemotherapy are also enhanced in older patients and certain drugs are particularly difficult for the older patient. Those used commonly in the treatment of HL include vinblastine and doxorubicin. Liver metabolism of other drugs is probably slowed in older persons.

Although there is an increased risk for toxicity, older HL patients may still be treated safely and with curative intent. Even for those in whom curative treatment is not indicated or who relapse from CR, significant palliation and prolongation of life can be achieved with localized radiation and single-agent or multiagent chemotherapy.

### Response to Treatment and Survival

Many published series have demonstrated poorer survival in older patients with HL, but these series have been difficult to interpret because modern staging and treatment were not applied consistently, and it is now understood that age bias may influence cancer therapy outcomes.

The ECOG study cited earlier reported decreasing freedom from relapse with increasing age in patients treated from 1968 to 1981. The 5-year freedom-from-relapse rate was 81% for those younger than age 17 years, 70% for those aged 17 to 49 years, 63% for those aged 50 to 59 years, and 38% for those aged 60 years and older. Multivariate analysis revealed that age was the most important factor in determining freedom from relapse. Older patients with HL have not been a focus of clinical research as yet and it seems likely that improvements in outcome are at hand.

### Multiple Myeloma and Related Plasma Cell Dyscrasias

Malignant plasma cells typically remain in the bone marrow and grow as either a solitary mass (solitary myeloma of bone [SMB]) or as nests of cells distributed throughout the bone marrow (multiple myeloma [MM]). Occasionally, plasma cell tumors will arise outside of the marrow, particularly within the aerodigestive tract (extramedullary plasmacytoma [EMP]). Whereas SMB and EMP are relatively uncommon, MM accounts for approximately 17.8% of lymphoid malignancies (Figure 104-1) or 19 900 cases in 2007. MM is a disease characterized by destructive bone disease and cir-

culating monoclonal protein that can increase serum viscosity and infiltrate and damage organs.

### Epidemiology

In the United States, there are approximately 4 new cases per 100 000 population per year. Myeloma accounts for 1% of all malignancies. Although the age range is wide, it is considered a disease of older adults. The median age is 68 years. Cases are rare before 30 years of age. Males are affected slightly more frequently than females, and myeloma is nearly twice as common in African-Americans as in other races.

### Etiology

The cause of myeloma is not known. Radiation or other carcinogen exposure is involved in the cause of this disease. Japanese atomic bomb survivors have had a fivefold increase in risk. A number of chromosome alterations have been noted including 13q14 deletions, 17p13 deletions, and 11q abnormalities. The most common translocation is t(11;14) and many tumors show changes suggesting errors in heavy chain gene switch recombination, the process that occurs when cells change from producing IgM to another heavy chain isotype. Cytokine [particularly interleukin-6 (IL-6)] dysregulation is also an important feature of MM. IL-6 triggers proliferation through the Ras, Raf, MEK, mitogen-activated protein kinase cascade, and promotes cell survival by upregulation of antiapoptotic molecules. Serum levels of IL-6 are very high and correlate with tumor mass, the extent of bone destruction, and survival. Furthermore, in murine models of myeloma, plasma cell tumors did not develop in mice that were genetically engineered to be IL-6-deficient (IL-6 “knockouts”). Interactions between myeloma cells and bone marrow stromal cells and the extracellular matrix are critical to myeloma cell growth and survival. In addition to IL-6, insulin-like growth factor, vascular endothelial growth factor (VEGF), and the chemokine, stromal cell derived (SDF) 1-alpha play a role.

The frequency of particular heavy chain classes in myeloma roughly corresponds to the relative frequency of the different isotypes in the serum (Table 104-8).

### Clinical Manifestations of Disease and Their Pathogenesis

Many of the features of myeloma are caused by the effect of the paraprotein and other tumor products.

TABLE 104-8

#### Plasma Cell Disorders

DISEASE		FREQUENCY (%)	PROGNOSIS (MONTHS)
Multiple myeloma	IgG	52	29–35
	IgA	21	19–22
	IgD	2	9
	IgE	<0.01%	—
	Light chains only	11	10–28
	Non-secretor		
Waldenström's macroglobulinemia	IgM	12	50

## Bone Pain

Bone pain is the most common symptom in patients with myeloma (70%). Pain usually involves the back and ribs and is made worse by movement. X-rays reveal either localized “punched-out” lytic lesions or diffuse osteoporosis, usually in bones with active hematopoietic tissue. The discrete lytic lesions are characterized by numerous osteoclasts on the bone-reabsorbing surface without osteoblastic activity. Thus, bone scans are not useful in diagnosis as they detect new bone formation. The osteoclasts are activated by osteoclast-activating factors (OAF) made by the tumor including IL1, lymphotoxin, IL6, vascular endothelial growth factor (VEGF), receptor activator of NF- $\kappa$ B (RANK) ligand, and others. Localized bone lesions may expand to the point where they produce soft tissue masses and collapsed vertebrae can lead to cord compression.

With bone demineralization caused by osteoclast activation and with decreased activity because of pain, hypercalcemia may be expected. The symptoms of hypercalcemia (drowsiness, confusion, nausea, and thirst) are nonspecific, but their occurrence should alert the physician to investigate this possibility. Cardiac arrhythmias, renal insufficiency, and profound CNS depression can develop as hypercalcemia progresses.

## Infection

Susceptibility to bacterial infections is also a serious clinical problem in patients with myeloma. The most common sites of infection are the lungs and kidneys and the most common causative agents are *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Klebsiella pneumoniae* in the lungs and *Escherichia coli* and other Gram-negative organisms in the urinary tract. Recurrent infection is the presenting symptom in 25% of patients and >75% will have a serious infection at some time in the course of the disease. Several factors contribute to the susceptibility. If one discounts the paraprotein, most patients with myeloma have hypogammaglobulinemia related to both decreased production and increased catabolism of normal antibodies. In addition, granulocyte lysozyme levels and migration are impaired by products of the tumor. Complement functions are also abnormal. Furthermore, some therapeutic interventions also increase the risk of infection.

## Renal Failure

Renal failure occurs in about one-fourth of myeloma patients and some renal pathology is seen in over half. Its causes are many (Table 104-9). Hypercalcemia is the most common cause. In addition, glomerular deposits of amyloid, hyperuricemia, recurrent infections,

use of nonsteroidal anti-inflammatory agents, radiographic contrast material, bisphosphonate use, and occasional myeloma cell infiltration of the kidney can all contribute to the renal dysfunction. Renal tubular dysfunction is very common as a result of damage to the tubules by light chains. This tubular damage is often reflected in a type 2 proximal renal tubular acidosis with loss of glucose and amino acids and problems concentrating and acidifying the urine. Monoclonal lambda light chains are more likely to produce tubular injury than are kappa chains.

## Anemia and Bleeding

Anemia is seen in 80% of patients. It is generally related to the inhibition of hematopoiesis by products of the tumor cells, but in late stages of disease can be caused by crowding of normal hematopoietic cells in the marrow. The anemia is usually normocytic and normochromic. The high concentrations of serum protein interact with erythrocyte membranes and cause a coin-like stacking of red cells known as rouleaux formation. Mild hemolysis may be present and other causes of anemia (such as vitamin B-12 deficiency) may coexist. Coating of platelets results in diminished aggregation and purpura. The high protein level also may interfere with coagulation factors by inhibiting fibrin polymerization, and bleeding may result.

## Hyperviscosity

Hyperviscosity may occur at different levels of paraprotein based on its physical characteristics. Normal serum is about 1.8 times as viscous as water and symptoms of hyperviscosity (decreased cerebral blood flow, producing headache, nausea, visual impairment, and mental clouding) occur when the serum becomes five to six times more viscous than water. This level is generally reached at paraprotein levels of 4 g/dL for IgM, 5 g/dL for IgG3, and 7 g/dL for IgA. Decreased renal blood flow may contribute to the renal failure that is so common in MM. Total blood volume expands and may predispose to congestive heart failure.

## Neurological Symptoms

A minority of patients may experience neurologic signs or symptoms. Hypercalcemia may produce lethargy, fatigue, depression, and confusion. Hyperviscosity compromises CNS function and causes visual disturbances. Cord compression can result from bony destruction. Infiltration of peripheral nerves with amyloid or a paraprotein with antigen specificity for a nerve component can produce sensorimotor mono- and polyneuropathies.

## Diagnosis and Staging

The classic triad of myeloma is marrow plasmacytosis of 10% or greater, lytic bone lesions, and a serum and/or urine paraprotein. Bone marrow plasma cells are monoclonal and express CD138. A number of diseases may produce a monoclonal gammopathy including other lymphoid malignancies, other solid tumors (breast cancer, colon cancer), cirrhosis, sarcoidosis, parasitic diseases, Gaucher disease, and a number of autoimmune disorders including rheumatoid arthritis, myasthenia gravis, and cold agglutinin disease. However, the most common differential diagnosis is between myeloma and monoclonal gammopathy of uncertain significance (MGUS). Patients with myeloma typically have paraprotein levels >3 g/dL and some stigmata of end-organ damage such as lytic bone lesions,

**TABLE 104-9**

### Causes of Renal Failure in Myeloma

Light-chain deposition in tubules (“myeloma kidney”)
Hyperviscosity
Hypercalcemia
Hyperuricemia
Infection
Dehydration (especially after an intravenous pyelogram)
Associated amyloidosis

hypercalcemia, renal dysfunction, recurrent bacterial infections, or anemia.

### Monoclonal Gammopathy of Uncertain Significance

MGUS is an elevation of a clonal immunoglobulin molecule in the serum generally present at <3 g/dL. It occurs in about 1% of people aged older than 50 years and up to 10% of people aged older than 75 years. It is an indicator of dysregulated B-cell clonal expansion, but it is not considered to be the antecedent of MM. Patients with MGUS have fewer than 10% plasma cells in the bone marrow, have no lytic bone lesions, and are normocalcemic. Although not a malignant process itself, patients with MGUS have a 2-year decline in life expectancy compared with age-matched unaffected controls. About 15% of people with MGUS progress to overt myeloma after periods of up to 30 years and generally these individuals had higher levels of paraprotein at MGUS diagnosis. Typically, MGUS is distinguished from myeloma through examination of bone marrow, skeletal x-rays, renal function, and serum  $\beta_2$  microglobulin levels (Table 104-10). Early myeloma will show signs of disease progression over time and an increase in myeloma-related organ and tissue impairment, whereas MGUS will have stable protein readings, no bone disease, and a marrow that may or may not show a mild-to-moderate plasmacytosis but without dysplastic appearing plasma cells. It is important to make this distinction because MGUS is so much more common than myeloma and does not require therapy.

### Smoldering Myeloma

A small subset of patients who make diagnostic criteria for myeloma have a very slow progression of disease. It differs from MGUS in having 10% of greater plasmacytosis in the bone marrow and at least 3 g/dL of paraprotein. However, like MGUS, it is not associated with the usual myeloma-associated tissue or organ impairment (hypercalcemia, lytic bone lesions, renal dysfunction, infections). The rate of progression to overt myeloma is higher than MGUS; actuarial risk is 73% over 15 years. However, it is not clear that early treatment is beneficial and most authorities recommend that

patients be observed until disease progression to organ impairment before treatment is begun.

### Myeloma Staging

A number of staging schemes have been developed. However, the international staging system is now the most widely used. The staging system is based on serum albumin levels and serum beta-2-microglobulin levels. If the beta-2-microglobulin levels are less than 3.5  $\mu\text{g}/\text{mL}$  and the serum albumin is equal to or greater than 3.5 g/dL, patients are said to be stage I. This accounts for about 28% of all patients and is associated with a median survival of about 5 years. In stage II, the beta-2-microglobulin level is less than 3.5  $\mu\text{g}/\text{mL}$  and the albumin level is less than 3.5  $\mu\text{g}/\text{mL}$  or beta-2-microglobulin levels are 3.5 to 5.5  $\mu\text{g}/\text{mL}$ . Thirty-nine percent of patients are stage II and their median survival is about 4 years. Stage III patients are those with any albumin level and beta-2-microglobulin levels > 5.5  $\mu\text{g}/\text{mL}$ . This accounts for 33% of patients and is associated with a median survival of 29 months.

### Therapy

Effective treatment for myeloma patients includes chemotherapy, radiation therapy, and the use of several supportive care measures.

Three regimens are commonly used in newly diagnosed myeloma: intermittent oral melphalan (phenylalanine mustard) and prednisone with response rates of about 50% to 60%; melphalan plus prednisone with daily thalidomide added with response rates of 70% to 75%; and thalidomide plus dexamethasone with response rates around 65%. Younger patients are often managed with tandem autologous bone marrow transplants with the result that a substantial fraction experience long-term disease-free survival. Lenalidomide, a thalidomide analog, is being evaluated in first-line therapy as it has the advantage of being a more potent inhibitor of inflammatory cytokine production as well as being less sedating and with much diminished associated neuropathy. When used with dexamethasone response rates have been reported to be 70% to 90% with progression-free survival of greater than 1 year. Curiously, lenalidomide with dexamethasone is associated with an increased risk of deep vein thrombosis, but this does not have been observed when lenalidomide is used alone. Bortezomib is an antineoplastic agent that inhibits proteolytic activity of the proteasome. Bortezomib either alone or with dexamethasone, has shown excellent response rates; it is especially useful in the salvage setting. Secondary analyses of both lenalidomide and bortezomib studies reveal both to be well-tolerated in older patients. The current trend in therapy is to use lenalidomide and dexamethasone initially and to use bortezomib at the time of relapse.

Localized radiation therapy is used for pain relief and to decrease the risk of fractures. Measures designed to maintain activity and hydration are also important. Analgesics, orthopedic surgery, and orthotic supports facilitate mobilization. With adequate mobilization and fluid intake, the symptom complex of hypercalcemia, dehydration, and renal failure can usually be avoided. Bisphosphonates such as pamidronate or zoledronate have proven useful in both the prevention and treatment of myeloma-associated hypercalcemia and the American Society of Clinical Oncology recommends administration of either drug at monthly intervals for myeloma patients with lytic bone disease and without overt renal failure.

**TABLE 104-10**

#### Myeloma versus Monoclonal Gammopathy of Uncertain Significance (MGUS)

	MYELOMA	MGUS
Pathogenesis	Neoplastic plasma cell disorder (malignant)	Disordered immunoregulation
Bone marrow	Frequently >10% plasma cells	Usually less than 10% plasma cells, and these appear normal
Bone	Majority will have bone erosions or diffuse osteoporosis (even early)	No bone disease
Symptoms	Bone pain, fatigue, weight loss, or those associated with kidney failure	Usually no symptoms
Serum spike	Progressively rising	Stable level IgG <3 g/dL IgA <2 g/dL BJ <1 g/24 h (urine)

## Other Plasma Cell Dyscrasias Seen in Geriatric Populations

### Waldenström's Macroglobulinemia

This disorder is caused by a proliferation of a neoplastic clone of IgM-producing cells called lymphocytoid plasma cells. Bone destruction is not a feature of the disease. In many respects, macroglobulinemia resembles a SLL with infiltration of the marrow by lymphocytes or lymphocytoid plasma cells, lymphadenopathy, and splenomegaly.

The circulating monoclonal IgM (macroglobulin) appears to explain much of the pathophysiology. The macroglobulin coats platelets and interferes with clotting. The oncotic expansion of the plasma volume leads to spurious anemia and may result in congestive heart failure. The hyperviscosity syndrome is common.

Therapy is directed at both the proliferating malignant clone of cells and the abnormal circulating protein. Alkylating agents such as chlorambucil or cyclophosphamide or purine analog such as fludarabine have proven to be effective in prolonging survival. Rituximab has been used with moderate success and may be of particular value for those patients with Waldenström's associated polyneuropathy. Plasmapheresis is indicated for the acute management of patients with symptoms of hyperviscosity as 80% of IgM remains intravascular. Plasmapheresis removes a substantial fraction of the body's IgM paraprotein.

### Heavy-Chain Disease

These rare malignancies are characterized by the proliferation of plasma cells that produce an abnormal monoclonal heavy chain without associated light-chain synthesis. Like macroglobulinemia, these disorders resemble lymphoma more than they do myeloma. Bone disease does not occur, but lymphadenopathy and hepatosplenomegaly are common. Gamma, alpha, and mu heavy-chain diseases have been described. Alpha chain disease usually is associated with lymphoma involving the gastrointestinal tract and with malabsorption, whereas the mu heavy-chain disease is associated with long-standing CLL. Gamma heavy-chain disease can present as a lymphoma that histologically resembles HL.

### Amyloidosis

Amyloidosis is a heterogeneous group of disorders characterized by the deposition of insoluble proteins in tissues, with eventual compromise in the function of the involved organs. Several different proteins have been identified in deposits, but two are common. In type I amyloid, the principal protein is immunoglobulin light chains, whereas in type II, a nonimmunoglobulin protein (protein A) is found. In both types, the proteins form noncovalent polymers in a fibrillar pattern, which can be recognized on electron microscopy. Different patterns of tissue distribution are associated with the different types of protein deposited.

When amyloidosis is associated with plasma cell dyscrasia (type I), amyloid deposits are found primarily in the muscles (including the heart and tongue), gastrointestinal tract, and skin. In conditions associated with protein A deposition (such as chronic infections and familial Mediterranean fever), amyloid deposition occurs in the kidney, spleen, liver, and adrenals. Mixed patterns, however, are common, and the presenting site of involvement is not sufficient to classify the type of amyloid involved.

**TABLE 104-11**

### Summary Points for the Practicing Geriatrician

#### General

- Older patients will present with more advanced disease.
- Published cooperative trials on which standard therapy is based include disproportionately few elderly patients.
- Older patients are not a priori more resistant to chemotherapy. However, end organ toxicity, especially heart, lung, and bone marrow, may be greater.
- Do not risk letting your patient die from a curable tumor out of a fear of toxicity. Many older patients have less toxicity than expected.

#### Non-Hodgkin's lymphoma

- Increases in frequency with advancing age.
- DLBL (the most common lymphoma) is curable and must be treated aggressively or survival will be short.

#### Hodgkin's lymphoma

- Older patients have relatively more "unfavorable" histologies (i.e., mixed cellularity or lymphocyte-depleted).
- Chemotherapy has been less successful in achieving cures in older patients, perhaps because of comorbidity.

#### Multiple myeloma

- It is important to differentiate myeloma from benign monoclonal gammopathy (see Table 104-10).
- Myeloma should be a consideration for all older patients with persistent bone (especially low back) pain. The average delay in diagnosis from first seeking medical attention is 6 mo or more.

## TAKE HOME POINTS FOR THE GERIATRICIAN

Older patients with lymphoid malignancies should not be assumed to be incurable. Patients can be cured sometimes, have their lives extended often, and made more comfortable always. It should not be assumed that a patient will experience more treatment-related toxicity on the basis of chronological age alone. Nearly always any toxicity encountered in an individual patient will permit rational modifications of dose (and sometimes schedule) to permit delivery of effective treatment. The time for failing to treat a treatable illness in the name of "doing no harm" has passed. Any older patient with a lymphoid malignancy should be evaluated by a specialist before it is assumed that the treatment is worse than the disease. Table 104-11 summarizes some important points about NHLs, Hodgkin's disease, and myeloma.

# Thrombosis

*Martin O'Donnell* ■ *Jeffrey S. Ginsberg* ■ *Clive Kearon*

Venous thromboembolism (VTE), which includes deep venous thrombosis (DVT) and pulmonary embolism (PE), affects about 1 in 1000 persons annually. The incidence and case-fatality of venous and arterial thromboembolic events increase with age. The increased risk of VTE in elderly patients reflects the increased prevalence of risk factors (temporary and permanent), prothrombotic changes in coagulation with advanced age, and an independent contribution of advancing age.

The diagnosis of VTE is more challenging in the elderly patient, as clinical presentations are more often atypical than in younger patients and the diagnostic properties of some tests appear to be influenced by advancing age. However, the general approach to diagnosis of VTE in the elderly is much the same as in younger patients.

While anticoagulant therapies have comparable relative risk reductions for prevention of VTE in older compared to younger patients, elderly patients are at increased risk of major bleeding and particularly intracranial bleeding. Therefore, decisions regarding optimal duration of anticoagulant therapy for VTE are influenced by the patient's age.

In this chapter, we review the epidemiology, pathophysiology, natural history, diagnosis, and treatment of VTE in the elderly patient.

## EPIDEMIOLOGY

### Incidence of VTE

The incidence of VTE increases exponentially with advancing age (i.e., approximately twofold increase with each decade) rising from an annual incidence of 0.03% at age 40 years, to 0.09% at 60 years, and 0.26% at age 80 years.

### Risk Factors

Most patients with VTE have one or more clinical risk factors for venous thrombosis. The most common risk factors in hospitalized elderly patients are recent surgery, previous VTE, trauma, and immobility, as well as serious illness, including malignancy, chronic heart failure, stroke, chronic lung disease, acute infections, and inflammatory bowel disease. A particularly important major risk factor for VTE in elderly patients is major orthopedic surgery, both elective and after hip fracture, where fatal PE is a leading cause of in-hospital death. Common risk factors in outpatients include hospital admission within the past 3 months, malignancy, previous VTE, cancer chemotherapy, estrogen therapy, presence of an antiphospholipid antibody, and familial thrombophilia. Less common risk factors are paroxysmal nocturnal hemoglobinuria, nephrotic syndrome, and polycythemia vera. A recent study of elderly patients has reported frailty to be a risk factor for VTE.

Age is thought to have at least an additive influence on the risk of VTE when combined with other risk factors for VTE and the prevalence of many risk factors is greater in the elderly. Consequently, the risk of VTE in high-risk situations, such as following surgery, is greater in older than younger persons.

The risk of thrombosis is about 50-fold higher in persons with a previous VTE than in the general population, and recurrent thrombosis accounts for about one quarter of all acute episodes of VTE. When anticoagulant therapy is stopped after 3 or more months of treatment, the subsequent risk of recurrent VTE in the first year varies from about 2% in patients who had VTE provoked by a transient risk factor, to about 10% in those with an unprovoked VTE or a continuing risk factor for thrombosis. There is some evidence that older age may be associated with a higher risk of recurrent VTE after anticoagulants are stopped, but this is uncertain and poorly quantified.

## PATHOPHYSIOLOGY

Venous stasis and damage to the vessel wall predispose to thrombosis. Venous stasis is produced by immobility, obstruction or dilatation of veins, increased venous pressure, and increased blood viscosity. The critical role of stasis in the pathogenesis of venous thrombosis is illustrated by the observation that thrombosis occurs with equal frequency in the two legs of paraplegic patients but occurs with much greater frequency in the paralyzed limb than in the nonparalyzed limb in stroke patients.

Venous thrombi usually arise at sites of vessel damage, or in the large venous sinuses of the calves, or the valve cusp pockets of the deep veins of the calves, and are composed predominantly of fibrin and red blood cells. Thrombosis occurs when blood coagulation overwhelms the natural anticoagulant and fibrinolytic systems. Coagulation is usually triggered by exposure of blood to tissue factor on the surface of activated monocytes that are attracted to sites of tissue damage or vascular trauma. Clinical risk factors that activate blood coagulation include extensive surgery, trauma, burns, malignant disease, myocardial infarction, cancer chemotherapy, and local hypoxia produced by venous stasis.

Tissue damage also results in impaired fibrinolysis, which occurs through the release of inflammatory cytokines in response to the damage. These cytokines induce endothelial cell synthesis of plasminogen activator inhibitor-1 (PAI-1) and reduce the protective effect of the vascular endothelium by downregulating the endothelial-bound anticoagulant thrombomodulin.

Stasis resulting from venous dilatation occurs in elderly patients, in patients with varicose veins, and in women who are pregnant or using supplemental estrogen. Venous obstruction contributes to the risk of venous thrombosis in patients with pelvic tumors. Increased blood viscosity, which also causes stasis, may explain the risk of thrombosis in patients with polycythemia vera, hypergammaglobulinemia, or chronic inflammatory disorders. Direct venous damage may lead to venous thrombosis in patients undergoing hip surgery, knee surgery, or varicose vein stripping and in patients with severe burns or trauma to the lower extremities.

Blood coagulation is modulated by circulating, or by endothelial cell-bound, inhibitors of thrombosis. The most important circulating inhibitors of coagulation are antithrombin, protein C, and protein S. An inherited deficiency of one of these three proteins is found in about 20% of patients who have a family history of VTE and whose first episode of VTE occurs before 41 years of age. Some types of congenital dysfibrinogenemias can also predispose patients to thrombosis, as can a congenital deficiency of plasminogen. However, these are rare causes of venous thrombosis in the elderly presenting with first VTE episode. An inherited thrombophilic defect known as activated protein C (APC) resistance, or factor V Leiden, is the most common cause of inherited thrombophilia, occurring in about 5% of whites who do not have a family history of VTE and in about 20% of patients with a first episode of VTE. One case-control study reported that factor V Leiden was not a risk factor for VTE in patients older than 70 years but associated with threefold increase in younger patients. The second most common thrombophilic defect is a mutation (G20210A) in the 3'-untranslated region of the prothrombin gene that results in about a 25% increase in prothrombin levels. This mutation is found in about 2% of whites with no family history of VTE and in about 5% of patients with a first episode

of VTE. Elevated levels of clotting factors VIII and XI also predispose patients to thrombosis. Randomized trials have shown that the administration of estrogens in the doses used for postmenopausal hormone replacement therapy increase the risk of a first or recurrent thromboembolism about threefold, with highest risk being within the first 6 months of starting therapy.

## NATURAL HISTORY

Most venous thrombi produce no symptoms and are confined to the intramuscular and deep veins of the calf. Many calf vein thrombi undergo spontaneous lysis, but some extend into the popliteal and more proximal veins. Complete lysis of proximal vein thrombosis is less common. Most symptomatic pulmonary emboli and virtually all fatal emboli arise from thrombi in the proximal veins of the legs.

Although venous thrombosis can occur in any vein in the body, it usually involves superficial or deep veins of the legs. Thrombosis in a superficial vein of the leg is generally benign and self-limiting but can be serious if it extends from the long saphenous vein into the common femoral vein. Superficial thrombophlebitis is easily recognized by the presence of a tender vein surrounded by an area of erythema, heat, and edema. A thrombus can often be palpated in the affected vein. Thrombosis involving the deep veins of the leg maybe confined to calf veins or may extend into the popliteal or more proximal veins. Thrombi confined to calf veins are usually small, often asymptomatic, and are rarely associated with PE. About 20% of calf vein thrombi, however, extend into the popliteal vein and beyond, where they can cause serious complications. In most cases, extension of calf vein thrombosis occurs within a week. About 50% of patients with symptomatic proximal vein thrombosis also have clinically silent PE, and about 70% of patients with symptomatic PE have DVT, which is usually clinically silent. Untreated or inadequately treated VTE is associated with a high rate of complications, with about 50% of untreated proximal vein thrombi undergoing symptomatic extension or embolization (see "Treatment").

## Acute Consequences of Venous Thromboembolism

In general, one-third to one-half of first episodes of VTE present as PE, the remainder presenting as DVT. It is estimated that about 10% of symptomatic PE are rapidly fatal and that about 5% of patients that are treated for PE die of a recurrence (mostly within the first 3 months). There is evidence that in the elderly, a larger proportion of episodes of VTE presents as PE and, when PE occurs, it is more likely to be fatal (i.e., four times higher than in patients 45 years of age or younger). In patients who are being closely monitored (e.g., in clinical trials), about 5% of recurrent episodes of VTE that occur after anticoagulants have been stopped are fatal. If the initial episode of VTE is a PE, recurrent episodes are also more likely to be a PE than DVT and, therefore, are more likely to be fatal. As with a first episode of VTE, the case-fatality of recurrent episodes of thrombosis may be higher in the elderly although this is uncertain.

## Chronic Complications of Venous Thromboembolism

While PE is the most serious and most feared complication of venous thrombosis, important chronic conditions may also occur after

acute VTE. Postthrombotic syndrome is the most frequent chronic complication of DVT of the leg. Characterized by pain and swelling, it is responsible for considerable personal disability, reduced quality of life, and substantial health care costs (estimated at \$250 million per year in North America). The postthrombotic syndrome occurs as a long-term complication in about 25% (and is severe in about 10%) of patients with symptomatic proximal vein thrombosis in the 8 years after the acute event, with most cases developing within 2 years. The postthrombotic syndrome typically presents as chronic leg pain and swelling, which is worse at the end of the day. Some patients also have stasis pigmentation, induration, and skin ulceration. In a minority of patients, there is venous claudication on walking, caused by persistent obstruction in the iliac veins. Chronic pulmonary hypertension is a more serious complication that occurs in about 4% of patients within 2 years of treated PE.

## DIAGNOSIS

### Deep Vein Thrombosis (Tables 105-1 and 105-2)

#### Clinical Features

The clinical features of DVT include localized swelling, redness, tenderness, and distal edema. As these symptoms are nonspecific, the diagnosis should always be confirmed by objective investigations. However, clinical assessment does allow division of patients into low, moderate, and high probabilities of DVT, corresponding to prevalence of 15%, 25%, and 60%, respectively. Clinical prediction rules, such as the Well's Score, are based on four factors; (1)

**TABLE 105-1**

#### Model for Determining Clinical Suspicion of Deep Vein Thrombosis

VARIABLES	POINTS*
Active cancer (treatment ongoing or within previous 6 mo or palliative)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bedridden for more than 3 d, or major surgery within the past 4 wk	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Affected calf 3 cm greater than asymptomatic calf (measured 10 cm below tibial tuberosity)	1
Pitting edema confined to the symptomatic leg	1
Dilated superficial veins (nonvaricose)	1
Alternative diagnosis is at least as likely as that of deep vein thrombosis	-2
Total points	

\*Pretest probability is calculated as follows: total points,  $\leq 0$ , low probability; 1 to 2, moderate probability;  $\geq 3$ , high probability.

the presence or absence of risk factors (e.g., recent immobilization, hospitalization within the past month, or malignancy), (2) symptoms and signs at presentation are considered typical or atypical, and their severity, (3) severity of symptoms and signs, and (4) whether there is an alternative explanation for the symptoms and signs considered at least as likely as DVT (Table 105-1). The conditions

**TABLE 105-2**

#### Test Results That Effectively Confirm or Exclude Deep Vein Thrombosis

PURPOSE	TEST	SIGNIFICANT RESULT
Diagnostic for first DVT	Venography	Intraluminal filling defect
	Venous ultrasonography	Noncompressible proximal veins at two or more of the common femoral, popliteal, and calf trifurcation sites*
Excludes first DVT	Venography	All deep veins seen, and no intraluminal filling defects
	D-dimer	Negative result on a test that has at least a moderately high sensitivity ( $\geq 85\%$ ) and specificity ( $\geq 70\%$ ) and (1) normal results on venous ultrasonography of the proximal veins or (2) low clinical suspicion of DVT at presentation
	Venous ultrasonography	Negative result on a test that has a high sensitivity ( $\geq 98\%$ ) Normal proximal veins and (1) low clinical suspicion for DVT at presentation, or (2) normal D-dimer test at presentation, or (3) normal second test after 7 d Normal proximal and distal veins*
Diagnostic for recurrent DVT	Venography	Intraluminal filling defect
	Venous ultrasonography	(1) A new noncompressible common femoral or popliteal vein segment or (2) a $\geq 4.0$ mm increase in diameter of the common or popliteal vein since a previous test <sup>†</sup>
Excludes recurrent DVT	Venography	All deep veins seen and no intraluminal filling defects
	Venous ultrasonography	Normal or $\leq 1$ mm increase in diameter of the common femoral or popliteal veins on venous ultrasound since a previous test and continuing normal results (no progression of venous ultrasound) at 2 and 7 d
	D-dimer	Results as described as for a first episode of DVT; however, these criteria are less well evaluated for diagnosis of recurrence

\*The accuracy of, and need to treat, isolated distal vein abnormalities on ultrasound are uncertain. For this reason, and because examination of the calf veins is difficult to perform, many centers confine the examination to the proximal veins.

<sup>†</sup>If other evidence is not consistent with recurrent DVT (e.g., clinical assessment, or D-dimer), venography should be considered.

that are most likely to simulate DVT are ruptured Baker cyst, cellulitis, muscle tear, muscle cramp, muscle hematoma, external venous compression, superficial thrombophlebitis, and the postthrombotic syndrome. The prevalence of VTE is higher in the elderly who are investigated, compared to younger patients.

### Diagnostic Testing

Four objective tests—venography, impedance plethysmography, and venous ultrasonography, and D-dimer testing—have been rigorously evaluated for the diagnosis of DVT. Impedance plethysmography is now used infrequently, and will not be considered in the following review. Magnetic resonance venography and computed tomography (CT) venography appear to be promising new modalities but are less well evaluated.

**Venography** Venography provides the reference standard for diagnosis of DVT. It involves the injection of a radiocontrast agent into a distal vein. Venography detects both proximal vein thrombosis and calf vein thrombosis. However, it is technically difficult, expensive, requires injection of contrast dye and can be painful. Since contrast dye can cause allergic reactions or exacerbate renal impairment, venography is usually reserved to resolve discrepancies between findings on venous ultrasonography and clinical assessment of probability of DVT, or when venous ultrasonography is nondiagnostic (often in patients with previous DVT). The increased prevalence of renal impairment makes venography an even less attractive investigation option in the elderly.

**Venous Ultrasonography** Venous ultrasonography is the noninvasive imaging method of choice for diagnosing DVT. It is not painful and it is easier to perform than venography. The common femoral vein, femoral vein, popliteal vein, and calf vein trifurcation (i.e., very proximal deep calf veins) are imaged in real time and compressed with the transducer probe. Inability to fully compress or obliterate the vein is diagnostic of DVT. Duplex ultrasonography, which combines real-time imaging with pulsed Doppler and color-coded Doppler technology, facilitates imaging of the deep veins of the calf.

Venous ultrasonography is highly accurate for the detection of proximal vein thrombosis in symptomatic patients, with reported sensitivity and specificity approaching 95%. The sensitivity for symptomatic calf vein thrombosis is considerably lower and appears to be operator dependent. For this reason, many centers do not examine the deep veins of the calf with ultrasonography. Instead, if the initial test excludes proximal DVT, anticoagulants are withheld and the test is repeated in 7 days to exclude progression of a calf vein thrombosis not identified at the initial presentation. If the test remains negative after 7 days, the risk that thrombus is present and will subsequently extend to the proximal veins is negligible, and it is safe to continue withholding treatment.

While ultrasonography is an accurate test, if the results are inconsistent with the pretest probability, further investigations may be warranted. For example, if the pretest clinical suspicion for DVT is low and the ultrasound shows a localized abnormality (i.e., less convincing findings), or if clinical suspicion is high and the ultrasound is normal, venography should be considered. In about one quarter of such cases, the results of venography differ from those of the ultrasound. Because the prevalence of DVT is only about 2% (most of which is distal), a follow-up test is not necessary when the

clinical suspicion of thrombosis is low and the result of an initial proximal venous ultrasound is normal.

**D-dimer Blood Testing** D-dimer is formed when cross-linked fibrin in thrombi is broken down by plasmin; thus, elevated levels of D-dimer can be used to detect DVT and PE. A variety of D-dimer assays are available, and they vary markedly in their accuracy as diagnostic tests for VTE.

All D-dimer assays have a low specificity for DVT and, therefore, an abnormal result is associated with a low positive predictive value and cannot be used to diagnose DVT. D-dimer assays that are used for diagnosis of VTE can be divided into two groups based on their sensitivity and specificity. Very highly sensitive D-dimer assays (e.g., sensitivity  $\geq 98\%$ ; specificity  $\sim 40\%$ ) have a sufficiently high negative predictive value ( $\geq 98\%$ ) that a normal result can be used to exclude VTE without the need to perform additional diagnostic testing. Moderate to highly sensitive D-dimer assays (sensitivity 85% to 97%; specificity 50% to 70%) need to have a negative result combined with another assessment that identifies patients as having a lower prevalence of VTE in order to exclude DVT or PE. Management studies have shown that it is safe to withhold anticoagulant therapy in patients who have a normal result on a moderately sensitive D-dimer test in combination with (1) a low clinical suspicion for DVT or (2) a normal result on venous ultrasonography of the proximal veins. Baseline D-dimer levels are known to increase with age. Therefore, D-dimer testing are much less specific and, therefore, of less clinical utility (fewer negative tests among those without venous thrombosis) in the elderly. Also, D-dimer testing has less clinical utility among patients with a high clinical suspicion of VTE as negative results are rarely obtained, and the predictive value of a negative test is lower in this group, because of a higher prevalence of disease.

### Recurrent Deep Vein Thrombosis

The diagnosis of acute recurrent DVT can be difficult. A negative D-dimer test can exclude recurrent DVT, although the safety of this approach has been less well evaluated than for first episodes of DVT, and D-dimer test is less often negative compared with patients without a history of venous thrombosis. If D-dimer testing is positive, or has not been performed, venous ultrasonography is performed. If the result is normal, the test should be repeated twice over the next 7 to 10 days. If the result is positive in the popliteal or common femoral vein segments, and the result of the previous test was negative at the same site, a recurrence is diagnosed. This diagnosis can also be made if venous ultrasonography shows other convincing evidence of more extensive thrombosis than was seen on a previous examination (e.g., an increase in thrombus diameter of  $\geq 4$  mm at the inguinal ligament or the mid-popliteal fossa; unequivocal extension within the femoral vein of the thigh). If findings on venous ultrasonography are equivocal, as compared with a previous scan, or a previous scan is not available for comparison, venography should be performed or the test can be repeated twice over the next 7 to 10 days to detect extension of thrombosis. If the venogram shows a new intraluminal filling defect or evidence of thrombus extension since a previous venogram, recurrent DVT is diagnosed. If the venogram outlines all of the deep veins and does not show an intraluminal filling defect, recurrent DVT is excluded. If the venogram is nondiagnostic (i.e., nonfilling of segments of the deep veins), the patient

**TABLE 105-3****Model for Determining a Clinical Suspicion of Pulmonary Embolism**

VARIABLES	POINTS*
Clinical signs and symptoms of deep vein thrombosis (minimum leg swelling and pain with palpation of the deep veins)	3.0
An alternative diagnosis is less likely than pulmonary embolism	3.0
Heart rate > 100 beats/min	1.5
Immobilization or surgery in the previous 4 wk	1.5
Previous deep vein thrombosis/pulmonary embolism	1.5
Hemoptysis	1.0
Malignancy (treatment ongoing or within previous 6 mo or palliative)	1.0
Total points	

\*Pretest probability is calculated as follows: a total score of  $\leq 4$  indicates a low probability (also termed "unlikely"); a score of 4.5 to 6 indicates moderate probability; and a score of  $> 6$  indicates high probability.

can be followed with repeat venous ultrasonography (as described above) or recurrent DVT can be diagnosed based on the results of all assessments, including clinical features.

## Pulmonary Embolism (Tables 105-3 and 105-4)

### Clinical Features

Dyspnea is the most common symptom of PE. Chest pain is also common; it is usually pleuritic but can be substernal and compressive. Tachycardia is relatively common and hemoptysis is less frequent. Although most patients with PE also have DVT, fewer than 25% have associated clinical features. However, the clinical features of PE, like those of DVT, are nonspecific, and in only about one quarter of patients suspected with PE is the diagnosis confirmed by objective tests. Furthermore, elderly patients are more likely to

present with atypical symptoms and signs such as fatigue, dizziness, and syncope.

In the past, clinical assessment of the probability of PE was not standardized; physicians made the assessment informally on the basis of their experience and the results of initial routine tests (e.g., chest x-ray and electrocardiogram). Two groups have published explicit criteria for determining the clinical probability of PE. The model created by Wells and colleagues incorporates an assessment of symptoms and signs, the presence of an alternative diagnosis to account for the patient's condition, and the presence of risk factors for VTE. With this model, a patient's clinical probability of PE can be categorized as low or unlikely (prevalence of PE  $< 10\%$ ), moderate (prevalence  $\sim 25\%$ ), or high (prevalence of 60%) (Table 105-2).

### Diagnostic Tests

**Chest Radiography and Electrocardiography** In patients with PE, chest x-rays show either normal or nonspecific findings. Chest radiography, however, is useful for exclusion of pneumothorax and other conditions that can simulate PE. The electrocardiogram also frequently shows normal or nonspecific findings, but it is valuable for excluding acute cardiac conditions (e.g., myocardial infarction, acute pericarditis). In the appropriate clinical setting, electrocardiographic (ECG) evidence of right ventricular strain suggests PE.

**Pulmonary Angiography** Pulmonary angiography is considered the reference standard for PE, however, it is now rarely performed as it is invasive and can usually be replaced by computed tomographic pulmonary angiography (CTPA). Pulmonary angiography can be complicated by arrhythmias, cardiac perforation, cardiac arrest, and hypersensitivity to the contrast medium. Complications occur in 3% to 4% of patients undergoing pulmonary angiography.

**Ventilation-Perfusion Lung Scanning** In the past, ventilation-perfusion lung scanning was the most important test for diagnosing PE. More recently, CTPA has supplanted lung scanning, although

**TABLE 105-4****Test Results that Effectively Confirm or Exclude Pulmonary Embolism**

CONCLUSION	TEST	RESULT
Diagnostic for PE	Pulmonary angiography	Intraluminal filling defect
	CT pulmonary angiography (CTPA)	Intraluminal filling defect in a main or lobar or segmental pulmonary artery and moderate/high clinical probability
Excludes PE	Ventilation-perfusion scan	High-probability scan and moderate/high clinical probability
	Tests for DVT*	Evidence of acute DVT with nondiagnostic ventilation-perfusion scan or CTPA
	Pulmonary angiography	Normal
	CT pulmonary angiography	Negative <sup>†</sup>
	Lung perfusion scan	Normal
High-sensitivity D-dimer test <sup>‡</sup>	Moderate-sensitivity D-dimer test <sup>§</sup>	Negative
		Negative, plus (1) low clinical suspicion of PE or (2) normal alveolar dead space fraction or (3) nondiagnostic lung scan and negative ultrasonography of proximal leg veins
		Low clinical suspicion, nondiagnostic scan, and negative ultrasonography
	Combination of clinical assessment, ventilation-perfusion scan, ultrasonography of proximal leg vein	

DVT, deep vein thrombosis; PE, pulmonary embolism.

\*See Table 105-3.

<sup>†</sup>If high clinical suspicion, supplemental bilateral ultrasonography of the proximal leg veins is recommended.

<sup>‡</sup>D-dimer assay with very high sensitivity (i.e., 98%) and at least moderate specificity (i.e., 40%).

<sup>§</sup>D-dimer assay with at least moderately high sensitivity (i.e., 85%) and specificity (i.e., 70%).

lung scanning is still used, particularly when CTPA is contraindicated because of renal failure or associated radiation exposure to the chest (e.g., in young women). A normal perfusion scan excludes a diagnosis of PE, however, a normal result is only obtained in about 25% of consecutive patients with suspected PE and an even smaller proportion of elderly patients. An abnormal perfusion scan is non-specific. Ventilation imaging improves the specificity of perfusion scanning for the diagnosis of PE; when the ventilation scan is normal at the site of a segmental or larger perfusion defect, the prevalence of PE is 85% or higher (termed a “high probability” lung scan, which justifies anticoagulant therapy). About half of patients who have PE have a “high probability” lung scan. Therefore, among consecutive patients who are investigated for PE, about 25% have a normal perfusion scan and can have the diagnosis excluded, about 15% have a “high probability scan” and can (provided clinical probability is not low) have PE diagnosed, and about 60% have an abnormal but nondiagnostic lung scan that requires further diagnostic testing.

**Computed Tomographic Pulmonary Angiography** CTPA, performed using helical CT (also known as spiral or continuous volume CT), is able to directly visualize the pulmonary arteries. Helical CT technology has rapidly advanced from use of single detector scanners to use of progressively larger numbers of detectors (termed multidetector CT) and enables more detailed examination of the pulmonary arteries.

Current evidence from the PIOPED II study suggests that CTPA is nondiagnostic in 6% of patients, and that among adequate examinations, sensitivity is 83%, specificity is 96%, positive predictive value is 86%, and negative predictive value is 95%. Accuracy varies according to the size of the largest pulmonary artery involved: positive predictive value was 97% for abnormalities in the main or lobar artery, 68% for those in segmental arteries, and 25% for subsegmental abnormalities (4% of pulmonary emboli in this study). Predictive values were also influenced by clinical assessment of PE probability; positive predictive value was 96% with high, 92% with intermediate, and 58% with low clinical probability (8% of patients); negative predictive value was 96% with low, 89% with intermediate, and 60% with high clinical probability (3% of patients).

The ability of CTPA to exclude PE has also been evaluated in management studies in which anticoagulant therapy was withheld in patients with negative CTPA. More recent studies suggest that less than 2% of patients with a negative CTPA for PE will return with symptomatic VTE during follow-up.

Magnetic resonance imaging (MRI) is less well evaluated than helical CT for the diagnosis of PE and is expected to be less accurate. Both helical CT and MRI have the advantage of being able to identify alternative pulmonary diagnoses. MRI does not expose the patient to radiation. Both MRI and helical CT can be extended to look for concomitant DVT.

**D-dimer Blood Testing** As was discussed for evaluation of suspected DVT, D-dimer testing is also a valuable test for the exclusion of PE, either used alone (very sensitive D-dimer assay) or in combination with other assessments that are associated with a reduced prevalence of PE (e.g., low clinical probability for PE; nondiagnostic ventilation–perfusion scan in combination with a negative ultrasound of proximal lower limb veins [see below]).

**Compression Ultrasonography** Compression ultrasonography, usually evaluating the proximal deep veins of the legs, can aid in the diagnosis of PE. Demonstration of DVT, which occurs in about 5% of patients with nondiagnostic ventilation–perfusion lung scans, can serve as indirect evidence of PE. Exclusion of proximal DVT does not rule out PE in a patient with a nondiagnostic ventilation–perfusion scan, although it does reduce that probability somewhat. However, if there are no proximal DVT on the day of presentation, and if no proximal DVT are detected on two subsequent examination 1 and 2 weeks later (DVT is diagnosed during serial testing in ~2% of patients), anticoagulant therapy can be withheld with a very low risk that patients will return with VTE (less than 2% during 3 months of follow-up). Earlier studies that evaluated CTPA suggested that a negative result did not exclude PE and, therefore, should be followed by bilateral ultrasonography of the proximal veins. However, more recent studies of CTPA, which used mostly multidetector scanners, do not support the need for routine ultrasonography of the proximal deep veins in patients with a negative CTPA. Instead, it appears to be reasonable to only perform ultrasonography of the proximal deep veins in patients with a negative CTPA if clinical suspicion for PE is high. As for patients who have nondiagnostic ventilation–perfusion lung scans, withholding of anticoagulant therapy and performance of serial ultrasonography is a reasonable approach to management of patients who have a CTPA that is suspicious for isolated subsegmental PE.

## Uncommon Thromboembolic Disorders

### Subclavian or Axillary Veins

Thrombosis of the subclavian or axillary veins may be idiopathic or may occur as a complication of local vascular damage. It is now most frequently seen as a complication of chronic indwelling catheter use, but it also occurs as a complication after mastectomy and local radiotherapy for breast cancer. Idiopathic subclavian or axillary vein thrombosis may occur in young muscular individuals and maybe preceded by repetitive, strenuous activity involving the affected arm. Some of these persons have a fixed stenosis of the subclavian vein that is thought to be caused by compression of the vein between the first rib and the clavicle. Thrombosis of the subclavian vein or the superior vena cava is a rare complication of a transvenous cardiac pacemaker.

Subclavian or axillary thrombosis causes pain, edema, and cyanosis of the arm. In rare cases, the thrombosis extends into the superior vena cava and causes edema and cyanosis of the face and neck.

Definitive diagnosis is made by venography, venous ultrasonography, or CT angiography. Subclavian or axillary vein thrombosis is treated with anticoagulants using a similar approach for lower limb DVT and PE (see “Treatment”). Regional or systemic thrombolytic therapy is usually reserved for select young patients without contraindications.

### Mesenteric Vein

An uncommon disorder, mesenteric vein thrombosis usually occurs in the sixth or seventh decade of life. It generally involves segments of the small bowel, leading to hemorrhagic infarction. Affected patients often have associated disorders, such as inflammatory bowel disease, malignancy, portal hypertension, familial thrombophilia, or

polycythemia vera, or they may have a history of recent abdominal surgery. In about 20% of cases, no underlying cause is found.

The clinical manifestations of mesenteric vein thrombosis include intermittent abdominal pain, abdominal distention, vomiting, diarrhea, and melena. Blunt, semiopaque indentations of the bowel lumen (“thumbprinting”) caused by mucosal edema, or gas in the wall of the bowel or the portal vein, or free peritoneal air may occur secondary to bowel infarction. CT, which shows an intraluminal filling defect in the mesenteric vein, is the diagnostic test of choice, and both Doppler ultrasonography and MRI are also helpful. Management includes acute and long-term anticoagulation, supportive care and surgery if bowel resection is being considered, followed by anticoagulant therapy. Mortality is about 30%, and up to 30% of patients experience recurrence.

### Renal Vein Thrombosis

Renal vein thrombosis can be idiopathic or a complication of the nephrotic syndrome. Patients may be asymptomatic or may present with abdominal, back, or flank pain and tenderness. PE is a relatively common complication of renal vein thrombosis. Anticoagulant therapy results in a gradual improvement in renal function, but patients may have long-standing proteinuria. Thrombolytic agents have been used, but the data are inadequate for critical appraisal of this form of treatment.

## TREATMENT OF VENOUS THROMBOEMBOLISM

A detailed review of anticoagulants is provided in Chapter 106.

### Management of Acute Venous Thromboembolism

#### Overview

The objectives of treating patients with VTE are to prevent PE, the postthrombotic syndrome, thromboembolic pulmonary hypertension, recurrent VTE and to alleviate the discomfort of the acute event.

Superficial venous thrombosis usually can be treated conservatively with anti-inflammatory drugs. If superficial phlebitis is extensive or very symptomatic, a 2- to 4-week course of heparin or low-molecular-weight heparin (LMWH) therapy can be used. In patients with DVT or PE, anticoagulants reduce morbidity and mortality from recurrent DVT and PE. Vena caval interruption is generally used only if anticoagulant therapy has failed or is contraindicated because of the risk of serious hemorrhage. Retrievable inferior caval filters are an option in patients with an expected temporary contraindication to anticoagulants (e.g., acute VTE less than 2 weeks before major surgery).

Thrombolytic therapy is more effective than heparin in achieving early lysis of VTE and can reduce mortality in patients with massive PE associated with shock. A regimen of 100 mg of rt-PA administered over 2 hours is generally recommended. The role of thrombolytic therapy in the treatment of DVT is uncertain. Systemic thrombolytic therapy increases lysis of DVT, and may reduce the risk of developing the postthrombotic syndrome, however, it increases the frequency of major bleeding, including intracranial hemorrhage. Thromboendarterectomy is effective in selected cases of

chronic thromboembolic pulmonary hypertension caused by proximal pulmonary arterial obstruction. Routine early use of graduated compression stockings for 2 years has been reported to reduce the incidence of the postthrombotic syndrome by about 50%.

### Anticoagulant Therapy

Anticoagulants are the mainstay of treatment for most patients with VTE. In the past, the initial treatment of choice was heparin administered by continuous intravenous infusion or subcutaneous injection in doses sufficient to produce an adequate anticoagulant response. Current evidence indicates that LMWH administered by subcutaneous injection without laboratory monitoring is at least as effective and safe as heparin given intravenously.

Heparin therapy is usually monitored by the activated Partial Thromboplastin time (aPTT) and less frequently by heparin assays, which measure the ability of heparin to accelerate the inactivation of factor Xa or thrombin by antithrombin. The starting dose of intravenous heparin is a bolus of 80 U/kg (or a set dose of 5000 U) followed by an initial infusion of 18 U/kg/h (or a set dose of about 1300 U/h). The anticoagulant effect should be monitored every 6 hours until the aPTT is in the therapeutic range, and then daily. The therapeutic range of aPTT is equivalent to a heparin level between 0.35 and 7.0 U/mL as measured by an antifactor Xa assay. For many aPTT reagents, this range is an aPTT ratio of 1.8 to 2.5 times the mean of the normal laboratory control value. A recent study showed that acute VTE can be treated with subcutaneous, weight-adjusted, heparin without dose-adjustment and laboratory monitoring (initial dose of 333 U/kg followed by 250 U/kg every 12 hours).

LMWH is administered subcutaneously on a weight-adjusted basis at a dosage of about 100 anti-Xa U/kg every 12 hours or 150 to 200 anti-Xa units once daily. Monitoring is not required in the absence of marked renal impairment.

Treatment with heparin or LMWH is recommended for 5 to 6 days; warfarin therapy is started on the first or second day, overlapping the heparin therapy for 4 or 5 days, and is continued until an International Normalized Ratio (INR) of 2.0 is maintained for at least 24 hours. A 4- to 5-day period of overlap is necessary because the antithrombotic effects of oral anticoagulants are delayed. The initial course of heparin should be followed by warfarin for at least 3 months. Extended treatment with low-intensity warfarin (INR 1.5–2.0) is less effective than standard intensity (INR 2.0–3.0) and has not been shown to reduce bleeding. However, low-intensity warfarin has been used with less frequent INR monitoring (i.e., about every 2 months). Full to intermediate-dose LMWH can also be used in place of warfarin for long-term treatment and has been shown to be preferable to warfarin in patients with VTE and active cancer.

**Duration of Anticoagulant Therapy** During the past decade, a series of well-designed studies has helped to define the optimal duration of anticoagulation. The findings of these studies are summarized in [Table 105-5](#). Whether anticoagulant therapy (INR = 2.0–3.0) for proximal DVT or PE is recommended for 3 months, or an indefinite period (with annual review), depends primarily on the presence of a provoking risk factor for VTE (i.e., transient risk factor, no risk factor, or cancer), risk factors for bleeding, and patient preference (i.e., burden associated with treatment). Secondary factors that support indefinite therapy for unprovoked VTE include a second episode of VTE and presentation with PE rather than DVT. A

**TABLE 105-4****Findings from Randomized Controlled Trials and Observational Studies that Influence Optimal Duration of Oral Anticoagulant Therapy**

- Shortening the duration of anticoagulation from 3 or 6 mo to 4 or 6 wk results in a doubling of the frequency of recurrent VTE during 1–2 yr of follow-up.
- Patients with VTE provoked by a transient risk factor have a lower (about one third) risk of recurrence than those with an unprovoked VTE or a persistent risk factor.
- Three months of anticoagulation is adequate treatment for VTE provoked by a transient risk factor; subsequent risk of recurrence is about 3% in the first year of follow-up.
- After about 3 mo of anticoagulation, recurrent DVT is as likely to involve the contralateral leg; this suggests that systemic rather than local (including inadequate treatment) factors are responsible for recurrences after 3 mo of treatment.
- There is a persistently elevated risk of recurrent VTE after a first episode of VTE; this appears to be about 10% in the first year, and about 30% in the first 5 yr, after 6 or more mo of treatment for an unprovoked proximal DVT or pulmonary embolism.
- Extending duration of anticoagulation beyond 3–6 or 12 mo may delay, but ultimately not reduce, the risk of recurrence if therapy is then stopped.
- After 3 mo of initial treatment of unprovoked VTE with oral anticoagulants targeted at an INR of 2.5 (INR range 2.0–3.0), continuing treatment with:
  - oral anticoagulants targeted at an INR of  $\sim 2.5$  reduces the risk of recurrent VTE by over 90%;
  - oral anticoagulants targeted at an INR of  $\sim 1.75$  reduces the risk of recurrent VTE by about 75%;
  - oral anticoagulants targeted to an INR of  $\sim 2.5$  are more effective than using an INR target of  $\sim 1.75$ , without evidence of increased bleeding.
- A second episode of VTE predicts a higher risk of recurrence and favors indefinite anticoagulation after unprovoked VTE.
- Risk of recurrence is lower (about half) following an isolated calf (distal) DVT than after proximal DVT or PE; this favors a shorter duration of treatment.
- Risk of recurrence off treatment is similar after an episode of proximal DVT or PE.
- About 5% of recurrent episodes of VTE are expected to be fatal.
- Recurrent VTE is usually (about 60% of episodes) a PE after an initial PE, and usually (about 80% of episodes) a DVT after an initial DVT; this effect is expected to increase mortality from recurrent VTE by two- to threefold after a PE compared to after a DVT.
- Risk of recurrence is about threefold higher in patients with active cancer.
- Long-term treatment with low-molecular-weight heparin is more effective than warfarin in patients with VTE associated with cancer, and is a preferred option for such patients for at least 3 mo.
- Estrogen therapy is an important risk factor for first and recurrent episodes of VTE; consequently, if VTE occurred while on estrogen therapy, the risk of recurrent VTE is expected to be lowered by stopping estrogens.
- Risk of recurrence appears to be somewhat higher with antiphospholipid antibodies (anticardiolipin antibodies and/or lupus anticoagulants) and inherited thrombophilias.
- Males appear to have about a 50% higher risk of recurrent VTE than females.
- Other risk factors for recurrences may include: advanced age; elevated levels of clotting factors VIII, IX, XI and homocysteine; elevated D-dimer levels after stopping anticoagulant therapy; venal caval filters; and residual deep vein thrombosis on ultrasound; currently, these factors do not have clear implications for duration of treatment.
- The risk of anticoagulant-induced bleeding is highest during the first 3 mo of treatment and stabilizes after the first year.
- Risk of bleeding differs markedly among patients depending on the prevalence of risk factors (e.g., advanced age; previous bleeding or stroke; renal failure; anaemia; antiplatelet therapy; malignancy; poor anticoagulant control).
- About 10% of episodes of major bleeding are fatal.
- The risk of major bleeding in younger patients (e.g., younger than 60 yr) that do not have risk factors for bleeding and have good anticoagulant control (target INR 2–3) is about 1% per year. The risk of major bleeding is expected to be at least 10-fold higher in patients with multiple risk factors for bleeding.

key consideration in elderly patients is assessment of risk for major bleeding and we generally do not recommend indefinite anticoagulant therapy for a first unprovoked proximal DVT or PE in patients older than 75 years of age because of their increase risk of bleeding (see below).

## Primary Prevention of Venous Thromboembolism

### Overview

The most effective way of reducing the mortality associated with PE and the morbidity associated with the postthrombotic syndrome is to use primary prophylaxis in patients at high risk for VTE. Prophylaxis is achieved either by reducing blood coagulability or by preventing venous stasis using the following approaches: (1) low-dose subcutaneous heparin, (2) LMWHs, (3) fondaparinux, (4) coumarin anticoagulants, (5) graduated compression stockings, or (6) intermittent pneumatic compression of the legs. Antiplatelet agents, such as aspirin, are not recommended as sole therapy as they are less effective than the previously noted methods.

On the basis of well-defined clinical criteria, patients can be classified as being at low, moderate, or high risk for VTE, and the choice of prophylaxis should be tailored to the patient's risk of VTE and of bleeding (Table 105-6). In the absence of prophylaxis, the frequency of fatal postoperative PE ranges from 0.1% to 0.4% in patients undergoing elective general surgery and from 1% to 5% in patients undergoing elective hip or knee surgery, emergency hip surgery, major trauma, or spinal cord injury. Prophylaxis is cost-effective for most moderate and high-risk groups. Despite the merits of venous thromboprophylaxis, adherence with current guidelines for hospitalized patients is often poor, particularly in elderly patients.

### Therapies

Low-dose heparin is given subcutaneously at a dose of 5000 units 2 hours before surgery and 5000 U every 8 or 12 hours after surgery. In patients undergoing major orthopedic surgical procedures, low-dose heparin is less effective than warfarin, LMWH, or fondaparinux and is not recommended. Intermittent pneumatic compression of the legs enhances blood flow in the deep veins and may increase

TABLE 105-5

## Risk Categories for Venous Thromboembolism and Recommendations for Prophylaxis

	HIGH RISK	MODERATE RISK
Calf vein thrombosis	20%–50%	10%–20%
Proximal vein thrombosis	5%–20%	0.4%–5%
Fatal pulmonary embolism	2%–5%	0.1%–0.4%
Recommended prophylaxis	Low-molecular-weight heparin, oral anticoagulants, or fondaparinux (can be combined with graduated compression stockings or pneumatic compression)	Low-dose heparin, external pneumatic compression, or graduated compression stockings

\*Usually asymptomatic and detected by screening venography about 10 days after surgery.

blood fibrinolytic activity. This method of prophylaxis is particularly useful in patients who have a high risk of serious bleeding. It is the method of choice for preventing venous thrombosis in patients undergoing neurosurgery, is effective in patients undergoing major knee surgery, and is as effective as low-dose heparin in patients undergoing abdominal surgery.

Graduated compression stockings reduce venous stasis and prevent postoperative venous thrombosis in general surgical patients and in medical or surgical patients with neurologic disorders, including paralysis of the lower limbs. In surgical patients, the combined use of graduated compression stockings and low-dose heparin is more effective than use of low-dose heparin alone.

Standard-dose warfarin (INR = 2.0–3.0) is effective for preventing postoperative VTE and is started at the time of surgery, or in the early postoperative period. Because it is complex to use, warfarin is generally reserved for patients at very high risk, including patients with hip fractures and those who undergo joint replacement.

LMWH is a safe and effective form of prophylaxis in high-risk patients undergoing elective hip surgery, major general surgery, or major knee surgery, as well as in patients who have experienced hip fracture, spinal injury, or acute medical illness. LMWH is more effective than low-dose heparin in high-risk patients.

In patients who undergo hip or major knee surgery, LMWH is more effective than warfarin while patients are in hospital but is associated with more frequent bleeding; both of these differences may be caused by a more rapid onset of anticoagulation with LMWH. Fondaparinux reduces the frequency of venographically detected DVT (about 10 days after surgery) by 50% compared to LMWH but causes a small increase in bleeding.

## Indications for Venous Thromboembolism Prophylaxis

### General Surgery and Medicine

Low-dose heparin or LMWH prophylaxis is the method of choice for moderate-risk general surgical and medical patients. It reduces the risk of VTE by 50% to 70% and is simple, inexpensive, convenient, and safe. Heparin-induced thrombocytopenia may occur, particularly in surgical patients who receive heparin for more than 5 days. If anticoagulants are contraindicated because of an unusually high risk of bleeding, graduated compression stockings, intermittent pneumatic compression of the legs, or both, should be used.

**Major Orthopedic Surgery** LMWH, fondaparinux, or oral anticoagulants provide effective prophylaxis for VTE in patients who have undergone hip surgery. LMWH, warfarin, fondaparinux, and

intermittent pneumatic compression are effective in preventing VTE in patients undergoing major knee surgery.

Extended prophylaxis with LMWH, fondaparinux, or warfarin for an additional 3 weeks after hospital discharge should be considered after major orthopedic surgery and is strongly recommended for high-risk patients (e.g., those with previous VTE or active cancer). If extended prophylaxis with LMWH or fondaparinux is not used, there is indirect evidence supporting use of aspirin for 1 month after stopping anticoagulant therapy.

**Genitourinary Surgery, Neurosurgery, and Ocular Surgery** Intermittent pneumatic compression, with or without graduated compression stockings, is effective prophylaxis for VTE and does not increase the risk of bleeding.

## Complications of Antithrombotic Agents

### Risks of Major Bleeding

Bleeding is the main complication of antithrombotic therapy. “Major bleeding” is usually defined as clinically overt bleeding that results in a 2 gm/dL drop in hemoglobin, the need for transfusion or hospitalization, or serious residual consequences. With all antithrombotic agents, the risk of bleeding is influenced by the dose and by patient-related factors, the most important being recent surgery or trauma. Other patient characteristics that increase the risk of bleeding are older age, recent stroke, generalized hemostatic defect, a history of gastrointestinal hemorrhage, renal failure, and other serious comorbid conditions.

With heparin, the incidence of bleeding is influenced by dosage; independently of dosage, there is no clear relationship between bleeding and the aPTT. Bleeding rates appear to be lower with LMWH than with intravenous heparin.

Bleeding associated with coumarin anticoagulants is influenced by the intensity of anticoagulant therapy, particularly with progressive increases of the INR above 3.0. A study that compared long-term treatment of VTE with warfarin targeted to an INR of 1.75 compared with an INR of 2.5 found no difference in the rates of bleeding, suggesting that differences in the INR between 1.5 and 3.0 are not associated with clinically important difference in bleeding risk. Both heparin-induced bleeding and warfarin-induced bleeding are increased by concomitant use of aspirin, which impairs platelet function and produces gastric erosions. When the INR is less than 3.0, coumarin-associated bleeding frequently has an obvious underlying cause or is from an occult gastrointestinal or renal lesion.

Long-term anticoagulant therapy is associated with an average annual risk of major bleeding of about 1% to 3%. Advanced age is an independent risk factor for anticoagulant-induced major bleeding with patients greater than 65 years of age having a twofold or greater risk of bleeding than younger patients.

Intensity of anticoagulation is the strongest predictor of major bleeding and avoiding INR values above 3.0 appears to be particularly important in the elderly. This was most clearly shown in the Stroke Prevention in Atrial Fibrillation II (SPAF II) study that compared oral anticoagulation (INR 2.0–4.5) with aspirin. In the subgroup of patients older than 75 years of age, much of the benefit of anticoagulant therapy was lost because of a high frequency of intracranial bleeding that was attributable to the high intensity of anticoagulation. Additional risk factors for bleeding include (1) previous history of bleeding (e.g., gastrointestinal or intracerebral), (2) previous noncardioembolic stroke, (3) renal failure, (4) anemia, (5) erratic control of anticoagulant therapy, (6) malignancy, and (7) concomitant use of antiplatelet therapy. The risk of anticoagulant-induced bleeding differs markedly among patients. Patients less than 65 years of age without risk factors for bleeding have an annual risk of major bleeding of about 1%. This risk may be 10%/year or higher in patients with multiple risk factors. Careful control of anticoagulant therapy, with use of an expert clinical service and patient education, has been shown to reduce the risk of bleeding in the elderly.

### Consequences of Bleeding in Elderly

On average, about 10% of major bleeds that occur in anticoagulated patients are fatal. The most feared type of bleed is intracranial hemorrhage that is fatal in about 70% of cases. The risk of life-threatening bleeds is three to four times higher in patients aged 80 years or older compared with patients 50 years of age or younger. This reflects both a higher frequency of bleeding and a higher incidence of intracranial

hemorrhage in older patients (relative risk of 3.2 for age 75 years or older when compared with younger patients).

# Hemorrhagic Disorders

*Julia A. M. Anderson* ■ *Agnes Y. Y. Lee*

Although hemorrhage caused by intracranial, aneurysmal, and gastrointestinal pathologies account for a significant proportion of all deaths in the older-than-60-year age group, fatal bleeding caused by primary defects in coagulation and platelets are less common. Nevertheless, the development of a bleeding diathesis in an elderly patient presents clinical challenges that form the focus of this chapter.

Hemostasis is a highly regulated process involving a dynamic balance between coagulation and fibrinolytic proteins and their inhibitors, platelets, and the vascular endothelium. The overall aim of the coagulation system is to rapidly generate a hemostatic plug at sites of vascular injury to prevent catastrophic blood loss from severed vessels. Congenital or acquired disturbances of the delicate balance between coagulation and fibrinolysis may result in thrombotic or hemorrhagic clinical manifestations.

Elderly patients more commonly present with acquired bleeding disorders, but occasionally a mild congenital bleeding diathesis may remain hidden until later years when surgical procedures become common, when comorbid disease develops (such as renal or hepatic dysfunction), or when an additional acquired condition creates an additive challenge to the hemostatic system, such as the introduction of antiplatelet agents or anticoagulant therapy. Focusing on bleeding in the elderly, this chapter (a) provides a brief overview of hemostatic mechanisms, (b) discusses the clinical assessment of an elderly patient with a history of bleeding, (c) details the main inherited and acquired hemorrhagic conditions and their presentation in an elderly population, and (d) outlines the treatment of elderly patients with hemorrhagic states.

## OVERVIEW OF HEMOSTASIS

Following damage to the endothelium, blood is exposed to subendothelial components, such as von Willebrand factor (vWF) and collagen. Platelets adhere to the subendothelium and are activated, releasing substances that further recruit and activate platelets induc-

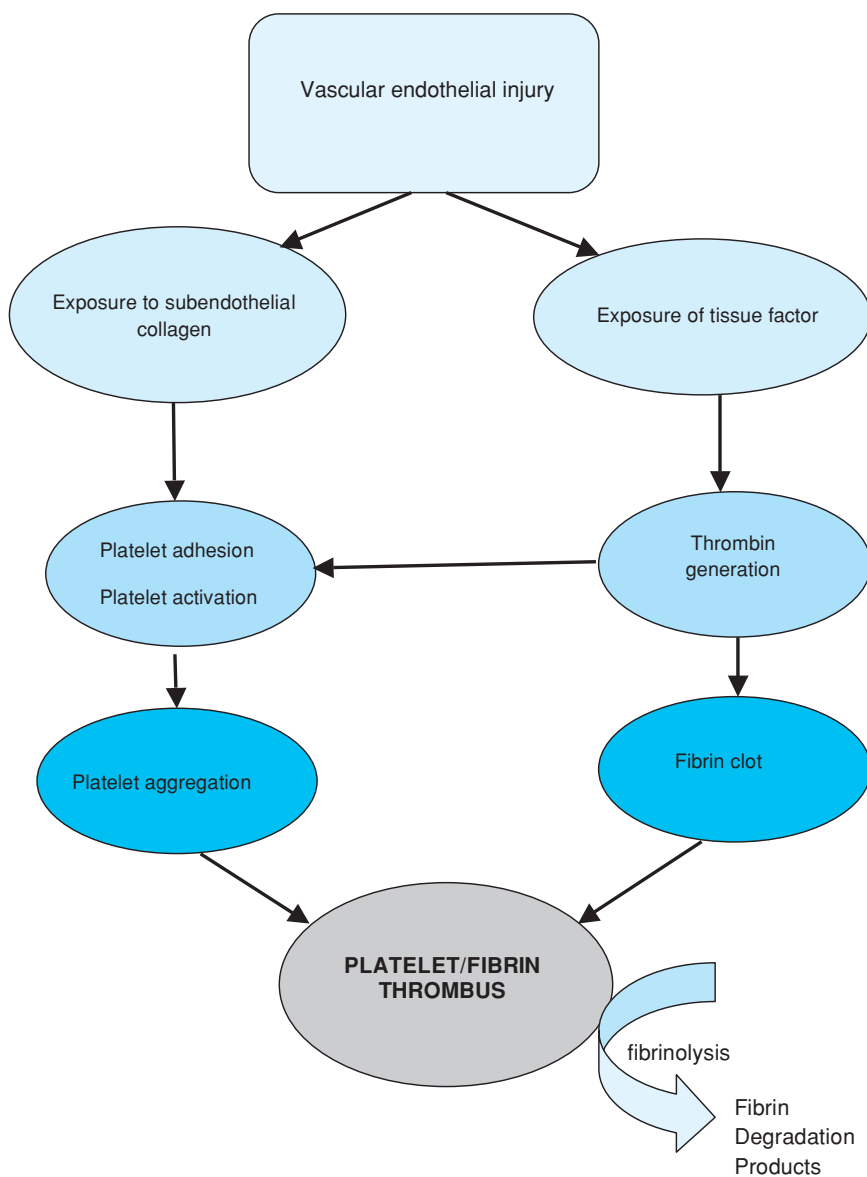

ing platelet aggregation. A platelet plug is formed at the site of injury providing initial arrest of bleeding, in a process known as “primary hemostasis”. A process referred to as “secondary hemostasis” follows to ensure stabilization of the platelet plug.

Vascular injury also exposes tissue factor (TF), a membrane-bound procoagulant factor that triggers the coagulation cascade. The coagulation cascade is a highly regulated series of enzymatic reactions involving the sequential conversion of proenzymes into their active forms. Activated platelets provide a phospholipid surface membrane on which coagulation enzymes localize and assemble into complexes that accelerate the serial enzymatic reactions. Such amplification processes translate a small initiating signal into an explosion of thrombin generation, thereby resulting in rapid fibrin formation. The polymerization of fibrin stabilizes the platelet plug and results in secondary hemostasis.

Removal of the fibrin clot takes place by activation of the fibrinolytic system. Plasminogen, a zymogen, is converted into plasmin, an enzyme that degrades the fibrin matrix of the clot into soluble fragments. Hemostatic mechanisms rely on dynamic interactions between platelets, the coagulation cascade, the fibrinolytic system, and the endothelium (see [Figure 106-1](#)). Disturbances of the equilibrium, caused by acquired or congenital factors, may result in unexpected or excessive bleeding or thrombosis.

## Age-Related Effects on the Hemostatic System

Two large epidemiological studies of men and women aged 25 to 74 years (the MONICA Project), and 60 to 79 years, demonstrate a significant effect of the ageing process on coagulation factors, inhibitors, and activation markers. However, these age-related changes do not cause an increased tendency to hemorrhage; instead, increases in fibrinogen and coagulation factors VII (fVII), VIII (fVIII), IX (fIX), and vWF are greater than increases in the coagulation inhibitors, antithrombin (AT), protein C, and protein S, resulting in a tendency toward thrombosis. This net procoagulant

**FIGURE 106-1.** The hemostatic mechanism involves a dynamic relationship between the vascular endothelium, platelets, coagulation cascade, and fibrinolysis. Abnormalities of any parts of the system can cause a bleeding diathesis. (Modified with permission from Liaw PC, Weitz JI. Coagulation overview. Section 8. Hematologic problems. In Albert RK, Slutsky A, Ranieri M, Takala J, Torres A, eds. *Clinical Critical Care Medicine*. Philadelphia: Elsevier; 2006:543–553).

effect appears to be more pronounced in men than women, and is reflected by an increase in thrombin–AT complexes, high plasma levels of activation peptides cleaved from prothrombin, fIX, and factor X (fX), and minor changes in thromboelastograph variables. Levels of plasminogen activator inhibitor-1 (PAI-1), an inhibitor of the tissue plasminogen activator (tPA), also increase in an age-dependent manner, adding to the relative prothrombotic state with ageing.

Megakaryopoiesis does not appear to alter with the aging process. Platelets are present in similar numbers with only a normal or moderate reduction in life span compared with platelets in younger individuals.

### CLINICAL APPROACH TO BLEEDING IN THE ELDERLY PATIENT

A patient may present for evaluation of new symptoms of bleeding or bruising, or may be referred postoperatively or postprocedurally following difficulty securing hemostasis. The immediate assessment

of a patient who has been bleeding intraoperatively can be particularly challenging from a laboratory viewpoint, and reassessment may be necessary several weeks later once the hemostatic system has had time to rebalance. Accurate historical details are essential in the overall evaluation process (see [Table 106-1](#)). Accompanying caregivers are often helpful in providing extra details about patients who cannot provide a reliable history.

### Age of Onset of Symptoms

Bleeding issues that are lifelong are likely to hold a congenital basis, rather than a recently acquired etiology. An assessment of previous hemostatic challenges should be made, such as dental surgery, trauma, and operations, including operations commonly performed in childhood such as tonsillectomy and adenoidectomy. Bleeding around the time of childbirth may be more difficult to interpret, but the need for blood transfusion is valuable information that may point to the severity of hemorrhage. Congenital causes may manifest late in life if they are mild and the patient has not experienced any previous hemostatic challenges.

**TABLE 106-1****Evaluation of Bleeding in the Elderly: Points of Historical Relevance**

HISTORICAL DETAILS	POINTS TO ELICIT
When did the bleeding start?	Duration of symptoms Lifelong or recent onset?
Nature of the bleeding?	Spontaneous or post trauma/procedure? Epistaxis, gingival bleeding Previous history of menorrhagia Joint bleeds, muscle bleeds
How long did the bleeding persist?	
Was the bleeding immediate or delayed?	
Any other associated forms of bleeding?	Gastrointestinal, hematuria
Response to past operative or dental challenges	Dental extraction is a hemostatic challenge
Medications	Include all recent medications Include herbal remedies
Diet	Any history of malabsorption? Recent administration of antibiotics? Balanced diet?
Family history	Are male and female members of the family equally affected?
Other questions	Any comorbidity to exacerbate a bleeding tendency? Does the bleeding require urgent attention or is this an evaluation to assess the potential to bleed during future operations?

## Bleeding Symptoms

The nature of bleeding symptoms may determine the etiology of the hemostatic defect: mucosal bleeding, epistaxis, and menorrhagia highlight defects in platelets or their interaction with the vascular wall; delayed bleeding, spontaneous hemarthroses, and muscle bleeds are consistent with coagulation factor deficiencies such as hemophilia. The significance of symptoms such as bruising, epistaxis, and menorrhagia may be challenging to define as there is a strong subjective component to each, and they are common symptoms. Sometimes it is useful to assess for any temporal changes in severity of these events. The clinician should also determine whether bleeding occurs spontaneously, or secondary to trauma or surgery.

### Bruising, Purpura, Petechiae, and Ecchymoses

The term “purpura” refers to a spontaneous extravasation of blood from the capillaries into the skin. “Petechiae” are purpuric lesions of pin-head size and ecchymoses are larger lesions.

The location and extent of bruising may be indicative of an underlying bleeding disorder. For example, large ecchymoses, presenting on the trunk without known trauma, may suggest an underlying bleeding disorder, whereas minor bruising on extremities are more likely benign. In an older person with no prior history of bleeding, extensive or truncal ecchymoses may suggest the development of

an acquired coagulation disorder such as liver disease, disseminated intravascular coagulation (DIC), or acquired hemophilia.

### Oral Mucosal Bleeding

Tonsillectomy, adenoidectomy, and dental extraction of the molar teeth create a significant hemostatic challenge, and the patient’s response to the challenge is of historical importance; bleeding that required resuturing or excessive packing, or that continued for several hours to days is suggestive of an underlying hemostatic disorder.

### Menorrhagia

This complaint is highly subjective and poorly correlates to actual blood loss; description of the passage of clots, a history of past iron-deficiency anemia, the requirement for blood transfusion or for hysterectomy at a young age may all highlight an underlying bleeding diathesis.

### Gastrointestinal Bleeding, Hemoptysis, and Hematuria

These symptoms are usually caused by localized blood loss from underlying pathology; an acquired or congenital bleeding disorder may unmask the symptoms and make them more florid. In an older person, such bleeding should prompt urgent investigations for the underlying cause as bleeding from such sites could be potentially life-threatening and may be a harbinger of malignancy or other serious conditions.

### Family History of Bleeding

A patient’s first hemostatic challenge may occur in older age, leading to the presentation of a hidden mild congenital disorder. A careful family history should record any hemorrhagic events affecting family members, including immediate and more distant relatives. However, one-third of cases of hemophilia A and B arise as a result of *de novo* mutations in whom there may be no family history. Female carriers of factor VIII (fVIII) or factor IX (fIX) deficiency, or male patients with mild hemophilia may have no bleeding history if coagulation factor levels are greater than 30% to 50%; lower baseline factor levels may cause bleeding problems after surgical or dental challenge.

### Medications

A careful history should be taken of all medications and herbal remedies (see Table 106-2) being administered. Aspirin, a cyclooxygenase-1 inhibitor, and ADP-receptor antagonists such as clopidogrel and ticlopidine cause platelet dysfunction; quinine, carbimazole, and penicillins may cause drug-induced immune thrombocytopenia (d-ITP) and anticoagulants including heparin, low-molecular-weight heparin, and warfarin may all cause hemorrhagic complications in elderly patients. The chronic administration of steroids may thin the skin increasing the likelihood of purpura (steroid-induced purpura). It may be difficult to solicit an accurate history of all medications used, so patients should be encouraged to bring all medications and dietary supplements with them to their consultation. It is also important to review the doses and frequency of administration.

**TABLE 106-2****Commonly Used Herbal Medicines That May Alter Hemostasis**

MEDICINE	ACTION	COMMENTS
Garlic	Inhibition of platelet aggregation; increased fibrinolysis	May increase bleeding when combined with other antiplatelet drugs
Gingko	Inhibition of platelet activation	May increase bleeding when combined with other antiplatelet drugs
Ginseng	Increases PT and aPTT	May increase bleeding risk; also reduces anticoagulant effect of warfarin
St John's Wort	Induction of cytochrome P450 enzymes	Interacts with warfarin

Data from, Ang-Lee MK, Moss J, Chiu-Su Y, et al. *JAMA*. 2001;286(2):208–216. © American Medical Association.

## Diet

In an elderly patient presenting with new onset bleeding, an assessment of nutritional status is important. The most common dietary deficiencies that contribute to bleeding or a coagulopathy are those of vitamin B-12, folate, vitamin K, and vitamin C.

Vitamin B-12 and folate are essential for normal hematopoiesis because of their roles in DNA synthesis. Although vitamin B-12 or folate deficiency may cause megaloblastosis and pancytopenia, including thrombocytopenia, these conditions alone are unlikely to present with a bleeding diathesis unless the patient is taking concurrent anticoagulants or antiplatelet medications, or other comorbidity is present. Nevertheless, it is important to exclude vitamin B-12 and folate deficiency in patients presenting with thrombocytopenia or other cytopenias as it is easily correctable.

Acute folate deficiency can develop quite rapidly, within a 3-week period; this may be found in up to one-third of hospitalized patients. Risk factors include anorexia, acute alcohol ingestion, and in patients receiving anticonvulsants. Rich sources of dietary folate include green leafy vegetables, fresh and minimally cooked, as folate is thermolabile and is destroyed following prolonged cooking.

Vitamin B-12, a cobalamin, is synthesized by microorganisms, and must be solely obtained from the diet; foods rich in vitamin B-12 include meat, fish, milk, and eggs. The normal body store is 2 to 5 mg in adults, and it usually takes 3 to 4 years to deplete if there is inadequate dietary intake. Vegetarian and vegans often have inadequate dietary intake of cobalamin and may develop low body stores. Other causes of vitamin B-12 deficiency include atrophic gastritis, total or partial gastrectomy, pernicious anemia, and malabsorption in the small bowel secondary to inadequate pancreatic protease and reduction of intrinsic factor-cobalamin receptors in the ileum.

Vitamin K is the cofactor required for gamma-carboxylation of glutamic acid residues on prothrombin, factors VII, IX, X, protein C, and protein S. Vitamin K deficiency occurs as a result of poor nutrition, malabsorption of fat-soluble vitamins, or intrahepatic cholestasis and may be present in any hospitalized or ill patient; patients with inadequate dietary intake are unlikely to develop severe vitamin K deficiency unless concurrently taking antibiotics, when the intestinal source of vitamin K<sub>2</sub> is eliminated.

Vitamin C is necessary for the conversion of hydroxyproline to proline, vital for collagen turnover. Inadequate vitamin C intake over a 2- to 3-month period may cause the clinical condition of scurvy manifested by bruising, ecchymoses, and perifollicular hemorrhage.

## Physical Examination

### General Examination

Clinical signs of chronic liver disease or renal impairment, abdominal masses, splenomegaly, and lymphadenopathy (indicative of bone marrow pathology such as leukemia, lymphoma, or myeloproliferative diseases), bone tenderness (paraproteinemia), and joint swelling (rheumatoid arthritis, connective tissue diseases) may all provide diagnostic information. An assessment should be made of skin elasticity and joint hypermobility, such as found in Ehlers Danlos or pseudoxanthoma elasticum, conditions that may present with microvascular hemorrhage. Infectious causes of purpura include infective endocarditis (clinical signs may include the presence of a new heart murmur, Osler's nodes, finger clubbing, and splinter hemorrhages) and meningococcal septicemia because of their associated DIC.

### Purpura

Evidence of skin bruising, its site, and extent should be recorded: this includes the presence of petechiae, ecchymoses, and subcutaneous hematoma. The site of purpura may provide diagnostic information: petechiae found on the distal limbs is suggestive of thrombocytopenia, on the face and periorbital area may be suggestive of amyloid and purpura sited on the extensor surfaces of legs, arms, and buttocks is a feature of vasculitic conditions. The presence of spongy-looking bleeding gums, purpura, and corkscrew hairs is suggestive of scurvy. Telangiectasia may appear to look purpuric, but classically these lesions are blanchable. Telangiectasiae affecting the face, mouth, tongue, and lips is diagnostic of hereditary hemorrhagic telangiectasia (HHT), a condition that may cause epistaxis and gastrointestinal bleeding throughout the patient's life, resulting in severe chronic iron-deficiency anemia. Telangiectasia is also associated with scleroderma, CREST (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly and telangiectasia) syndrome, and may be evident in patients who have received radiotherapy or solar damage.

### Importance of Correlation of Clinical and Laboratory Findings

Information from the history and physical examination must be carefully correlated with laboratory findings. A patient may be referred for laboratory evaluation of a hemostatic abnormality either as a result of a clinical history of bleeding, or to further assess abnormal blood tests found coincidentally or following routine screening. Screening tests are performed, with a view to focus on more specific tests of platelet, coagulation, and fibrinogen components of the hemostatic system if suggested by historical details, or if any laboratory screening defects are detected (see Table 106-3). No single global assay exists to predict the risk of either bleeding or thrombosis. Several assessments over a period of time may need to be performed to arrive at a diagnosis or an assessment of bleeding risk.

**TABLE 106-3****Screening Tests of Hemostasis**

LABORATORY TEST	DETAILS
Complete blood count	
Blood film examination	
Coagulation screen	Prothrombin time (PT) Activated partial thromboplastin time (aPTT) Thrombin time Fibrinogen D-dimer or fibrinogen degradation products (FDPs)
Tests of thyroid function	TSH, T <sub>4</sub> , T <sub>3</sub>
Tests of renal function	Urea, creatinine
Tests of liver function	Albumin, bilirubin, transaminases

**QUANTITATIVE DISORDERS OF PLATELETS****Isolated Thrombocytopenia**

There are numerous causes of isolated thrombocytopenia in the elderly and many are listed in [Table 106-4](#). The most common and relevant causes of thrombocytopenia are discussed here.

**Pseudothrombocytopenia**

Pseudothrombocytopenia is a relatively common phenomenon (found in approximately 0.1% of adults) caused by platelet clumping in the presence of the anticoagulant ethylenediaminetetraacetic acid (EDTA), which is used in vacutainer tubes for drawing complete blood counts. It should be excluded in any patient with an unexpected low platelet count by examination of the blood film

**TABLE 106-4****Causes of Acquired Thrombocytopenia in the Elderly**

Immune	Non-immune
<i>Immune thrombocytopenia</i>	<i>Decreased production</i>
Primary	Megaloblastic anemia; B-12 and folate deficiency
Secondary: SLE	Primary bone marrow disorders: leukemia, lymphoma, myeloma
Posttransfusion purpura	Aplastic anemia
Drug-induced: vancomycin, quinine, heparin	Infiltration by solid tumor, TB, sarcoidosis
	Drugs: chemotherapy
	Alcohol
	<i>Sequestration: hypersplenism</i>

(see [Figure 106-2](#)). An accurate platelet count can be estimated by prompt analysis of a fresh blood sample in an alternative anticoagulant such as citrate buffer. Abciximab, a glycoprotein (GP) IIb/IIIa antibody, commonly used in patients with acute coronary syndromes, can cause pseudothrombocytopenia as well as a true drug-induced thrombocytopenia.

**Immune Thrombocytopenia**

Immune thrombocytopenia (ITP) is an autoimmune disorder characterized by a persistently low platelet count ( $<150 \times 10^9/L$ ). It is caused by autoantibodies binding to platelet antigen(s) and the resultant premature destruction of the platelets by the reticuloendothelial system, especially the spleen. The diagnosis is made by the exclusion of pseudothrombocytopenia and other causes of true thrombocytopenia. Differentiating between hereditary and acquired thrombocytopenia, especially ITP, is of clinical importance to ensure

**A****B**

**TABLE 106-5****Differentiating Congenital and Acquired Thrombocytopenia from the History**

Clinical Details	Hereditary Thrombocytopenia	Immune Thrombocytopenia
Duration of thrombocytopenia	Lifelong	Recent
History of bleeding after previous procedures	Yes/No	No
Positive family history of thrombocytopenia or of bleeding	Yes	No
Prior normal platelet count?	Never	Yes
Response to treatment with steroids, ivIgG, anti-D?	None/small effect	Increases platelet count
Response to platelet transfusion?	Normal increment	Poor response

Modified with permission from Drachman JG. *Blood*. 2004;103:390-398.

the patient is not subjected to potentially harmful therapies or procedures (see Table 106-5).

The incidence of adult chronic ITP in United States is approximately 60 new cases per 1 million population per year. The majority of cases are idiopathic. In contrast, childhood ITP has a higher incidence and often presents abruptly following a viral illness or immunization. Secondary ITPs occur in patients with systemic lupus erythematosus or malignant disease, such as chronic lymphocytic leukemia (CLL).

In ITP, the blood film shows no abnormalities excepting a low platelet count. Bone marrow morphology appears normal with increased numbers of megakaryocytes, in addition to normal myelopoiesis and erythropoiesis. Bone marrow examination is not necessary in childhood or young adults, but may be appropriate in older patients to exclude underlying marrow pathology such as myelodysplasia, and particularly if there are any atypical features to the history, examination, or investigations. An autoimmune profile should be performed to exclude other autoimmune diseases. As platelet-associated IgG may be elevated in both immune and non-ITP, assays of antiplatelet antibodies are not informative and are not routinely used in the management of patients with ITP.

Adult ITP differs from the acute disorder in childhood: it usually has an unclear date of onset with no preceding viral or systemic illness; symptoms and signs vary from mild bruising and mucosal bleeding to frank hemorrhage dependent on the presenting platelet count, the presence of comorbidities and if the patient is taking antiplatelet drugs. Overall, bleeding is uncommon unless the ITP is severe (platelet count  $< 30 \times 10^9/L$ ). At any age, there can be spontaneous remission, but one-third of patients may require treatment with steroids and/or splenectomy. In young adults, the 5-year mortality rate is around 5% and it is unclear if this rate increases with age.

There are few randomized controlled trials addressing treatment so an individual approach is necessary. The aim of treatment is to achieve a safe platelet count, not necessarily a normal platelet count. Review of data from 17 case series shows the rate of fatal hemorrhage ranges between 0.02 and 0.04 cases per patient-year. Patients with persistent platelet counts of more than  $30 \times 10^9/L$  need to be followed but interventions are usually not needed. However, such patients should be referred to a hematologist if invasive procedures are needed.

For patients with platelet counts of less than  $30 \times 10^9/L$  or those who experience bleeding, first-line therapy includes corticosteroids and intravenous immunoglobulin G (ivIgG) with a view to splenectomy if medical therapies fail. Anti-D may also have a role in selected patients. About 11% to 35% of patients will fail to respond to corticosteroids, ivIgG, or splenectomy, and can be problematic to manage. Commonly considered second-line therapies include danazol, dapsone, and intensive immunosuppressive regimens, including the combination of cyclophosphamide, vincristine, and methylprednisolone. Rituximab, a selective immunosuppressive agent (anti-CD20 monoclonal antibody) developed for patients with low-grade B-cell lymphoma, has been used with some success to treat refractory ITP.

### Posttransfusion Purpura

Posttransfusion purpura (PTP) is a rare bleeding disorder characterized by severe and sudden thrombocytopenia (usually  $< 10 \times 10^9/L$ ) within 3 to 12 days following a transfusion. It is caused by preformed antibodies directed against common human platelet alloantigens (HPA), especially HPA-1a. The majority of the affected patients are multiparous women who have been sensitized during a previous pregnancy. Thrombocytopenia usually resolves spontaneously within several weeks, but patients may develop severe or fatal bleeding during the course of the disease. Ecchymoses, bleeding from mucosal surfaces, and postoperative wounds are common presenting features. Bone marrow examination reveals normal numbers of megakaryocytes, and a coagulation screen reveals no abnormalities. The diagnosis is confirmed by the finding of antibodies to platelet-specific antigens, and the active exclusion of disseminated intravascular coagulation (DIC) and heparin-induced thrombocytopenia. Management includes ivIgG, corticosteroids, and plasmapheresis. Platelet transfusion is ineffective and may worsen the clinical condition. The recurrence of PTP is minimized by using blood products from a platelet-compatible donor.

### Drug-Induced Thrombocytopenias

Drugs may induce thrombocytopenia by several mechanisms (see Table 106-6), including generalized or selective suppression of megakaryopoiesis and increased platelet destruction by immune and nonimmune mechanisms. Drug-induced thrombocytopenias may

**TABLE 106-6****Mechanisms of Drug-Induced Thrombocytopenia**

Mechanism	Example	Further Details
Myelosuppression	Chemotherapeutic agents	Dose-dependent, predictable
Immune mediated	Gold	Autoantibody-induced immune thrombocytopenia
	Quinine	Drug-dependent antibodies against drug/platelet glycoprotein complexes
	Heparin	IgG antibodies bind to platelet factor 4 and heparin causing platelet activation and generation of platelet-derived microparticles

present with clinical features of bleeding, bruising, and petechiae or may be asymptomatic. Heparin-induced thrombocytopenia can cause severe and rapid drops in the platelet count but is associated paradoxically with thrombosis, not bleeding.

The management of drug-induced thrombocytopenia involves immediate cessation of the drug, plus supportive measures to increase the platelet count, such as ivIgG.

## QUALITATIVE DISORDERS OF PLATELETS

In the elderly, a number of disorders may cause acquired platelet dysfunction (see [Table 106-7](#)).

### Antiplatelet Agents

The most common cause of acquired platelet dysfunction is the use of antiplatelet agents. Five classes of drugs are administered therapeutically to specifically inhibit platelet function (see [Figure 106-3](#)). These include the cyclo-oxygenase inhibitors, such as aspirin and nonsteroidal anti-inflammatory agents, ADP receptor antagonists, such as ticlopidine and clopidogrel, GP IIb/IIIa antagonists, such as abciximab, tirofiban, and eptifibatid, and drugs that increase cyclic AMP or cyclic GMP, such as phosphodiesterase inhibitors, including dipyridamole. Many other drugs also adversely affect platelet function, including antimicrobials such as penicillins and cephalosporins, tricyclic antidepressants, and phenothiazines. The administration of these drugs should be avoided, if possible, in patients with moderate and severe thrombocytopenia to prevent hemorrhagic issues.

### Myeloproliferative Disorders

Myeloproliferative disorders are clonal stem cell disorders and include polycythemia rubra vera (PRV), essential thrombocythemia (ET), and myelofibrosis; all three conditions show features of bone marrow hypercellularity, varying degrees of leukocytosis and thrombocytosis, and elevated hematocrit.

Platelet dysfunction is usually encountered when the absolute platelet count increases over  $1500 \times 10^9/L$  and may be caused by a reduction in platelet survival, loss of high-molecular-weight vWF, and decreased platelet aggregation responses. Treatment of the underlying myeloproliferative disorder is required to control any bleeding diathesis.

**TABLE 106-7**

#### Causes of Acquired Disorders of Platelet Function in the Elderly

Primary bone marrow disorders

Myeloproliferative disorders: PRV, ET, MF

Medications

Inhibition of cyclo-oxygenase: ASA, nonsteroidal anti-inflammatory drugs

Inhibition of ADP receptors: clopidogrel, ticlopidine

Inhibition of GP IIb/IIIa: abciximab, eptifibatid

Chronic renal failure

Cardiopulmonary bypass

Paraproteinemias

\* See text for abbreviations.

## Uremia/Chronic Renal Failure

Chronic renal failure creates a complex coagulopathy of unclear clinical significance. The primary hemostatic abnormality is partly caused by platelet dysfunction. Hence laboratory findings of a prolonged bleeding time and abnormal platelet aggregation are common. However, these parameters are poor predictors of the risk of bleeding, fail to correlate with the degree of renal dysfunction, and do not constitute an indication for therapeutic intervention. In addition, anemia of chronic renal failure is associated with an increased bleeding time as a result of the diminished displacement of platelets to the periphery of the blood vessel, causing a reduced platelet–endothelial interaction. Anemia is an independent cause of a prolonged bleeding time and the relationship of the hematocrit to the bleeding time is well recognized and corrected by transfusion of packed red blood cells and administration of erythropoietin.

L-Deamino-8-*o*-arginine vasopressin (DDAVP, desmopressin) has been used in the management of bleeding in uremia. The effect is transient, lasting 1 to 4 hours, and correlates to increases in vWF functional activity. Its mode of action is by the stimulation of release of vWF from Weibel–Palade bodies in the endothelium. Side effects include facial flushing, tachycardia, water retention and hyponatremia of sufficient severity to cause cerebral edema, coma, and seizures. Conjugated estrogens have been reported to shorten bleeding times in rat models of uremia, and remain an option in problematic cases. Both peritoneal dialysis and hemodialysis improve platelet function and normalize the bleeding time, reducing the risk of bleeding. Should bleeding remain problematic, the patient should be investigated as in any other patient.

## COAGULATION DISORDERS

### Congenital Coagulation Disorders in Elderly Patients

It is unusual for classic hemophilias and severe von Willebrand's disease to present late in life but many patients with congenital coagulation disorders are living longer and will require ongoing specialized support. Referral of such patients to comprehensive hemophilia centres or specialists with expertise in their management is mandatory.

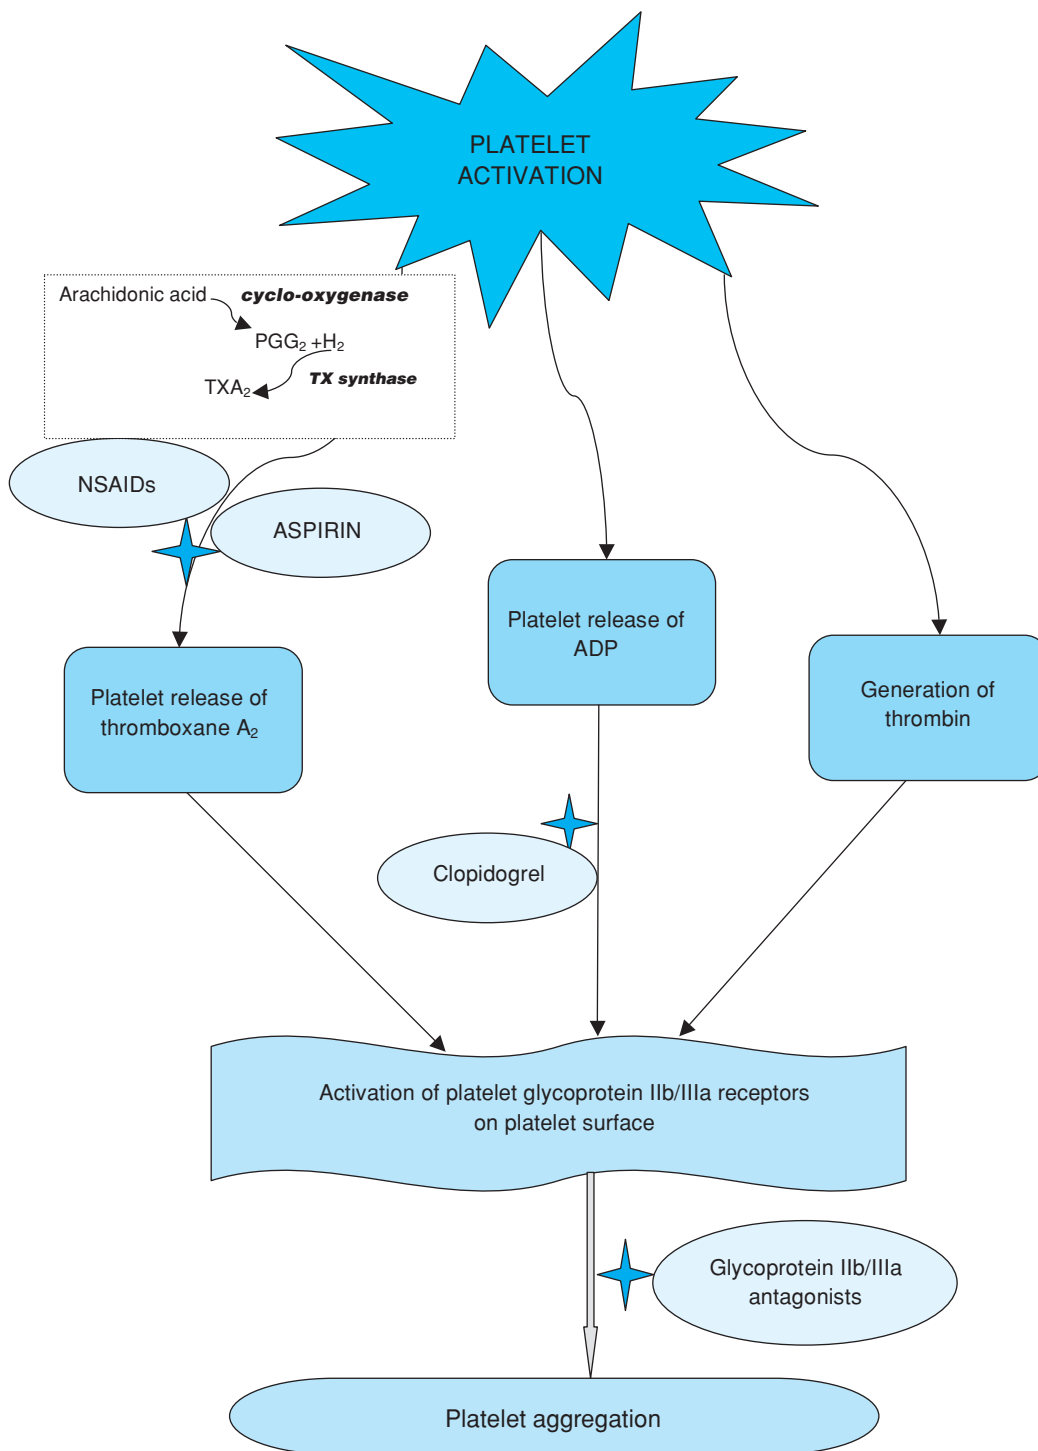

### Acquired Coagulation Factor Inhibitors

#### Acquired Hemophilia (Inhibitors to Factor VIII (fVIII))

The spontaneous development of an inhibitor to fVIII in an individual with previously normal hemostatic function and no clinically significant personal or family history of bleeding episodes is known as acquired hemophilia.

Although rare, with an incidence of 0.2 to 1.0 cases per 1 million persons per year, acquired hemophilia mainly affects individuals older than of 60 years of age, and may present with spontaneous life- and limb-threatening bleeding manifestations (see [Figure 106-4](#)). It commonly presents with bleeding into soft tissues, mucous membranes, and skin, as well as the retroperitoneal and retropharyngeal spaces. This is distinctly different from the pattern of bleeding encountered in congenital hemophilia, where intramuscular and intra-articular bleeds are more common (see [Table 106-8](#)).

**FIGURE 106-3.** Sites of action of antiplatelet drugs. Aspirin irreversibly acetylates the enzyme cyclo-oxygenase and blocks the synthesis of thromboxane A<sub>2</sub> by platelets. Non-steroidal anti-inflammatory agents reversibly inhibit cyclo-oxygenase. Clopidogrel inhibits a key ADP receptor, thereby inhibiting ADP-induced platelet aggregation. Glycoprotein IIb/IIIa antagonists block platelet aggregation by inhibiting fibrinogen or vWF binding to activated glycoprotein IIb/IIIa receptors. (Modified with permission from Liaw PC, Weitz JI. Coagulation overview. Section 8. Hematologic problems. In: Albert RK, Slutsky A, Ranieri M, Takala J, Torres A, eds. *Clinical Critical Care Medicine*. Philadelphia: Elsevier; 2006:543–553.)

**TABLE 106-8**

**Bleeding Symptoms in Acquired and Congenital Hemophilia**

CONGENITAL	ACQUIRED
Hemarthroses	Subcutaneous hematoma
Muscle bleeds	Frank hematuria
Soft tissue bleeds	Retropharyngeal hematoma
	Retroperitoneal hematoma
	Cerebral hemorrhage
	Compartment syndrome

Acquired hemophilia has been reported in association with autoimmune disorders, systemic lupus erythematosus, rheumatoid arthritis, and solid and hematologic malignancies (see Table 106-9) but in 50% of cases, there may be no obvious associated disease state. Drugs such as sulphonamides, penicillin, and phenothiazines have also been reported as causes. One-third of cases resolve spontaneously. Autoantibody inhibitors are usually of IgG<sub>1</sub> and IgG<sub>4</sub>, subclasses that appear to disrupt assembled coagulation factors on the surface of the phospholipid membrane that are integral to the production of activated coagulation factors.

If acquired hemophilia is suspected, an urgent hematology (hemostasis) consultation is recommended. The diagnosis is made by

**FIGURE 106-4.** Severe bleeding diathesis in a patient with an acquired inhibitor to factor VIII (acquired hemophilia). (A) Close-up view of right hand; (B) right arm; (C) lower limbs; (D) hematoma in medial aspect of right thigh. (With permission from Dr. E Horn, Edinburgh Royal Infirmary.)

the demonstration of a solitary prolonged activated partial thromboplastin time (aPTT) that fails to correct on mixing with equal volumes of normal plasma (50:50 mix). The prothrombin time (PT), thrombin time (TT), and fibrinogen activity are all normal. The presence of lupus anticoagulant must be excluded.

The diagnosis of an inhibitor to fVIII is confirmed by specific assays of the factor and quantification of the inhibitor by a Bethesda assay.

**TABLE 106-9**

**Etiology of Acquired Inhibitors to Factor VIII**

- Elderly with no apparent underlying disease
- Postpartum (rarely during pregnancy)
- Underlying disorders
  - Autoimmune disorders e.g., SLE, rheumatoid arthritis
  - Adverse drug reactions (especially penicillins; phenothiazines)
  - Malignancy (solid, lymphoproliferative)
  - Monoclonal gammopathies

The management of acquired hemophilia depends on the underlying disease state, the extent and severity of the hemorrhagic complications, and the magnitude of the Bethesda titer. Prevention of further bleeds by careful nursing and the avoidance of frequent venepunctures are simple practical measures. Antiplatelet drugs, heparin, and anticoagulants must not be administered and intramuscular injections are contraindicated. Invasive diagnostic procedures should be avoided as hemostasis is often difficult to secure.

With a low-inhibitor titer (<5 Bethesda Unit/mL), patients can be treated with human factor VIII concentrates given at sufficiently high dose to overcome the inhibitor effect. Desmopressin may be used in patients with low titer inhibitors for minor bleeds, but may have side effects of hyponatremia and hypotension, limiting its use. With higher inhibitor titers (>5 Bethesda Unit/mL), fVIII concentrates and DDAVP are not effective and more aggressive therapy is needed. Bypassing agents, so called because they bypass critical steps in the coagulation pathway requiring fVIII, are plasma-derived factor concentrates that contain activated vitamin K-dependent coagulation factors, and may be used to treat hemorrhage. By generating thrombin, these agents have potential side effects of

**FIGURE 106-5.** Extensive ecchymosis in a patient with acquired von Willebrand's Syndrome. (With permission from Professor C.A. Ludlam, Edinburgh University.)

thromboembolism. Recombinant-activated factor VIIa (rFVIIa) (Novoseven, Niastase), a genetically engineered product, has been demonstrated to be clinically safe and efficacious as a treatment for acute bleeding episodes in acquired hemophilia. Immunosuppressive therapies are used in severe cases to inhibit the cell clone responsible for the synthesis of the autoantibody. Cyclophosphamide is used as a sole agent, or in combination with corticosteroids, for a 3- to 6-week period and the doses adjusted to the therapeutic response. The blood count must be monitored carefully in view of potential neutropenia and myelosuppression.

High-dose ivIgG has been shown to be effective in reducing the inhibitor titer in certain individuals and can be considered as a therapy in patients who do not respond, or are intolerant of, other immunosuppressive regimens. Cyclosporine, 2-chlorodeoxyadenosine (2-CDA), and interferon alpha have also been successfully used. Rituximab has been used with success; however, the optimal dose, its mechanism of action and long-term side effects are unclear.

### Acquired von Willebrand's Syndrome

Acquired von Willebrand's Syndrome (AVWS) is a rare, adult-onset bleeding diathesis, mainly presenting with mucocutaneous and skin bleeding (see Figure 106-5 and Table 106-10). AVWS is most commonly associated with underlying low-grade hematological malignancies, in addition to solid tumors and autoimmune disease (see Table 106-11).

Desmopressin and plasma-derived vWF-rich concentrates can be used to treat hemorrhagic episodes, but are limited by their extremely short duration of action. Long-term disease modification of

**TABLE 106-11**

#### Laboratory Evaluation of Acquired von Willebrand's Syndrome

- Prolonged bleeding time
- Normal platelet count
- Normal PT
- Prolonged aPTT
- Decreased levels of von Willebrand factor antigen and functional activity
- Decreased factor VIII levels
- Absence of inhibitor to factor VIII

the AVWS can be achieved by high-dose ivIgG and usually induces a transient correction of vWF parameters for 1 to 3 weeks.

### Anticoagulants

Older persons have a higher risk for anticoagulant-related bleeding compared with younger persons. In particular, older than 75 years of age, comorbid disease, concurrent use of antiplatelet therapy, propensity to falls, and the need for dosing changes all contribute to the elevated risk. Other factors that determine the risk of anticoagulant-related bleeding, including intensity of anticoagulation, duration of exposure, genetic polymorphism, also apply to older persons. The most important comorbidities associated with bleeding during anticoagulant therapy include uncontrolled hypertension, cerebrovascular disease, ischemic stroke, history of gastrointestinal bleeding, malignancy, liver disease, and renal insufficiency. Older patients may also tolerate the consequences of bleeding and the necessary interventions, such as surgery, less well than younger patients.

For warfarin, it is clearly established that the risk of bleeding, in particular intracranial hemorrhage, is strongly determined by the intensity of the anticoagulant effect. The risk increases dramatically with an international normalized ratio (INR) greater than 4.0. Therefore, because of warfarin's narrow therapeutic effect, its unpredictable interpatient and inpatient variability in the dose response and the borderline nutritional status in many older persons, frequent laboratory monitoring of the INR is important. This can be a burden to patients who do not have reliable means of transportation or have difficulty understanding the needs for dose adjustment. Older persons often require lower doses than younger patients. One study showed that a starting dose of 5 mg per day led to overanticoagulation in an estimated 82% of female patients and 65% of male patients older than 70 years of age. Interaction with other drugs is another limitation with warfarin. Concurrent use of drugs that may interact with warfarin is associated with a 3- to 4.5-fold increased risk of serious bleeding in long-term warfarin users. This is a real and challenging concern in elderly patients who are often subjected to polypharmacy. Computer-based surveillance systems in long-term care facilities, and drug-alerts systems within hospitals and community pharmacy settings, have been demonstrated to reduce the potential for serious drug interactions between warfarin and other medications.

Anticoagulation with unfractionated heparin, low-molecular-weight heparin, or fondaparinux is also associated with a high bleeding risk. As these agents are excreted by the renal route, an assessment of renal function is essential when they are prescribed. Body weight

**TABLE 106-10**

#### Etiology of Acquired von Willebrand's Syndrome

- Hematological disorders
  - Myeloproliferative disorders
  - Lymphoproliferative disorders
  - Monoclonal gammopathy of undetermined significance
  - Autoimmune disorders
  - Solid tumors
  - Hypothyroidism
  - Loss of high-molecular-weight multimers: aortic stenosis, angiodysplasia

is also important for guiding the doses of these agents. Weight-based nomograms are available for heparin infusions and should be used to facilitate rapid achievement of a therapeutic anticoagulant effect and reduce the risk of overdose.

Management of patients with anticoagulant-related bleeding is similar to other bleeding situations. The drug should be discontinued and supportive blood products given if necessary. The anticoagulant effect of warfarin should be reversed with vitamin K, given either orally or parentally. However, it will take a minimum of 6 to 8 hours before functional coagulation factors are produced by the liver so the INR correction will be delayed. Fresh frozen plasma should be given in the interim if the patient has active bleeding. Protamine sulfate can be used for reversing the anticoagulant effects of heparin and low-molecular-weight heparin. Repeat boluses or continuous intravenous infusions of protamine sulfate are required to provide adequate neutralization of the anticoagulant effects. A specific antidote for fondaparinux is not available but recombinant activated factor VII will reverse abnormal laboratory parameters and is likely effective in stopping active hemorrhage. Because spontaneous bleeding does not occur with therapeutic doses of anticoagulants, aggressive measures should be undertaken in such circumstances to identify and eliminate, if possible, the bleeding source. Following an episode of serious bleeding, reintroduction of anticoagulant therapy should be considered only if the source of bleeding is identified, reversed, and the overall risk–benefit ratio continues to favor anticoagulation.

## COMBINED HEMOSTATIC DEFECTS

### Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is a clinicopathologic syndrome characterized by the systemic activation of coagulation. The mainstay of the syndrome involves the dysregulated and excessive generation of thrombin and a reactive fibrinolytic response. This leads to the widespread deposition of fibrin in the circulation contributing to microvascular thrombosis and multiorgan failure. Further activation of the coagulation system depletes platelets and coagulation factors, and may precipitate bleeding manifestations. Clinical manifestations are diverse, forming a spectrum from asymptomatic laboratory abnormalities to hemorrhagic and thrombotic complications.

The presence of DIC is clinically important as the syndrome increases the risk of mortality beyond that associated with the primary disease. No single test exists with sufficient diagnostic accuracy to confirm the diagnosis of DIC; the diagnosis rests on the correlation of clinical features, taking into account the relevant causative factor (see Table 106-12), and laboratory findings (Table 106-13). Monitoring the trend in serial tests is often more important than the absolute results. Screening for the presence of overt DIC can be made by a combination of simple, reliable, readily available laboratory tests, and forms the basis of a clinical scoring system. A scoring system is also being developed for the diagnosis of nonovert stages of DIC.

The management of DIC involves an individual approach, with prompt recognition and removal of the precipitating cause (Table 106-14). The efficacy of treatment with plasma, fibrinogen, cryoprecipitate or platelets lacks clinical trial evidence, but is widely accepted

**TABLE 106-12**

#### Clinical Conditions Associated with Overt DIC

Diagnosis	Causes
Sepsis, severe infection	Gram-negative and gram-positive bacterial infections Viral infections Fungal infections Parasitic infections
Trauma	Shock, hypoxia, brain injury, burns, heat stroke
Malignancy	Solid tumors, including mucin-producing adenocarcinoma; Hematological malignancies, especially acute promyelocytic leukemia
Obstetric emergencies	Amniotic fluid embolism, abruptio placentae, retained dead fetus, eclampsia
Vascular abnormalities	Large vessel aneurysm, giant hemangioma including Kasabach-Merritt syndrome
Toxic	Drugs (recreational) Venoms—snake and spider bites
Immunological	Drugs (therapeutic)—heparin-induced thrombocytopenia ABO incompatible transfusion
Advanced liver disease	LeVeen shunt

as supportive and aimed at replacing depleted coagulation factors. Plasma and blood product therapies should not be administered on the basis of laboratory results alone but are given only in a patient with active bleeding or someone with a high bleeding risk who must undergo invasive procedures. The use of coagulation factor concentrates, such as prothrombin complex concentrates (PCCs), are not usually appropriate as they contain only single or a small combination of factors; minute traces of activated coagulation factors may precipitate thromboembolism or worsen the coagulopathy.

The successful use of heparin and low-molecular-weight heparin have been anecdotally reported in specific settings such as chronic DIC associated with solid tumors, and in overt cases of thromboembolism or situations involving extensive fibrin deposition, such as purpura fulminans and acral necrosis. A beneficial effect of heparin on clinically important outcome events in patients with DIC has never been demonstrated in clinical trials.

Fibrinolytic inhibitors act by blocking secondary fibrinogenolysis, and in the setting of DIC may have adverse consequences such as

**TABLE 106-13**

#### Screening Tests for Overt DIC

<i>Blood count and blood film:</i> Decreasing trend in the platelet count is a sensitive marker of DIC; blood film may show red cell fragmentation; also may highlight cause of DIC, e.g., blasts in acute leukemia; toxic granulation in sepsis
<i>Global assays of hemostasis:</i> Prolongation of PT, aPTT, TCT; reflective of factor consumption and reduced factor synthesis
<i>Fibrinogen:</i> As an acute phase reactant may remain normal before falling; hypofibrinogenemia is found in acute head injury, prostatic adenocarcinoma and obstetric calamities
<i>Fibrinogen degradation products</i>

**TABLE 106-14****Management of DIC**

- Removal of precipitating cause
- Supportive care
  - Maintain oxygenation
  - Prevent acidosis and hypothermia
  - Replace folate
  - Replace vitamin K
- Plasma and blood products
  - If active bleeding
  - At high risk of bleeding
  - Undergoing invasive procedures
- Anticoagulant therapy
  - Chronic DIC in the setting of hyperfibrinolysis
- Fibrinolytic inhibitors
  - Used on occasion in fibrinogenolysis, such as vascular malformations
- Activated protein C concentrate
  - Efficacy demonstrated in randomized clinical trials of DIC in sepsis

the prevention of tissue perfusion. Consideration may be warranted in situations of intense fibrinogenolysis such as the Kasabach-Merritt syndrome, vascular malformations, and in coagulopathies secondary to metastatic prostate cancer and acute promyelocytic leukemia.

Phase III clinical trials have been performed with three natural anticoagulants—AT, activated protein C (aPC), and TF pathway inhibitor (TFPI)—in the setting of patients with severe sepsis. To date, only a beneficial effect of recombinant human aPC (rhaPC) has been demonstrated. Recombinant human aPC is licensed for the treatment of patients with severe sepsis and two or more organ failures. It is administered as a 96-hour intravenous infusion, but caution is required in patients with thrombocytopenia ( $<30 \times 10^9/L$ ) to avoid the risk of intracranial hemorrhage. In situations where protein C is not available, the strategy to replace protein C by plasma exchange has proven successful in a small case series.

### Liver Disease

Acute hepatic failure and end-stage liver disease (ESLD) cause many hemostatic defects (Table 106-15). The management of coagulation issues in elderly patients with severe liver disease requires an individual approach with attention to the nature, site, and extent of bleeding. Surgical, endovascular, and pharmacologic interventions may be necessary to reduce the portal pressure. Administration of

**TABLE 106-15****Underlying Hemostatic Defects in End-Stage Liver Disease**

- Reduced synthesis of coagulation factors
- Vitamin K deficiency: Causing deficiencies of procoagulant and anticoagulant systems
- Thrombocytopenia: Secondary to hypersplenism and portal hypertension
- Platelet dysfunction
- Impaired synthesis of fibrinolytic proteins
- Impaired clearance of activated coagulation factors
- Acquired dysfibrinogenemia
- Hyperfibrinolysis

vitamin K slowly by the intravenous route for a few days is advisable to correct any underlying deficiency of vitamin K.

Fresh frozen plasma (FFP) contains all the coagulation factors and inhibitors except vWF present in circulating blood. It may be given to correct hemostatic defects prior to invasive procedures and to control active bleeding. Effective replacement may be difficult as large amounts of plasma are necessary to correct a prolonged PT as a result of the short half-life of factor VII, and infusions of FFP every 6 to 12 hours may be necessary. Fibrinogen can be replaced using cryoprecipitate.

Platelet transfusions may be helpful in patients with severe thrombocytopenia and bleeding, although the platelet increment may be less than anticipated as a result of sequestration within an enlarged spleen. PCCs are pooled plasma-derived factor concentrates that contain fIX and variable concentrations of factors X, VII, and II and protein C. PCCs may transiently correct deficiencies of vitamin K-dependent factors but also contain variable amounts of activated coagulation factors that may give rise to thromboembolic complications including venous thromboembolism and DIC, particularly in liver failure where clearance of activated coagulation factors may be impaired.

Clinical trials of recombinant fVIIa (rfVIIa) in patients with liver cirrhosis with active bleeding, and in patients undergoing orthotopic liver transplantation, have failed to demonstrate any significant benefit with this agent to date. Fibrinolytic inhibitors, such as  $\epsilon$ -aminocaproic acid (EACA) and tranexamic acid, can be considered in the setting of hyperfibrinolysis and may be useful in patients with diffuse mucosal, subcutaneous, or gastrointestinal bleeding, but prospective controlled studies to demonstrate efficacy are lacking.

### VASCULAR PURPURA

Elderly patients with normal hemostatic parameters may present with purpura secondary to vascular abnormalities (see Table 106-16).

#### Senile Purpura

With the aging process, the turnover of collagen and elastin are altered, and along with chronic solar damage, skin thins causing a characteristic pattern of purpura on the forearms and hands. In this benign condition, vitamin C administration is not effective.

**TABLE 106-16****Causes of Purpura in Elderly Patients with Normal Coagulation Parameters**

*Senile purpura*

*Vasculitis* Polyarteritis nodosa, Wegener's granulomatosis,

*Steroid excess:* Cushing's syndrome, exogenous steroids

*Vitamin C deficiency*

*Abnormal connective tissue disorder:* Ehler Danlos, Pseudoxanthoma elasticum

*Amyloid infiltration of blood vessels*

*Infections:* Bacterial, fungal

## Scurvy

Vitamin C stores are readily depleted after 1 month on a vitamin C-free diet. Initial symptoms include fatigue, depression, and lethargy. Scurvy is primarily found in persons addicted to alcohol with poor nutritional intake, persons who have a liking for food fads, and in individuals eating highly refined or purified diets. The last group of individuals includes elderly patients with swallowing difficulties, or who may be edentulous, often in long-term institutional care. The most common presenting symptoms are bruising, arthralgia, or joint swelling. Hemorrhagic manifestations occur late in the disease and include perifollicular hemorrhages with corkscrew hairs affecting the arms, legs, back, and buttocks, “plate-like ecchymoses” affecting the legs or trunk; spongy friable gums and loosening of teeth. The finding of a serum ascorbic acid level lower than 2.5 mg/L confirms the diagnosis; the administration of vitamin C resolves the symptoms and signs promptly.

## Hereditary Hemorrhagic Telangiectasia (Osler-Weber-Rendu Syndrome)

HHT is an uncommon, often under-recognized condition that presents with characteristic mucocutaneous telangiectasia (not purpura) affecting the buccal area, lips, and finger tips. Epidemiological studies in Europe and Japan point to an incidence of 1:5000–10 000. Diagnostic criteria were established in 2000, and the clinical diagnosis is based on the presence of at least three of the following features: recurrent epistaxis, mucocutaneous telangiectases, evidence of autosomal dominant inheritance and visceral arteriovenous malformations. Telangiectasia consists of localized collections of noncontractile capillaries that bleed for a prolonged time following rupture. The manifestations are often not present at birth, but develop with age, and presentation is with persistent nasal, oropharyngeal bleeding, and gastrointestinal bleeding, leading to chronic iron deficiency. The management involves the aggressive replacement of depleted iron stores with intravenous iron.

Methods to arrest bleeding include packing, electrocautery, cryosurgery, arterial embolization, arterial ligation, and hormonal manipulation (estrogens), in addition to the use of lasers. An evidence base is accumulating, but at present no single method to arrest bleeding has been demonstrated to be superior to others.

## CONCLUSIONS

The correct and timely diagnosis of a bleeding diathesis in an elderly patient involves attention to meticulous history taking, careful general examination, and focused investigation. The ageing process itself does not cause a tendency to bleed. However, polypharmacy, increased comorbidities, and other acquired risk factors for bleeding may unmask underlying mild congenital disorders or other primary pathologies. The rare disorders of acquired hemophilia and PTP predominantly affect elderly patients and must be quickly recognized and referred on to a hematologist.

# Aging of the Endocrine System and Selected Endocrine Disorders

*David A. Gruenewald* ■ *Alvin M. Matsumoto*

## PRINCIPLES OF GERIATRIC ENDOCRINOLOGY

### Impaired Homeostatic Regulation

As in other organ systems, the normal aging of the endocrine system is characterized by a progressive loss of reserve capacity, resulting in a decreased ability to adapt to changing environmental demands. This loss of homeostatic regulation reflects important alterations in hormonal synthesis, metabolism, and action, but these changes may not be clinically apparent under baseline conditions. In fact, basal plasma concentrations of many hormones and metabolic fuels are essentially unchanged with normal aging. This is illustrated by fasting plasma glucose levels that exhibit little change with normal aging, but after a glucose challenge, glucose levels increase much more in healthy older persons as compared to young adults. In some instances, the function of aging endocrine systems is maintained by compensatory changes in secretion of one hormone to offset the loss of function of another hormone in a feedback system, or to compensate for alterations in metabolic clearance. For example, in many older men with testosterone levels in the normal range, pituitary luteinizing hormone (LH) secretion and serum LH levels are increased (although levels usually remain within the normal range), partially offsetting a reduction in testicular testosterone secretion. However, in other cases, these compensatory mechanisms are inadequate to maintain normal function with aging even under basal conditions. For example, unlike cortisol, adrenal production of aldosterone and dehydroepiandrosterone (DHEA) declines disproportionately to clearance rates with aging, leading to age-related decreases in plasma levels of these hormones even under baseline conditions.

### Altered Presentation of Endocrine Diseases

The presenting manifestations of endocrine disorders in older adults are often nonspecific, muted, or atypical. For example, hypothy-

roidism and hyperthyroidism may present similarly with nonspecific symptoms in older people, such as weight loss, fatigue, weakness, constipation, and depression. Endocrine diseases may also present with signs and symptoms that are classic for older patients yet atypical compared to those commonly observed in younger patients. As illustrations, thyrotoxic older patients may exhibit apathy and depression with psychomotor retardation (“apathetic hyperthyroidism”), and diabetes mellitus may present with hyperosmolar nonketotic state, a classic presentation rarely seen in individuals younger than age 50 years (see Chapters 108 and 109). In addition, with aging, it is increasingly common for illnesses to present without any appreciable symptoms, such as hypothyroidism or hypercalcemia secondary to hyperparathyroidism. Finally, the manifestations of endocrine disease may be altered or masked by coexisting illnesses and medications used to treat comorbidities that commonly occur in older people. For example, exacerbations of congestive heart failure or angina may be precipitated by hyperthyroidism in older patients with preexisting cardiac disease, but practitioners may mistakenly attribute the symptoms to worsening primary cardiac disease rather than to thyrotoxicosis in such patients.

### Changes in Diagnostic and Therapeutic Approach

Based on the above discussion, it is clear that a high index of suspicion for endocrine (and other) diseases is required in older patients with nonspecific signs and symptoms or functional decline. Indeed, the presence of these diseases may be appreciated only upon routine laboratory screening. However, there is no firm consensus on appropriate screening practices for endocrine disorders in asymptomatic older adults. Furthermore, even with normal aging, alterations in endocrine system function may have an important impact on the diagnostic evaluation of the older patient. For example, several factors contribute to an age-related decrease in intestinal calcium absorption, including decreased renal production of 1,25-dihydroxyvitamin D (1,25(OH)<sub>2</sub>D) and reduced intestinal

responsiveness to  $1,25(\text{OH})_2\text{D}$ . In turn, these alterations in vitamin D metabolism and action cause an increase in parathyroid hormone (PTH) levels to maintain calcium homeostasis, and ultimately a reduction in bone mass. As a result of these changes, together with the effects of sex hormone deficiency (a common problem in both older women and men), many asymptomatic older people require evaluation for osteoporosis (see Chapter 117). In addition, the presence of concomitant medical problems, medications, and changes in nutritional status and body composition may lead to a mistaken impression of endocrine disease in older as well as in younger people. For example, decreased serum triiodothyronine and thyroxine levels may occur in patients who are systemically ill but euthyroid (“euthyroid sick” syndromes), or thyroxine levels may be increased in others receiving certain medications such as estrogen supplements, falsely giving the impression of an endocrine abnormality (see Chapter 108).

Another factor complicating the evaluation of the older patient is the lack of age-adjusted normal ranges for most endocrine laboratory tests. Normal values for these tests are usually determined in healthy young subjects, or young to middle-aged blood donors, which may or may not reflect normal values in healthy older adults. Furthermore, most studies of aging and endocrine function are cross-sectional rather than longitudinal. Because interindividual variability and heterogeneity are important concomitants of aging, the usefulness of cross-sectional studies in predicting age-related changes within an individual is limited. Finally, normative studies in older populations are often confounded by the inclusion of subjects with age-associated diseases.

Alterations in the therapeutic approach for geriatric patients with endocrine disease are similar to those required in older people with illnesses involving other body systems. First, treatment plans must take into account coexisting medical illnesses, medications, alterations in clearance rate of hormones and medications, and changes in target organ sensitivity and effects. As a result of these factors, interventions such as hormone replacement may have different outcomes in older than in young persons. For example, data from the Women’s Health Initiative suggest that postmenopausal estrogen replacement therapy has a favorable benefit/risk ratio in many newly postmenopausal women, whereas in older women the risk of adverse effects such as coronary heart disease events tends to outweigh the benefits. Second, to minimize the risk of drug toxicity and polypharmacy, dosage levels for hormone replacement and medications must be adjusted for changes in clearance rate with aging, and patients should receive the lowest dose of medication needed to achieve the therapeutic effect. Third, new medications should be initiated at low doses and increased very gradually if needed. Fourth, the medication regimen should be reviewed periodically and medications should be discontinued if no longer needed. Finally, approaches that improve physical or cognitive function are of paramount importance for older people.

## NEUROENDOCRINE REGULATION

### Neurotransmitters and Neuropeptides

Studies directly assessing parameters of hypothalamic neuroendocrine function have not been performed *in vivo* in humans. How-

ever, age-related effects on hypothalamic function may be studied indirectly by examining alterations in pulsatile secretion of pituitary hormones, which reflect changes in pulsatile secretion of hypothalamic releasing and/or inhibiting hormones. Other indices of the effects of aging on hypothalamic function in humans include pituitary hormonal responses to administration of (1) hypothalamic releasing hormones, (2) agents that block end-organ feedback (e.g., clomiphene and metyrapone), and (3) agents that stimulate hypothalamic/pituitary hormonal secretion (e.g., the use of hypertonic saline to stimulate antidiuretic hormone [ADH] secretion, or arginine to stimulate growth hormone [GH] secretion).

A number of neurotransmitters and neuropeptides within the central nervous system (CNS) have been found to affect the secretion of hypothalamic and pituitary hormones. Changes in activity of these neurotransmitters and neuropeptides are responsible for many age-related alterations in the function of the endocrine system.

### Dopamine

Dopamine released by hypothalamic neurons inhibits pituitary prolactin secretion. In turn, prolactin stimulates hypothalamic dopaminergic neurons, forming a short feedback loop. In humans, to a greater extent than some of the other hypothalamic neurotransmitters, changes in dopamine secretion are indirectly observable with commonly available methods. This is because dopamine is the major regulator of prolactin secretion, and changes in hypothalamic dopamine activity can be inferred through observation of changes in pulsatile prolactin secretion. The frequency of pulsatile prolactin secretion is unchanged with aging, suggesting an intact pulse generator. However, humans become relatively hypoprolactinemic with normal aging. Furthermore, the circadian rhythm of prolactin secretion is altered in older men, with a blunted or absent nocturnal rise in prolactin and reduced amplitude of prolactin pulses, as compared to young controls. Metoclopramide, a dopamine antagonist, increases nocturnal prolactin secretion to a greater degree in older people than in young subjects, suggesting that this blunted nocturnal elevation in prolactin in older men may be caused by an increase in dopaminergic tone with aging. In turn, these age-related alterations in dopaminergic activity may contribute to alterations in secretion of other anterior pituitary hormones. For example, after administration of the dopamine precursor L-dopa, plasma gonadotropins increase and thyroid-stimulating hormone (TSH) levels decrease in old but not in young male subjects, implying altered dopaminergic regulation of these hormones with aging.

### Norepinephrine

Studies of postmortem brain tissue in normal older persons demonstrate a modest decrease in the number of noradrenergic neurons in the locus coeruleus, the primary source of noradrenergic innervation within the CNS. However, levels of norepinephrine (NE) in the cerebrospinal fluid (CSF) of normal older subjects are increased as compared to young adults, both in the basal state and in response to yohimbine, a stimulator of central noradrenergic activity. CSF NE is thought to be produced by noradrenergic neurons within the CNS rather than the peripheral sympathetic nervous system. Taken together with the observation that NE clearance from the CNS is unchanged in older adults, these findings suggest that central noradrenergic neuronal activity is increased with aging.

The noradrenergic neuronal system is thought to exert an important influence on pituitary secretion of a number of hormones, including GH, TSH and LH; therefore, an age-associated increase in central noradrenergic tone may be an important factor underlying age-related changes in the secretion of these hormones.

### Opioid Peptides

Endogenous opioid peptides are believed to be important regulators of neuroendocrine systems. The products of proopiomelanocortin metabolism are the most extensively studied of these peptides, including adrenocorticotrophic hormone (ACTH),  $\beta$ -endorphin,  $\beta$ -lipotropin, and  $\alpha$ -melanocyte-stimulating hormone.  $\beta$ -Endorphin, for example, is thought to exert a tonic inhibitory influence on gonadotropin-releasing hormone (GnRH) secretion and to be an important regulator of reproductive function. In older men, administration of the opioid receptor antagonist naltrexone causes a smaller increase in LH levels than it causes in young men, and unlike in young men, there is no increase in LH pulse frequency. Taken together, these observations suggest a decrease in central opioid tone with aging. However, in the periphery, basal plasma levels of  $\beta$ -endorphin are unaffected, and basal ACTH levels are unchanged or increased with normal aging. Furthermore, plasma ACTH, cortisol and  $\beta$ -endorphin responses to physostigmine, a drug that increases CNS cholinergic activity, and ACTH and cortisol responses to administration of corticotropin-releasing hormone (CRH), are increased in older compared to younger adults. Increased responsiveness of  $\beta$ -endorphin and the hypothalamic–pituitary–adrenal (HPA) axis with aging may alter the function of other endocrine systems.

### Melatonin

Melatonin is a hormone produced in the pineal gland that is involved in the organization of circadian and seasonal biorhythms. Its synthesis and release are stimulated by darkness and inhibited by light. Therefore, the diurnal rhythm of melatonin secretion mirrors the day–night cycle. This circadian rhythm of melatonin production is controlled by a “pacemaker” in the suprachiasmatic nucleus of the brain, but changes in environmental lighting can alter the timing of this rhythm. For example, light exposure inhibits melatonin release in a dose-dependent fashion and it is possible to reverse the diurnal melatonin rhythm within a few days by reversing the diurnal pattern of light exposure. Melatonin affects reproductive function in a variety of species, with antigonadotropic effects that are more pronounced in species with marked seasonal variation in reproductive function and breeding patterns. However, even in humans dwelling in the Arctic, conception rates and pituitary–gonadal function are reduced during the winter as compared to the summer. Melatonin levels are increased in women with hypothalamic amenorrhea, and there has been some interest in very-high-dose melatonin (75–300 mg) as a potential contraceptive agent, used in combination with a progestin.

During development and aging, melatonin production is negligible in young infants, but rises markedly between 3 months and 1 to 3 years of age, when nighttime levels are at their highest. After early childhood, melatonin secretion appears to gradually decrease, with a progressive decline in melatonin secretion by the age of 30 years. Nocturnal and 24-hour melatonin secretion appears

to be similar in healthy older men and women free of confounding conditions and medications, as compared to healthy young men. Additionally, MT1 melatonin receptor expression is reduced in suprachiasmatic nucleus neurons of aged subjects and to a greater extent in persons with Alzheimer’s disease, compared to young adult subjects.

Melatonin has long been known to have sedative effects, suggesting a role in sleep production. A meta-analysis of 17 studies of the effects of exogenous melatonin on sleep in subjects of various ages showed improvement in several parameters of sleep quality. In older people with insomnia, serum melatonin levels were lower than in age-matched controls without insomnia, suggesting that insomnia in older adults is caused, at least in part, by melatonin deficiency. Older adults are often exposed to significantly less environmental light than younger adults, a factor that is associated with diminished nocturnal melatonin secretion. Supplementary exposure to bright light during midday increased melatonin secretion in older adults, and tended to improve sleep disturbances in older insomniacs. In older insomniacs, short-term administration of melatonin in doses of 0.1 to 6 mg per day improved some measures of sleep quality. In older people without sleep complaints, melatonin improved sleep quality in some studies but not others. No long-term studies of melatonin supplementation have been performed in older subjects. Ramelteon, an MT1/MT2 melatonin receptor agonist, improved some measures of sleep quality in older people with chronic primary insomnia, and is approved by the U.S. Food and Drug Administration for improving sleep in individuals with difficulty falling asleep and has not been associated with dependence.

Melatonin is a potent free radical scavenger and it has been proposed that if the age-related decline in melatonin were prevented, then potentially the degenerative changes of aging could also be delayed. However, others have noted that the reported antioxidant effects of melatonin probably occur only at pharmacologic concentrations. In humans, high-affinity melatonin receptors are present on CD4 T lymphocytes and mononuclear cells in peripheral blood synthesize melatonin. Moreover, inhibition of serotonin-*N*-acetyltransferase, the enzyme catalyzing melatonin synthesis, was reported to cause a significant decrease in interleukin-2 (IL-2) secretion that was restored by melatonin administration. It has been proposed that melatonin may be an intracrine and paracrine regulator of immune function.

Based in part on the assumption that a decline in endogenous hormone levels constitutes a deficiency needing replacement, there has been considerable enthusiasm in the lay community for supplementation of certain hormones, including melatonin. Melatonin is readily available without a prescription in the United States, and many older people take melatonin without physician consultation. It is noteworthy that melatonin dosages of 1 to 5 mg contained in preparations commonly available over-the-counter boost nighttime levels 10 to 100 times higher than the usual maximum within an hour after administration, and only very low doses (0.1–0.3 mg) achieve peak serum levels within the normal nighttime range. Thus far, no serious side effects have been reported in humans after melatonin ingestion (aside from sleepiness after the dose), even with pharmacologic melatonin doses. However, large, long-term studies of melatonin use are still lacking, and the long-term risks and benefits of melatonin supplementation remain to be determined. Until this information is available, it is premature to advocate its use.

## Hormonal Changes in Alzheimer's Disease

Alzheimer's disease is characterized by a profound impairment of cholinergic neuronal function within the CNS, but changes in the function of many other neurotransmitter and neuropeptide systems have also been described. In turn, these CNS alterations are associated with changes in pituitary and peripheral hormone levels. One important endocrine system abnormality observed in patients with Alzheimer's disease is an increase in HPA axis activity with elevated plasma ACTH and cortisol levels, and lack of suppression of cortisol levels by dexamethasone, suggesting decreased glucocorticoid feedback inhibition. In addition, ACTH responses to exogenous administration of CRH are blunted, which may be a result of downregulation of pituitary responsiveness to CRH secondary to chronically increased hypothalamic CRH stimulation. Elevated cortisol levels are associated with memory impairment in older nondemented people, and appear to predict subsequent decline in memory function. Finally, cortisol and ACTH responsiveness to physostigmine, which increases central cholinergic activity, is markedly increased in patients with Alzheimer's disease and normal older persons, as compared to young subjects.

This elevated glucocorticoid milieu may play a role in the pathogenesis of Alzheimer's disease. It has been hypothesized that chronically increased glucocorticoid stimulation damages the hippocampal neurons that mediate glucocorticoid feedback inhibition of the HPA axis, leading, in turn, to a "glucocorticoid cascade" of neurodegeneration in Alzheimer's disease (and to a lesser extent in the aging brain). While controversial, this hypothesis remains under active study to determine whether glucocorticoid levels are a potentially modifiable risk factor for Alzheimer's disease.

Numerous epidemiological studies indicate a link between type 2 diabetes mellitus and increased risk of Alzheimer's disease. In normal physiology, and when exogenous insulin is administered at optimal doses, insulin appears to enhance some aspects of memory. However, the presence of insulin resistance as in the metabolic syndrome and type 2 diabetes mellitus is associated with an increased risk of cognitive dysfunction and possibly of Alzheimer's disease. Insulin might play a role in the pathophysiology of Alzheimer's disease through a number of mechanisms. For example, insulin may increase levels of beta-amyloid, the primary component of senile plaques, by competing with beta-amyloid for insulin-degrading enzyme, which catalyzes the breakdown of both peptides within the CNS. Insulin-degrading enzyme has a high affinity for insulin, so under conditions of high insulin availability in the brain insulin degradation is favored over degradation of beta-amyloid, thereby potentially promoting plaque formation. Additionally, increased insulin may promote cerebral inflammation, which is thought to be part of the pathophysiology of Alzheimer's disease. Inflammatory markers such as C-reactive peptide and interleukin-6 are elevated in older people with insulin resistance, and peripheral administration of high doses of insulin under hyperinsulinemic-euglycemic clamp conditions increases levels of proinflammatory cytokines within the CNS.

Many other alterations in hormone, hormone receptor, neuropeptide, and neurotransmitter levels have been reported in plasma, CSF, and postmortem brain tissue specimens in Alzheimer's disease. However, such changes have not generally controlled for the effects of nutritional status, medications, or coexisting medical illnesses and depression. NE levels in CSF are increased both in individuals with Alzheimer's disease and in normal older people. This increase

is apparently caused by an increase in NE biosynthesis without a change in NE clearance. Because there is a marked loss of noradrenergic neurons in the locus coeruleus of the brain in patients with Alzheimer's disease, these findings suggest compensatory activation of the remaining noradrenergic neurons in these patients.

## Anterior Pituitary

### Prolactin

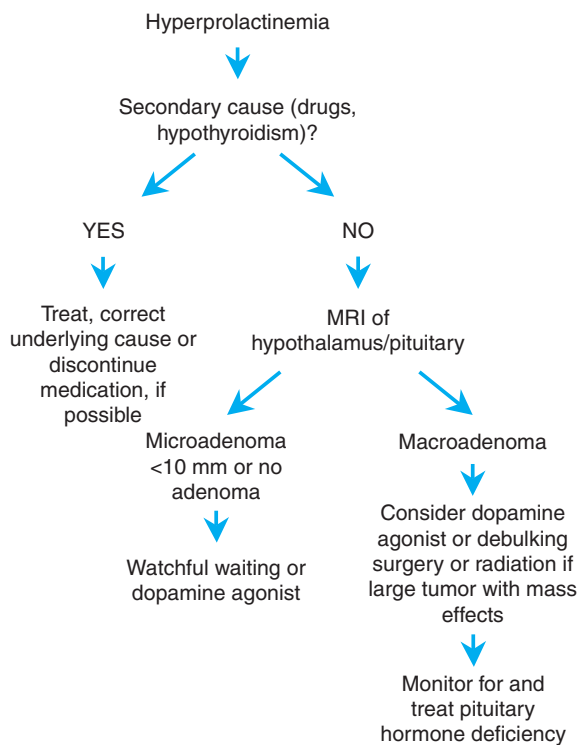

Healthy aging is associated with a decrease in prolactin secretion in both men and postmenopausal women, reflecting a decrease in both basal prolactin secretion and the amplitude of pulsatile prolactin release. However, serum prolactin levels may vary considerably as they can increase in many situations including stress, exercise, and sleep. Mild hyperprolactinemia observed in some older adults may result from any of several underlying causes (Table 107-1), including hypothalamic diseases that interfere with the production of dopamine (prolactin-inhibitory factor). A number of medications commonly used by older adults inhibit dopaminergic activity and increase prolactin levels, and primary hypothyroidism increases thyrotropin-releasing hormone (TRH), which stimulates prolactin secretion.

The clinical manifestations of hyperprolactinemia are typically subtle and often unrecognized. Hyperprolactinemia causes secondary hypogonadism and may exacerbate sexual dysfunction and cause gynecomastia. Rarely, galactorrhea may occur. In addition, hyperprolactinemia can accelerate age-related bone loss primarily because of the antigonadotropic effects of prolactin and resulting hypogonadism. Thus, measurement of prolactin is important in the

evaluation of secondary causes of osteoporosis, especially when hypogonadism is present. The diagnostic approach for older adults with hyperprolactinemia is summarized in [Figure 107-1](#). If drugs and hypothyroidism have been ruled out as causes of hyperprolactinemia, it is appropriate to obtain magnetic resonance imaging (MRI) to rule out the presence of a pituitary tumor or hypothalamic lesion (computerized tomography is much less sensitive.). Dynamic pituitary testing, such as a TRH test, is of no value in the diagnosis of this disorder.

If the hyperprolactinemia is secondary to another disorder such as hypothyroidism or a medication, the underlying cause should be corrected or the offending medication should be discontinued if possible, which often results in normalization of prolactin levels. However, if the etiology is a microadenoma (defined as a pituitary tumor <10 mm in size) or idiopathic hyperprolactinemia, options include watchful waiting or dopamine agonist medications. The natural history of microadenomas is incompletely understood, especially in older adults, but most prolactin-producing microadenomas are stable or involute with time. Accordingly, observation is the most appropriate strategy in many patients although treatment may be indicated if sexual dysfunction or additional risk factors for osteoporosis are present. Dopamine agonists such as bromocriptine or cabergoline are effective in reducing prolactin levels and normalizing reproductive axis function in most patients, but gastrointestinal, behavioral, and other side effects such as hallucinations are common in older patients. These side effects can be minimized by following a “start low, go slow” approach when beginning these medications. Of note, high doses of cabergoline may be associated with an increased risk of valvular heart disease. Surgery is rarely indicated, but may be necessary in those with macroadenomas (>10 mm) and persistent visual field defects or inability to tolerate dopamine agonists.

Alternatively, radiation therapy may be an option for patients with large tumors who are unable to tolerate medical therapy and are not surgical candidates. However, the clinical response to radiation is often delayed for months to years, and anterior pituitary insufficiency eventually occurs in many, if not most, of these patients.

Age-associated alterations in secretion of other anterior pituitary hormones are discussed below, under the individual hormonal systems, and in Chapter 108 (Thyroid Disorders) and Chapter 46 (Menopause and Midlife Health Changes).

### Pituitary Adenomas

Although the incidence of pituitary tumors increases with aging, symptomatic pituitary tumors are uncommon even in people of advanced age. However, the prevalence of pituitary tumors at autopsy ranges from 8.5% to 27%, indicating that the vast majority of these tumors are clinically “silent.” In case series of pituitary tumors in older adults, the majority of lesions are apparently nonfunctioning adenomas, whereas 9% to 17% are GH-secreting tumors and 4.5% to 10% are prolactinomas. However, many, if not most, apparently nonfunctioning adenomas actually produce quantities of gonadotropins or the  $\alpha$ -subunit of these glycoprotein hormones.

Nonsecreting tumors and tumors that secrete LH, follicle-stimulating hormone (FSH), or  $\alpha$ -subunit are usually large at the time of diagnosis, because there are few or no symptoms of hormone overproduction. Gonadotropin hypersecretion from such tumors usually does not result in excessive gonadal hormone secretion although LH hypersecretion occasionally results in elevated testosterone levels. Clinical manifestations of these tumors are usually a result of a mass effect, including visual field abnormalities caused by compression of the optic chiasm, headaches, and panhypopituitarism. Gonadotropin-secreting pituitary tumors are particularly difficult to diagnose in postmenopausal women in whom gonadotropin levels are elevated as a result of ovarian failure. For these women, exaggerated  $\alpha$ , LH- $\beta$ , and FSH- $\beta$  subunit responses, and/or intact gonadotropin responses to TRH are useful in diagnosing these tumors. However, pituitary “incidentalomas” are being increasingly identified during neuroimaging evaluations for comorbid conditions, accounting for 5% to 15% of pituitary tumors identified in older adults. Most of these are asymptomatic though endocrine and visual disturbances should be sought in these patients. Diagnosis of pituitary tumors depends on neuroimaging (especially magnetic resonance imaging). Management of large pituitary tumors usually involves transsphenoidal decompression and debulking, along with assessment of anterior pituitary hormone function and replacement of hormone deficiencies. Macroprolactinomas may be managed with dopamine agonists in many cases even when large or associated with visual field changes although these agents may be less effective in older than in young adults ([Figure 107-1](#)). Pituitary function should be reassessed in patients started on dopamine agonists for a prolactinoma because recovery of pituitary function occurs in some individuals treated with these medications.

### Hypopituitarism and the Empty Sella Syndrome

As a pituitary macroadenoma grows, destruction of normal surrounding pituitary tissue occurs, leading ultimately to a predictable

**TABLE 107-2****Causes of Hypopituitarism in Older Persons**

Pituitary adenomas
Sequelae of irradiation or surgery for pituitary tumors
Peripituitary tumors (e.g., meningioma, glioma, metastatic cancer)
Vascular conditions (e.g., pituitary infarction, carotid artery aneurysm, subarachnoid hemorrhage)

Infiltrative or granulomatous diseases (e.g., lymphocytic hypophysitis, hemochromatosis, histiocytosis X, sarcoidosis)
Infections (e.g., tuberculosis, mycoses, abscesses)

loss of gonadotropins and GH followed by TSH and eventually ACTH secretion. The resulting panhypopituitarism may present clinically as a constellation of symptoms including supine and/or postural hypotension, fatigue, loss of libido, weight loss, hypogonadism, hyponatremia, and hypoglycemia. Many of these symptoms are nonspecific and common in older patients without panhypopituitarism, so a high index of suspicion is required to make the diagnosis. Causes of hypopituitarism in adults are summarized in Table 107-2.

Initially, measurements of basal serum levels of morning cortisol and ACTH; total or free testosterone (in men) and gonadotropins; free thyroxine and TSH; IGF-1; and prolactin may be sufficient to confirm panhypopituitarism. Measurement of both the pituitary hormone and the target hormone concentration allows assessment of the appropriateness of both levels together. Dynamic ACTH (cortrosyn) stimulation testing is indicated to confirm the diagnosis of secondary hypoadrenalism. ACTH and other dynamic tests of adrenal function are discussed below under “Laboratory Testing of HPA Axis Function” (also see Chapter 108).

As computed tomography (CT) and MRI have come into widespread use, it is increasingly common to discover incidentally the presence of both pituitary masses and empty sella syndrome. MRI studies of healthy young and older subjects found that pituitary height and volume tend to decrease with aging, with empty sella occurring in 19% of subjects. No relationship was found between pituitary volume and anterior pituitary hormone levels. Most cases of primary empty sella syndrome (i.e., not associated with prior pituitary tumor, surgery or irradiation) occur in obese, hypertensive middle-aged women. Clinically apparent pituitary dysfunction is uncommon, although up to 15% of subjects may manifest endocrine dysfunction including hyperprolactinemia, hypogonadism, or panhypopituitarism. However, the functional significance of an empty sella as an incidental finding on imaging studies in apparently healthy older patients is unclear. In such patients, conservative management is appropriate, including visual field testing and serum hormone testing to rule out subclinical pituitary dysfunction and suprasellar involvement.

### Posterior Pituitary

Antidiuretic hormone (ADH), or arginine vasopressin (AVP), is synthesized in “magnocellular” neurons of the hypothalamus and released into the systemic circulation from nerve terminals in the posterior pituitary gland in response to increased plasma osmolality, decreased arterial pressure, and reductions in circulating blood vol-

ume. In addition, ADH synthesized in “parvocellular” hypothalamic neurons is released into the hypothalamic–pituitary portal circulation, in turn stimulating release of ACTH from the anterior pituitary into the systemic circulation. ADH appears to be colocalized with corticotrophin-releasing hormone (CRH) in parvocellular neurons of the hypothalamus. Administration of ADH together with CRH amplifies the effect of CRH on ACTH release, suggesting a role for ADH in responses to stress.

Older people are at higher risk than young adults for the development of both volume depletion and excess free water states. This is a result of age-related changes occurring in the systems that maintain volume status and osmolality, including ADH secretion, osmoreceptor and baroreceptor systems, renal concentration of urine and hormone responsiveness, and thirst mechanisms. There is evidence for a state of relative ADH excess with aging, with normal to increased basal ADH levels, increased ADH release after an osmotic stimulus such as hypertonic saline infusion, and impaired ethanol inhibition of ADH secretion in older persons, as compared with young adult subjects. Furthermore, renal free water clearance decreases with aging in proportion to declining glomerular filtration rate (GFR). With a reduction in GFR, proximal renal tubular fluid absorption is increased, leading to a decrease in fluid delivery to the distal diluting portions of the nephron. The net result is a decrease in the diluting capacity of the kidney and a decreased ability to excrete a free water load. This age-related reduction in free water clearance, together with relative ADH excess and the increased prevalence of conditions such as congestive heart failure, hypothyroidism, and the use of sulfonylurea and diuretic medication all contribute to the common occurrence of free water excess and hyponatremia in older people. When present, hyponatremia in frail older adults is usually mild and asymptomatic, but these individuals may develop more marked symptomatic hyponatremia in the setting of acute illness.

In contrast to the increased osmoreceptor sensitivity to ADH, baroreceptor regulation of ADH is decreased with aging, resulting in decreased ADH release in response to hypotension or hypovolemia and increased risk of volume depletion. Furthermore, renal responsiveness to ADH is diminished with aging, possibly because of chronic exposure to elevated ADH levels, leading to a decrease in maximal urine concentrating ability. Decreased aldosterone and increased atrial natriuretic hormone activity with aging contribute to the potential for volume depletion by decreasing the capacity of the kidneys to conserve sodium under conditions of fluid deprivation (see “Renin–Angiotensin–Aldosterone System” later in this chapter). Finally, healthy older adults exhibit decreased thirst and reduced fluid intake in response to fluid deprivation, hyperosmotic stimuli, and hypovolemia, further contributing to the risk of dehydration with aging. Older patients with immobility or dementia, such as nursing home residents, are at particularly high risk for severe dehydration and hypernatremia.

A number of factors predispose older people to nocturnal polyuria. These include age-related blunting of the circadian rhythm of circulating ADH, with loss of the nocturnal increase in ADH levels, and an increase in nighttime plasma atrial natriuretic hormone levels. Patients with Alzheimer’s disease have lower circulating ADH levels than cognitively intact people of the same age, and appear to be particularly prone to nocturnal polyuria. Superimposed on age-related changes in bladder function and mobility, altered ADH regulation can contribute to urinary incontinence. Older patients with nocturnal polyuria may benefit from administration of the ADH

## HYPOTHALAMIC–PITUITARY–ADRENAL AXIS

### Physiology

Compared to the other hypothalamic–pituitary–end-organ axes, hypothalamic–pituitary–glucocorticoid function is relatively intact with aging in humans (Table 107-3). The cortisol secretion rate is decreased with aging, but this is matched by a decrease in the cortisol metabolic clearance rate. As a result, basal plasma concentrations of cortisol are unchanged with aging even in very old subjects. Consistent with intact cortisol secretion, basal ACTH levels are also unaffected by aging. Furthermore, glucocorticoid responsiveness of the HPA axis to stimulation is well-maintained in older adults, with intact cortisol responses to exogenous ACTH stimulation (except at very low doses of ACTH [0.06 μg]) and normal or slightly prolonged cortisol and ACTH responses to metyrapone, ovine CRH,

and insulin-induced hypoglycemia. ACTH pulse frequency appears to be maintained in older men, suggesting intact hypothalamic regulation of glucocorticoid function. Moreover, the circadian rhythm of ACTH and cortisol secretion is intact in healthy older subjects although the amplitude of the cortisol rhythm is reduced and the nighttime cortisol nadir is increased in older compared to young adults. In addition, a phase advance of the cortisol rhythm occurs in older people, with earlier nadir and peak secretion, as compared to young adults. This phase advance has been attributed to behavioral changes, possibly reflecting an earlier bedtime in older adults.

Although still controversial, many studies have reported age-related alterations in the cortisol response to stress. After a stressful stimulus such as surgery, peak cortisol levels are higher and remain elevated longer in older compared to young adult subjects. Furthermore, dexamethasone is less effective in suppressing cortisol levels in older subjects, and in studies using metyrapone to remove endogenous cortisol feedback inhibition, the decline in ACTH levels after exogenous cortisol infusion was blunted and delayed in older compared to young adult subjects. Taken together, these studies indicate that the sensitivity of the HPA axis to glucocorticoid negative feedback is decreased with aging. The clinical implications of this decreased responsiveness to glucocorticoid feedback inhibition are unclear. However, it has been proposed that the resulting chronic increase in glucocorticoid exposure may damage hippocampal neurons regulating glucocorticoid secretion and important to cognitive function, leading to a vicious cycle of further glucocorticoid hypersecretion and damage to mechanisms regulating HPA feedback inhibition.

### Laboratory Testing of HPA Axis Function

Although glucocorticoid function is well-preserved with aging, certain factors may interfere with testing of HPA axis function in older patients (Table 107-4). For example, excretion of steroids commonly measured in urine is decreased with renal impairment, and measurements are unreliable in people with a creatinine clearance of less than 50 mL/min. Moreover, because the acute cortisol stress response may be higher and prolonged in older patients, testing for Cushing's syndrome should be delayed for at least 48 hours after major stresses such as high fever, trauma; or surgery.

**TABLE 107-4****Potential Pitfalls in Laboratory Diagnosis of Cushing's Syndrome in Older Adults**

TEST	POTENTIALLY CONFOUNDING FACTORS	TEST ALTERATION	COMMENTS
24-hour urine cortisol	Renal impairment, undercollection Overcollection, severe malnutrition, stress, chronic anxiety, alcoholism, depression	False-negative urine cortisol False-positive urine cortisol	Normal level excludes Cushing's syndrome
DST	Obesity, estrogens, anticonvulsant medications, depression, alcoholism, acute illness	False-positive DST (Pseudo-Cushing's)	Cortisol nonsuppression common in older adults (high sensitivity but low specificity)
Late-night salivary cortisol	Hypertension, advanced age, psychiatric diagnoses	False-positive (increased) salivary cortisol	Repeat testing often normal in false-positive situations
Urine 17-hydroxycorticosteroid levels	Medications (e.g., phenytoin, phenobarbital)	Falsely decreased urine 17-hydroxycorticosteroid levels (false-negative test for hypercortisolism)	

DST, dexamethasone suppression test.

The ACTH stimulation test is used to screen for both primary and chronic secondary (central) adrenal insufficiency. Expected cortisol responses to the standard dose of 250  $\mu\text{g}$  of ACTH (absolute serum cortisol level of  $> 20 \mu\text{g/dL}$  at 30 or 60 minutes after an IV bolus of ACTH or cortrosyn) do not change with aging. The rationale for its use in assessing pituitary function is that in patients with chronic pituitary disease, the absence of sufficient stimulation of the adrenal glands by endogenous ACTH leads to adrenal atrophy and hyporesponsiveness to exogenous ACTH. Thus, a serum cortisol  $> 20 \mu\text{g/dL}$  either at baseline or after ACTH rules out adrenal insufficiency. However, the standard ACTH stimulation test lacks sensitivity for mild secondary adrenal insufficiency. The low-dose ACTH stimulation test, performed with 1  $\mu\text{g}$  of ACTH and measurement of cortisol 30 minutes after injection, has been proposed as a more sensitive test, but a meta-analysis demonstrated similar diagnostic utility for the low-dose and standard-dose ACTH tests. In patients with a positive ACTH stimulation test, a plasma ACTH level obtained at 8:00 A.M. may help to distinguish primary from secondary adrenal insufficiency with a high plasma ACTH, indicating primary adrenal insufficiency and normal or low ACTH indicating secondary adrenal insufficiency. However, additional dynamic testing of adrenal axis function may be indicated for borderline abnormal ACTH stimulation test results. Furthermore, the ACTH stimulation test should never be used in cases of suspected acute or recent onset of hypopituitarism, because the adrenal glands may still be able to respond normally to any ACTH challenge. In patients with septic shock, a reduced increment between basal and post-ACTH cortisol level ( $< 9 \mu\text{g/dL}$ ) may be a more useful indicator of “relative adrenal insufficiency” that is associated with improved pressor responsiveness and mortality in response to glucocorticoid treatment.

The cortisol response to insulin-induced hypoglycemia is a reliable test for primary or secondary adrenal insufficiency, but may be inappropriate in frail older patients because of the potential risks associated with severe hypoglycemia. In patients with a normal response to ACTH stimulation, the metyrapone test can be used to confirm suspected secondary adrenal insufficiency. Metyrapone inhibits  $11\beta$ -hydroxylase, the final step in cortisol synthesis, and in normal individuals, ACTH secretion increases, stimulating adrenal secretion of 11-deoxycortisol. However, oral metyrapone may cause dizziness, nausea, and vomiting in some older patients, and it has been suggested that intravenous metyrapone infusion is safer and better tolerated in older people.

### Hyperadrenocorticism

Cushing’s syndrome is an eponym for the constellation of signs and symptoms of chronic corticosteroid excess, including central obesity; catabolic effects on muscle, skin, and bone; glucose intolerance; hypertension; hypogonadism; and hirsutism and acne (in women).

### Glucocorticoid Therapy

The most common cause of Cushing’s syndrome in older adults, as in other age groups, is the pharmacological administration of glucocorticoids. The undesirable effects of glucocorticoid treatment are similar in older and younger patients, but in older people glucocorticoids may cause major adverse effects upon function (Table 107-5). When it is necessary to use pharmacologic doses of glucocorticoids, older patients should receive the minimum necessary dosage for the shortest possible period of time, and the dosage requirement should

be reviewed at frequent intervals. Bone densitometry measurements using dual-energy x-ray absorptiometry (DXA) should be performed prior to initiating long-term corticosteroid therapy and after 6 to 12 months of therapy (Figure 107-2). As for the evaluation of osteoporosis not associated with corticosteroid use, all patients should be assessed for modifiable osteoporosis risk factors, secondary causes of osteoporosis, primary hyperparathyroidism, and vitamin D deficiency.

Some of the adverse effects of corticosteroid use in older people can be minimized with other interventions (Figure 107-2). For example, because corticosteroids decrease intestinal calcium absorption and increase urinary calcium losses, ensuring an intake of at least 1500 mg elemental calcium per day together with at least 800 to 1000 IU/day of vitamin D helps to minimize bone loss. In individuals with low 25-hydroxyvitamin D levels ( $< 32 \text{ ng/mL}$ ), high-dose vitamin D (e.g., ergocalciferol 50 000 IU should be given weekly for 12 weeks after which a repeat 25-OH vitamin D level should be performed; the goal is to normalize the 25-OH vitamin D level). Occasionally, high-dose vitamin D (ergocalciferol 50 000 IU weekly or twice weekly) or calcitriol (0.25 or 0.50  $\mu\text{g/day}$ ) may be needed to maintain vitamin D sufficiency, but follow-up of both serum and

**FIGURE 107-2.** Prevention and management of glucocorticoid-induced osteoporosis. DXA, dual-energy x-ray absorptiometry; BMD, bone mineral density.

urine calcium levels is required. Furthermore, dietary sodium restriction (2–3 g/d) and thiazide diuretics (e.g., hydrochlorothiazide, 25 mg/day) are useful to reduce hypercalciuria associated with corticosteroid use, although their effects on bone density have not been adequately determined in patients receiving corticosteroids.

Hormone replacement therapy can be considered to counteract corticosteroid-induced suppression of sex hormones. Estrogen supplementation (e.g., conjugated estrogens 0.625 mg/day with medroxyprogesterone acetate 2.5–5.0 mg daily for women with an intact uterus) may help postmenopausal women taking corticosteroids, but its use is controversial. Men with corticosteroid-induced and/or other causes of hypogonadism should receive androgen-replacement therapy (e.g., testosterone enanthate or cypionate, 100–200 mg IM every 2 weeks, or daily transdermal application of a testosterone patch or gel). Although testosterone therapy in hypogonadal men has not been demonstrated to reduce fracture risk, it has been shown to improve bone mineral density and to ameliorate other manifestations of androgen deficiency. Bisphosphonates should be considered as first-line therapy for patients who will be taking the equivalent of prednisone 7.5 mg per day or more for at least 3 months, because clinically significant bone loss may occur with this dose and duration of therapy. Bisphosphonates used for prevention and treatment of corticosteroid-induced osteoporosis increase bone mineral density at the lumbar spine and hip, and reduce the risk of

fractures of the vertebral spine. However, the cost effectiveness of bisphosphonates in the treatment of glucocorticoid-induced osteoporosis is best established in individuals of more advanced age and with lower (more abnormal) T-scores for bone mineral density. Options include alendronate 70 mg weekly (or 10 mg daily), risedronate 35 mg weekly (or 5 mg daily), or ibandronate 150 mg monthly. For patients who cannot tolerate oral bisphosphonates, intravenous bisphosphonates (e.g. zoledronic acid 5 mg iv once yearly) may be considered, although its efficacy in glucocorticoid-induced osteoporosis has not been established. As an alternative to bisphosphonates in persons with severe glucocorticoid-induced osteoporosis, teriparatide (recombinant human PTH 1–34) 20 µg sc daily may be used. However, expense and daily subcutaneous injections from cartridges requiring refrigeration may make teriparatide therapy less desirable for older persons. Calcitonin (e.g., 200 IU intranasally per day) preserves bone mass at the lumbar spine but not at the femoral neck in patients taking glucocorticoids. However, it is a weak antiresorptive agent that has significant tachyphylaxis and its efficacy in fracture prevention in these patients has not been established.

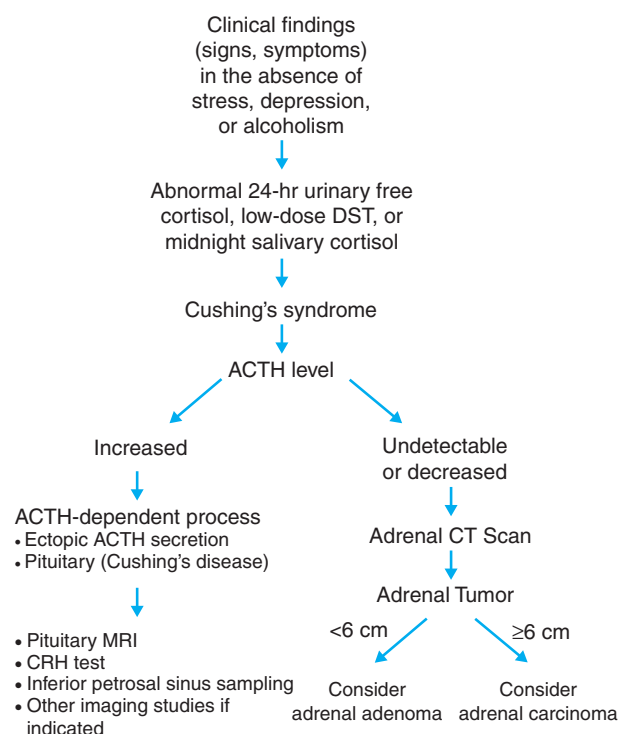

Corticosteroid-induced myopathy is characterized by weakness and atrophy of the muscles of the hip, thigh, and proximal upper extremities, which may result in an increased risk of falls in older people with age-related loss of muscle mass. The best approach for this difficult problem is to minimize the dose of corticosteroid or to eliminate it altogether if possible. For those who require ongoing corticosteroid therapy and cannot be tapered off these drugs, resistance and endurance exercise, and androgen-replacement therapy in men, may help to prevent glucocorticoid-induced muscle atrophy. However, the effectiveness of these approaches in preventing functional decline in older patients has not been determined.

### Hypercortisolism

Cushing's disease, or hypercortisolism caused by excessive pituitary ACTH secretion, is most common in persons between 20 and 40 years of age. Accounting for approximately two-thirds of cases of endogenous hypercortisolism in younger adults, Cushing's disease is a much-less-common cause of cortisol excess in older people, although its exact prevalence in older adults is unclear. In contrast, the ectopic ACTH syndrome is more common in older people, most of whom have obvious neoplasms such as small cell lung cancer although other tumors may be clinically undetectable as in the case of some bronchial carcinoid tumors. Patients with the ectopic ACTH syndrome caused by small-cell lung cancer or other rapidly growing tumors typically present with cachexia rather than central obesity, hypertension, and metabolic disturbances including hypokalemia, metabolic alkalosis, and hyperglycemia. Cortisol-producing adrenal carcinomas are more common in older people than in young adults, with a bimodal peak incidence in children and in people older than age 60 years. These tumors may produce severe Cushing's syndrome with virilization in women and mineralocorticoid excess, although many of these tumors are nonfunctioning and do not cause symptoms of Cushing's syndrome. Adrenocortical carcinomas are typically large (>100 g) and palpable unlike benign adrenal adenomas which are usually 10 to 20 g (size 1–6 cm) at presentation.

**Diagnostic Testing** If there is a clinical suspicion of Cushing's syndrome, diagnostic options include a 24-hour urinary free cortisol, a

**FIGURE 107-3.** Diagnostic evaluation for suspected Cushing's syndrome. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; DST, dexamethasone suppression test.

low-dose dexamethasone suppression test (DST), or a midnight salivary cortisol level (Figure 107-3). False-positive results are common with the low-dose DST in older people, even in apparently normal individuals, and the urinary-free cortisol test may be confounded by inadequate urine collections or the presence of renal insufficiency. Additionally, one or both tests may be confounded by other conditions commonly encountered in older adults including obesity, medications such as phenytoin, depression, active alcoholism, or other coexisting stressful illnesses (Table 107-4). In these instances of “pseudo-Cushing's syndrome,” patients retain normal circadian variation in serum cortisol levels despite increased cortisol secretion, whereas circadian rhythmicity is lost in patients with bona fide Cushing's syndrome. A midnight salivary cortisol level distinguishes patients with Cushing's syndrome from those with pseudo-Cushing's syndrome with a high degree of specificity and sensitivity in young and middle-aged adults. However, elevated late-night salivary cortisol levels are common in older adults and individuals with type 2 diabetes mellitus without Cushing's syndrome, suggesting a need to increase the diagnostic threshold of the test in these populations. Cortisol secretion usually normalizes in patients with pseudo-Cushing's syndrome with remission of the underlying condition.

After the diagnosis of Cushing's syndrome is established, simultaneous plasma ACTH and cortisol levels are obtained to determine whether the cortisol excess is ACTH-dependent or ACTH-independent. If ACTH levels are undetectable or low and cortisol levels are high, then an ACTH-independent process is present, suggesting an adrenal tumor. In this case, CT scanning of the adrenals is indicated to confirm the diagnosis. If ACTH and cortisol levels are increased, then hypercortisolism is ACTH-dependent, usually reflecting a pituitary adenoma (Cushing's disease) or ectopic ACTH

secretion. Most patients with ectopic ACTH syndrome have extremely high ACTH levels. Identification of a definite pituitary mass at least 6 mm in size on pituitary MRI in patients with elevated ACTH and cortisol levels is sufficient for a diagnosis of Cushing's disease when clinical features of an ectopic ACTH secreting tumor are absent. Infusion of CRH can distinguish ectopic ACTH secretion from Cushing's disease; most patients with a pituitary tumor will show an increase in cortisol and ACTH levels after CRH, whereas patients with ectopic ACTH-secreting tumors will not. However, many patients with Cushing's disease do not meet the stringent response criteria for the CRH stimulation test. Venous sampling from the inferior petrosal sinus is required in these cases, and referral to an endocrinologist is usually indicated. Imaging to search for an occult ACTH secreting tumor is indicated only after Cushing's disease has been ruled out with inferior petrosal sinus sampling.

**Treatment** In patients with Cushing's disease, transsphenoidal surgery performed by a neurosurgeon with extensive experience is the treatment of choice, although radiotherapy and the steroidogenesis inhibitor ketoconazole are alternatives in those who are unable to undergo surgery. When possible, surgical tumor removal is indicated for most patients with functional adrenal adenomas or the ectopic ACTH syndrome, although for those who are not surgical candidates, aminoglutethimide, mitotane, or metyrapone and spironolactone or eplerenone may be useful in reducing the symptoms of glucocorticoid and mineralocorticoid excess, respectively. Additionally, adjuvant mitotane may prolong survival after surgical resection of adrenocortical carcinoma, although there is little experience with this approach in older patients.

### Adrenal Insufficiency

Primary adrenal insufficiency is less common in older persons than in young adults; less than 10% of patients with adrenocortical failure are older than age 60 years at initial presentation. As in younger patients, most cases of adrenal insufficiency in older people are a result of acute stress or rapid withdrawal of glucocorticoids in patients with suppressed adrenal function caused by chronic glucocorticoid administration. Autoimmune adrenocortical insufficiency is rare in older patients, but other causes of adrenal insufficiency, including tuberculosis, adrenal hemorrhage, and metastatic disease, are much more common in older persons than in young adults. Tuberculous involvement of the adrenals is nearly always associated with evidence of past or current tuberculosis infection elsewhere in the body, and may manifest with large calcified adrenal glands on plain x-rays or CT scans. Adrenal hemorrhage typically presents acutely in anticoagulated patients with symptoms such as nausea, vomiting, hypotension, and tachycardia, and is likely to be the cause if bilateral adrenal enlargement is demonstrated on CT scan. Metastatic disease involving the adrenals occurs most commonly with lymphomas and carcinomas of the lung, colon, and prostate, although even when metastases are present, it is unusual for cortisol secretion to be impaired.

The presentation of chronic adrenal insufficiency is usually vague and nonspecific in older patients, with symptoms of “failure to thrive” including weight loss, anorexia, confusion, weakness, and decreased functional status. Examination findings may include orthostatic hypotension, supine hypotension, cachexia, and hyperpigmentation, and laboratory testing may reveal hyponatremia,

hyperkalemia, azotemia, and hypoglycemia. However, one-third of older patients with primary adrenal insufficiency are not hyperkalemic at initial presentation, and hyperpigmentation, hyperkalemia, and orthostatic hypotension are not present in patients with secondary adrenal insufficiency. These signs and symptoms are nonspecific and common in older people and are, therefore, easily attributable to another condition. Consequently, it is important to suspect this diagnosis in older patients with worsening functional status and vague symptoms. Unfortunately, adrenal insufficiency has historically been more commonly fatal in older people and more likely to be diagnosed only at autopsy, as compared to younger patients.

Once the diagnosis is suspected, the evaluation is the same as for younger patients: the ACTH stimulation test establishes the diagnosis. Treatment is also the same as in young adults. In patients with primary adrenal insufficiency and less-severe mineralocorticoid deficiency, replacement doses of hydrocortisone may provide sufficient mineralocorticoid activity. However, those with absent mineralocorticoid function (manifested by orthostatic hypotension and electrolyte abnormalities such as hyperkalemia and hyponatremia) also require fludrocortisone, titrated to normalize electrolyte abnormalities. These patients should be monitored closely to avoid volume overload and hypertension. During minor illnesses or other stresses, maintenance glucocorticoid doses should be doubled for 2 to 3 days, whereas for major surgery or trauma, much higher doses of hydrocortisone (e.g., 50 to 100 mg intravenously every 8 hours) are usually administered initially. Patients with adrenal insufficiency should be given a parenteral glucocorticoid to be used if nausea and vomiting prevent ingestion of oral glucocorticoid replacement, and they should also have a bracelet or necklace identifying them as being adrenally insufficient.

Women with adrenal insufficiency and impaired mood and health-related quality of life may benefit from replacement of the adrenal androgen DHEA (25–50 mg per day), which has been shown to improve mood, fatigability, sexuality, and sense of well-being in these patients. Of note, high-density lipoprotein cholesterol levels decreased in one study of DHEA replacement in women with adrenal insufficiency. The long-term safety of DHEA replacement in people with adrenal insufficiency has not yet been established, including the possible risk of sex steroid-dependent tumor growth (see Adrenal Androgens and Aging).

Chronic glucocorticoid therapy suppresses HPA axis function and results in adrenal atrophy because of the loss of ACTH stimulation. As a result, cessation of corticosteroids may be associated with a prolonged period of decreased pituitary ACTH secretion and adrenal responsiveness to ACTH. Recovery of HPA axis responsiveness is variable and may not occur for months in some individuals. Older people may be particularly at risk to develop adrenal insufficiency as a consequence of withdrawal of steroid therapy for several reasons. For example, older adults may forget medicines or become confused about their medicines because of a complicated regimen or associated cognitive impairment. Other patients may discontinue medicines abruptly without consulting their physician because of expense or unacceptable side effects. The clinical features of adrenocortical insufficiency secondary to withdrawal of glucocorticoids (or hypopituitarism) are nonspecific and similar to those of primary adrenal insufficiency, although findings suggesting mineralocorticoid insufficiency (orthostatic hypotension and hyperkalemia) and hyperpigmentation (associated with high ACTH production) are

usually absent. Based on the foregoing, a high index of suspicion is necessary to detect adrenocortical insufficiency in older people caused by cessation of chronic glucocorticoid therapy. It is appropriate to perform the ACTH stimulation test in such patients, and those with persistent adrenocortical insufficiency should receive glucocorticoid coverage for major surgery or other stresses until HPA axis function has normalized.

## Adrenal Androgens and Aging

The adrenal steroids DHEA and its sulfated form (DHEAS) are the most abundant steroids in the human circulation. DHEA and DHEAS are precursors of both male and female sex steroids including testosterone, estradiol, and progesterone, as well as the glucocorticoid corticosterone. Neither DHEA nor androstenedione bind to or activate the androgen receptor to a significant degree, so they are considered to be very weak androgens that act mostly as prohormones. However, these prohormones may exert physiological actions indirectly via tissue-specific conversion to active androgens or estrogens.

In men, 5% to 30% of DHEA is of testicular origin, with the remainder synthesized in the zona reticularis of the adrenal cortex. In women, DHEA is produced almost exclusively by the adrenal cortex, whereas androstenedione and testosterone are secreted by both the adrenal glands and the ovaries. Total circulating androgens decline with aging as a result of both ovarian failure and a decrease in adrenal production of androgens and androgen precursors. However, in contrast to estrogen deficiency, ovarian androgen secretion may persist after menopause and the decline in androgens is more gradual, typically beginning at least a decade before menopause.

The Princeton Consensus Statement proposed a definition of “female androgen deficiency syndrome” consisting of symptoms of impaired libido and well-being in the setting of low testosterone levels and adequate estrogenization either through normal ovarian function or estrogen replacement therapy. This definition has been criticized on several grounds. First, impairment of libido is typically multifactorial in origin and is not a specific indicator of androgen deficiency. Additionally, clinical studies in women across the life span have not found a correlation between testosterone levels and sexual function although interpretation of such studies is confounded by the lack of testosterone assays with sufficient sensitivity and accuracy at the very low concentrations of testosterone present in women, the lack of consensus on the most appropriate measures to assess sexual function, and other issues. Furthermore, the risks and feasibility of offering androgen replacement to all women with self-rated impaired well-being and low circulating androgen levels has been questioned.

Women who have undergone bilateral oophorectomy or who develop adrenal insufficiency develop severe androgen deficiency and may present with symptoms of decreased libido, energy, and well-being. Androgen replacement therapy may be justifiable in these women to treat severe, symptomatic androgen deficiency. On the other hand, a recent Endocrine Society guideline recommended against attempts to diagnose androgen deficiency in women at present, based on the lack of a clearly defined clinical syndrome and the unavailability of normative data on testosterone levels across the life span that can be used to define androgen deficiency. Based on the foregoing discussion, androgen replacement does not appear indicated for postmenopausal women with decreased libido.

## Dehydroepiandrosterone Supplementation for Older Adults

Studies in rodents have reported a variety of beneficial effects of DHEA administration, including enhancement of immune function and prevention of a variety of disorders including cancer, obesity, and diabetes mellitus. However, these data have limited applicability to humans, because rodents have negligible production of adrenal androgens such as DHEA, and many of these studies used grossly supraphysiological doses of DHEA. In humans, some epidemiological studies have reported associations between DHEA levels and overall health. For example, DHEA levels are decreased in people with active rheumatoid arthritis, acquired immunodeficiency syndrome (AIDS), cancer, and cardiovascular disease, and DHEA levels are positively correlated with vigor and longevity. Additionally, high-functioning older adults have higher DHEAS levels than low-functioning individuals. Based on these findings and the marked decline in DHEA levels with aging, there has been considerable interest in the potential therapeutic effects of DHEA supplementation in older people.

Randomized controlled trials of DHEA in older adults have not revealed clear evidence of meaningful benefits. A 2-year trial of DHEA in people older than 60 years of age (75 mg daily in men and 50 mg daily in women, achieving circulating DHEA levels in the high-normal range for young adults) found no notable effects on body composition, physical performance, or insulin sensitivity. Earlier studies of DHEA supplementation at physiological to supra-physiological doses for up to 1 year reported inconsistent effects on body composition, glucose tolerance, and muscle strength. Several studies have reported small and inconsistent increases in bone mineral density that was deemed minimal in comparison to the effects of established osteoporosis treatments. A study of DHEA supplementation in 280 healthy older people 60 to 79 years of age reported an increase in libido in female subjects. However, androgen supplementation in older women remains controversial as noted above. Several randomized, placebo-controlled studies have failed to show improvements in well-being, mood, and cognition in healthy older adults receiving DHEA. No consistent effects of DHEA supplementation have been reported in vivo on immune function in older humans, for example, in studies of antibody responses to influenza vaccination or tetanus toxoid. It is possible that subgroups of older patients such as depressed or cognitively impaired people may benefit from DHEA supplementation, but these subgroups have not yet been defined.

To date, there have been no reports of significant adverse effects of DHEA supplementation in older people. DHEA is metabolized to sex steroids within prostate and breast tissue, but deleterious changes such as elevations in PSA and prostate volume have not been reported. Nevertheless, large and long-term studies on the scale of the Women's Health Initiative would be required to address these potential concerns definitively.

## Adrenal Neoplasms

Benign adrenal neoplasms are common, with autopsy studies identifying these masses in approximately 6% of cases. Adrenocortical nodularity increases with aging, and the probability of identifying an adrenal "incidentaloma" on computerized tomography of the abdomen increases from 0.2% in people between 20 and 29 years of age to 6.9% in people older than 70 years of age. Most of these are

adrenocortical adenomas, but adrenal carcinomas and pheochromocytomas also occur. One large survey reported that 4.2% of adrenal incidentalomas are pheochromocytomas. The goals of assessment are to determine whether the incidentaloma is functional (hormone-secreting) and to characterize it as benign or malignant.

Patients with adrenal incidentalomas should be queried for a history or episodes of hypertension, palpitations, headaches, and diaphoresis, suggestive of pheochromocytoma. Examination findings of proximal muscle wasting and weakness, purple striae, osteoporosis (height loss), hirsutism, and central obesity, suggestive of Cushing's syndrome, should be noted. Appropriate screening tests to determine whether the tumor is functional include a 24-hour urine collection for total and fractionated metanephrines and catecholamines, or plasma-free metanephrines to rule out pheochromocytoma, and in hypertensive patients, a morning plasma aldosterone concentration to plasma renin activity ratio. Androgen-secreting tumors are rare, and endocrine screening for androgen overproduction is not indicated in the absence of clinical signs and symptoms of hormone excess. Screening for corticosteroid hyperfunction is controversial. Many adrenal cortical adenomas have a degree of functional autonomy. In 57 patients (mean age 59 years) with adrenal incidentalomas screened with a 2-day low-dose DST, 12% had serum cortisol levels of 5 to 7.8  $\mu\text{g/dL}$ , 67% had values of 1 to 5  $\mu\text{g/dL}$ , and cortisol was undetectable in only 21%, whereas all control subjects suppressed cortisol to undetectable levels. Furthermore, higher cortisol levels after the DST were associated with larger adrenal incidentaloma size, higher midnight cortisol levels, and lower basal ACTH levels. Moreover, hypertension and obesity are significantly more prevalent in people with adrenal incidentalomas than in the general population. Indeed, most middle-aged patients with incidentalomas and cortisol nonsuppression after low-dose DST experienced improvement in hypertension, obesity, and diabetes control after adrenalectomy.

These data suggest that subtle autonomous glucocorticoid secretion is common in adrenal cortical adenomas, and that this secretory activity may be clinically significant. Some experts advocate screening individuals with adrenal incidentalomas for "subclinical" Cushing's syndrome using the overnight low-dose DST, with confirmatory tests in people with a positive result (24-hour urinary free cortisol, midnight salivary cortisol, and/or 2-day high-dose DST; and subsequent plasma ACTH) to rule out false-positives. However, tests of glucocorticoid function, such as the low-dose DST, have a high sensitivity but a relatively low specificity, therefore screening all older people with adrenal incidentalomas for subclinical Cushing's syndrome would result in a large proportion of false-positive results and additional evaluation in these cases. Furthermore, many of the tests proposed for confirmation of the diagnosis of subclinical Cushing's syndrome (e.g., 24-hour urinary free cortisol) lack sufficient sensitivity to identify mild hypercortisolemia, and there is no consensus on the appropriate laboratory criteria for this diagnosis. Of note, patients followed longitudinally for up to 7 years showed spontaneous normalization of hormonal hypersecretion in many cases, whereas a few others with apparently nonfunctioning adenomas developed subclinical hormonal hypersecretion. Finally, the long-term outcomes of adrenalectomy versus medical management of hypertension, diabetes, and obesity in older patients with adrenal cortical adenomas are unknown. Therefore, it may be prudent to restrict screening for corticosteroid hyperfunction to younger patients and those with a symptom complex including weight gain, muscle weakness, osteoporosis, hypertension, diabetes mellitus, and skin atrophy, suggesting Cushing's syndrome. However, screening is

indicated in patients with adrenal incidentalomas who are scheduled for major surgery, because postoperative adrenal crisis may occur in patients with unrecognized subclinical Cushing's syndrome. For older patients undergoing surgery, laparoscopic adrenalectomy offers a less-invasive approach, but it is unknown whether adrenalectomy will prove superior to careful observation and management of the metabolic syndrome in these patients.

The other major issue in the evaluation of adrenal incidentalomas is assessment of malignancy risk. The size of the mass is a useful indicator of risk, with benign adenomas usually ranging in size from 1 to 6 cm, and adrenal carcinomas usually greater than 6 cm in diameter. In a survey of 1004 patients with adrenal incidentalomas, a size cutoff of 4 cm yielded optimal sensitivity but low specificity for malignant adrenal lesions. However, patients with carcinoma were significantly younger than were patients with adenoma. Imaging characteristics other than size may also be helpful in assessing malignant potential, including image attenuation on noncontrast CT, enhancement with contrast media, and magnetic resonance signal intensity on T2-weighted images. Although an increase in mass size has been considered suggestive of malignancy, excision of enlarging masses has generally identified benign underlying pathology. Indeed, studies of the natural history of adrenal incidentalomas indicate that with long-term follow-up, most of these lesions remain clinically insignificant and morphologically unchanged. Subclinical hormone hypersecretion develops in some individuals, but the risk of progression to overt hypersecretion is minimal. Furthermore, aggressive evaluation and management of adrenal incidentalomas in all older adults would be cost-prohibitive.

Based on the foregoing discussion, a conservative approach is warranted in the management of most older people with apparently nonfunctioning adrenal incidentalomas. In surgical candidates, tumors associated with overt hormonal hypersecretion and lesions larger than 6 cm should generally be removed. Masses less than 3 cm in size probably do not need further evaluation or follow-up. Lesions between 3 and 6 cm without other imaging characteristics suggesting malignancy may be followed with serial imaging studies, although the benefits of serial imaging have been questioned.

## SYMPATHOADRENAL SYSTEM

### Physiology

The sympathetic nervous system (SNS) plays a key role in the regulation of physiological homeostasis, including cardiovascular and metabolic functions. For example, postganglionic sympathetic neurons projecting to the heart and blood vessels regulate cardiac output and arterial blood pressure. The SNS stimulates release of epinephrine from the adrenal medulla, which in turn plays an important role in the regulation of both cardiovascular function and energy metabolism. SNS dysfunction has been implicated in the pathogenesis of a variety of age-associated disorders, including hypertension, obesity, congestive heart failure, type 2 diabetes mellitus, and sudden cardiac death.

NE is the primary neurotransmitter released by sympathetic postganglionic neurons. After release, most of the NE is taken up again into the presynaptic and postsynaptic axon terminals, whereas only a small fraction diffuses into the circulation. The adrenal medulla

contains specialized postganglionic sympathetic neurons that enzymatically convert NE into epinephrine, the major secretory product of these cells.

There is a general consensus that SNS activity is increased with aging in humans. Basal plasma NE levels are increased in older people because of an increase in NE secretion and, to a lesser extent, a decrease in clearance. Furthermore, plasma NE responses to various stimuli such as upright posture, cold pressor tests, exercise, and hand grip are also increased with aging. By comparison, adrenal medullary function is relatively unchanged until 75 to 80 years of age. Clearance of epinephrine is increased with aging. However, in subjects younger than age 75 years, increased clearance appears to be balanced by a proportionate increase in epinephrine secretion, with no change in circulating epinephrine levels. However, in people older than age 80 years, levels of epinephrine are increased both at baseline and after cold-pressor testing, suggesting important effects of advanced age on both the sympathoneural and the sympathoadrenomedullary components of the SNS.

Although SNS tone is increased with aging, physiologic responses to adrenergic receptor-mediated stimulation generally decrease with aging. For example, the increased NE levels in older subjects do not increase basal heart rate, and stimulation of  $\beta$ -receptors by isoproterenol produces less of an increase in heart rate and contractility in aging, as compared to young individuals. Furthermore, aging subjects exhibit decreased  $\beta$ -receptor-mediated chronotropic responses to stimuli such as hypoxia, and decreased arterial vasoconstrictor responses to  $\alpha$ -adrenergic stimulation. This decreased responsiveness to catecholamines appears to be a result of changes at both the receptor and the postreceptor level, including reduction in receptor number, decreased receptor affinity, and receptor-effector uncoupling.

### Clinical

#### Hypertension

Clinical consequences of this age-related hyperadrenergic state may include the development of hypertension. Several studies report unchanged  $\alpha$ -mediated arterial vasoconstriction with normal aging. Based on these studies, together with observations that  $\beta$ -adrenergic-mediated vascular smooth muscle relaxation is decreased with aging, it has been hypothesized that older people are predisposed to develop hypertension as a result of relatively unopposed  $\alpha$ -adrenergic tone. However, this hypothesis was cast into doubt by studies that found a decrease in arterial  $\alpha$ -adrenergic responsiveness to NE in normal older people, implying an appropriate compensatory response to elevated SNS tone with aging. When compared with older normotensive people, older hypertensive subjects exhibit an increase in vascular  $\alpha$ -adrenergic receptor responsiveness despite equal or greater SNS activity. Therefore, a combination of an increase in systemic SNS tone and enhanced  $\alpha$ -adrenergic receptor responsiveness may contribute to essential hypertension in older adults. In clinical practice, antihypertensive drugs that block CNS sympathetic outflow or SNS-mediated peripheral vasoconstriction may cause orthostatic hypotension in older adults, especially postprandially when gastrointestinal vasodilation occurs.

#### Metabolic Syndrome

Several lines of evidence suggest an important role of the SNS in the pathogenesis of the metabolic syndrome. First, various components

of the metabolic syndrome such as obesity and hypertension are associated with an increase in SNS activity. For example, individuals with insulin resistance, hypertension, and obesity exhibit resting tachycardia, elevated plasma NE levels, increased secretion of NE from sympathetic nerves, and adrenoceptor down-regulation. Second, increased sympathetic tone is associated with a decrease in insulin sensitivity. For example, experimental maneuvers in healthy subjects that decrease venous return cause an increase in NE release and peripheral vasoconstriction, together with an acute reduction in insulin sensitivity. Finally, adrenergic overactivity is associated with end-organ damage associated with the metabolic syndrome. Distensibility of medium and large arteries is decreased by sympathetic tone, which over time may promote atherogenesis.

Based on the foregoing discussion, inhibition of sympathetic overactivity is a potential therapeutic goal in people with the metabolic syndrome. This can be achieved either by adhering to an energy-restricted diet or by physical training. Of note, although moderate dietary sodium restriction is commonly recommended for people with hypertension, even a moderate restriction of sodium intake in people with the metabolic syndrome may precipitate SNS activation and potentially worsen insulin resistance. Angiotensin-converting enzyme inhibitors and angiotensin II receptor antagonists have sympathoinhibitory effects, and are useful antihypertensive agents in people with the metabolic syndrome.

### Autonomic Insufficiency

Autonomic insufficiency may result from primary peripheral nervous system failure, coexisting diseases such as diabetes mellitus or multiple system atrophy, or drugs that interfere with SNS function. The most common clinical manifestation of these conditions is orthostatic hypotension, defined as a decrease in systolic blood pressure of at least 20 mm Hg, or a fall in diastolic blood pressure of at least 10 mm Hg within 3 minutes after arising from a supine to a sitting or standing position. In addition, the pulse rate may fail to increase despite a significant fall in blood pressure in more advanced cases. Other manifestations of autonomic insufficiency may include erectile dysfunction, urinary incontinence, urinary retention, constipation, gastroparesis, and anhidrosis. Aside from these clinical observations, and the identification of underlying disorders such as diabetes mellitus, routine laboratory testing of SNS function is not indicated. Management options for orthostatic hypotension associated with autonomic insufficiency are summarized in [Table 107-6](#). Multiple interventions are usually employed simultaneously. Midodrine, an  $\alpha_1$ -adrenergic receptor agonist with few cardiac or CNS side effects, is often better tolerated by older adults than fludrocortisone. For management of other clinical manifestations of autonomic insufficiency, see Chapter 49 (Sexual Dysfunction), Chapter 59 (Incontinence), and Chapter 93 (Constipation).

### Pheochromocytoma

Pheochromocytoma is a rare tumor, with an incidence of less than 1% in patients with hypertension. Most cases are thought to occur in young and middle-aged adults, but epidemiologic and autopsy data indicate a progressive age-specific increase in the incidence rate. It is unclear whether some pheochromocytomas diagnosed at autopsy are nonfunctioning and of no clinical significance, or whether the disease is underdiagnosed in older patients. However, based on the

**TABLE 107-6**

### Management Approaches For Orthostatic Hypotension Caused by Autonomic Insufficiency

#### Nonpharmacological

- Eliminate or reduce medications associated with postural hypotension
- Dangle legs for several minutes prior to arising from bed
- Dorsiflex ankles several times before arising from bed or chair
- Avoid rapid changes in position when arising from bed or chair
- Avoid dehydration
- Wear elastic support stockings to maximize venous return
- Liberalize dietary sodium intake
- Eat frequent, small meals to minimize postprandial hypotension
- Elevate head of bed up to 20 degrees
- For patients with a history of prolonged bedrest, increase amount of time spent sitting up each day

#### Pharmacological

- Fludrocortisone (mineralocorticoid, volume expander)
- Midodrine ( $\alpha_1$ -adrenergic receptor agonist)
- When antihypertensive therapy is required, ACE-I, ARB, and  $\beta$ -blockers with intrinsic sympathomimetic activity are less likely to worsen OH

ACE-I, angiotensin converting enzyme inhibitors; ARB, angiotensin-receptor blockers; OH, orthostatic hypotension.

foregoing discussion, the age-related decrease in responsiveness to catecholamines may result in a muting or an absence of symptoms of excessive adrenergic stimulation such as diaphoresis and palpitations. Furthermore, pheochromocytomas present with protean symptoms and signs that may mislead the clinician, earning it the title of the “Great Masquerader.” The diagnosis may be especially challenging in older adults with signs and symptoms of comorbid illnesses that further confound the diagnosis. Therefore, a high index of suspicion is necessary to make this diagnosis in older patients. A symptom complex of headaches, palpitations, and diaphoresis; refractory or severe hypertension of unknown cause; or a paradoxical blood pressure response to beta-blocking medications may suggest the diagnosis.

The diagnosis depends on the documentation of elevated 24-hour urinary total and fractionated catecholamines and metanephrines, or plasma metanephrines in a patient who is hypertensive or symptomatic at the time of specimen collection. Although some groups have advocated for the use of plasma free metanephrines as a sensitive and specific diagnostic test, debate remains regarding the relative merits of the various tests. Diagnostic accuracy may be improved by using a combination of tests. Of note, medications such as tricyclic antidepressants,  $\alpha_1$ - and  $\beta$ -adrenergic blocking agents, and calcium channel-blockers may cause false-positive results for one or more biochemical tests for pheochromocytoma. Imaging studies are useful for preoperative localization of tumor but generally not for diagnosis.

Surgical intervention is indicated in older patients with resectable pheochromocytomas, in view of the potential for surgical cure and the poor prognosis with medical management. Preoperative localization of tumor should be undertaken using abdominal CT or MRI scanning, with localization of extraadrenal foci using  $^{123}\text{I}$ - or  $^{131}\text{I}$ -metaiodobenzylguanidine (MIBG) scintigraphy. An additional benefit of MIBG scintigraphy is that the compound is taken up by adrenergic cells, confirming that the mass is adrenergic in cases where biochemical studies are indeterminate.  $6\text{-}^{18}\text{F}$ fluorodopamine

positron emission tomography scanning may be valuable in cases where conventional imaging modalities fail to locate the tumor despite compelling biochemical and clinical evidence of pheochromocytoma.

A careful cardiologic evaluation is warranted preoperatively in all patients with pheochromocytoma; the presence of coronary artery disease or cardiomyopathy may influence preoperative medical management.  $\alpha$ -Receptor blockade is usually initiated preoperatively for blood pressure control even in normotensive patients, often in combination with  $\beta$ -blockers. However,  $\beta$ -receptor-blocking agents should not be given until after  $\alpha$ -blockade is achieved, to avoid an increase in blood pressure induced by unopposed  $\alpha$  activity. In addition, patients with pheochromocytoma have a contracted plasma volume and saline infusion is indicated for moderate volume expansion.

Occasionally, a pheochromocytoma will present as an adrenal incidentaloma with normal urinary metanephrines and catecholamines, and negative MIBG scintigraphy, but during surgery. Its intraoperative behavior and subsequent histological findings indicate pheochromocytoma. It is important to take prophylactic measures during surgery for this possibility, including placement of an arterial line and arrangement for immediate access to intravenous nitroprusside.

## RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

Aldosterone secretion decreases with aging. Despite a concomitant decline in clearance rate, basal plasma aldosterone levels are 30% lower in healthy octogenarians compared to younger adults (Table 107-7). Aldosterone secretion is also reduced after stimuli such as sodium depletion or upright posture. However, these changes do not appear to be secondary to adrenal dysfunction because aldosterone responsiveness to ACTH is intact with aging. The primary defect responsible for these changes in aldosterone secretion is thought to be a reduction in plasma renin activity, which is decreased by 50% in older persons, as compared to younger adults. This decline

**TABLE 107-8**

### Risk Factors for Hyperkalemia in Older People

Diabetes mellitus*
Renal insufficiency or failure
Intravascular volume depletion
Adrenocortical insufficiency
Acidosis
Medications
Aldosterone antagonists (spironolactone, eplerenone)
Sodium channel antagonists ("potassium-sparing" diuretics: triamterene, amiloride)
Trimethoprim-sulfamethoxazole
Angiotensin-converting enzyme inhibitors
Angiotensin antagonists
Beta-adrenergic blocking agents
Nonsteroidal anti-inflammatory agents
Potassium-containing salt substitutes
Tissue injury with rapid release of potassium from cells
Crush injury
Tumor lysis syndrome
Hemolysis

\*Multiple contributors, including insulin deficiency, renal insufficiency, hyporeninemic hypoaldosteronism, type IV renal tubular acidosis, and use of angiotensin-converting enzyme inhibitors.

in active renin concentration is thought to be a result of diminished conversion of inactive to active renin. In addition, age-related increases in atrial natriuretic hormone secretion contribute to the suppression of aldosterone secretion with aging, both directly and by inhibiting renal renin secretion, plasma renin activity, and angiotensin II levels. See Chapter 88 for additional information on effects of aging on salt and water regulation.

The clinical consequences of decreasing aldosterone levels with aging include a predisposition to renal sodium wasting, which, in combination with reduced thirst and decreased renal ADH responsiveness, further increases the potential for volume depletion and dehydration in geriatric patients. Furthermore, this state of relative hyporeninemic hypoaldosteronism places older adults at increased risk of hyperkalemia, especially patients with diabetes mellitus and renal insufficiency (Table 107-8). The addition of aldosterone antagonists,  $\beta$ -blocking agents, nonsteroidal antiinflammatory drugs, or heparin may lead to potentially life-threatening hyperkalemia in such patients.

## GROWTH HORMONE AXIS

### Physiology

Secretion of GH from the pituitary is regulated by the hypothalamic peptides GH-releasing hormone (GHRH) and somatostatin. These two peptides exert an opposing effect on GH secretion, with GHRH stimulating and somatostatin inhibiting GH secretion by the pituitary somatotropes. In humans, GH secretion appears to be controlled primarily by pulsatile GHRH secretion. In turn, insulin-like growth factor-1 (IGF-1 or somatomedin C), which is secreted by the liver and other peripheral tissues in response to GH, mediates most of the actions of GH. Furthermore, IGF-1 exerts a negative

**TABLE 107-7**

### Effects of Aging on Hormonal Regulation of Fluid and Sodium Balance

feedback effect on GH secretion through a direct effect at the pituitary level and indirectly by increasing somatostatin production. Most IGF-1 circulates in protein complexes with IGF binding protein-3 (IGFBP-3) or IGFBP-5. IGFBPs act in concert to regulate circulating levels of free IGF-1. In addition, IGFBPs appear to inhibit as well as stimulate IGF-1-mediated bioactivity, and in some cases, they may exert effects independent of IGF-1. Secretion of GH is pulsatile in response to pulsatile GHRH secretion, generally with very low circulating levels except for several pulses occurring during the first few hours of sleep, after meals or exercise, or without apparent cause. In young adult men, most of the GH is secreted within the first 4 hours after sleep onset, with large amplitude pulses occurring during slow-wave sleep, with IGF-1 levels remaining fairly constant over a 24-hour period. In contrast, young women have multiple episodes of GH secretion and a high basal output of GH during the daytime, with relatively low GH release during the night.

GH release is affected by numerous other factors, including other neurotransmitters and neuropeptides, medications, hormonal influences, blood glucose levels, degree of obesity, and physiologic states such as sleep and exercise. For example, the neurotransmitter dopamine and CNS-active dopaminergic agonists such as bromocriptine exert a stimulatory effect on GH release by promoting hypothalamic GHRH release. NE and  $\alpha$ -adrenergic agonists also increase GHRH and GH release, whereas  $\beta$ -adrenergic agonists and dopamine- or  $\alpha$ -receptor-blocking agents inhibit GH secretion. Furthermore, the GH-releasing effects of other stimuli such as exercise, stress, hypoglycemia, and arginine are thought to be mediated via  $\alpha$ -adrenergic stimulation. Estrogens stimulate GH release, and premenopausal women have higher peak GH levels with exercise, arginine, and insulin-induced hypoglycemia than age-matched men. In contrast, GH secretion is inhibited in those treated chronically with glucocorticoids. Hyperglycemia is associated with decreased GH levels and GH responses to GHRH. Similarly, obese subjects exhibit decreased spontaneous GH secretion and reduced GH responsiveness to pharmacological stimulation compared to nonobese subjects, although IGF-1 levels are typically within normal limits. GH levels are acutely elevated during exercise, and there is indirect evidence that regular exercise may enhance GH secretion over the long term.

### Age Effects

GH secretion reaches maximum levels at puberty, followed by a gradual but progressive decline with age. In adult men, GH secretion declines by approximately 14% per decade, such that by age 70 to 80 years, about half of all individuals have no significant GH secretion during a 24-hour period. Plasma IGF-1 levels exhibit a corresponding decline of 7% to 13% per decade, and by age 70 to 80 years, approximately 40% have plasma IGF-1 levels in the range found in GH-deficient children. In addition, serum levels of IGFBP-3 decline with aging in healthy adults, but it is unclear whether this affects the metabolic activity of IGF-1 with aging.

Collectively, these decreases in pituitary secretion of GH and circulating IGF-1 levels are often referred to as the somatopause. The age-related decrease in GH production appears to be primarily caused by a decrease in hypothalamic GHRH secretion and an increase in hypothalamic somatostatin release, rather than attenuation in pituitary responsiveness to GHRH. Accordingly, GH secretion and IGF-1 levels can be normalized with exogenous GHRH ad-

ministration. The age-related decrease in GH secretion is partially reversed by fasting in older people without an associated alteration in sleep quality, suggesting that lifestyle modification may augment endogenous GH secretion in older adults.

### Growth Hormone Deficiency in Adults with Hypothalamic–Pituitary Disease

GH deficiency in adults with established hypothalamic–pituitary disease is associated with reduced lean body mass, muscle strength, and exercise capacity; diminished psychological well-being; insulin resistance; increased total body adiposity; higher waist-to-hip ratio of fat distribution; reduced bone density; adverse effects on lipid metabolism; and increased risk of death from cardiovascular disease, despite adequate replacement of other hormones including thyroxine, cortisol, and sex steroids. Many of these effects can be improved or corrected with daily subcutaneous administration of one of a number of recombinant human GH formulations, and GH supplementation is approved in the United States for adults with hypopituitarism and GH deficiency. Improvements in cardiac function, muscle strength, body composition, bone mass, metabolic indices, and health-related quality of life have been sustained in small trials lasting up to 10 years, and treatment has generally been well tolerated. The most commonly reported adverse effects of GH treatment in adults with hypopituitarism are fluid retention/edema, arthralgias, myalgias, and carpal/tarsal tunnel syndrome. These symptoms are most likely to occur in people who are older or obese, and are more common in those with the greatest increase in IGF-1 levels during treatment. However, these symptoms often resolve spontaneously during treatment and disappear with treatment cessation. Insulin sensitivity is further reduced in the short term with GH treatment, but later returns to baseline with prolonged treatment in studies of up to 7 years' duration. To date, there is no evidence that GH replacement increases the risk of diabetes mellitus in adults. Moreover, glycosylated hemoglobin and serum triglyceride levels tend to decline in patients treated with GH for more than 3 years. Retrospective studies have reported an increased rate of neoplasia as well as cancer-related mortality in patients with pituitary adenomas although it is unclear whether these findings reflect inherent risk, increased surveillance, or the effects of treatments received.

The diagnosis of GH deficiency in adults is suggested clinically by the presence of multiple pituitary hormone deficiencies and should be suspected in any patient with a history of hypothalamic–pituitary disease. However, laboratory criteria for distinguishing older adults with organic GH deficiency from those with normal age-related reductions in GH secretion have not yet been clearly defined. Furthermore, assessment of GH function is complicated by the need for GH stimulation tests, the lack of adequate normative data for many laboratories, assay variability, and the unavailability of appropriate age-adjusted normal values for diagnostic tests. Static GH levels are unsuitable for diagnosis, because GH is secreted episodically. IGF-1 levels decline during normal aging and are not a reliable indicator of GH deficiency secondary to pituitary disease in people older than 40 years of age, although IGF-1 levels below the age-adjusted normal range may suggest the diagnosis. Normal IGF-1 levels do not exclude the diagnosis of GH deficiency at any age. The insulin tolerance test is considered the most definitive test for GH deficiency in adults, but this test may be dangerous in older patients with ischemic heart disease. Arginine-induced GH secretion remains intact with normal

aging, and the arginine/GHRH stimulation test has been proposed as a safer yet reliable alternative to distinguish GH deficiency secondary to hypopituitarism from normal age-related reductions in GH secretion. In patients with hypothalamic causes of suspected GH deficiency, arginine should be used without GHRH to avoid falsely normal results, because GHRH directly stimulates the pituitary. In adults with milder hypopituitarism, for example, two or fewer pituitary hormone deficiencies, it is advisable to use two independent stimulation tests to confirm GH deficiency.

As with younger adults, older people with GH deficiency related to hypopituitarism also appear to benefit from GH replacement. People with more severe biochemical and clinical manifestation of GH deficiency are more likely to derive benefit from GH replacement. In prospective cohort studies, GH-deficient adults older than age 65 years receiving GH replacement therapy for at least 12 months experienced significant improvements in knee flexion/extension and handgrip strength, total and low-density lipoprotein cholesterol levels, waist/hip ratio, and quality-of-life measures without significant deterioration in glucose homeostasis. The GH replacement dose in older GH-deficient adults is lower than that required by younger adults. In one study, a dose of 0.5 mg of GH per day resulted in elevated serum IGF-1 levels in half of older subjects, and 25% developed side effects on this dose. Most older subjects maintained IGF-1 levels within the normal range on 0.17 to 0.33 mg per day. By contrast, younger adults may require doses up to 1 mg per day. Treatment should begin at a low dose (e.g., 0.1–0.2 mg per day) with slow upward titration at no more than monthly or bimonthly intervals based on clinical and biochemical responses. Serum IGF-1 levels should be maintained within the normal adult range to optimize the beneficial effects of GH replacement while minimizing the potential for side effects such as carpal tunnel syndrome, arthralgias, fluid retention, and gynecomastia. Patients with an active malignancy should not receive GH supplementation. It should be noted that GH therapy is costly, which along with the need for daily sc injections may limit its use in an older population with limited resources. Longer-acting GHRH analogs and GH secretagogues are being developed for the treatment of adult GH deficiency, which will eventually increase the range of therapeutic options for older people with this disorder.

### Growth Hormone Supplementation for Older People Without Hypothalamic–Pituitary Disease

Normal aging is associated with alterations in body composition similar to those in GH-deficient younger patients, including decreased muscle mass and strength, reduced bone mass, and increased adiposity. In turn, declining strength and bone mass are associated with increasing risk for falls and fractures in older people. These observations suggest that the reduction in GH secretion associated with aging (the somatopause) may contribute to alterations in body composition and increased frailty in older adults, and that GH supplementation, GHRH, or GH secretagogue treatment might be clinically useful in preventing or reversing these age-related changes.

Since the initial publication of a study by Rudman and colleagues that reported potentially beneficial changes in body composition with short-term GH supplementation in older men, interest in GH as an “antiaging” hormone has increased dramatically. It is estimated that 20,000 to 30,000 individuals in United States used GH for this purpose in 2004, and that up to one-third of the prescrip-

tions for GH worldwide are for “off-label” use. However, its use to prevent aging-related changes has remained controversial and it is illegal in the United States to distribute GH for use as an antiaging remedy.

A systematic review in 2007 of randomized, controlled trials of GH supplementation for up to 1 year in healthy older people found modest decreases in fat mass and increases in lean body mass in subjects receiving GH compared to placebo-treated subjects. These potentially beneficial effects on body composition were largely confined to men, possibly reflecting the observation that women require larger doses of GH over a longer period of time than men to achieve physiological replacement of GH. Although body composition improved (increase in lean mass and decrease in fat mass) in men treated with physiological amounts of GH for 6 months, muscle strength, endurance and functional status did not improve. Total serum cholesterol levels tended to decrease, but no significant changes occurred in bone mineral density or other serum lipid levels with GH supplementation. Older subjects receiving GH were more likely to develop peripheral edema, carpal tunnel syndrome, arthralgias, and gynecomastia. GH-treated subjects tended to have a higher incidence of impaired fasting glucose and type 2 diabetes mellitus, but this was not significant. Because of the limited study duration and small size of the study groups, no effect of GH treatment was reported on cancer risk or death. Overall, there is little evidence that GH supplementation improves other relevant outcomes in healthy older people, including strength, function, or quality of life. Based on the observations of minimal clinical benefit and a high rate of adverse effects, GH supplementation is not recommended as an antiaging treatment in healthy older adults.

## THE HYPOTHALAMIC–PITUITARY–TESTICULAR AXIS

### Age Effects

Significant age-related changes occur in male reproductive function with aging, including a decrease in sexual activity, libido, and fertility rates. However, in contrast to the relatively rapid and complete loss of gonadal function in women at the time of menopause, changes in testicular function in aging men occur gradually, vary considerably between individuals, and often do not result in severe hypogonadism. Many healthy older men exhibit a degree of primary testicular failure, with decreases in total and free or bioavailable testosterone levels, testosterone responses to exogenous gonadotropin administration, and daily sperm production, together with increased serum gonadotropin levels (Figure 107-4). Occasionally, community-dwelling older men present with overt testicular failure with total testosterone levels well below normal and symptoms of androgen deprivation including hot flashes, decreased libido, and gynecomastia. However, it is more common to see older patients with mildly decreased testosterone levels and relatively nonspecific symptoms such as impotence, loss of libido, osteopenia, and muscle weakness. In contrast, more marked testosterone deficiency is common in frail older men. For example, in male nursing home residents, it has been reported that 45% exhibit testosterone levels within the hypogonadal range.

Several factors contribute to this decrease in testosterone levels with aging (Table 107-9). First, testicular testosterone production

**FIGURE 107-4.** Age-related changes in male hypothalamic–pituitary–gonadal axis function. GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone; E<sub>2</sub>, estradiol; DHT, dihydrotestosterone. Small solid arrows denote direction of change with aging.

is markedly reduced with aging, which is reflected in the decreased number and volume of Leydig cells in the aging testis. This reduction in testosterone production capacity may manifest as a more severe and prolonged depression of testosterone levels during intercurrent illness or other stresses in older men. Second, both production rates

and metabolic clearance of testosterone are reduced in aging men, but in contrast to adrenal cortisol secretion and metabolism, the decrease in testosterone production is not completely offset by a decrease in clearance. Third, the normal circadian variation in testosterone levels observed in young men, with highest levels in the morning, is blunted with aging, resulting in reduced serum testosterone concentrations. Fourth, the concentration of the major testosterone binding protein, sex hormone-binding globulin (SHBG), increases with aging. Therefore, serum free or non-SHBG-bound (bioavailable) testosterone concentrations decline to a greater extent with aging than total testosterone. Finally, impairment of testicular function is associated with medical illnesses, medications, and malnutrition, which are commonly present in aging men. However, hypogonadism does not occur in all aging men; many healthy men older than age 80 years maintain serum testosterone levels within the normal young adult range.

In addition to these deficits in testicular function, hypothalamic/pituitary control of testicular function is also impaired with aging. Although gonadotropin levels increase with aging, they usually remain within normal limits, and the hormonal profile of a low testosterone and normal gonadotropin levels is consistent with aging-related secondary hypogonadism. Even in men with elevated levels of LH and FSH, the increases in gonadotropins are sometimes inappropriately low in comparison to younger men with similar reductions in testosterone levels, and FSH levels are more commonly elevated than LH levels. Furthermore, the ratio of bioactive to immunoreactive LH and FSH is decreased in older men, indicating that gonadotropin levels measured by radioimmunoassay may underestimate the extent of gonadotropin deficiency. Finally, healthy older men exhibit intact LH and FSH responsiveness to prolonged exogenous pulsatile GnRH administration but an inappropriately normal or decreased LH pulse frequency (an indicator of hypothalamic GnRH pulse-generator activity), as compared to young men. Based on the above evidence, it appears that age-related hypogonadism is a consequence of combined testicular and hypothalamic dysfunction.

The physiologic significance of the decrease in testicular androgen production associated with aging (often referred to as “late-onset hypogonadism,” “partial androgen deficiency of the aging male,” or “andropause”) is uncertain. However, as testosterone levels decline with aging, various functional changes occur in androgen-dependent body tissues. In the testes, there are significant age-related decreases in the number of Sertoli cells, volume of seminiferous tubules, daily sperm production, and to some extent testicular volume. Serum levels of inhibin B, which is secreted by Sertoli cells and mediates feedback inhibition of pituitary FSH secretion, also decrease with aging. In studies controlled for the increased length of time between ejaculations in older men, sperm concentrations were unchanged with age, but older men exhibited lower ejaculated volume, decreased sperm motility, and a higher percentage of abnormal spermatozoa. However, these parameters remained within normal limits in most of the older subjects. Sperm fertilizing capacity by *in vitro* testing remains intact in healthy older men. Male fertility is thought to decrease with aging, mostly as a result of reduced sexual activity and sexual dysfunction. The causes of declining libido and sexual activity with aging are multifactorial, including the presence of chronic illnesses such as diabetes mellitus, vascular or neuropathic disease of the penis, medications, and depression (see Chapter 49).

Testosterone and other androgens are also important in the maintenance of normal body composition in men, including bone mass,

muscle mass, strength, and adiposity. Bone mass declines progressively with age in men, and hypogonadism in men is associated with premature osteoporosis and an increased risk of fractures. Additionally, younger hypogonadal men exhibit excessive visceral adiposity and reduced lean body mass that are reversible with testosterone replacement, and supraphysiologic doses of testosterone increase muscle strength and lean body mass in healthy young men. Testosterone supplementation has been proposed not only to treat older men with frank hypogonadism caused by pathological disease in the hypothalamic–pituitary–testicular axis, but also to ameliorate age-associated changes in body composition, sexual functioning, and overall well-being in older men with low testosterone levels related to aging per se. The role of androgens in the evaluation and management of erectile dysfunction in older men and the potential benefits and risks of testosterone supplementation in older men are discussed in Chapter 49.

### Laboratory Diagnosis of Hypogonadism

The signs and symptoms of hypogonadism in older men may include diminished energy, vitality, and libido; depressed mood; erectile dysfunction; increased total and abdominal obesity, and decreased lean body and muscle mass, strength, and bone mineral density; objective impairment of cognitive function (e.g., spatial ability, visual and verbal memory); mild anemia; and impaired subjective well-being. However, these manifestations are nonspecific and common in eugonadal older men, and may be attributable to other common age-associated comorbidities. Therefore, laboratory evidence as well as signs and symptoms are required to make the diagnosis of hypogonadism. Questionnaires have been developed as potential screening tools to diagnose androgen deficiency in older men, but they lack sufficient specificity to identify men requiring laboratory evaluation.

Currently, there are no clinically useful biomarkers of androgen action available, and the laboratory diagnosis of testosterone deficiency depends upon measurement of low circulating testosterone concentrations. As discussed previously, because SHBG levels increase with aging, total testosterone measurements may not fully reflect age-related reductions in biologically active testosterone. Therefore, older men with symptoms or signs consistent with androgen deficiency should be evaluated with a free or bioavailable (non-SHBG-bound) testosterone level using an accurate and reliable assay, e.g., free testosterone by equilibrium dialysis or calculated from measurements of total testosterone and SHBG. Free testosterone assays using the direct analog radioimmunoassay method do not accurately or reliably measure free testosterone and therefore are not recommended. Because testosterone levels exhibit considerable biological and assay variability, low values should be confirmed on repeat testing. Serum testosterone should be measured only after reversible causes of low testosterone such as acute illness and malnu-

trition are treated, or medications such as glucocorticoids or opiates are discontinued, if possible.

The laboratory evaluation of men with suspected hypogonadism should include serum LH and FSH levels to differentiate between primary (testicular) and secondary (hypothalamic/pituitary) hypogonadism, as well as a prolactin level if gonadotropins are inappropriately low-normal or low in the presence of reduced testosterone levels. Hyperprolactinemia inhibits hypothalamic GnRH secretion, resulting in a decrease in LH and FSH secretion, and could indicate the presence of a pituitary adenoma or a hypothalamic disorder. In patients with secondary hypogonadism suspected on the basis of low serum testosterone associated with low or inappropriately normal gonadotropins, additional studies may be warranted, including magnetic resonance imaging of the pituitary fossa, measurements of other pituitary hormones such as GH and thyroid hormone levels, and an ACTH stimulation test. Furthermore, bone densitometry measurement is indicated in hypogonadal men to evaluate for asymptomatic osteoporosis.

# Thyroid Diseases

Jerome M. Hershman ■ Sima Hassani ■ Mary H. Samuels

Thyroid disorders in the elderly population are common, often challenging diagnostically, and frequently overlooked. The clinical presentations of thyroid diseases may be subtle, with nonspecific signs and symptoms that are attributed to other illnesses or to a normal aging process. Thyroid function tests can be misleading in the presence of concurrent acute or chronic diseases and may be affected by some medications. This chapter describes the most common thyroid disorders encountered in the elderly population.

## THE AGING HUMAN THYROID

### Anatomy

The thyroid gland is the largest endocrine organ in the human body, and weighs approximately 12 to 20 g in adults. The structural and functional changes of the thyroid gland that occur with aging are controversial. Some investigators report that there were no size or weight changes, others found increases to twice normal size after age 70 years, whereas other reports indicated that the thyroid gland undergoes atrophy, fibrosis, and decrease in weight. The thyroid gland is also more nodular with advancing age, and there is an increase in fibrosis and lymphocytic infiltration. Despite these changes, normal thyroid function is maintained by the vast majority of the elderly population. Estimation of the thyroid size and its palpation may be difficult in elderly patients because of cervical kyphosis, obesity, or chronic pulmonary disease.

### Physiology

Iodine, an essential substrate for synthesis of thyroid hormone, is absorbed from the diet and enters the circulation as inorganic iodide that is distributed in extracellular fluids as well as in salivary, breast, and gastric secretions. The average daily iodine intake is about

250  $\mu\text{g}/\text{day}$  in the United States. A 24-hour urinary iodine measurement is an index of dietary iodine intake.

Iodide is actively concentrated by the thyroid gland or cleared from the plasma by the kidney. The thyroid gland, compared with the kidneys, is the active participant in the competition for plasma iodide and adjusts the rate of entry of iodide into the thyroid tissue based on the changes in thyroid hormone synthesis rather than renal avidity for iodide ion. The active transport of iodide from plasma to follicular cell is carried out by the sodium iodide symporter, a transport protein on the follicular cell plasma membrane. The extracellular fluid iodide concentration is usually very low because of the rapid clearance of iodide from extracellular fluid by the thyroidal uptake and renal clearance.

Table 108-1 summarizes the aging effects on thyroid function. The renal and thyroidal iodide clearance rate diminishes with advancing age. Thyroid iodide clearance, estimated by a 24-hour radioactive iodine uptake by the thyroid gland, decreases in euthyroid subjects after age 60 years. Urinary iodine excretion also was found to be significantly reduced in subjects older than 80 years of age.

In the thyroid cell, the iodide is oxidized by the peroxidase enzyme and incorporated into tyrosines in thyroglobulin to form the thyroid hormone precursors monoiodotyrosine (MIT) and diiodotyrosine (DIT). The MIT and DIT within the large thyroglobulin molecule couple to form thyroxine ( $\text{T}_4$ ) and triiodothyronine ( $\text{T}_3$ ). In the plasma, the main binding protein is thyroid-binding globulin (TBG), which binds about 70% of serum  $\text{T}_4$  and  $\text{T}_3$ . The other binding proteins are transthyretin and albumin. Only 0.02% of  $\text{T}_4$  and 0.3% of  $\text{T}_3$  are free and metabolically active because only the free hormone is rapidly transported into cells. Total serum  $\text{T}_4$  and  $\text{T}_3$  are readily measured. Free  $\text{T}_4$  ( $\text{FT}_4$ ) and free  $\text{T}_3$  ( $\text{FT}_3$ ) concentrations also can be measured to evaluate thyroid function.

The daily production rate of  $\text{T}_4$  is about 85  $\mu\text{g}/\text{day}$  and that of  $\text{T}_3$  is about 30  $\mu\text{g}/\text{day}$  in normal adults. About 85% of  $\text{T}_3$  production is derived from  $\text{T}_4$ -to- $\text{T}_3$  conversion by 5'-deiodinase, a selenoprotein (Figure 108-1), in extrathyroidal tissues such as the

liver, muscles, and kidneys. The other 15% of T<sub>3</sub> production is that secreted directly by the thyroid gland. Selenium deficiency results in reduced 5-deiodinase activity and serum T<sub>3</sub> concentration. Reverse T<sub>3</sub> (rT<sub>3</sub>), inactive biologically, differs from T<sub>3</sub> because it is missing an iodine from the inner or tyrosyl ring of T<sub>4</sub> rather than from the outer ring or phenolic ring. T<sub>4</sub> is converted to rT<sub>3</sub> by 5-deiodinase in peripheral tissue. Total T<sub>4</sub> production and degradation decline with aging, but T<sub>4</sub> concentration and TBG concentration remain unchanged in healthy individuals throughout adult life. In contrast, the concentration of T<sub>3</sub> was reported to decrease by 10% to 20% with advancing age and the concentration of rT<sub>3</sub> increases. These findings suggest that 5'-deiodinase activity decreases with increasing age.

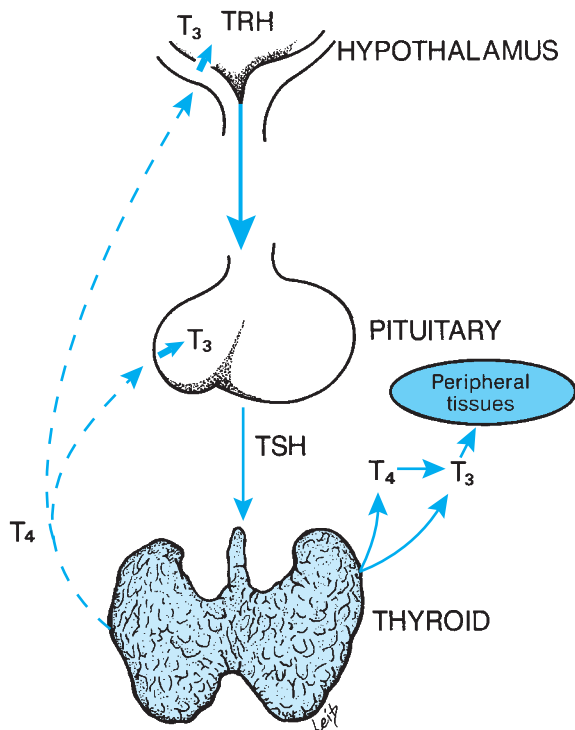

Thyroid hormone regulation is through a negative feedback loop involving the hypothalamus, the anterior pituitary, and the thyroid gland (Figure 108-2). Thyrotropin-releasing hormone (TRH), synthesized and stored within the hypothalamus, stimulates the release of thyroid-stimulating hormone (TSH) from the anterior pituitary gland. TSH binds to the TSH receptor located on the outer side of the thyroid cell plasma membrane and increases thyroid hormone synthesis and secretion. In turn, T<sub>4</sub> and T<sub>3</sub> from the serum feedback on the pituitary and the hypothalamus to inhibit TSH and TRH production and secretion.

The secretory response of TSH to TRH stimulation in aging men has been reported to be decreased to 38% of the values in young men. This may be an adaptive mechanism to the reduced need for thyroid hormone in old age. However, other reports of TRH-stimulated TSH secretion with aging have shown an unchanged or even increased response.

The serum TSH concentration has been either unchanged, lowered, or increased with aging in various reports. The heterogeneity of the populations studied may explain some of these discrepancies. Studies employing sensitive TSH assays have raised the question of whether the abnormal TSH reflects the prevalence of thyroid disorders or physiologic changes related to aging. In a random selection of the community-based population followed in the Framingham Heart Study, euthyroid older persons were found to have the same level of TSH as younger persons, although older euthyroid women had a slightly lower serum TSH level than middle-aged women. In a study of healthy centenarians (age range, 100–110 years), the median serum TSH level was lower than that of older individuals (age range, 65–80 years). The data of this study are consistent with TSH being well preserved until the eighth decade of life in healthy elderly subjects, whereas a decline in TSH may occur in those older

**FIGURE 108-1.** Structures of T<sub>4</sub> and the enzymatic pathways for deiodination of T<sub>4</sub> to its major active metabolite, T<sub>3</sub>, and to reverse T<sub>3</sub> in peripheral tissues.

than 100 years of age. TSH levels rise about 50% in the late evening before the onset of sleep. Sleep attenuates this nocturnal peak of TSH secretion, and sleep deprivation exaggerates nocturnal TSH secretion. The diurnal variation of TSH levels has been reported to be absent in the elderly. The data from the healthy centenarians and individuals older than age 65 years also showed an age-related blunting of the nocturnal TSH peak. An increased prevalence of thyroid autoantibodies is also associated with human aging.

## SCREENING FOR THYROID DISEASE

Both functional and anatomic abnormalities of the thyroid gland occur with increasing prevalence as patients age, and may present with nonspecific clinical findings. Therefore, the clinician should maintain a low threshold for testing if a patient presents with symptoms or signs that suggest the presence of thyroid disease or with atypical clinical findings (e.g., unexplained weight loss caused by apathetic hyperthyroidism). Testing should also be carried out in patients with a prior history of thyroid disease, other autoimmune disease, unexplained depression, cognitive dysfunction, or hypercholesterolemia.

Whether truly asymptomatic older subjects should be screened for thyroid disease is more controversial. The American Thyroid Association recommends screening all adults older than age 35 years for thyroid dysfunction and every 5 years thereafter. However, the American College of Physicians does not recommend routine screening

of asymptomatic patients because of presumed lack of demonstrated efficacy or proven benefit in treatment of subclinical thyroid disease. In our opinion, the high prevalence of hypothyroidism and often subtle or nonspecific symptoms in patients older than 65 years of age justifies periodic screening for hypothyroidism.

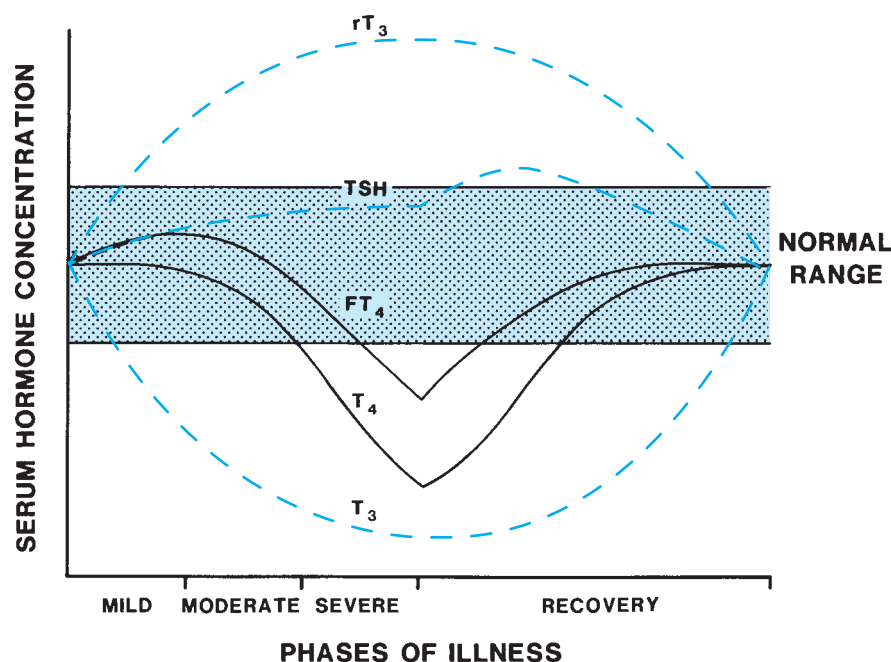

In most ambulatory patients, the measurement of a serum TSH level is sufficient to screen for thyroid dysfunction. Modern TSH assays are sufficiently sensitive to distinguish normal from low or high values. TSH levels become abnormal before serum T<sub>4</sub> or T<sub>3</sub> levels because of the exquisite sensitivity of the pituitary gland to small increments in thyroid hormone feedback. However, there are certain patient populations where TSH levels alone may not provide accurate information about thyroid function. Patients with pituitary or hypothalamic disorders may have altered thyroid function with misleading TSH levels, and a full panel of thyroid tests is required to characterize their thyroid function. More commonly, patients with serious acute or chronic illnesses or receiving certain drugs may have altered thyroid hormone and TSH levels that do not accurately reflect their thyroid function. These common scenarios are described in the sections below on nonthyroidal illness and drug effects on thyroid function.

## NONTHYROIDAL ILLNESS

The terms *sick euthyroid syndrome* or *nonthyroidal illness* (NTI) refer to altered serum thyroid hormone concentrations secondary to the physiologic stress of severe illness. By definition, patients with NTI have no apparent intrinsic thyroid disease. The types of illnesses responsible for thyroid function abnormalities include sepsis, surgery, trauma, burns, infections, malignancy, and chronic metabolic diseases such as malnutrition, starvation, and poorly controlled diabetes mellitus. An understanding of the effect of NTI on thyroid function tests is important, especially in the elderly patient who has multiple other underlying medical problems.

The effects of NTI on thyroid function have been described as the low T<sub>3</sub> and low T<sub>4</sub> states. The low T<sub>3</sub> state is associated with a decrease in extrathyroidal T<sub>3</sub> production, resulting in a low serum total T<sub>3</sub> level and usually low free T<sub>3</sub> level with a normal serum TSH concentration. With more severe illness, the serum T<sub>4</sub> level decreases. In severe NTI, the decreases in T<sub>4</sub> and T<sub>3</sub> maybe an adaptation to spare the patient from the catabolic effect of thyroid hormone during the periods of extreme stress. A reduction in serum T<sub>3</sub> concentration is the most common change of thyroid function tests in NTI with a frequency of 25% to 50%. The severity of the underlying illness correlates with the degree of the fall in serum T<sub>3</sub> concentration. The mechanisms responsible for low T<sub>3</sub> concentration are (1) a decrease in the peripheral conversion of T<sub>4</sub> to T<sub>3</sub> either because of inhibition of the 5′-deiodinase that is responsible for this conversion or because of a deficiency of a cofactor, such as glutathione, which is necessary for the activity of 5′-deiodinase; (2) a decrease in T<sub>3</sub> secretion from the thyroid gland; and (3) a decrease in tissue uptake of T<sub>4</sub> that limits the conversion of T<sub>4</sub> to T<sub>3</sub> in the extrathyroidal tissues. The serum rT<sub>3</sub> is increased in NTI because of the impaired rT<sub>3</sub> clearance as a consequence of the decreased activity of 5′-deiodinase with illness. The central question is how does the body maintain a euthyroid state when serum T<sub>3</sub> is reduced? The basis for an apparent euthyroid status in NTI is still unclear. There are several possible explanations: (1) T<sub>3</sub> concentrations may remain normal in the

### CONTINUUM OF THYROID HORMONE AND THYROTROPIN PROFILES IN NONTHYROIDAL ILLNESS AND RECOVERY

**FIGURE 108-3.** The relative changes in serum thyrotropin and thyroid hormone concentrations with increasing severity of nonthyroidal illness and with recovery. Serum  $T_4$  and free  $T_4$  falls with more severe illness, whereas serum  $T_3$  is subnormal in mild illness. The recovery is generally a reverse of the illness pattern with a slight elevation of serum TSH in many instances.

intracellular compartment even though serum  $T_3$  level is decreased; (2)  $T_3$  maybe converted to triiodothyroacetic acid (Triac), which is metabolically active; and (3) studies of patients with various acute illnesses showed an increase in  $T_3$ -receptor messenger ribonucleic acids (mRNAs) and  $T_3$ -receptor protein that results in an increase in production of proteins that express the action of thyroid hormone, hence maintaining a euthyroid state in NTI.

The patients with the low  $T_4$  state, also known as a low  $T_3/T_4$  state, exhibit a low serum thyroxine level as well as low  $T_3$  with a normal serum TSH concentration. Low serum total  $T_4$  correlates with a poor prognosis. The mortality of critically ill patients with NTI is inversely related to serum  $T_4$  concentration and has been reported to be as high as 84% in patients with serum  $T_4$  concentration less than  $3 \mu\text{g/dL}$ . There is no clear mechanism to fully explain the low  $T_4$  state; however, possibilities include (1) reduced TBG concentration as a consequence of reduced hepatic protein synthesis; (2) inhibition of serum  $T_4$  binding to TBG, probably by a substance released by injured tissue, or an acquired structural alteration of TBG that reduces its affinity for  $T_4$ ; (3) alterations in hepatic uptake and metabolism of  $T_4$ ; and (4) reduced secretion of  $T_4$  caused by alteration in the structure of TSH, resulting in decreased biologic activity. Proinflammatory cytokines produced by the mononuclear cells (macrophages, lymphocytes, and monocytes) of the immune system in patients with NTI are probably responsible for the changes in thyroid function tests. Administration of proinflammatory cytokines such as tumor necrosis factor (TNF)- $\alpha$  and interleukin (IL)-1 to experimental animals made the animals sick and reduced serum  $T_4$ ,  $T_3$ , and TSH concentrations. These cytokines inhibit thyroid iodide uptake by reducing the activity and transcription of the sodium iodide symporter, and they inhibit  $T_3$  production by reducing the activity and transcription of 5'-deiodinase.

Recovery from the underlying illness results in improvement of the low  $T_3$  and  $T_4$  states. Serum  $T_4$  level returns to normal faster than

serum  $T_3$  level. Serum TSH concentration usually remains normal except in those patients receiving pharmacologic doses of dopamine or glucocorticoids, which reduce serum TSH levels. During the recovery stage, serum TSH usually remains in the normal range, but it may transiently increase above the normal range. [Figure 108-3](#) diagrams the changes in thyroid hormone and serum TSH levels in NTI.

The effects of thyroid hormone replacement in NTI have been studied. Treatment of the low  $T_3$  state with replacement doses of  $T_3$  was found to be detrimental in a fasting model of NTI, resulting in an increase in protein catabolism and possibly muscle breakdown.  $T_3$  given intravenously to cardiac patients undergoing open-heart surgery improved cardiac performance, but this was not confirmed in randomized trials.  $T_4$  therapy in severe NTI had no beneficial effects and did not improve survival.

### DRUGS AND THYROID FUNCTION

Altered sensitivity to drugs is particularly relevant in elderly patients with thyroid diseases. The metabolism and secretion of many drugs are attenuated in hypothyroidism and accelerated in thyrotoxicosis. Hypothyroidism results in increases in the plasma half-life of digoxin, insulin, glucocorticoids and morphine; consequently, sensitivity to the toxic effects of these drugs increases and doses should be decreased until the patient is euthyroid. Opposite metabolic changes in hyperthyroidism result in increased maintenance doses of these drugs while the patient is hyperthyroid. Resistance to the anticoagulant effect of warfarin in hypothyroidism is a result of slower-than-normal clearance of vitamin K-dependent coagulation factors; an augmented response is seen in hyperthyroidism.

Medications can affect many aspects of thyroid hormone secretion, absorption, transport, or metabolism, as listed in [Table 108-2](#).

**TABLE 108-2****Drugs That Affect Thyroid Function**

## Decrease TSH secretion

Dopamine  
 Glucocorticoids  
 Octreotide  
 Bexarotene

## Increase thyroid hormone secretion

Iodine and iodine-containing compounds  
 Amiodarone  
 Lithium  
 Interferon alpha and IL-2

## Decrease thyroid hormone secretion

Thionamides (propylthiouracil, methimazole)  
 Lithium  
 Iodine and iodine containing compounds  
 Amiodarone  
 Aminoglutethimide  
 Interferon alpha and interleukin 2  
 Sunitinib

Decrease T<sub>4</sub> absorption

Calcium  
 Proton pump inhibitors  
 Cholestyramine, Colestipol  
 Aluminum hydroxide, sevelamer  
 Ferrous sulfate  
 Sucralfate  
 Raloxifene (?)

## Increase serum TBG

Estrogen  
 Tamoxifen and raloxifene  
 Clofibrate  
 Fluorouracil and capecitabine  
 Mitotane  
 Heroin  
 Methadone

## Decrease serum TBG

Androgen  
 Anabolic steroids (danazol)  
 Glucocorticoid

## Inhibit thyroid hormone binding to transport proteins

Phenytoin and carbamazepine  
 Furosemide  
 Salicylates and salsalate  
 Fenclufenac and meclufenamate  
 Heparin  
 Sulfonylureas

Decrease T<sub>4</sub> 5'-deiodinase activity

Propylthiouracil  
 Amiodarone  
 Glucocorticoids

Increase hepatic T<sub>4</sub> and T<sub>3</sub> metabolism

Phenobarbital  
 Rifampin  
 Phenytoin  
 Carbamazepine  
 Sertraline

A few drugs have been shown to suppress TSH secretion, most commonly seen in patients with critical illnesses receiving glucocorticoids and/or dopamine who can have low or undetectable TSH levels as a result. Low TSH levels are also seen during octreotide therapy for acromegaly or other rare endocrine diseases, and during administration of the retinoid X receptor ligand bexarotene for malignancies. Some of these patients develop central hypothyroidism and require thyroxine therapy.

A second major category of drugs that affect thyroid function include agents that directly increase thyroid hormone secretion. This may occur as a result of stimulation of a thyroid gland with underlying autonomous function, such as latent Graves' disease or a multinodular goiter. Iodine, iodine-containing radiocontrast agents, and amiodarone all act in this way to increase thyroid hormone synthesis and precipitate hyperthyroidism. A second mechanism is induction of destructive thyroiditis, leading to release of preformed thyroid hormone and transient thyrotoxicosis, as can occur with amiodarone, lithium, or the cytokines interferon alpha and IL-2.

Another class of drugs decreases thyroid hormone secretion. The thionamides propylthiouracil and methimazole are potent inhibitors of thyroid hormone synthesis and are used to treat hyperthyroidism. This class also includes iodine and iodine-containing agents, which can suppress thyroid hormone secretion in patients with underlying defective thyroid glands (e.g., Hashimoto's disease). It also includes some of the same drugs that cause thyroiditis, including amiodarone, lithium, and interferon alpha and IL-2. During drug-induced thyroiditis, the initial thyrotoxic phase is followed by a phase of reduced thyroid hormone secretion until the injured gland can recover synthetic function. The tyrosine kinase inhibitor, sunitinib, used to treat renal cancer and gastrointestinal stromal tumor, and aminoglutethamide, used to treat adrenal cancer, have also been reported to decrease thyroid hormone secretion.

A number of agents decrease thyroid hormone absorption from the gastrointestinal tract, including drugs commonly prescribed for elderly patients like calcium, ferrous sulfate, and proton pump inhibitors. These drugs do not affect thyroid hormone levels in euthyroid subjects, but they can lead to thyroxine malabsorption in patients taking exogenous thyroxine. Thyroxine should be given separately from these drugs, and the dose may have to be increased as well.

Drugs that cause increased serum TBG levels lead to increases in serum total T<sub>4</sub> and total T<sub>3</sub>. Free T<sub>4</sub>, free T<sub>3</sub>, and TSH levels remain normal, attesting to the patient's euthyroid state. The most common cause of increased serum TBG and T<sub>4</sub> concentrations in postmenopausal women is estrogen replacement therapy. The serum TBG concentration is increased by 30% to 50% in women receiving 0.625 mg of conjugated estrogen daily. Less common are drugs that lower serum TBG (and therefore total T<sub>4</sub> and total T<sub>3</sub>) levels.

Other drugs inhibit thyroid hormone binding to TBG and other transport proteins. Like agents that decrease TBG levels, this inhibition causes low total T<sub>4</sub> levels, with normal free T<sub>4</sub> and TSH levels, with the patient remaining euthyroid. The most frequently prescribed drugs in this category include high-dose aspirin or salsalate, high-dose furosemide, and heparin.

Drugs that inhibit 5' deiodinase activity include propylthiouracil, amiodarone, propranolol, and glucocorticoids. These agents block T<sub>4</sub> to T<sub>3</sub> conversion, but do not lead to clinical thyroid disease in euthyroid subjects.

The activity of the hepatic microsomal enzymes that metabolize  $T_4$  and  $T_3$  is increased by phenobarbital, rifampin, phenytoin, and carbamazepine. Hypothyroid patients treated with levothyroxine may become hypothyroid again when these agents are administered, and some patients require substantial increases of thyroxine dose.

## HYPOTHYROIDISM

### Definition

*Hypothyroidism* is a general term that refers to a state of decreased thyroid hormone availability to peripheral tissues. *Overt hypothyroidism* occurs when serum  $FT_4$  levels are below the normal range and usually is associated with some symptoms of hypothyroidism. Mild thyroid failure with an elevated serum TSH level and normal  $FT_4$  concentration is referred to as *subclinical (biochemical) hypothyroidism*. Subclinical hypothyroidism is discussed in depth at the end of this section.

### Prevalence

The prevalence of hypothyroidism varies based on the population under study (i.e., geriatric inpatient vs. primary care setting), age range, ethnicity, iodine content of the diet, and prevalence of antithyroid antibodies. In patients older than 60 years of age in the general population, the incidence of overt hypothyroidism is 2.3% to 10.3%. As dietary iodine intake increases, these rates also increase as a result of iodine effects to suppress the thyroid gland. In a comparative study of healthy elderly female patients, the prevalence of hypothyroidism in Regio Emilia, Italy, where there is low dietary iodine intake, was 0.9%, whereas a prevalence of 14% was found in Worcester, Massachusetts, where the dietary iodine is much higher.

### Etiology and Pathogenesis

Table 108-3 lists the main causes of hypothyroidism. Primary hypothyroidism accounts for the vast majority of cases of thyroid failure. Less than 1% of cases are caused by central hypothyroidism.

In the areas of adequate iodine intake, chronic autoimmune (Hashimoto's) thyroiditis is the most common cause of primary hypothyroidism in elderly people, and is more common in women. Chronic autoimmune thyroiditis is characterized pathologically by a focal or diffuse lymphocytic infiltration of thyroid parenchyma and damaged or atrophic follicles. The thyroid may be enlarged or atrophic. Thyroid atrophy has been attributed to blocking antibodies that bind to the TSH receptor and inhibit the action of TSH.

Autopsy reports from the United Kingdom and the United States reveal the presence of focal thyroiditis in 40% to 50% of women and in 20% of men with no prior history of thyroid diseases. The incidence of chronic autoimmune thyroiditis was significantly higher in Caucasians than in African-Americans in the same study. Antithyroid peroxidase (antimicrosomal) or antithyroglobulin antibodies are present in the serum of greater than 90% of patients with chronic autoimmune thyroiditis. The prevalence of positive thyroid antibodies increases with age, with frequencies as high as 33% in women

**TABLE 108-3**

### Causes of Hypothyroidism in the Elderly Population

Primary hypothyroidism
Chronic autoimmune thyroiditis (Hashimoto's thyroiditis)
Radiation
$^{131}I$ therapy for hyperthyroidism
Radiation therapy for head and neck cancer
Surgical thyroidectomy
Drugs
Iodine-containing drugs: amiodarone, radiocontrast agents containing iodine
Antithyroid drugs (propylthiouracil, methimazole)
Other drugs that decrease TSH or thyroid hormone secretion (see Table 108-2)
Central hypothyroidism
Hypothalamic tumors or infiltrative lesions
Pituitary tumors or infiltrative lesions
Pituitary surgery
Radiation

older than 70 years of age. The presence of antithyroid antibodies increases the risk of developing subclinical or overt hypothyroidism, and also increases the risk of progression from subclinical to overt hypothyroidism.

The second most common cause of hypothyroidism is iatrogenic, caused by radiation treatment to the thyroid gland or thyroid surgery. Radiation-induced hypothyroidism is caused by either radioactive iodine treatment of hyperthyroidism or by external radiation therapy of head and neck cancers. Hypothyroidism has been reported in 76% of hyperthyroid patients treated with radioiodine and 20% to 47% of patients receiving radiotherapy for treatment of various malignancies of the head and neck region. This may take many years to develop, so patients having received radiation treatment at a young or middle age may develop hypothyroidism in old age.

Hypothyroidism in the elderly person maybe precipitated by certain drugs listed in Table 108-2. Patients with underlying autoimmune thyroid disease are more susceptible to developing iodine-induced hypothyroidism. This effect is a result of iodine-induced inhibition of thyroid hormone synthesis. Exposure of an elderly patient to iodine can occur as a result of administration of iodine-containing radiocontrast agents used during computed tomography (CT) scanning. Another source of exposure is the use of amiodarone, an iodine-containing drug used for treatment of arrhythmias. The incidence of amiodarone-induced hypothyroidism varies with the environmental iodine intake, with frequency of 10% to 30% in the United States. Overtreatment of hyperthyroidism with thionamide drugs (propylthiouracil, methimazole) can lead to hypothyroidism. A number of other drugs that suppress TSH or  $T_4$  secretion (listed in Table 108-2) can precipitate hypothyroidism in elderly patients. Finally, there are drugs that interfere with exogenous thyroid hormone absorption, also listed in Table 108-2. These drugs do not cause hypothyroidism in euthyroid subjects, but they can lead to inadequate thyroid hormone dosing and hypothyroidism in thyroxine-treated patients who previously had normal TSH levels. Common culprits include calcium, ferrous sulfate, and proton pump inhibitors, all frequently prescribed in the elderly population.

Central hypothyroidism, resulting from an anatomic or functional disorder of the pituitary gland or the hypothalamus or both, is relatively rare. Thyroid hormone secretion is reduced secondary to deficient stimulation of the normal thyroid gland by TSH. The impairment of TSH secretion is caused by either primary or metastatic pituitary tumors, infiltrative lesions, external radiotherapy, or surgery.

### Clinical Manifestations

The classic signs and symptoms of hypothyroidism include fatigue, weight gain, cold intolerance, dry skin, and constipation. Many elderly hypothyroid patients exhibit these classic findings, but they are often attributed to other comorbid conditions or to the aging process itself. This is because they are nonspecific and because hypothyroidism usually has an insidious onset and slow progression over months to years. Hypothyroidism may also present in a less typical fashion in elderly patients. Table 108-4 lists the common clinical features of symptomatic hypothyroidism in older patients, including findings that tend to occur at all ages, as well as neurologic, psychiatric, and cardiac features that particularly affect older patients. Table 108-5 compares signs and symptoms of overt hypothyroidism between elderly and younger patients. In the study summarized in this table, the mean serum TSH and FT<sub>4</sub> levels and duration of disease were similar between the two groups of patients. This study showed that the classic signs of overt hypothyroidism such as cold intolerance, paresthesias, weight gain, and muscle cramps were less frequent in older patients. The remainder of this section

**TABLE 108-5**

#### Comparison of Clinical Features of Overt Hypothyroidism in Elderly versus Young Patients

Symptoms and Signs	Elderly, ≥70 Years (%)	Young, ≤55 Years (%)
Bradycardia	12	19
Fatigue	68	83
Weight gain	24	59
Cold intolerance	35	65
Depression	28	52
Disorientation	9	0
Hypoactive reflexes	24	31
Weakness	53	67
Paresthesia	18	61
Dry skin	35	45
Hair loss	12	28
Reduced hearing	32	25
Muscle cramps	20	55
Snoring	18	22
Constipation	33	41

From Hassani S, Hershman JM. Thyroid diseases. In: Hazzard WR et al., eds. *Principles of Geriatric Medicine & Gerontology*. 5th ed. New York, New York: McGraw-Hill; 2003:843.

reviews some of the clinical aspects of hypothyroidism that are most relevant to the elderly population.

The neuropsychiatric features of hypothyroidism in the elderly population are initially nonspecific. Patients may report slowing of thought processes. As the patient becomes less motivated and responsive to others, disoriented, and less interested in usual activities, the diagnosis may be confused with that of depressive mood disorder. Older people who present with deterioration in personality, retardation of thought or action, apathy, or global loss of intellectual function should be evaluated for hypothyroidism. As hypothyroidism becomes more severe, paranoia, delusions, hallucinations, and psychosis may develop. Because of these symptoms, hypothyroidism can be a cause of “pseudodementia” in some elderly people. However, hypothyroidism as a major contributing cause of dementia is rare; in one study of patients with dementia, the incidence of hypothyroidism was the same as in the general population. In another study of demented patients, 2.3% were found to have hypothyroidism, of whom only 25% improved with treatment.

Abnormalities in plasma lipids are among the most important metabolic changes that occur in hypothyroidism. Both hypercholesterolemia and hypertriglyceridemia can occur, and may exacerbate primary hyperlipidemia in older patients. In the majority of overt hypothyroid patients, hypercholesterolemia (plasma cholesterol level >250 mg/dL) is present. A reduction in cholesterol uptake because of reduced number of low-density lipoprotein (LDL) receptors results in an increase in low-density cholesterol-carrying apolipoprotein concentration. The synthesis rate of free fatty acids and triglycerides is normal in hypothyroidism; the hypertriglyceridemia is caused by a decreased fractional removal rate of triglycerides.

Thyroid hormone deficiency causes several cardiac abnormalities. Cardiomegaly is secondary to hypothyroid-induced pericardial effusion, bradycardia, diastolic hypertension, and/or atherosclerosis.

**TABLE 108-4**

#### Clinical Features of Hypothyroidism in Elderly Patients

Dry skin
Hair loss
Edema of face and eyelids
Cold intolerance
Neurologic
Paresthesia (carpal tunnel syndrome)
Ataxia
Dementia
Psychiatric and behavioral
Depression
Apathy or withdrawal
Psychosis
Cognitive dysfunction
Metabolism
Weight gain
Hypercholesterolemia
Hypertriglyceridemia
Peripheral edema
Musculoskeletal
Myopathy
Arthritis/arthralgia
Cardiovascular
Bradycardia
Pericardial effusion
Congestive heart failure

Pericardial effusion is found in approximately 30% to 50% of patients with overt hypothyroidism. The volume of the effusion correlates with the severity of the disease. The electrocardiogram may show ST and T wave changes, QT prolongation, and more often low-amplitude QRS complexes or a low voltage that is a result of pericardial effusion rather than a myocardial conduction defect. Cardiac tamponade and hemodynamic compromise are very rare. Bradycardia results from the effects of thyroid hormone deficiency on the cardiac conducting system. The slowing of the heart rate is moderate and its role in the development of fatigue in hypothyroid patients is unclear. Hypothyroidism may mask typical symptoms of coronary artery disease by causing depressed myocardial contractility and bradycardia, resulting in reduced myocardial oxygen consumption.

Exertional dyspnea and reduced exercise tolerance are present in 50% of elderly patients with overt hypothyroidism and maybe related to skeletal muscle dysfunction rather than impaired cardiac function. Anginal chest pain was reported in 25% of patients with overt hypothyroidism, suggesting an increased prevalence of coronary heart disease in these patients. Patients with a long-standing history of hypothyroidism are especially at risk of developing atherosclerotic vascular disease that may have been induced by diastolic hypertension and hypercholesterolemia. Hypothyroidism predisposes to diastolic hypertension by impairment of the diastolic relaxation phase. Approximately 1% of patients with diastolic hypertension may have hypothyroidism as the cause. Blood pressure normalizes with thyroid hormone replacement therapy in such patients.

Given the prevalence of hypothyroidism in the elderly population and the comorbidities listed above, it is not uncommon to be faced with an untreated elderly hypothyroid patient who requires surgery. A few small, retrospective studies suggest that surgery is relatively safe in hypothyroid subjects, and urgent surgery does not need to be postponed while therapy is started. However, particular attention must be given to anesthetic and drug administration since hypothyroid patients clear medications more slowly than euthyroid patients.

## Diagnosis

The diagnosis of primary hypothyroidism is relatively straightforward since all cases are associated with elevated serum TSH levels. The serum-free  $T_4$  level will be low in overt hypothyroidism and will be normal in subclinical hypothyroidism. Serum  $T_3$  concentrations are not helpful in diagnosing hypothyroidism since they are normal in about one-third of overtly hypothyroid patients and since they do not decrease below normal until the free  $T_4$  is already low. Therefore, TSH and free  $T_4$  levels are sufficient diagnostic tests for hypothyroidism.

There is some controversy regarding what TSH level indicates hypothyroidism. Most laboratories currently report upper limits of the TSH normal range to be approximately 4.5 to 5.0 mU/L. However, the upper normal range is lowered to 3.5 to 4.0 mU/L if subjects with antithyroid peroxidase antibodies are excluded, suggesting that the reported normal range includes subjects with incipient thyroid disease. This has led some experts to recommend a narrower TSH normal range, with TSH levels above 3.5 mU/L consistent with mild thyroid disease. If adopted, this would reclassify millions of patients as being hypothyroid or undertreated with thyroid hormone. There is almost no information on putative clinical effects in patients with

TSH levels of 3.5 to 5.0 mU/L, and therefore at this time it is premature to adopt this recommendation.

There are a few other caveats to the biochemical diagnosis of hypothyroidism. An elevated serum TSH level also may be seen during the recovery period from NTI or after withdrawal of certain drugs that suppress TSH levels. Therefore, the serum TSH measurement must be interpreted in the context of the clinical situation. Central hypothyroidism results in low serum  $T_4$  and  $T_3$  levels with a low or normal serum TSH concentration, rather than an elevated TSH level.

## Treatment

The purpose of treatment of hypothyroidism, regardless of its cause, is to achieve a euthyroid state that is reflected by normal thyroid function tests. Synthetic levothyroxine is the preferred preparation for treatment of hypothyroidism because of its long half-life (approximately 7 days), reliable absorption, and relatively constant serum  $T_4$  concentration after single daily doses. The replacement therapy dose of levothyroxine depends on the weight and age of the patient. Thyroxine requirements are decreased in the elderly because of a decline in the degradation of thyroid hormone. The average requirement of  $T_4$  in elderly patients is 25% less than in young adults.

In elderly patients with coexisting cardiovascular disease, starting treatment with full replacement doses can result in exacerbation of angina and worsening of the underlying heart disease. Therefore, it is crucial that the starting dose of thyroxine should be small, such as 12.5 to 25  $\mu\text{g}/\text{day}$ . The replacement dose titration needs to be done cautiously with close monitoring of the patient's symptoms and thyroid function tests. The dose should be adjusted at 6-week intervals by an increment of 12.5 to 25  $\mu\text{g}$  until the patient is euthyroid and the serum TSH is in the mid-normal range. Once the serum TSH level is within the normal range, its measurement may be done every 6 to 12 months to monitor the dose and compliance. Patients with primary hypothyroidism can be monitored with a TSH alone, while patients with central hypothyroidism should be monitored by free  $T_4$  measurement.

Levothyroxine absorption is decreased by food, a high-fiber diet, conditions associated with impaired gastric acid production, and a number of medications (see [Table 108-2](#)). Drugs that block its absorption include calcium carbonate, ferrous sulfate, proton pump inhibitors, cholestyramine, colestipol, sucralfate, and aluminum hydroxide. This malabsorption of thyroxine can be avoided to a large extent by instructing the patient to allow a time interval of at least 4 hours between the ingestion of the two drugs, but in some cases, an increase in thyroxine dose maybe required (such as during proton pump inhibitor therapy). Other medications accelerate thyroxine clearance, including rifampin, carbamazepine, phenytoin, and sertraline. Therefore, a higher levothyroxine replacement dose is required. Finally, estrogen therapy increases TBG levels, leading to a greater amount of administered thyroxine being bound to TBG and an increased thyroxine dose requirement.

## Subclinical Hypothyroidism

*Subclinical hypothyroidism* is the term applied to the state in which serum TSH concentration is raised while free  $T_4$  and  $T_3$  concentrations are normal in a patient with no clinical features of hypothyroidism. Serum TSH concentrations bear a logarithmic relation to

free T<sub>4</sub> levels; small decrements in free T<sub>4</sub> concentration (even within the population normal range) result in large increases in serum TSH concentration.

The prevalence of subclinical hypothyroidism is age dependent. The classic Whickham survey in Great Britain reported increasing prevalence of elevated TSH levels with age, up to 18% in women older than 74 years of age. The more recent Colorado Health Fair study reported a prevalence of elevated TSH levels of 9.5% in the entire study population, rising to 19% in those older than 74 years of age. Finally, the most recent National Health and Nutrition Examination Survey in the United States found that 12% to 14% of the population older than age 70 years had high serum TSH, as compared with approximately 2% of the population younger than age 40 years.

Most studies show that older women are at greatest risk for subclinical hypothyroidism. In the Whickham survey, the prevalence of subclinical hypothyroidism was more than threefold increased in older women compared to older men. In a survey in the United States, the prevalence of serum TSH elevation was 8.5% in women and 4.4% in men older than age 55 years. However, rates of subclinical hypothyroidism among older men in the Colorado Health Fair study approached those of older women.

The common causes of subclinical hypothyroidism are the same as the causes of overt hypothyroidism (see Table 108-3). The majority of patients have chronic autoimmune thyroiditis with positive antithyroid peroxidase antibodies. Those patients with high titers of antithyroid antibodies and more than twice the upper limit of serum TSH are most likely to develop overt hypothyroidism. In the 20-year follow-up study of patients with subclinical hypothyroidism in the Whickham Survey, the annual rate of thyroid failure was 4.3% in those with positive thyroid antibodies, as compared to 0.3% in thyroid-antibody-negative patients.

The clinical manifestations of subclinical hypothyroidism are debated; some studies have suggested adverse effects on serum lipids, cardiac function, or neuropsychiatric function. Cardiac and lipid effects have received particular attention since a large-scale survey of elderly women in Rotterdam showed that subclinical hypothyroidism increased the risk for myocardial infarction two- to threefold. Lipid abnormalities associated with subclinical hypothyroidism have primarily included cholesterol or LDL levels slightly higher than euthyroid control groups. Cardiovascular abnormalities associated with mild thyroid failure include left ventricular diastolic and endothelial dysfunction. The cardiac structure and function remain normal at rest, but ventricular function and cardiovascular and respiratory adaptation are impaired during exercise. Left ventricular ejection fraction is similar to the euthyroid state at rest, but reduced with exercise. In terms of neuropsychiatric function, previous cross-sectional studies have suggested increased rates of anxiety, depression, or cognitive impairment in subclinical hypothyroidism. However, a recent large cross-sectional study failed to find any association between subclinical hypothyroidism and numerous measures of mood and cognition.

Further studies have assessed the effects of thyroxine treatment on serum lipid concentrations, cardiac function, cognitive function, and psychiatric status in subclinical hypothyroidism. Results have been mixed, with some studies showing decreased cholesterol and LDL levels, improved cardiac function, or improved cognitive and affective symptoms. However, not all studies have demonstrated these effects, which are often of small magnitude and unclear clinical rel-

evance. An expert consensus panel reviewed the efficacy of treating subclinical hypothyroidism. The panel concluded that treatment was reasonable in patients with TSH levels greater than 10 mU/L, those with symptoms, or those with elevated cholesterol levels. If implemented, the goal of therapy is to normalize the serum TSH concentration. In older people, 12.5 to 25  $\mu\text{g}$  levothyroxine is recommended as the initial dose. With minimal TSH elevations and absence of clinical features, treatment is not necessary, but patients should be followed at intervals of 6 months.

## Myxedema Coma

Myxedema coma is a rare syndrome that represents the result of severe untreated hypothyroidism. Most patients are older than 60 years of age. It is characterized by lethargy, progressive weakness, stupor, hypothermia, hyponatremia, cardiovascular shock, and coma. The mortality rate is very high in older patients, approximately 80% in untreated cases. Myxedema coma may be precipitated by exposure to cold weather; drugs such as narcotics, sedatives, analgesics, anesthetics, or tranquilizers; pulmonary or urinary tract infections; and other coexisting medical conditions such as cerebrovascular accidents or congestive heart failure.

The patient may have a history of a previous thyroid disease, radioiodine therapy, or thyroidectomy. The medical history is of gradual onset of progressive weakness and impaired cognitive function, depression, and stupor. Physical findings include marked hypothermia, bradycardia, hoarseness, delayed reflexes, dry skin, and periorbital edema. Laboratory evaluation may indicate hyponatremia, elevated creatine phosphokinase level, neutropenia with a left shift, elevated serum cholesterol level, increased cerebrospinal fluid protein, carbon dioxide retention, and hypoxia. Serum tests reveal a low FT<sub>4</sub> level and a markedly elevated TSH concentration, except in central hypothyroidism, in which case an increased serum TSH is not found.

Myxedema coma is an acute medical emergency and treatment should be initiated immediately; 500- $\mu\text{g}$  levothyroxine should be given by intravenous bolus because such patients absorb drugs poorly through the gastrointestinal tract. This is followed by daily administration of 50- $\mu\text{g}$  thyroxine intravenously. Because the possibility of concomitant adrenal insufficiency (because of autoimmune adrenal or pituitary insufficiency) may exist, hydrocortisone hemisuccinate 100 mg intravenously should be administered followed by 50 mg every 6 hours. A serum cortisol level should be obtained prior to hydrocortisone infusion. If the serum cortisol level is greater than 20  $\mu\text{g}/\text{dL}$ , then the corticosteroid can be discontinued. The patient's renal function, fluid status, and cardiopulmonary status must be monitored closely.

## HYPERTHYROIDISM

### Definition

*Hyperthyroidism* refers to a state of excessive thyroid hormone availability to peripheral tissues. *Overt hyperthyroidism* occurs when serum FT<sub>4</sub> and/or T<sub>3</sub> levels are above the normal range and usually is associated with symptoms of hyperthyroidism. Mild thyroid overactivity with a suppressed serum TSH level and normal FT<sub>4</sub> and

T<sub>3</sub> concentrations is referred to as *subclinical (biochemical) hyperthyroidism*. Subclinical hyperthyroidism is discussed in depth at the end of this section.

## Prevalence

There is a considerable variation reported in the prevalence of hyperthyroidism in older subjects. Based on different ethnic and geographic regions and the criteria used for diagnosis, the prevalence varies from 0.5% to 2.3% in the elderly population. Approximately 10% to 17% of all hyperthyroid patients are older than age 60 years.

## Etiology and Pathogenesis

By far the most common cause of hyperthyroidism in the general population is Graves' disease, or diffuse toxic goiter. In older patients, Graves' disease remains a common cause of hyperthyroidism, but other etiologies become more frequent. Graves' disease is an autoimmune disorder that results from the action of a thyroid-stimulating antibody on TSH receptors. TSH receptor antibodies are detectable in the serum of approximately 80% to 100% of untreated patients with Graves' disease. The cause of the extrathyroidal manifestations of Graves' disease, such as ophthalmopathy and dermopathy, is unknown. The proposed mechanism for the ophthalmopathy is the development of retrobulbar autoimmune inflammation caused by the release of cytokines, thickening of extraocular muscles, and swelling of orbital contents.

Toxic multinodular goiter is more common in the elderly population and has been reported in about one half of older patients with hyperthyroidism, especially in regions of relative iodine deficiency. It occurs most often in patients with a long-standing history of multinodular goiter. In most cases, the etiologic factor causing the transition from nontoxic to toxic multinodular goiter is unclear. However, there is generation of new follicles within the gland with functional autonomy independent from TSH stimulation. Autonomously functioning thyroid nodules synthesize and secrete thyroid hormones despite suppression of TSH secretion. Thyrotoxicosis can be precipitated in patients with nontoxic multinodular goiter by administration of a large iodine load such as radiocontrast agent or amiodarone.

Thyroiditis, either acute or subacute, occurs with less frequency in the aged as compared with younger patients with hyperthyroidism. Thyrotoxicosis results from extensive destruction of follicular cells by either an inflammatory or infectious process and release of T<sub>4</sub> and T<sub>3</sub> into the circulation. Certain drugs, including amiodarone, lithium, and cytokines such as interferon alpha and IL-2, may cause destructive thyroiditis and thyrotoxicosis.

Amiodarone-induced hyperthyroidism is particularly complex and difficult since the drug is prescribed to elderly patients with underlying cardiac disease or arrhythmias, which increases the risks of the superimposed hyperthyroidism. Amiodarone-induced thyrotoxicosis (AIT) in association with iodine excess is termed type 1 AIT, while destructive thyroiditis is called type 2 AIT. A combination of type 1 and type 2 AIT can also occur. Treatment can be difficult, and recommendations vary depending on whether the patient has type 1 or type 2 AIT. Unfortunately, distinguishing between the two types of AIT is sometimes impossible, especially in the acute situation, and patients are often treated simultaneously for both.

Hyperthyroidism resulting from a TSH-secreting pituitary adenoma or pituitary resistance to thyroid hormone is very rare. Clinical manifestations are similar to those of Graves' disease except that the patient does not have a suppressed TSH level.

## Clinical Manifestations

The classic signs and symptoms of hyperthyroidism include weight loss with increased appetite, heat intolerance, excessive sweating, diarrhea or loose stools, tremor, tachycardia, and palpitations. Although they can be present, these classic findings are less common in older patients with hyperthyroidism. Absence of the typical manifestations of hyperthyroidism in the elderly patient was first described in 1931 by Lahey as "apathetic hyperthyroidism," in which there was only slight evidence of hypermetabolism. Instead, the dominant clinical findings maybe weight loss or cardiac or gastrointestinal manifestations, and the diagnosis of hyperthyroidism maybe overlooked. [Table 108-6](#) lists the signs and symptoms of hyperthyroidism in the elderly patient. Recognition of these important clues will facilitate detection of the disease at an earlier stage.

[Table 108-7](#) compares clinical findings of hyperthyroidism in elderly and young patients independent of etiology. In this study, thyroid hormone levels were similar in both groups, and there was no correlation between serum TSH and FT<sub>4</sub> levels and the prevalence of signs and symptoms of hyperthyroidism. The results of this study confirm that the presentation of hyperthyroidism in older patients is associated with fewer classic signs or symptoms and increased frequency of anorexia, atrial fibrillation, and a lack of goiter. Interestingly, palpable goiter is absent in approximately 50% of the older patients with hyperthyroidism, whereas 80% of the younger patients have thyroid enlargement on physical examination.

The cardiovascular manifestations of thyrotoxicosis may predominate in elderly patients, especially atrial fibrillation or supraventricular tachycardia. Occult hyperthyroidism should be ruled out in any elderly patient with a new onset of tachyarrhythmias. Elderly hyperthyroid patients with atrial fibrillation are at risk for systemic embolization and stroke, especially those with coexisting cardiac disease.

**TABLE 108-6**

### Clinical Features of Hyperthyroidism in Elderly Patients

Cardiovascular
Palpitations
Chronic or intermittent atrial fibrillation
Congestive heart failure
Psychiatric and behavioral
Depression
Apathy
Lethargy
Irritability
Gastrointestinal
Decreased appetite
Weight loss
Nausea
Constipation
Musculoskeletal
Proximal muscle weakness
Muscle atrophy

**TABLE 108-7****Comparison of Clinical Features of Hyperthyroidism in Elderly versus Young Patients**

Symptoms and Signs	Elderly, >70 Years (%)	Young, <50 Years (%)
Tachycardia	71	96
Fatigue	56	84
Weight loss	50	51
Tremor	44	84
Dyspnea	41	56
Apathy	41	25
Anorexia	32	4
Nervousness	31	84
Hyperactive reflexes	28	96
Weakness	27	61
Depression	24	22
Increased sweating	24	95
Diarrhea	18	43
Muscular atrophy	16	10
Confusion	16	0
Heat intolerance	15	92
Constipation	15	0

The excessive amounts of thyroid hormones in hyperthyroidism increase myocardial oxygen demand and may unmask coronary artery disease or exacerbate underlying cardiac conditions such as angina pectoris or congestive heart failure. Elderly patients with thyrotoxicosis and evidence of cardiac contractile dysfunction caused by hypertension, coronary artery disease, valvular heart disease, or atrial fibrillation are at higher risk of developing congestive heart failure.

Dyspnea on exertion and exercise intolerance are also common complaints of thyrotoxic patients. These symptoms can be caused by weakness of the skeletal and respiratory muscles rather than compromised cardiac function. Marked weakness and atrophy of muscles may have an insidious onset and slow progression in some elderly patients with thyrotoxicosis that has been long-standing as a result of delayed diagnosis because of its atypical presentation. Weakness involves mostly the proximal muscles, especially those of the shoulder girdle and the pelvis.

The classic gastrointestinal signs and symptoms of hyperthyroidism are increased appetite, rapid intestinal transit, resulting in more frequent defecation, and weight loss. However, some elderly patients with apathetic hyperthyroidism present with weight loss, anorexia, nausea, vomiting, and constipation. In a group of 880 patients with Graves' disease, weight loss became a major diagnostic finding in 80% of patients older than age 70 years. This weight loss is secondary to increased metabolic demands and reduced appetite. Thus, hyperthyroidism should be ruled out as a cause of weight loss in elderly patients before proceeding with an extensive evaluation for occult malignancy or gastrointestinal disease.

The neurobehavioral and psychiatric changes associated with hyperthyroidism in young adults include anxiety, emotional lability, insomnia, lack of concentration, restlessness, and tremulousness. In contrast to these features, apathy, lethargy, pseudodementia, and depressed mood frequently are present in older people with hyperthyroidism. Patients with an atypical depression (an increased

prevalence of somatic complaints, anxiety, and fewer complaints of sadness or guilt) later in life should be evaluated for hyperthyroidism.

## Diagnosis

The preferred approach to diagnosis of hyperthyroidism is the combination of free thyroxine or free thyroxine index level (either of which will be elevated) and a sensitive TSH assay (which will be suppressed). Although serum TSH level is suppressed in hyperthyroidism, there are other reasons for a suppressed TSH, so this test alone in a geriatric patient is not diagnostic of hyperthyroidism. In fact, most elderly subjects with low serum TSH levels are not hyperthyroid (see "Subclinical Hyperthyroidism" later in this chapter). Medications such as dopamine or glucocorticoids and conditions such as hypothalamic or pituitary disorders may cause suppression of the serum TSH level.

An elevation of serum  $T_3$  level in addition to an elevated serum  $T_4$  level is a strong confirmation of hyperthyroidism. However, the serum  $T_3$  level is not increased in every elderly patient with hyperthyroidism and was found to be elevated in only 50% of such patients between 75 and 95 years of age. The relative absence of  $T_3$  elevation maybe a reflection of less conversion of  $T_4$  to  $T_3$  peripherally in the aged population.

Patients with a low serum TSH and normal  $FT_4$  levels should have the  $T_3$  level measured to identify  $T_3$  thyrotoxicosis, a condition seen in 1% or 2% of hyperthyroid patients in the United States.  $T_3$  thyrotoxicosis is more common in elderly patients with a solitary adenoma or with early toxic multinodular goiter. Its causes and treatment are the same as for hyperthyroidism in general.

Once hyperthyroidism is detected, a 24-hour radioactive iodine uptake should be done to exclude conditions causing thyrotoxicosis with low thyroid uptake: thyroiditis, exogenous intake of thyroid hormone, or iodine-containing drugs. If there is concern for a toxic nodule or toxic multinodular goiter, a 24-hour radioactive iodine scan can be added to the uptake measurement.

## Treatment

The preferred mode of therapy for hyperthyroidism in the elderly is radioactive iodine-131. To avoid postradiation release of preformed thyroid hormone from glandular stores and subsequent exacerbation of hyperthyroidism, severely affected patients should be treated with antithyroid drugs for at least 3 months to achieve a normal or near-normal serum free  $T_4$  level prior to use of  $^{131}I$ . The usual doses are 5 to 15 mCi of radioactive  $^{131}I$  for Graves' disease and 15 to 50 mCi for large multinodular glands. The antithyroid drugs should be discontinued 7 days before administration of the radioiodine dose and restarted 7 days after  $^{131}I$  treatment. Beta-blockers are often used as an adjuvant, especially in cases of symptomatic tachycardia, and should be continued until the patient is euthyroid. The incidence of hypothyroidism in the first year after radioiodine treatment is dose-dependent, ranging up to 90%, and hypothyroidism continues to develop in subsequent years. Therefore, the patient should be monitored regularly for the development of hypothyroidism, and thyroxine therapy should be started promptly after the diagnosis of hypothyroidism is established.

Therapy with thionamide antithyroid drugs is also appropriate for otherwise healthy elderly patients with Graves' disease or toxic nodular goiters. Propylthiouracil and methimazole are the antithyroid drugs available in the United States. Methimazole is preferred over propylthiouracil since it can be given once a day and has a better side effect profile. When used for Graves' disease, thionamides are usually given for 12 to 18 months and then discontinued to see if a sustained remission has been achieved. Beta-blockers can be used temporarily until euthyroidism is achieved. Retrospective analysis of the therapeutic response to antithyroid drugs in patients with hyperthyroid Graves' disease has shown that euthyroidism was achieved in 2 to 3 months in patients older than age 60 years after treatment with methimazole. In long-term follow-up after thionamides are discontinued, recurrence rates are up to 50%. They were found to be the highest in patients younger than age 30 years and were significantly less with advanced age. If a relapse occurs after discontinuing a thionamide, the drug can be restarted, or radioactive iodine can be used. When used for toxic nodular goiters, thionamides have to be given indefinitely since these conditions do not remit.

Patients should be warned about the side effects of antithyroid drugs, which include rash, hepatic injury, and agranulocytosis. The latter two side effects are rare but potentially life-threatening. Routine monitoring of blood counts and liver function tests is not recommended, since these side effects can occur abruptly. If the patient develops sore throat, chills, fever, or signs of liver damage, the antithyroid drug should be stopped until the patient is assessed clinically. Fortunately, these side effects are reversible with supportive care.

Surgery for hyperthyroidism is only advised if there are obstructive symptoms from a large goiter or the presence of a nodule that is suspicious for malignancy. Preparation for thyroidectomy includes using a beta-adrenergic antagonist drug for several weeks before surgery in doses sufficient to lower the resting pulse rate to less than 90 beats per minute. If surgery must be done urgently, then sodium iopanoate has been reported to be safe and effective when given for 5 days together with a  $\beta$ -adrenergic antagonist. Although the mortality from subtotal thyroidectomy is very low, the complications of recurrent laryngeal nerve damage and hypoparathyroidism can result in lifelong disability. Because of the complications, surgery is rarely advisable in the elderly patient.

Atrial fibrillation in the context of hyperthyroidism is more common in elderly patients and is treated with standard agents while the hyperthyroidism is being treated. Atrial fibrillation may resolve once euthyroidism is achieved. Approximately 8% of hyperthyroid patients with atrial fibrillation may develop embolic stroke, with increasing rates in older patients with underlying structural heart disease; therefore, such patients should be given anticoagulation unless there is a contraindication. Anticoagulant doses must be carefully monitored, since hyperthyroidism affects clotting factor levels and drug metabolism.

### Subclinical Hyperthyroidism

Subclinical hyperthyroidism is defined as a state of suppression of serum TSH with normal free thyroxine ( $FT_4$ ) and triiodothyronine ( $T_3$ ) levels in a patient who lacks clinical features of thyrotoxicosis. The most common cause of subclinical hyperthyroidism is iatrogenic because of the use of TSH-suppressive doses of thyroxine. This is done purposely in patients with thyroid cancer and inadvertently

in patients with hypothyroidism. Other endogenous causes of subclinical hyperthyroidism are the same as for overt hyperthyroidism, including Graves' disease, toxic nodules or toxic multinodular goiters, and iodine or amiodarone administration.

In addition to subclinical hyperthyroidism, there are other reasons a patient might have a low or suppressed TSH. These include acute or chronic illness (the NTI syndrome described earlier in this chapter), drugs that suppress TSH levels, and transient thyroiditis. In fact, depending on the population, most patients with a low TSH level will have one of these other conditions, and not subclinical hyperthyroidism. For this reason, a thorough evaluation must be done before a patient receives a diagnosis of subclinical hyperthyroidism.

The prevalence of subclinical hyperthyroidism in older patients varies according to whether patients receiving exogenous thyroid hormone are included. If these patients are excluded, the prevalence is less than 2% of older subjects. The progression of subclinical hyperthyroidism to overt thyrotoxicosis is variable, with some patients eventually becoming hyperthyroid, while others remain stable or revert to a normal TSH level.

Most of the available data on pathophysiologic effects of TSH suppression have been derived from patients with either thyroid carcinoma or nontoxic nodular goiter on levothyroxine suppressive therapy. These effects have been studied in three main areas: symptoms and neuropsychiatric effects, bone loss, and cardiac effects. It should be noted that many of these studies included few if any older patients, so their generalizability to elderly people is unclear.

There are relatively few studies regarding symptoms and neuropsychiatric effects in patients with a suppressed TSH level, but some do suggest that these patients may have increased rates of hyperthyroid symptoms and decrements in mood or cognition. However, most of these studies suffer from bias, since patients were aware of their diagnoses and often treated with thyroxine. The largest and most recent cross-sectional study failed to find any associations between subclinical hyperthyroidism and a number of measures of mood and cognition.

Mild thyroid hormone excess is associated with increased bone turnover rate; the bone resorption rate exceeds the formation rate and bone loss results. However, there is extensive and conflicting information on whether this is clinically significant. Many studies in postmenopausal women with suppressed TSH have shown an accelerated bone loss in the hip, lumbar spine, and distal radius, whereas other studies have failed to demonstrate this. Two meta-analysis studies found a significant 10% loss of bone density in postmenopausal women with suppressed serum TSH. However, many women in these studies were treated with doses of thyroxine that would clearly be considered supraphysiologic today. The only large-scale study of fracture rates in women (the Study of Osteoporotic Fractures [SOF]), concluded that subclinical hyperthyroidism increased fracture rates at both the hip and the vertebrae. In sum, subclinical hyperthyroidism probably causes clinically relevant bone loss in postmenopausal women (not in men or premenopausal women), which can be attenuated with antiresorptive therapy.

Atrial fibrillation is probably the best documented and most serious consequence of subclinical hyperthyroidism. In the Framingham Heart Study of patients older than 60 years of age with subclinical hyperthyroidism, 28% of patients developed atrial fibrillation in a 10-year follow-up, as compared to 11% of the elderly population with normal TSH levels. This finding has since been replicated in other studies. In terms of cardiac structure and function, a number

of studies have shown subtle but statistically significant increases in left ventricular mass and decreases in left ventricular diastolic function. Again, it should be noted that most of these subjects were young, and were receiving thyroxine in suppressive doses for thyroid cancer. Very little is known about cardiac structure and function in subclinical hyperthyroidism in elderly patients, but one could reasonably assume that the subtle decrements seen in young subjects may contribute to clinically relevant deterioration in cardiac function in older patients. In terms of mortality, one recent longitudinal study suggested an increase in cardiovascular mortality in older patients with subclinical hyperthyroidism, while a similar recent study failed to find such an association.

Therapy for subclinical hyperthyroidism should be considered in any patient with neuropsychiatric symptoms, osteoporosis, atrial fibrillation, or cardiac disease. A trial of antithyroid drugs to normalize the serum TSH level is warranted. In patients with more severe features, such as atrial fibrillation, ablation of the hyperfunctioning thyroid with radioactive  $^{131}\text{I}$  can be considered.

## THYROID NODULES

### Prevalence

Thyroid nodules, either solitary or multiple, increase in frequency with advancing age. The lifetime risk of developing a palpable thyroid nodule was estimated to be 5% to 10% in the United States based on a prospective follow-up of more than 5000 patients in the Framingham, Massachusetts, population study. The prevalence of thyroid nodules was found to be higher in women than in men, approximately 5:1, in the same study. An ultrasound survey of 704 people in Sicily without a history of thyroid disease detected nodules in approximately 40% of those older than 60 years and 25% of those younger than 60 years. Three-fourths of the nodules were less than 10 mm in size, only 7% were 20 mm or larger, and the ratio of women to men with nodules was 1.4. Autopsy examination commonly has revealed thyroid nodules. A large autopsy series in the United States indicated that 50% of the population with no known history of thyroid disease had discrete nodules, 35% of whom had nodules greater than 2 cm in diameter.

### Clinical Evaluation

In formulating an effective management of a patient with a thyroid nodule, a careful history and physical examination should be done to assess the risk of malignancy. The patient's age and gender are important risk factors for malignancy. Although thyroid nodules are found more frequently in women, the likelihood of a thyroid nodule being malignant is higher in men than in women. The cancer risk in a cold nodule was about sixfold higher in male patients older than 70 years according to a 10-year follow-up study of more than 5000 patients.

The history of radiation exposure during childhood is important because thyroid nodule or thyroid carcinoma can develop years later. Most patients received radiation therapy for treatment of benign conditions such as tonsillitis, acne, tinea capitis, impetigo, sinusitis, or an enlarged thymus. The earlier the age of exposure, the higher was the likelihood of cancer development. However, the latency

period probably does not exceed 50 years, so the chance of radiation induction from childhood exposure is very low in the elderly person.

A family history of thyroid cancer suggests familial papillary thyroid cancer or familial medullary thyroid cancer as a component of multiple endocrine neoplasia (MEN) type 2. However, patients with MEN usually present in childhood or early adulthood rather than in the geriatric age group. Familial papillary thyroid cancer is much more common than familial medullary thyroid cancer. A history of goiter in the family maybe reassuring of a benign disorder.

Most thyroid nodules do not cause symptoms. Currently a large majority of nodules are found incidentally during a procedure such as carotid ultrasonography or CT scan or magnetic resonance imaging (MRI) of the neck in the elderly person, giving rise to the term *incidentaloma*. Pain may occur with a hemorrhage into a preexisting colloid nodule or a benign adenoma. Symptoms of rapid nodular growth over a period of weeks or months are suspicious of malignancy. Other symptoms that suggest malignancy are persistent hoarseness or change in voice consistent with recurrent laryngeal nerve dysfunction.

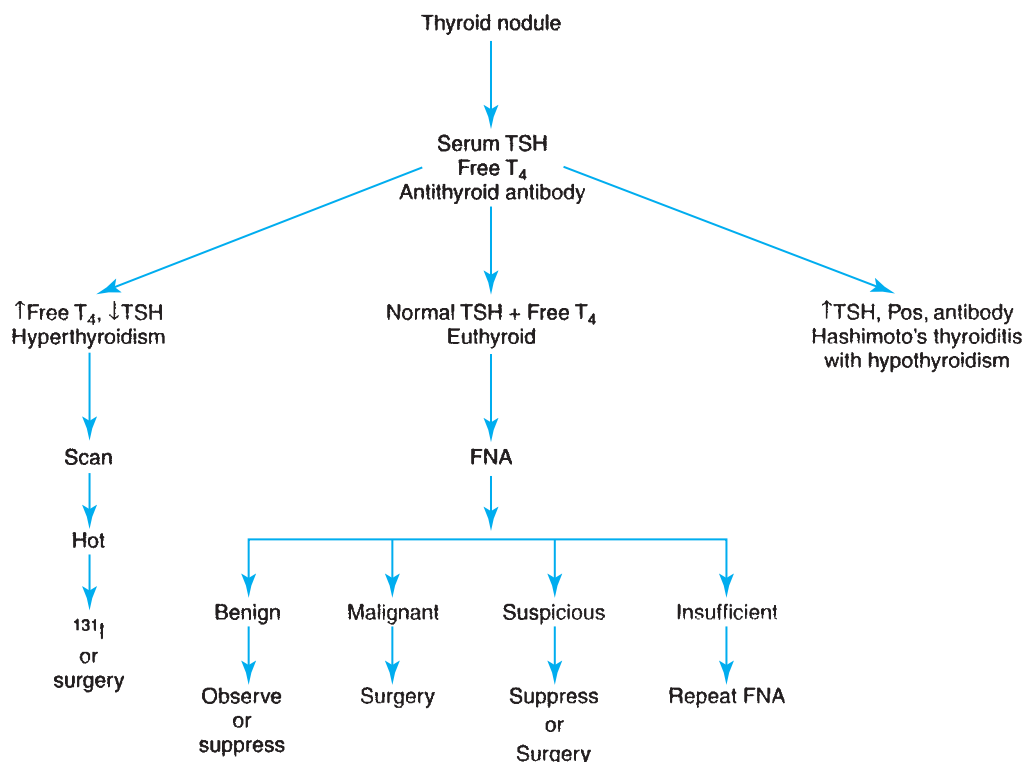

The physical examination of the patient with a thyroid nodule should include careful palpation of the neck with attention to the size and consistency of the nodule and the presence of adenopathy. The location of the nodule within the thyroid gland and the anatomy of the patient's neck maybe the limiting factors in palpatory examination of the neck. In general, most nodules larger than 3 cm in diameter are easily recognized on palpation. A hard and fixed nodule is more likely to be malignant, but many papillary carcinomas or follicular tumors are soft or cystic. Lymphadenopathy is strongly suggestive of malignancy in older patients; therefore, after finding a thyroid nodule, the neck should be examined carefully for the central and deep cervical lymph nodes.

A distinction between solitary and multiple nodules by neck examination maybe limited. In approximately 50% of patients with a clinically solitary nodule on palpation, the lesion subsequently was found to be a dominant nodule in a multinodular goiter on ultrasound or histologic examination. The relative risk of cancer in solitary versus multinodular thyroid glands is controversial. Older studies reported lower rates of thyroid carcinoma in palpable multinodular glands (5% to 13%) as compared with solitary nodules (9% to 25%), but recent studies have found similar incidences of cancer in multinodular and single nodule glands.

### Diagnostic Tests

Laboratory and radiographic evaluation of thyroid function is useful to assist in determining whether a nodule is benign or malignant. [Figure 108-4](#) illustrates a recommended approach to diagnostic evaluation. Nearly all patients with either thyroid carcinoma or a benign nodule are euthyroid. An abnormal thyroid function test in a patient with a thyroid nodule does not rule out thyroid cancer but may make thyroid carcinoma a less likely possibility. Low serum TSH concentration in the setting of a nodular goiter suggests the presence of either an autonomously functioning adenoma or a toxic multinodular goiter. Elevated antiperoxidase and antithyroglobulin antibody titers indicate lymphocytic thyroiditis, which may present as a nodule. The serum thyroglobulin level is not a useful test to distinguish benign from malignant nodules because it is increased with any goitrous process.

**FIGURE 108-4.** Algorithm for evaluation and management of patients presenting with nodular thyroid disease.

Thyroid ultrasound is a noninvasive test that discriminates cystic from solid lesions. It is useful for differentiating thyroid from nonthyroid neck masses and for localizing nodules deep within the gland. It is routinely used to guide fine-needle aspiration (FNA) biopsy. Thyroid ultrasonography is capable of identifying impalpable solid and cystic nodules as small as 0.2 mm in diameter. The clinical significance of nodules smaller than 8 mm detected by ultrasonography remains uncertain. The ultrasonographic features that suggest the diagnosis of malignancy are fine stippled calcifications and intranodular vascularity.

FNA biopsy is the most important diagnostic technique. It reliably identifies thyroid nodule cytology and is the most effective method to diagnose malignancy. In experienced hands, it is safe, with accuracy, sensitivity, and specificity of 98% to 99%. Use of FNA has been reported to result in reduction in thyroid nodule management costs by 25%, and the number of patients requiring surgery declined by more than 40%. FNA biopsy should be performed on solid nodules larger than 1.5 cm, on nodules with both a solid and cystic component larger than 2.0 cm, on the solid component of large cystic nodules, and on nodules with evidence of recent growth.

Results of FNA biopsies are divided into four basic categories: (1) benign, (2) suspicious (includes aspirates with some features of thyroid carcinoma but not conclusive), (3) malignant, and (4) insufficient. In a large series of patients with FNA biopsy of the thyroid, benign cytology was found in 69% (mainly colloid goiter), malignant cytology in 3.5%, and suspicious cytology in 10%. The suspicious category consists of variants of follicular neoplasm, but follicular adenomas are about 10-fold more common than follicular carcinomas. The presence of nuclear atypia in a follicular lesion gives a 44% prevalence of malignancy, and absence of nuclear atypia denotes a benign lesion. The insufficient or nondiagnostic cytology was reported as an average of 17% in the same report and has been

attributed to lack of operator experience, nodular vascularity, or a small or posteriorly located nodule. Those patients with a nondiagnostic or “insufficient” cytologic diagnosis should have a repeat biopsy. An adequate specimen is obtained in a majority of repeat FNA of nodules.

By thyroid scans with radioiodine, nodules are classified into hyperfunctional or “hot” nodules, nonfunctional or “cold” nodules, or normal functioning or “warm” nodules. This classification is based on the extent of radioiodine incorporation into a nodule compared with the rest of the gland. In a study of more than 5000 patients with thyroid nodules undergoing preoperative scanning, approximately 85% of the nodules were cold, 10% were normal, and 5% were hot. These patients underwent thyroidectomy regardless of the scan result. Thyroid cancer was found in 16% of patients with cold nodules, in 9% with warm nodules, and in 4% with hot nodules. The last figure is higher than expected because most other studies show that a hot nodule is rarely malignant. The finding of a cold nodule has relatively low specificity because the majority of both benign and malignant solitary thyroid nodules appear hypofunctional relative to adjacent normal thyroid tissue. Because the thyroid scan generally is not useful for diagnosis of malignancy, it is not recommended in the initial evaluation of a thyroid nodule. In patients with nodules that are follicular lesions by FNA, radioiodine scan should be performed. Hot or functional nodules are rarely malignant.

Positron emission tomography (PET) has been used to localize recurrent thyroid cancers, but more quantitative studies of the uptake of the glucose analog [<sup>18</sup>F]2-deoxy-2-fluoro-D-glucose are needed to determine its utility for diagnosis of a malignant thyroid nodule.

## Management

The treatment of the thyroid nodule depends on the functional state of the nodule and cytologic diagnosis with FNA biopsy (see

**Figure 108-4).** The hyperfunctioning “hot” nodule is treated with radioiodine ablation or surgery. Older patients who refuse definitive therapy or who are poor candidates can be treated with thionamides, but these must be continued indefinitely, since hyperfunctioning nodules rarely remit. Patients treated with  $^{131}\text{I}$  ablation become euthyroid in a few months, and hypothyroidism develops in only a small proportion of such patients.

The vast majority of thyroid nodules are benign and should be followed with observation alone or with thyroxine suppression therapy in selected patients. Spontaneous regression of thyroid nodules may occur. Thyroid hormone suppressive therapy is based on the assumption that growth of the nodule depends on TSH. The aim of therapy is to reduce serum TSH to the low-normal range. L-Thyroxine suppressive therapy is useful for nodules that do not decrease in size over several months of initial observation. Suppressing therapy in the treatment of benign thyroid nodules has been challenged in the past few years by failure of some studies to show a significant decrease in nodule size and concern about reducing mineral bone density or triggering atrial fibrillation, especially in the elderly. Several controlled studies showed greater than 50% reduction in nodular size in one fourth of patients with a single nodule. Generally, patients are followed by palpation at intervals of 4 months. Ultrasonographic examination can be performed to assess growth or shrinkage of a nodule if more objective documentation is required on an annual basis.

If the cytologic diagnosis indicates malignancy or is strongly suspicious for malignancy, the nodule should be removed surgically. In the 10% to 20% of “suspicious” cytologic findings for malignancy by FNA, approximately one-fourth of patients who undergo surgery are found to have a malignant lesion. Altogether, only approximately 5% to 10% of thyroid nodules are malignant.

## THYROID CANCER

Thyroid cancer accounts for 2.2% of all new cancers in the United States. Mortality from thyroid cancer is 0.3% of all cancer deaths. Epidemiologic studies during the last two decades report an increased incidence of thyroid carcinoma in the United States because of improved diagnosis; however, the mortality has decreased because of earlier detection and improved treatment, in addition to a decline in incidence of anaplastic thyroid carcinoma.

Thyroid carcinoma is classified into five major types: papillary, follicular, medullary, anaplastic, and thyroid lymphoma. Most thyroid cancers are indolent and grow slowly over years, whereas a few grow aggressively and cause death in a year. Thyroid carcinomas tend to be more aggressive clinically and more poorly differentiated in elderly patients compared with younger individuals.

### Papillary Thyroid Carcinoma

Papillary carcinoma, the most common type of thyroid cancer, accounts for more than 80% of all thyroid tumors. In autopsy studies, the prevalence of occult papillary carcinoma (<1 cm) was found to be 7% in patients older than 80 years of age. Papillary carcinoma arises from follicular thyroid cells and is often indolent and slow growing. The tumor tends to invade lymphatics and metastasize to the regional lymph nodes and the lungs. Hoarseness and vocal cord paralysis secondary to locally invasive thyroid cancer were found to

predict death from papillary carcinoma. Hematogenous spread also can occur to the bone and the central nervous system. The disease is more aggressive in the older patients. The prognosis of papillary thyroid carcinoma depends on the age of the patient at the time of initial diagnosis, the size of the primary lesion, local invasion, and the degree of metastases. Death rates are greater in adults older than 45 years of age. The 10-year survival was only 47% for patients older than 70 years of age.

In a 12-year follow-up of patients older than 47 years of age with papillary thyroid carcinoma, the death rate was 70% in patients with distant metastases versus 0.8% in patients with intrathyroidal disease. Thyroid tumors smaller than 1.5 cm in diameter rarely metastasize to distant sites, whereas larger tumors are associated with higher mortality rates. Extension of the tumor through the thyroid capsule and into the surrounding structures is associated with poorer prognosis. Cervical lymph node metastases occur in about 50% of patients and carry only a slightly higher rate of recurrence and mortality.

Surgery, either near-total or total thyroidectomy, is the initial treatment of choice for patients with papillary carcinoma. Near-total thyroidectomy is performed for extensive unilateral tumors with local metastases. Total thyroidectomy is performed for patients with extensive multifocal disease with metastases to the cervical lymph nodes, contiguous neck structures, or distant sites. The main disadvantage of total thyroidectomy is the higher incidence of hypoparathyroidism.

The prophylactic use of radioactive iodine-131 after surgery reduces the mortality rate and increases survival by destroying any residual thyroid tumor. It is used in nearly all older patients because of their worse prognosis based on age alone. Radioiodine therapy is also used to treat patients with residual or recurrent papillary cancer in the neck.

In order to scan and treat patients with  $^{131}\text{I}$ , thyroxine therapy must be withheld for 4 to 6 weeks to allow serum TSH levels to rise. Alternatively, patients can be placed on 25- $\mu\text{g}$  triiodothyronine (liothyronine) twice daily for 1 month instead of thyroxine; then the triiodothyronine is stopped for 2 weeks before administration of  $^{131}\text{I}$ . This alternative procedure shortens the period of symptomatic hypothyroidism. Thyroid hormone in a suppressive dose is given after thyroidectomy to reduce thyroid cancer recurrence rates. TSH stimulates thyroid tumors that contain TSH receptors. The dose of thyroxine should be adjusted to keep the TSH suppressed without causing clinical thyrotoxicosis. The degree of suppression should be based on the staging of the patient. In patients with a good prognosis, TSH should be suppressed to the slightly subnormal range. In patients with worse prognosis, which includes many elderly patients, TSH should be suppressed to less than 0.1 mU/L without causing clinical thyrotoxicosis, if this can be done safely.

Recombinant human TSH (rhTSH) may be used to stimulate radioiodide uptake in scanning patients with well-differentiated thyroid cancer while they continue to take levothyroxine. This avoids the symptoms of hypothyroidism that occur after withdrawal of levothyroxine. rhTSH stimulates radioiodine uptake and thyroglobulin secretion in normal and abnormal thyroid tissue. A clinical trial comparing 48-hour  $^{131}\text{I}$  whole-body scan results showed 89% concordance in patients receiving rhTSH, as compared to the withdrawal of levothyroxine therapy. Of the discordant results, 8% of scans were superior after levothyroxine withdrawal, while 3% were superior after stimulation with rhTSH (no significant difference).

Because stimulated serum thyroglobulin is a more sensitive assessment of recurrence, this has replaced radioiodine scans for follow-up of patients with differentiated thyroid cancer. The use of recently developed very sensitive assays of thyroglobulin may replace the need for stimulating thyroglobulin with rhTSH or thyroid hormone withdrawal because an undetectable sensitive serum thyroglobulin correlates well with a negative (low) stimulated serum thyroglobulin measurement.

Ultrasonography of the neck is also used for following patients after surgery because most recurrences are in the central neck region or in cervical lymph nodes.

### Follicular Thyroid Carcinoma

Follicular thyroid carcinoma accounts for about 10% of all thyroid cancers in the United States and is relatively more common in regions of iodine deficiency. It occurs more frequently in elderly people. Approximately 80% of follicular cell neoplasms are benign. Larger follicular cell neoplasms are more likely to be malignant, especially in men and patients older than age 50 years. Follicular thyroid carcinoma is slightly more aggressive than papillary carcinoma. Cervical lymph node involvement is less common compared to papillary thyroid cancer, but distant metastasis is more frequent.

With minimally invasive follicular carcinoma, there is usually invasion of small vessels, whereas with more invasive tumors there is vascular and capsular invasion and penetration into the surrounding tissue, causing a poorer prognosis. Hürthle cell carcinoma is considered a variant of follicular thyroid carcinoma and carries an even worse prognosis. Follicular carcinoma also metastasizes to the lung, bone, central nervous system, and other soft tissues with higher frequency than papillary carcinoma. Tumor recurrence in distant sites is seen more frequently with follicular than with papillary carcinoma and occurs with higher prevalence in highly invasive tumors.

Treatment includes total thyroidectomy and  $^{131}\text{I}$  therapy to ablate residual tumor. Radioiodine is the principal treatment of metastatic tumors. If the tumor does not concentrate the isotope, external radiation maybe effective. As with papillary carcinoma, thyroxine therapy should be given to suppress serum TSH levels to the subnormal range.

### Medullary Thyroid Carcinoma

Medullary carcinoma accounts for 2% to 4% of thyroid cancers and is derived from the calcitonin-secreting cells or parafollicular cells. Elevated serum calcitonin levels establish the diagnosis and correlate with tumor mass. Approximately 20% are familial tumors and are associated with other endocrine neoplasias (MEN type 2A or 2B). The recognition of point mutations in the *ret* protooncogene on chromosome 10 has enhanced the ability to detect these neoplasms at an early and potentially curable stage in suspected family members. Approximately 80% of medullary carcinoma is sporadic and diagnosed later in life, mostly after age 50 years. Three fourths of patients with sporadic medullary carcinoma present with a thyroid mass and 15% have local symptoms of dysphagia, dyspnea, or hoarseness.

Immunohistochemical studies demonstrate the presence of calcitonin in the tumor that is also able to synthesize calcitonin gene-related peptide, ACTH, serotonin, prostaglandin, histamine, and carcinoembryonic antigen. Diarrhea occurs in 30% of patients with advanced disease and correlates directly with the tumor mass. Re-

currence rate increases in frequency with age. About two thirds of patients older than age 70 years have persistent disease or a higher recurrence rate after surgery.

### Anaplastic Thyroid Carcinoma

Anaplastic carcinoma of the thyroid, the most aggressive and lethal neoplasm, accounts for 2% of all thyroid carcinomas. It is often derived from a well-differentiated thyroid carcinoma. The peak occurrence of this tumor is in the seventh decade of life; three quarters of patients are 60 years of age or older and it is more common in women. Examination of the neck usually reveals a fixed, large, firm mass that often makes it difficult to detect neck nodes clinically. Hemorrhage and necrosis within the tumor may result in soft, fluctuant masses. Large axillary nodes are sometimes seen.

Treatment includes surgery, followed by external radiation and chemotherapy, which may result in disease-free intervals of 1 to 5 years. The mortality exceeds 80% at 12 months. Long-term survivors usually have only a small focus of anaplastic cells.

### Thyroid Lymphoma

Thyroid lymphoma accounts for about 1% of thyroid malignancies. It is often engrafted on a background of chronic lymphocytic thyroiditis. At the time of presentation with lymphoma, the patient is usually older than 60 years of age. There is a female preponderance. This tumor arises from B-cell lymphocytes. It usually invades the walls of blood vessels and extends outside the thyroid gland. The usual clinical presentation is a rapidly enlarging thyroid mass in a patient with long history of a goiter or diagnosis of Hashimoto's thyroiditis that was treated with thyroid hormone. The patient may complain of neck pressure, local swelling of the thyroid gland, hoarseness, and dysphagia. FNA may suggest the diagnosis, but definitive diagnosis usually requires an open biopsy. Surgical removal of the lymphoma by total thyroidectomy is unwise. Treatment with external radiation and four to six courses of chemotherapy usually produces a permanent remission.

# Diabetes Mellitus

Annette M. Chang ■ Jeffrey B. Halter

Diabetes mellitus is a common metabolic disorder affecting elderly people. Although it is recognized by its effects on carbohydrate metabolism to cause hyperglycemia, diabetes mellitus usually also affects lipid and protein metabolism. With time, effects of diabetes on the cardiovascular system, the kidneys, the retina, and the peripheral nervous system, often referred to as long-term complications of diabetes, substantially increase mortality and morbidity in older adults. Furthermore, diabetes may accelerate the risk and contribute to worse outcomes for other common age-related disorders. In general, diabetes mellitus in older adults is underdiagnosed and undertreated. A growing body of evidence assessing outcomes of interventions and an increasing number of therapeutic options for diabetes management has increased the importance of making a diagnosis and offering appropriate intervention strategies to elderly patients who have this potentially devastating disorder. There is also growing evidence of the ability to prevent the development of diabetes, including in older people. Management of diabetes is often considered to be synonymous with treatment of hyperglycemia. However, it is now recognized that appropriate diabetes management of an older patient must be much broader, addressing many factors that contribute to long-term complications.

## DEFINITION AND CLASSIFICATION

Diabetes mellitus is a heterogeneous set of disorders affecting multiple body systems; however, diagnostic criteria are based on documentation of elevated circulating blood glucose levels. Because glucose levels vary during the course of the day, and even in the fasting state form a continuous variable in populations, the definition of a single cut point that separates normal from abnormal is somewhat arbitrary. The challenge of establishing appropriate diagnostic criteria for elderly subjects is made more difficult by well-described effects of aging on glucose metabolism (summarized later in this chapter in the section on “Effects of Aging”). Similar to criteria for hypercholesterolemia and hypertension, the diagnostic criteria for

diabetes mellitus are based on values that predict poor outcomes in population studies.

Table 109-1 summarizes the currently accepted diagnostic criteria, which were established by an expert panel convened by the American Diabetes Association (ADA) and published in 1997 with a follow-up report in 2003.

### Type 1 Diabetes

Type 1 diabetes is a condition characterized by destruction of the insulin-producing beta cells of the endocrine pancreas, resulting in absolute deficiency of insulin. While evidence of cell-mediated autoimmunity is a hallmark of type 1 diabetes, some patients develop a type 1 diabetes phenotype with evidence of severe insulin deficiency and episodes of diabetic ketoacidosis (DKA) with no detectable autoimmunity. Such individuals have idiopathic type 1 diabetes. Although the incidence of new-onset type 1 diabetes in older adults is very low, effective treatment of type 1 diabetes may prevent or delay the development of long-term complications and increased mortality. Thus, people who develop type 1 diabetes earlier in life may live to old age and therefore become a part of the spectrum of diabetes mellitus in an older adult population.

### Type 2 Diabetes

Approximately 90% of older adults with diabetes have type 2 diabetes mellitus. Hyperglycemia, often asymptomatic, is the hallmark and DKA is not part of the clinical syndrome. Obesity is often present, and resistance to insulin's metabolic effects is a characteristic feature. Impaired insulin secretion is also part of the picture, but severe absolute insulin deficiency is not. While there is a strong genetic predisposition to development of type 2 diabetes, its etiology remains unknown and is likely to be both highly heterogeneous and multifactorial. The interaction between genetics, lifestyle factors, and aging in the development of type 2 diabetes is discussed later in this chapter in the section on “Pathophysiology of Diabetes.”

**TABLE 109-1****1997 and 2003 American Diabetes Association Diagnostic Criteria for Diabetes Mellitus, Impaired Glucose Tolerance, and Impaired Fasting Glucose**

Diabetes mellitus
Classic diabetes symptoms plus a random glucose level $\geq 200$ mg/dL (11.1 mmol/L)
Fasting* glucose level $\geq 126$ mg/dL (7.0 mmol/L) <sup>†</sup>
Glucose level $\geq 200$ mg/dL (11.1 mmol/L) at 2 hours during a standard OGTT <sup>†</sup>
Impaired glucose tolerance (IGT)
Glucose level $\geq 140$ mg/dL (7.8 mmol/L) and $< 200$ mg/dL (11.1 mmol/L) at 2 hours during a standard OGTT
Impaired fasting glucose (IFG)
Fasting glucose level $\geq 100$ mg/dL (5.6 mmol/L) and $< 126$ mg/dL (7.0 mmol/L)

OGTT, oral glucose tolerance test.

\*No caloric intake for at least 8 hours.

<sup>†</sup>Either of these criteria should be confirmed on a separate day to establish a diagnosis of diabetes.

## Other Specific Types of Diabetes

The 1997 ADA classification for diabetes mellitus identifies a number of specific conditions that lead to development of diabetes mellitus, each of which is relatively uncommon. One group of disorders includes genetic defects of the pancreatic beta cell. The clinical phenotype for these genetic disorders is maturity-onset diabetes of youth (MODY). These genetic disorders have autosomal-dominant inheritance with first presentation of asymptomatic hyperglycemia early in life. Patients with MODY can live to old age, however, and therefore can be a part of the spectrum of diabetes in an elderly population. The metabolic disorder in some affected individuals may be mild, whereas others may develop symptomatic hyperglycemia and long-term complications of diabetes mellitus similar to patients with typical type 2 diabetes. Another type of genetic defect has been identified in a few families in which insulin processing prior to secretion is impaired, which can predispose to development of hyperglycemia.

Other families have genetic defects affecting insulin action. Severe insulin resistance results, and when it is not adequately compensated for by increased insulin secretion, hyperglycemia occurs. Diseases of the exocrine pancreas can lead to damage to pancreatic beta cells, diminished insulin secretion, and hyperglycemia. Hyperglycemia also can occur in patients with excessive secretion of hormones that adversely affect carbohydrate metabolism, such as in acromegaly, Cushing's syndrome, glucagonoma, and pheochromocytoma. Similarly, tumors making aldosterone can cause hyperglycemia as a result of hypokalemia-induced inhibition of insulin secretion. A number of drugs or toxins can impair insulin secretion or insulin action and lead to the development of hyperglycemia. [Table 109-2](#) lists such drugs. Several genetic neuromuscular disorders are associated with diabetes mellitus, but they are rare in the older adult population.

## Gestational Diabetes Mellitus

Gestational diabetes mellitus (GDM) is a separate category in the 1997 ADA classification and refers to the first identification of an alteration in glucose metabolism during pregnancy. While GDM per se is not part of the spectrum of diabetes in older adults, a history of

**TABLE 109-2****Drugs That May Increase Glucose Levels**

Diuretics
$\alpha$ -Adrenergic agonists
$\beta$ -Adrenergic blockers
Alcohol
Ca <sup>2+</sup> channel-blockers
Caffeine
Clozapine
Glucocorticoids
Growth hormone
Nicotine
Nicotinic acid
Nonsteroidal anti-inflammatory drugs
Female sex steroids (estrogen/progesterone)
Pentamidine
Phenytoin

GDM may be part of the background of an older woman presenting with type 2 diabetes. As GDM has been aggressively screened for and treated, increasing numbers of women reaching the geriatric age group will have this history, as GDM affects approximately 4% of all pregnancies in the United States. After pregnancy, 5% to 10% of women with gestational diabetes are found to have type 2 diabetes. Women who have had gestational diabetes have a 20% to 50% chance of developing diabetes in the next 5 to 10 years.

## Diagnostic Criteria

The rationale for the circulating glucose level criteria shown in [Table 109-1](#) is based on prediction of risk for diabetes-related complications. Thus, a 2-hour value during the oral glucose tolerance test (OGTT) greater or equal to 200 mg/dL is a strong predictor of diabetes complications, even when the fasting glucose level is less than 126 mg/dL. The term "isolated postchallenge hyperglycemia" (IPH) is sometimes used for individuals who meet the 2-hour OGTT criterion for diabetes, but who do not meet the fasting glucose criterion.

There is no age adjustment in the recommended criteria for the diagnosis of diabetes mellitus because the same glucose level cut points that predict complications appear to apply regardless of age. There is no current criterion for diagnosis of diabetes mellitus based on measurement of hemoglobin A1c, as no level of hemoglobin A1c accurately identifies people who meet glucose level diagnostic criteria.

The 1997 and 2003 ADA criteria shown in [Table 109-1](#) also identify intermediate categories of altered glucose metabolism that identify an earlier stage (prediabetes) in the development of diabetes mellitus. Impaired glucose tolerance (IGT) is based on results of an OGTT and the category of impaired fasting glucose (IFG) is defined from fasting glucose levels. Because OGTTs are not routinely performed in clinical practice, the IFG category allows easy identification of some, but not nearly all, of the individuals who would meet criteria for IGT if an OGTT were performed. People with IGT and IFG are at increased risk for cardiovascular disease, as well as for subsequent development of overt diabetes mellitus. There is no recommended age adjustment for the criteria for either IGT or IFG, as

these criteria predict risk for subsequent diabetes and cardiovascular disease similarly in older people.

### Diagnostic Testing for Older Adults

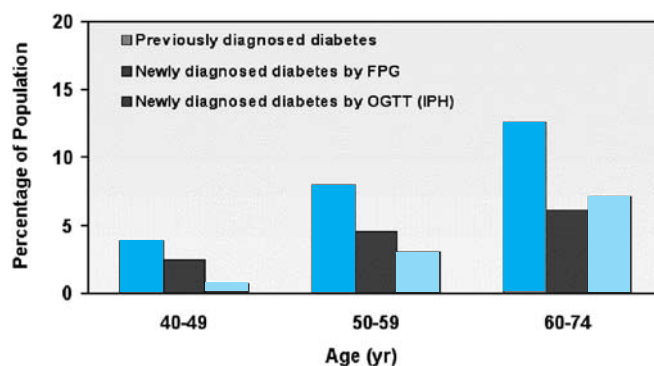

One advantage of the 1997 and 2003 ADA recommendations is that a simple fasting glucose level can be used to classify patients and establish a diagnosis of diabetes mellitus, or even the intermediate stage of IFG. Unfortunately, many older individuals who meet diabetes criteria by OGTT will be missed by this method (see “Epidemiology of Diabetes and its Complications” later in this chapter). The ADA recommends that screening to detect prediabetes or diabetes with either fasting glucose level or 2-hour OGTT be considered in all individuals older than age 45 years at 3-year intervals, particularly in those with a body mass index (BMI)  $\geq 25$  kg/m<sup>2</sup>. The rationale for such screening includes the high rate of undetected diabetes mellitus in population studies (discussed further subsequently in the section on “Epidemiology of Diabetes”) and the substantial current evidence that early intervention delays the development of diabetes in people with prediabetes, including those older than 60 years of age. Yearly follow-up and retesting of people at higher risk should be considered. Such high-risk individuals include those who are overweight (BMI  $\geq 25$  kg/m<sup>2</sup>; see Chapter 39), those with a strong family history of diabetes that includes a first-degree relative, those with a history of prior GDM, people with hypertension or dyslipidemia (particularly elevated triglyceride and/or low high-density lipoprotein [HDL] cholesterol levels), and those who have had IFG or IGT on previous testing. In addition, members of ethnic groups with higher risks of diabetes should be considered for more frequent testing. Such populations include African-Americans, Hispanics, Pacific Islanders, Asian Americans, and Native Americans.

What about testing to classify the type of diabetes mellitus? The ADA reports do not define criteria for classifying types of diabetes mellitus. In theory, it is possible to measure insulin levels and various pancreatic islet antibodies to identify most individuals with type 1 diabetes. At this time, however, the differentiation between types of diabetes is primarily based on clinical history. While clinical history is imprecise, it is sufficient under most circumstances to guide treatment interventions. Insulin therapy should be a key part of the approach to patients with type 1 diabetes and interventions targeted at enhancing endogenous insulin secretion are unlikely to be useful for such individuals, even in the early stages of their disease. Insulin can also be used in patients with other types of diabetes depending on the clinical situation (as described in more detail subsequently in the section on “Insulin”). Accurate classification maybe more important in the future. For example, if interventions are identified to prevent progression of autoimmune diabetes, it would be important to establish a specific diagnosis early so that such interventions could be used appropriately.

## EPIDEMIOLOGY OF DIABETES AND ITS COMPLICATIONS

### Diabetes Mellitus and Prediabetes

More than 50% of people in the United States with diabetes are older than 60 years of age. **Figure 109-1** illustrates the dramatic age-related

**FIGURE 109-1.** Prevalence of type 2 diabetes among elderly people according to age and ADA diagnostic criteria (National Health and Nutrition Examination Survey [NHANES] III). IPH, isolated postchallenge hyperglycemia. (Data from Harris MI, et al. *Prevalence of diabetes, impaired fasting glucose and impaired glucose tolerance in US adults. Diabetes Care. 1998;21:518*, and Resnick HE, et al. *American Diabetes Association diabetes diagnostic criteria, advancing age, and cardiovascular disease risk profiles: Results from the Third National Health and Nutrition Examination Survey. Diabetes Care. 2000;23:176*.)

increase in the prevalence rate of diabetes mellitus in men and women in the United States. This analysis from the Third National Health and Nutrition Examination Survey (NHANES III) was carried out from 1988 to 1994 by the National Center for Health Statistics of the Centers for Disease Control on a nationally representative sample of the U.S. noninstitutionalized population. Based on the 1997 ADA criteria, approximately 25% of people older than age 60 years have diabetes mellitus. The high prevalence rate was confirmed in the population-based Cardiovascular Health Study and extended to people older than age 75 years. Approximately half of these older affected persons had a physician diagnosis of diabetes mellitus, but the other half were previously undiagnosed. Among the 12% to 13% of previously undiagnosed older people, approximately half were detected by an elevated fasting glucose. However, the other half had IPH, requiring an OGTT to detect the presence of diabetes.

Comparison with similar data collected in the late 1970s during NHANES II indicates that the prevalence of diabetes increased by 30% to 40% during the interval between studies. Diabetes prevalence varies by ethnic group, with the lowest rates in non-Hispanic whites, higher rates in non-Hispanic blacks, and the highest rates in Mexican Americans. Even higher rates are observed in some Native American populations. These ethnic group differences appear to persist throughout the age range.

The prevalence, or percent of the population with diabetes mellitus at any given age, includes both incident or new cases plus all of those with diabetes who were diagnosed at an earlier age. Part of the dramatic age-related increase in prevalence of diabetes is a result of survival of people initially diagnosed at middle age. However, other studies of the incidence of diabetes indicate an age-related increase and the prevalence of undiagnosed diabetes in NHANES III and other studies also increases with age.

After excluding people who meet criteria for diabetes mellitus, the prevalence rate for IGT and IFG also both increase with age. In NHANES III, approximately 14% of the U.S. population older than 60 years of age had IFG and approximately 20% met criteria for IGT, rates substantially higher than for younger individuals. When prevalence rates for both diabetes and IGT are combined, the rate in

**TABLE 109-3****Long-Term Complications of Diabetes in Elderly People**

COMPLICATION	RELATIVE RISK*

Renal disease	2
Neuropathy	Uncertain

\*Risk compared to people of the same age who do not have diabetes.

elderly people in the United States exceeds 40%. It could be argued that a finding prevalent in nearly half of the population should not be considered “abnormal” and that the criteria for these conditions should thus be age-adjusted. However, these criteria identify older people at risk for progression to overt hyperglycemia and at increased risk for the complications of diabetes.

## Diabetes Complications

Older adults with diabetes mellitus are susceptible to all the usual complications of diabetes. Although clinical outcomes of many of the diabetes complications including end-stage renal disease, loss of vision, myocardial infarction, stroke, peripheral vascular disease, and peripheral neuropathy all increase with age in the absence of diabetes, their incidence and cooccurrence are all exaggerated by the presence of diabetes, as summarized in [Table 109-3](#). Diabetes-specific pathologic findings exist for some of these complications, but pathological information is generally not available for epidemiologic studies that depend on the more gross clinical outcomes. It is more difficult to be certain of the specific role of diabetes, and especially of hyperglycemia per se, in contributing to an outcome such as visual loss or end-stage renal disease in an older patient, as compared with a younger patient with diabetes, who would not otherwise be expected to have one of these problems.

In an older adult population, the presence of hyperglycemia and diabetes mellitus should be viewed as a risk factor for such complications, analogous to hypertension or hypercholesterolemia. Using this approach, there is substantial evidence that the presence of diabetes in an older adult increases risk for adverse outcomes, as summarized in [Table 109-3](#). Overall, it is estimated that a diagnosis of diabetes is associated on average with a 10-year reduction in life expectancy. However, this figure becomes progressively reduced at advanced old age when risks of competing causes of mortality rise exponentially. Nonetheless, diabetes is associated with a higher mortality rate at any age, approaching twice the rate in older people of comparable age without diabetes in some studies. Similarly, the rates of myocardial infarction, stroke, and end-stage renal disease are increased approximately twofold, and the risk of visual loss is increased approximately 40% in older people with diabetes. This level of increased relative risk may appear modest on an individual level. However, since the elderly population has by far the highest rates of these conditions, the increase in absolute risk is more substantial. Thus a twofold relative risk increase represents a very large number of added ad-

verse outcomes. The risk for lower-extremity amputation is dramatically increased in older people with diabetes mellitus, approximately 10-fold greater than that for older people without diabetes.

## PATHOPHYSIOLOGY OF DIABETES AND ITS COMPLICATIONS

Although the rate of new onset of type 1 diabetes is relatively low in older people, the mechanism for type 1 diabetes does not appear to be different in this population. Usually, patients with type 1 diabetes have markers of immune destruction of pancreatic beta cells such as islet cell antibodies, antibodies to insulin, or other pancreatic beta cell-specific antibodies. There are also strong human leukocyte antigen (HLA) associations.

Type 2 diabetes is by far the most prevalent form in older adults. Autoimmune destruction of pancreatic beta cells is not observed. Limited pathologic investigation suggests that total beta cell mass maybe moderately reduced, but severe loss of beta cell mass is uncommon. The pathophysiology of type 2 diabetes is unknown, but it appears to occur as a result of a complex interaction among genetic, lifestyle, and aging influences, as illustrated in [Figure 109-2](#). The heterogeneity of type 2 diabetes likely reflects the varying contributions of each of multiple factors to the development of hyperglycemia in a given individual or family.

## Effects of Aging

Many studies have demonstrated age-related glucose intolerance in humans, as illustrated in [Figure 109-3](#). In normal people who do not meet criteria for either diabetes mellitus or IGT, there is a slight age-related increase in fasting glucose levels and a more dramatic slowing of return to normal of glucose levels following an oral glucose challenge.

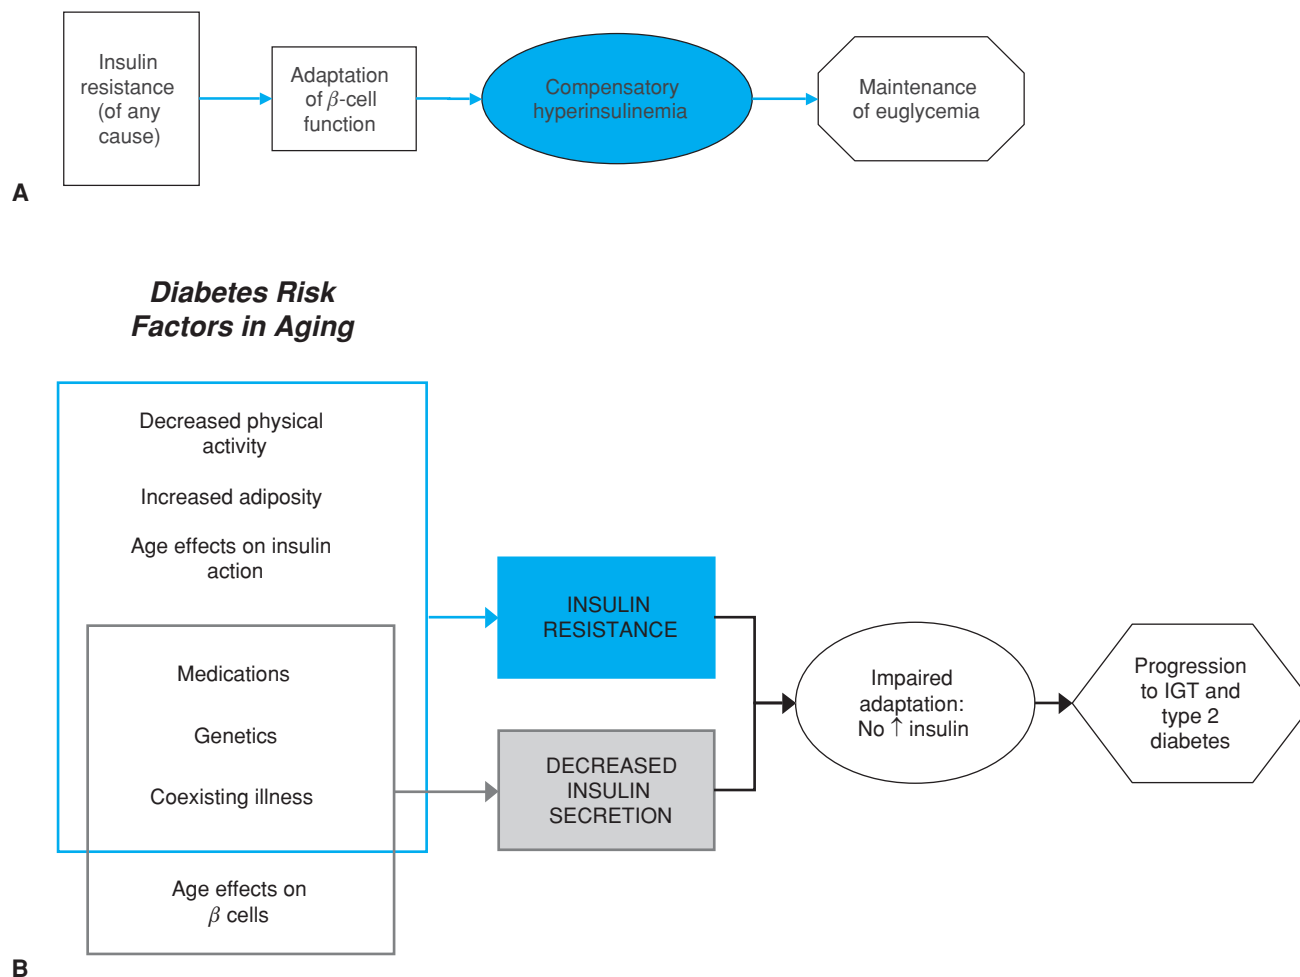

## Insulin Resistance

There is a decline in sensitivity to the metabolic effects of insulin with age. An age-related impairment of intracellular insulin signaling reduces insulin-mediated mobilization of glucose transporters, which are critical to glucose uptake and metabolism in insulin-dependent tissues such as muscle and fat. There is currently little evidence for an age-related impairment of insulin effects on protein or fat metabolism.

An absolute or relative increase of body adiposity, particularly central body adiposity, has been well-documented with advancing age and appears to account in large part for the age-related increase in insulin resistance. Decreased physical activity is associated with insulin resistance and exercise training can improve insulin sensitivity. Thus, diminished physical activity in an older individual can also contribute to decreased insulin sensitivity. Both in animal studies and in humans, it has been difficult to demonstrate a residual effect of aging on insulin action when the changes in body composition and physical activity are controlled for.

## Impaired Insulin Secretion

The progression from normal glucose tolerance to IGT and type 2 diabetes in aging is characterized by progressive defects in pancreatic

**FIGURE 109-2.** Model for age-related hyperglycemia. (A) Normal adaptation to insulin resistance. In normal individuals, pancreatic beta cell function compensates for insulin resistance with an adaptive response resulting in hyperinsulinemia, but maintenance of normal glucose levels (euglycemia). (B) Multiple risk factors for type 2 diabetes associated with aging predispose older adults to develop hyperglycemia. Some of these factors contribute to increased insulin resistance and some to decreased insulin secretion. As older individuals with impaired pancreatic beta cell function are unable to adapt adequately to insulin resistance, impaired glucose tolerance (IGT) and progression to type 2 diabetes can occur. A vicious cycle may ensue as hyperglycemia develops and leads to further deterioration of beta cell function and more severe insulin resistance. (Adapted from Chang AM, Halter JB. Aging and insulin secretion. *Am J Physiol Endocrinol Metab.* 2003;284:E7.)

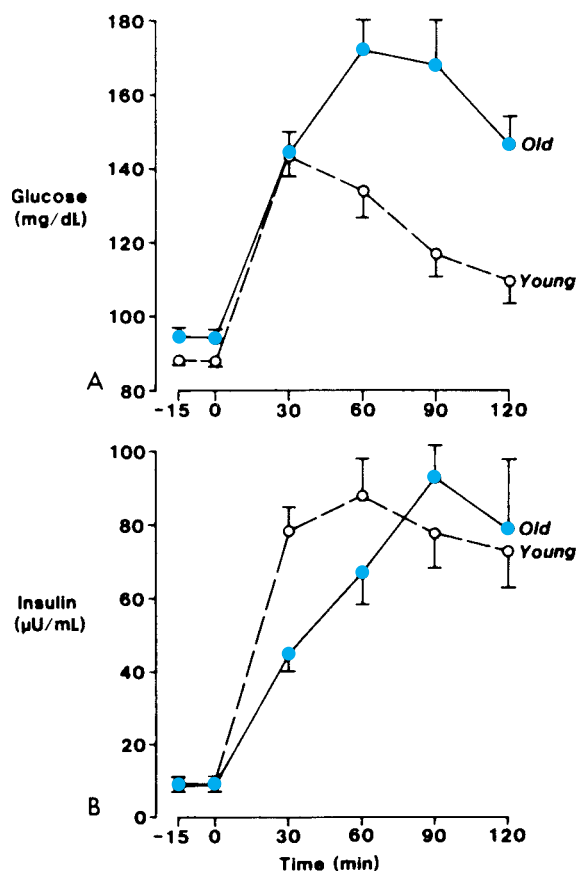

beta cell function. Animal studies have demonstrated an age-related decline in beta cell function. However, there has been great variability in previous studies examining insulin secretion in older people. These human studies, however, may have failed to address adequately the importance of the normal adaptive response to insulin resistance. As most older individuals demonstrate insulin resistance, as already described, a compensatory increase of insulin secretion, leading to increased circulating insulin levels would be expected. As illustrated in Figure 109-2A, this is the normal adaptive response to insulin resistance that is observed in younger people who have obesity or other causes of insulin resistance. Such individuals have elevated fasting insulin levels and an increased insulin response to a glucose challenge. However, both basal and stimulated insulin levels in older adults are similar to those of insulin-sensitive young people, as illustrated in Figure 109-3, despite the coexistence of insulin resistance in the elderly subjects. Furthermore, when older and younger people are carefully matched for degree of insulin sensitivity, absolute impairments in betacell function with normal human aging have been demonstrated. Such defects are greater in older people with IGT, as

shown in Figure 109-4. Impaired pancreatic beta cell adaptation to insulin resistance is an important contributing factor to age-related glucose intolerance and risk for diabetes.

#### Interaction Between Impaired Insulin Secretion And Insulin Resistance

As summarized in Figure 109-2, in the setting of impaired beta cell function, there is a maladaptive response leading to impaired insulin secretion and progression to IGT and type 2 diabetes. Hyperglycemia, in turn, is known to contribute directly to insulin resistance and to impair pancreatic beta cell function, thereby setting up a vicious cycle of maladaptive mechanisms.

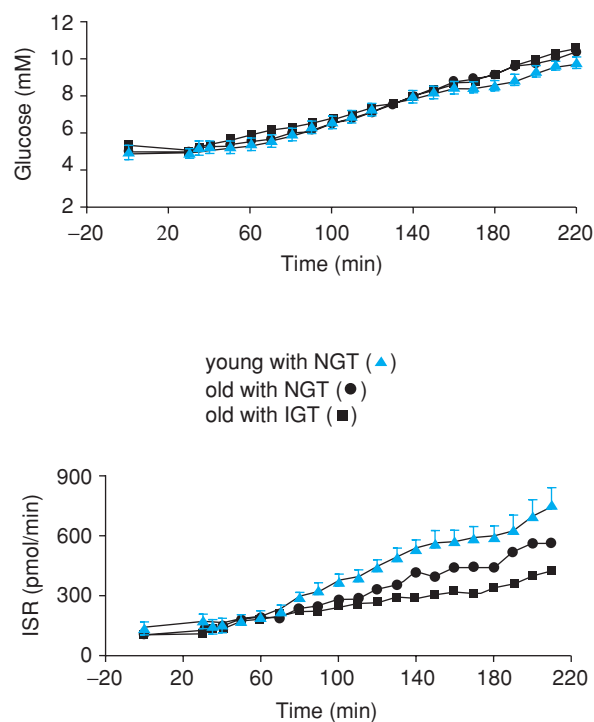

Coexisting illness is another factor affecting both insulin sensitivity and insulin secretion in an older person. Both hypertension and hyperlipidemia are common in older people and have been associated with diminished insulin sensitivity. In fact, a metabolic syndrome has been described that includes coexisting hypertension, hyperlipidemia, central obesity, and glucose intolerance. Some have

**FIGURE 109-3.** Plasma glucose (upper) and insulin (lower) levels before and following oral ingestion of 100 g of glucose in healthy old ( $n = 18$ ) and young ( $n = 18$ ) subjects matched for relative body weight and socioeconomic group. Subjects were eating an ad libitum diet. Note the slight elevation of fasting glucose levels in the old group and the delay in recovery of glucose levels following oral glucose. Also note the overall similarity of insulin levels between old and young subjects. (Reprinted with permission from Chen M, et al. *The role of dietary carbohydrate in the decrease glucose tolerance of the elderly.* *J Am Geriatr Soc.* 1987;35:417.)

proposed that insulin resistance is a unifying feature linking the components of this metabolic syndrome; however, there is uncertainty about whether the insulin resistance in these circumstances is primary or a secondary result of these other conditions. Furthermore, any acute illness can precipitate hyperglycemia because of effects of stress hormones to cause insulin resistance combined with the  $\alpha$ -adrenergic effects of catecholamines released during stressful illness to inhibit insulin secretion. Drugs that may be used by older people may also contribute to hyperglycemia by causing insulin resistance (see Table 109-2).

Finally, a pathogenetic sequence common to many syndromes in old age can be readily illustrated by diabetes in an elderly patient: Hyperglycemia becomes frank diabetes, leading to acute complications and such syndromes as hyperosmotic nonketotic coma or, with time, to microvascular or macrovascular complications such as renal disease, stroke, or myocardial infarction, with superimposed drug-induced aggravation of impaired glucose regulation and decreased physical activity, progressive disability, and functional decline; that is, a downward spiral of mutually reinforcing conditions perhaps triggered by an event such as influenza or a fall that would be readily withstood by a younger person, especially a younger person without diabetes.

Chang et al, *J Clin Endocrinol Metab* 91: 3303–3309, 2006

**FIGURE 109-4.** Effect of age on insulin secretion rate (ISR) in humans with normal glucose tolerance (NGT) or impaired glucose tolerance (IGT) by American Diabetes Association criteria. Plasma glucose concentrations and ISR are shown over time during intravenous glucose infusions, comparing young with NGT ( $n = 15$ , mean age = 26 yrs), old with NGT ( $n = 16$ , mean age = 70 yrs), and old with IGT ( $n = 14$ , mean age = 70 yrs). Glucose levels during variable rate glucose infusion begun at time 0 were well-matched in the three study groups, and degree of insulin resistance was also similar in the three study groups. ISR was significantly and progressively decreased in the two older groups, with the greatest impairment in old IGT ( $P = 0.0002$ , old IGT vs. young and old IGT vs. old NGT; and old NGT vs. young NGT). Data are means  $\pm$  SE. (Adapted from Chang AM, et al. *Impaired  $\beta$ -cell function in human aging: response to nicotinic acid-induced insulin resistance.* *J Clin Endocrinol Metab.* 2006;91:3303.)

## Genetics

There is a strong genetic predisposition to type 2 diabetes mellitus. For example, the concordance rate for type 2 diabetes in identical twins approaches 100%. However, the genetic predisposition is complex and likely a key part of the heterogeneity of this disorder. As described previously, there are a few simple genetic abnormalities that cause a diabetes syndrome such as MODY. However, even within this narrow subtype of diabetes mellitus, there is considerable heterogeneity, as different families have now been described with defects in at least six different genes, all resulting in a similar phenotype. Furthermore, there is heterogeneity within each gene defect, as various alterations of the gene have been described in different families.

The situation in typical type 2 diabetes is likely to be much more complex, with multiple genes involved in different individuals in different families. Ultimately, there may be hundreds of different subtypes of type 2 diabetes identified as different combinations of genetic alterations are identified in different families. As these genes are identified and their functions determined, new therapeutic approaches to treatment may develop, enabling targeting of therapeutic

interventions to the specific genetically determined defects present. Genome-wide scanning of large populations has now identified at least 10 genetic markers associated with type 2 diabetes. However, these markers in aggregate account for only a small percentage of type 2 diabetes risk.

In summary, the high rate of diabetes in older adults likely represents the interaction of genetic background with the linked age and lifestyle-related changes in insulin secretion and insulin action described here.

### Mechanisms for Diabetes Complications

Chronic exposure to hyperglycemia may contribute directly to the development of diabetes complications in a number of ways. One mechanism may be the interaction of glucose with proteins to cause protein glycosylation and subsequent formation of advanced glycosylation end (“AGE”) products. The AGE products can accumulate in proteins of slow turnover such as collagen, potentially leading to tissue damage and injury. Tissue exposure to high concentrations of glucose can also lead to accumulation of metabolic products of the aldose reductase system including nonmetabolized molecules such as sorbitol. Such accumulation can potentially affect cellular energy metabolism and contribute to cell injury and death. Given the complexity of the genetic background contributing to type 2 diabetes, the possibility also exists that some of the genetic background of an individual may directly contribute to the risk for one or more long-term complications of diabetes (e.g., end-stage renal failure) independently of the effects of hyperglycemia. However, such a possibility remains speculative. Interactions between diabetes and other comorbidities may contribute to the manifestation and severity of diabetes-related complications. Diabetic patients who also have hypertension are at greater risk for renal disease and for macrovascular disease than diabetic patients without hypertension. Similarly, neuropathy is more likely in a diabetic patient who is exposed to a neurotoxic agent.

### PREVENTION

Type 2 diabetes is a gradually progressive disorder of carbohydrate metabolism that develops over a long period of time. It has been estimated that abnormalities of glucose regulation can be detected 8 to 10 years before the clinical diagnosis of type 2 diabetes is made. The importance of lifestyle factors in the pathophysiology of type 2 diabetes and the epidemiological associations of healthy lifestyles with reduced risk for diabetes suggest that lifestyle interventions might prevent the development of diabetes. Given the progressive nature of impairments of glucose regulation, there is great interest in trying to identify people early in this course who are at high risk and therefore candidates for intervention to prevent progression. There is now substantial evidence that high-risk individuals can be identified and that progression to type 2 diabetes can be delayed. People with IGT and obesity appear to benefit from such interventions. Individuals from high-risk ethnic groups or who have a history of GDM also appear to benefit.

In the largest of these studies, the multicenter Diabetes Prevention Program (DPP) in the United States, an effort was made to recruit older adults with IGT. A lifestyle intervention program including both caloric restriction and exercise was shown to be remarkably

effective in reducing the rate of progression to type 2 diabetes, even though only 5% to 7% weight reduction was achieved. In the DPP, the lifestyle intervention program was even more effective in people older than age 60 years than in younger people at risk, reducing progression to diabetes by more than 70% as compared to a control group. Drug interventions have also been tested. Metformin was used in the DPP and was effective in slowing progression in younger adults, but had surprisingly much less effect in people older than age 60 years.

As more is learned about the genetics of type 2 diabetes, it may be possible to identify high-risk individuals early in life based on genotype and to effectively target interventions. The success of the initial intervention trials to prevent progression has raised the question, not yet resolved, about whether and how screening should be carried out to identify high-risk individuals for more widespread clinical interventions.

### PRESENTATION

The finding of an elevated glucose level on routine laboratory testing is the most common presentation for type 2 diabetes in an elderly person. The classical clinical hallmarks of diabetes are symptoms associated with marked hyperglycemia, including polydipsia, polyuria, polyphagia, and weight loss. Older patients with type 2 diabetes may present with such symptoms, although it is relatively uncommon for them to do so. Some of these patients may have sufficient hyperglycemia to cause mild classical symptoms, while others may have had gradual unexplained weight loss. Other older patients may present with atypical symptoms from hyperglycemia such as falls, urinary incontinence, fatigue, or confusion. Because type 2 diabetes may go undetected for years, some older adults first present with symptoms or findings related to diabetes complications, such as visual loss with classic retinopathy on examination, proteinuria, or symptomatic peripheral neuropathy.

With the profound insulin deficiency of type 1 diabetes, mobilization of fatty acids occurs leading to accelerated production of ketoacids, potentially resulting in life-threatening DKA. Although type 1 diabetes usually occurs in early life, it can occur at any age, including first presentation in an elderly patient. Development of DKA is the classic form of presentation for a patient with type 1 diabetes, but it is now recognized that people with type 1 diabetes may have long periods of abnormal circulating glucose levels before the development of DKA. Furthermore, with early detection of such hyperglycemia and appropriate diabetes management, an episode of DKA might never occur. An older person with type 1 diabetes may be particularly more likely to present with an indolent course.

### EVALUATION

Diabetes mellitus is a complex disorder that can have effects on many body systems, and its treatment may require a complex program including medication plus lifestyle changes. The choice of intervention strategies and the patient’s capability to adhere to a diabetes treatment program may be limited by the presence of other health problems, as well as by the patient’s living situation, economic status, availability of caregiver support, and the like. A comprehensive geriatric assessment (Chapter 11) is highly appropriate to pro-

vide the basis for developing a treatment plan for an older person with diabetes mellitus.

## Medical Evaluation

Once a diagnosis of diabetes is established, a thorough medical evaluation is needed. Because the risk for developing diabetes complications is related to the duration of hyperglycemia, effort should be made to pinpoint the time of onset. Unless patients at risk have been followed up carefully with yearly measurement of a fasting glucose level, as currently recommended by the ADA, it may be difficult to establish a time of onset for type 2 diabetes mellitus in a given patient. Because of the usual uncertainty about time of onset, a careful search for existing diabetes complications is warranted even when a new diagnosis is made in an older adult. Such an evaluation is even more justified in a patient with a multiyear history of diabetes mellitus who is establishing a new relationship with a health care system or primary care provider. The evaluation for eye complications of diabetes should be carried out by an ophthalmologist with a detailed retinal examination, as early signs of diabetic retinopathy can easily be missed.

Evaluation of diabetic nephropathy should include a screening serum creatinine level. An elevated serum creatinine is a poor prognostic sign, suggesting that substantial kidney damage has already occurred and that an irreversible course of progressive renal insufficiency has already started. Depending on the patient's overall situation, referral to a nephrologist may be warranted to assess other potential causes of renal insufficiency. Urine screening for proteinuria should be carried out to detect earlier stages of diabetic nephropathy that are amenable to intervention. A positive qualitative urine for protein (dipstick method) indicates gross proteinuria. If confirmed on repeat testing, this finding in itself is an indication for treatment intervention. However, a negative qualitative urine protein test does not rule out early diabetic nephropathy. If the qualitative dipstick test is negative, a spot urine sample should be sent for quantitative measurement of urine protein and creatinine. A value greater than 30 mg/g, often referred to as microalbuminuria, suggests early diabetic nephropathy. Such a test should be repeated twice in subsequent months for confirmation. If two of three tests are positive, intervention is warranted.

A careful neurologic examination should be carried out for signs of diabetic neuropathy. This examination should include monofilament testing. This is a qualitative test with a 10-g nylon monofilament carried out at different points along the foot with simple yes or no responses by the patient about feeling the pressure of the monofilament. Vibration sense should also be tested with a tuning fork. This neuropathy evaluation should be carried out in conjunction with a careful foot examination to identify possible structural abnormalities that might contribute to risk for skin breakdown and damage.

The medical evaluation of an older patient with diabetes should also include information about other coexisting risk factors including hypertension, hyperlipidemia, and use of cigarettes. These conditions interact with diabetes to increase risk of adverse cardiovascular events and therefore need to be addressed in an overall patient management program. Blood pressure should be assessed both in the supine position and with upright posture, as an orthostatic drop in blood pressure may be another marker of diabetic neuropathy and is often associated with supine hypertension. The genitourinary

system should also be assessed, as patients with diabetes may be prone to bladder dysfunction associated with autonomic neuropathy, thereby increasing the risk for urinary tract infection and kidney damage. Sexual dysfunction has been reported in a high percentage of older men with diabetes, suggesting an interaction between aging, neuropathy, and vascular disease in this population.

A thorough evaluation of the cardiovascular system also should be carried out, given the high rate of vascular disease in older people with diabetes mellitus. The history and physical examination should carefully assess evidence for cerebrovascular disease, coronary heart disease, and peripheral vascular disease. Suggestive history or physical findings should be documented with more in-depth testing including Doppler evaluation for carotid artery stenosis or extremity blood flow, or cardiovascular stress testing if there is any suggestion of coronary artery disease. Silent ischemia and myocardial infarction appear to be more common in people with diabetes mellitus. Thus, the threshold for stress testing should be rather low.

The drug history of an older patient with diabetes is important both to identify drug therapy that may be contributing to the patient's hyperglycemia (see [Table 109-2](#)), as well as to identify potential drug interactions that may affect diabetes management. The initial assessment should also include a diet history, a review of potential nutritional problems, and an oral health assessment, as dietary intervention is a key component of a treatment program for virtually all patients with diabetes. The assistance of a nutritionist who has a particular interest in diabetes is often very helpful for this part of the evaluation. Particular attention should be paid to dietary habits, ethnic food preferences, and meal patterns.

## Other Evaluation Components

### Diabetes Knowledge

Because of the complexity of diabetes management, usually requiring both lifestyle and medication interventions, the patient or caregivers must be actively involved in their own care and take responsibility for its many aspects. It is particularly important to review the patient's knowledge base regarding diabetes and its complications. Standardized diabetes knowledge tests are available, or an interview with a diabetes educator or suitably trained nurse can establish the status of the patient's knowledge base. The diabetes education program that becomes part of the treatment plan can then provide this base for new patients or fill in needed gaps for existing patients.

### Functional Status

A review of activities of daily living and instrumental activities of daily living should be a part of comprehensive assessment of an elderly patient with diabetes mellitus. Diabetes puts the patient at increased risk for functional deficits. Such functional limitations must also be considered in developing a diabetes treatment program. In addition to general assessment of functional status, the ability of the patient and caregiver to carry out diabetes-specific functional tasks needs to be evaluated. For example, the ability to carry out home glucose monitoring or self-injection of insulin requires certain functional abilities.

## Cognitive and Psychosocial Status

Given the complexity of diabetes management programs, an assessment of a patient's cognitive status is essential to developing an appropriate treatment plan. A screening cognitive test should be carried out, with more detailed testing as indicated by the screening test or a history of cognitive decline. Cognitive function may be affected directly by diabetes as a result of cerebrovascular disease, postulated direct effects of hyperglycemia to cause subtle impairments of cognition, as well as by diabetes treatment, which can result in hypoglycemia. Complex cognitive skills are required for a number of aspects of diabetes treatment. Similarly, the presence of other psychiatric disorders such as depression or bipolar disorder could have a major impact on the decision about diabetes treatment interventions. Both cognitive disorders and clinical depression are more common in older people with diabetes than in those without diabetes.

The patient's socioeconomic and living situation can also have an important impact on the diabetes treatment plan. The availability of caregivers in the home or nearby can compensate for some limitations in the patient's self-care abilities and influence lifestyle factors that can affect diabetes management. Economic issues may affect the patient's ability to adhere to a costly medical regimen, and cultural influences may need to be considered as a treatment plan is developed. The availability of a social worker or suitably trained nurse to assist in this aspect of the patient evaluation can be extremely helpful.

## Overall Health Status

The presence of other medical problems needs to be documented, as decisions about the extent of intervention for diabetes need to be put in the context of the patient's overall health situation, disease burden, and prognosis in terms of functional status and estimated longevity. The presence of a coexisting illness such as congestive heart failure or uncontrolled cancer, which would substantially limit a patient's future life expectancy, will influence the decision about intensity of diabetes management.

# DIABETES MANAGEMENT

## General Approach

The first key step in developing a diabetes management program for an elderly patient is to establish the treatment goals. The overall treatment goal of a basic diabetes care plan is to prevent metabolic decompensation and to control other risk factors that may contribute to long-term complications in any patient with diabetes. Control of hyperglycemia as a means to reduce what some have termed glucose toxicity as a contributing factor to long-term diabetes complications is one part of an overall strategy of risk reduction. Such a strategy must include intensive effort at identifying and controlling hypertension, lipid disorders, and cigarette smoking. Thus, a complex, multifaceted treatment program is important for many older patients with diabetes. As other chapters cover the management of hypertension (Chapter 81) and lipid disorders (Chapter 110), these will be referred to only briefly in this chapter, which will focus on management of

**TABLE 109-4**

### Factors to Consider in Setting a Diabetes Treatment Goal for Elderly Patients

Patient's estimated remaining life expectancy
Patient's preference and commitment
Beliefs of the primary care provider (e.g., whether glycemic control can prevent complications)
Availability of social support and services
Economic issues
Coexisting health problems
Major psychiatric disorder
Major cognitive disorder
Diabetes complications
Major limitation of diabetes functional status
Complexity of medical regimen
Risk of severe hypoglycemia

hyperglycemia. However, control of the traditional cardiovascular risk factors is absolutely critical to successful diabetes management. Unfortunately, many studies have documented the overall lack of success of standard clinical practice in achieving these goals.

It may be neither feasible nor appropriate to attempt to achieve a complex diabetes management program for some patients. [Table 109-4](#) lists some of the factors to consider when deciding whether to strive for a treatment goal designed to minimize risk for diabetes complications. It is true that a limited remaining life expectancy shortens the time for long-term complications to develop and progress. Given the increasing life expectancy of older adults, only the very oldest segment of the population or those with coexisting illness that markedly shortens remaining life expectancy should be excluded from consideration for an aggressive treatment program. For example, it would be hard to justify abandoning risk reduction goals in an otherwise healthy 75-year-old woman with a recent diagnosis of diabetes, as such a person's remaining life expectancy may be 15 years or more. Given the potential complexity of treatment programs designed to minimize diabetes risks, the commitment on the part of an adequately informed patient is clearly critical. Availability of a supportive environment including a strong diabetes treatment team and adequate economic support for an intensive treatment program are also important. Such a treatment goal is also difficult to achieve without commitment of the health care team, which must believe that achievement of the treatment goal will really make a difference in the patient's long-term health.

Any decision about an intensive treatment program must take into account coexisting conditions and the overall complexity of the patient's medical regimen. For example, the existence of advanced diabetes complications in an elderly patient may provide a rationale for less strict control of hyperglycemia or dyslipidemia. A significant psychiatric or cognitive disorder may also preclude an intensive management program. The target for hyperglycemia control would need to be higher for a patient at risk for severe hypoglycemia (see the section on "Hypoglycemia" later in this chapter). On the other hand, some older adults are able to devote a substantial amount of time to their own health care and are able to manage complex multidrug interventions for multiple health problems. Based on the initial comprehensive patient assessment as described here, many older

adults with diabetes may fit in a category for which an intensive treatment goal is appropriate.

### Management of Cardiovascular Risk Factors

Management of hypertension and abnormal lipid metabolism is discussed in Chapters 81 and 110, respectively. Because of the high risk status of patients with diabetes, the Seventh Report of the Joint National Committee on Detection, Evaluation and Treatment of High Blood Pressure and the ADA recommend a blood pressure goal of less than 130/80. As described in Chapter 110, many diabetic patients have a dyslipidemia, requiring that attention be paid to triglycerides as well as cholesterol levels. Diabetes is considered a cardiac disease equivalent. Thus, an aggressive target for intervention (low-density lipoprotein [LDL] cholesterol <100 mg/dL) is recommended by the ADA and the National Cholesterol Education Program (NCEP), even in the absence of a known cardiac history. For people older than 40 years with diabetes, statin drug therapy to achieve an LDL reduction of 30% to 40% regardless of baseline LDL levels is recommended. In diabetic individuals with overt cardiovascular disease, the ADA also suggests an LDL cholesterol goal of <70 mg/dL as an option and recommends goals of triglyceride levels <150 mg/dL and HDL >40 mg/dL.

Use of aspirin reduces cardiovascular risk in patients with diabetes. Thus, older patients with diabetes should be treated with one aspirin per day unless there is a contraindication. Alternative approaches may be developed to reduce systemic glucose toxicity other than simply lowering circulating glucose levels. There have been efforts to develop drugs that inhibit formation of AGE products, although none are yet available clinically. In addition, aldose reductase inhibitors have been tested and continue to be under investigation.

### Prevention of Microvascular Complications

Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers reduce the rate of progression from microalbuminuria to overt proteinuria and diabetic nephropathy. An ACE inhibitor or angiotensin receptor blocker should be added to a treatment program for any patient who has evidence of nephropathy. Also, rigorous blood pressure control is particularly important for such individuals.

Laser therapy reduces the rate of visual loss in patients with diabetic retinopathy. Thus, early detection is critical. Despite clear evidence of efficacy of retinopathy screening by ophthalmological examination and appropriate intervention, only 50% or fewer of diabetes patients receive recommended annual screening for retinopathy.

### Other Diabetes Complications

Prevention of amputation in older people with diabetes requires careful attention to peripheral vascular disease, neuropathy, and foot care. While microvascular disease and peripheral neuropathy may contribute to skin damage and impaired healing, it is clear that patients with diabetes can benefit from treatment of large vessel disease, which is the primary factor responsible for lower-extremity ischemia in people with diabetes mellitus. As the development of neuropathy is insidious, patients should be instructed to examine their feet carefully on a daily basis, and a foot examination should be a routine part of a diabetes clinic visit. Although there is no

current therapeutic approach to reduce the rate of development of neuropathy other than reducing glucose levels toward normal, a number of drugs are under development that target neuropathy.

Painful neuropathy is a common complication of diabetes. The first step in the management of patients with neuropathy should be to aim for stable and optimal glycemic control. Many patients will require pharmacological treatment for painful symptoms. Many agents have efficacy for the management of painful diabetic neuropathy. Pain management can start with acetaminophen. Opioid analgesics may be necessary at times. Nonsteroidal anti-inflammatory drugs should be avoided in elderly patients, especially those with nephropathy. Two drugs have been approved by the Food and Drug Administration (FDA) for treatment of painful diabetic neuropathy: the norepinephrine and serotonin reuptake inhibitor, duloxetine, and the inhibitor of excitatory neurotransmitter release, pregabalin. Other drugs that have been used include tricyclic antidepressants, alpha-lipoic acid, gabapentin, carbamazepine, and locally administered capsaicin cream.

### Management of Hyperglycemia

A major challenge in diabetes management is to set an appropriate treatment goal for hyperglycemia. The ADA recommends preprandial glucose levels of 90 to 130 mg/dL and a hemoglobin A<sub>1C</sub> ≤7%, with hemoglobin A<sub>1C</sub> as the primary target for glycemic control. However, the ADA also indicates that goals should be individualized and that certain populations (including elderly people) require special considerations. Similarly the California Healthcare Foundation/American Geriatrics Society (CHF/AGS) Panel on Improving Care for Elders with Diabetes recommended in 2003 that the hemoglobin A<sub>1C</sub> target should be individualized and that a target of ≤7% is reasonable for relatively healthy older adults who have good functional status. A more stringent glycemic goal (i.e., a normal hemoglobin A<sub>1C</sub> <6%) may further reduce complications at the cost of increased risk of hypoglycemia. Thus, such a goal is not currently recommended, pending the results of ongoing intensive treatment trials. The CHF/AGS Panel also recommended a less stringent hemoglobin A<sub>1C</sub> target such as 8% for frail elderly patients, for persons with a life expectancy less than 5 years, and for those in whom the risks of more intensive treatment appear clinically to outweigh the benefits.

Because of the difficulty in measuring the rates of diabetes complications and the long time it takes for them to develop, a detailed picture of the relationship between the degree of hyperglycemia and rate of development of complication has not yet been completed. A growing body of evidence from studies such as the National Institutes of Health's Diabetes Control and Complications Trial in people with type 1 diabetes and the United Kingdom Prospective Diabetes Study in people with type 2 diabetes has established that intensive diabetes management designed to achieve near normal glucose levels can reduce the rate of development of the microvascular complications of diabetes. At this point, there is also no evidence that the fundamental mechanisms contributing to diabetes complications differ between type 1 and type 2 diabetes. Until further information becomes available, the recommendations of the ADA and the CHF/AGS Panel seem reasonable for many elderly patients. Unfortunately, as in other patient groups, only a minority of older people with diabetes achieve these goals for hyperglycemia treatment, as illustrated in [Figure 109-5](#).

**FIGURE 109-5.** Percentage of elderly diabetes patients in NHANES III who did not achieve the level of hemoglobin A<sub>1c</sub> (HbA<sub>1c</sub>) recommended by the American Diabetes Association (HbA<sub>1c</sub> >7%). Patients were analyzed by age group and according to whether their HbA<sub>1c</sub> was in the range at which the ADA recommends therapeutic action (>8%) or not (7% to 8%). (Data from Shorr RI, et al. *Glycemic control of older adults with type 2 diabetes: Findings from the Third National Health and Nutrition Examination Survey, 1988–1994.* *J Am Geriatr Soc.* 2000;48:264.)

Regardless of whether a decision is made to try to prevent diabetes complications with intensive hyperglycemia management, a basic set of objectives should be part of the treatment plan for virtually all patients with diabetes. Metabolic decompensation with weight loss, muscle wasting, and a catabolic state is unlikely to occur if the average circulating glucose level is in the range of 200 mg/dL. This seems like a reasonable minimum target goal for basic diabetes care. Such a goal translates to a fasting glucose level in the range of 160 mg/dL and a hemoglobin A<sub>1c</sub> value of 8% to 9%.

### Basic Care

All patients with diabetes should receive a basic diabetes education about what diabetes is, what the long-term complications are, and the importance of periodic evaluation for them as well as basic lifestyle modifications that can improve risk and assist with diabetes management, including basic principles of diet and exercise. Basic diabetes care should include yearly follow-up and reevaluation for the development of diabetes complications, and intervention for those complications as appropriate. Recognition and treatment of hypoglycemia should also be part of the basic diabetes education program for any patient treated with insulin or a sulfonylurea drug.

### Aggressive Care

Individuals who are selected for an aggressive treatment program should also receive all aspects of basic diabetes care. While the ADA and the CHF/AGS Panel recommended treatment goal of achieving a hemoglobin A<sub>1c</sub> of 7% may require considerable effort and attention, it is important not to forget about aggressive detection and treatment of hypertension, dyslipidemia, and cigarette smoking. Regular monitoring for diabetes complications and institution of complication-specific interventions should also be carried out. In addition to basic diabetes education, the patient participating in an aggressive treatment program should be trained to carry out home blood glucose monitoring on a regular basis and should become familiar with various treatment approaches for hyperglycemia including diet, exercise, and medications. Such patients should participate in a formal diabetes education program to cover this material thoroughly. Access to a multidisciplinary diabetes care team should be part of an aggressive treatment program.

### Specific Interventions for Hyperglycemia

A decision about setting a goal for either basic diabetes care or an aggressive treatment program should be made for each older person with diabetes. Once this decision has been made, a growing range of therapeutic options enables the treatment program to be individualized according to the specific situation of the individual patient, as determined in part by the initial comprehensive assessment carried out.

#### Diet

Dietary intervention has long been a cornerstone of hyperglycemia management. The ADA currently recommends that medical nutrition therapy be included in any diabetes care program, but that it should be individualized for each patient. Fundamental to any dietary recommendation is ensuring that essential dietary needs are met with adequate provision of vitamins and minerals. Over the years, dietary supplements have been proposed to assist in diabetes treatment such as vitamins C, E, or B complex, or minerals such as zinc or chromium to replace possible diabetes-related losses, thereby improving the metabolic state and possibly reducing the rate of various complications. There is, however, no convincing evidence that any of these dietary supplements improves hyperglycemia control or influences diabetes complications. Two aspects of diet need to be addressed in any dietary program: the total caloric intake, which is a key to maintenance of body weight or weight reduction; and dietary composition, or the distribution of fat, carbohydrate, and protein calories.

**Caloric Intake** Caloric restriction is usually part of the initial approach to management of overweight patients with diabetes mellitus. Because it is generally desirable to maintain muscle and bone mass, the target of caloric restriction is reduction in adiposity, particularly the central adiposity that seems to be critical in mediating obesity-related insulin resistance. One criterion for obesity is a BMI of 30 kg/m<sup>2</sup>. A serious effort at weight reduction should be considered for any patient with a BMI in excess of 30 kg/m<sup>2</sup>. A BMI greater than 25 kg/m<sup>2</sup> is used as a marker of overweight and may also be an indication for caloric restriction. As reviewed in Chapter 39, because of an age-related decline in lean body mass, older individuals may

have increased adiposity and central adiposity without being overweight by usual BMI criteria. Documentation of central adiposity by waist measurement or computed tomography may suggest a role for caloric restriction in such individuals. Relatively normal-weight people with central adiposity likely already have diminished lean body mass, which will be further threatened by caloric restriction. For individuals who are not overweight and who do not have central adiposity, there is no role for caloric restriction as part of the hyperglycemia treatment program.

Although many types of diets are successful in the short-term in achieving weight reduction, long-term maintenance of weight reduction continues to be a major challenge. Some individuals are able to lose a significant amount of weight and maintain it. Therefore patients should be offered assistance with caloric restriction and supported for a weight loss program. In general, behavioral modification to change dietary habits is the most successful approach long-term. Relatively modest weight reduction can have a significant impact on the degree of insulin resistance and on control of glucose levels. Part of the approach should be to set a realistic goal of no more than 5% to 10% reduction of body weight, even if that will not achieve a normal BMI of less than 25 kg/m<sup>2</sup>. The role for medications to assist weight loss in an older person with diabetes mellitus is uncertain. With the current explosion of knowledge about regulation of food intake in relation to obesity, it is likely that new medications will appear in the market to assist in weight reduction. These should be integrated into diet treatment if justified by results of clear studies of efficacy and risks in an older adult population, evidence lacking to date for any pharmacological weight loss agent.

**Diet Composition** The average American diet includes approximately 45% of calories as carbohydrate, 40% as fat, and 15% as protein. While varying changes of overall dietary composition have been recommended in the past, there is currently no such recommendation. Current recommendations by the ADA are consistent with those of the American Heart Association and other groups, all of which recommend a diet relatively low in saturated fat (less than 7% of total calories), minimizing intake of trans fat, and limiting cholesterol intake to less than 200 mg per day. This recommendation for patients with diabetes especially makes sense given the very high rate of atherosclerosis-related complications in this patient population. These recommendations are not in conflict with the diet prescription if there is coexisting dyslipidemia that needs management.

Consistency of dietary intake in terms of meal composition, carbohydrate intake, and timing is particularly an issue in patients treated with insulin. The ADA's diet exchange program is one means of providing guidance to such patients to maintain consistency of dietary intake. Nutritional counseling can be particularly helpful in assisting patients to adhere to a dietary program.

**Dietary Issues in Older People** As summarized in Table 109-5, there are a number of special issues to consider in dietary management of older adults with diabetes. Older adults with a significant mobility limitation may be relatively inactive and have low caloric utilization. Thus, caloric intake may need to be limited to rather low levels to achieve significant weight reduction. The potential benefit of caloric restriction and weight reduction under such circumstances needs to be balanced against the potential risk for complications related to undernutrition. Such patients also may have difficulty with access to food both in terms of food preparation and shopping to

**TABLE 109-5****Dietary Therapy: Special Considerations for Older Adults with Diabetes Mellitus**

Access to food
Functional disability
Poor meal preparation skills
Lack of formal or informal support to obtain food
Limited financial resources
Food intake
Decline in taste and smell appreciation
Poor dentition and/or xerostomia
Ingrained dietary habits
Past experience and ethnic food preference
Impaired cognitive function

bring food in. Furthermore, dietary habits established for a lifetime and often with a cultural background may be particularly difficult to modify. Older persons, especially men living alone, may have limited food preparation skills. The presence of impaired cognitive function may make following a dietary prescription particularly difficult. Any of these issues can be modified if there is sufficient caregiver support and/or social services that can assist with providing meals in the home setting.

Problems with taste and oral health, which are common in older people, may further limit adaptation to a prescribed diet. Oral health problems can be exacerbated by diabetes, which may increase the rate of periodontal disease. This may be a growing issue as more older adults are keeping their teeth for longer periods. Xerostomia is also more common in older people owing to decreased salivary gland flow, sometimes exacerbated by coexisting medication use.

**Exercise**

An exercise program may be an important adjunct to hyperglycemia management. By increasing caloric expenditure, an exercise program can facilitate the effectiveness of a weight reduction program for overweight people with diabetes mellitus. It may also help prevent reaccumulation of weight following caloric-restriction-facilitated weight loss. Simple increases of physical activity, such as with stretching exercises or walking, while potentially useful to improve overall functional capability, will have only a very modest effect on total caloric expenditure. There is, however, a growing body of evidence that exercise training can also enhance sensitivity to insulin by improving insulin-mediated glucose uptake. Thus, exercise training may have a beneficial affect beyond simply enhancing the effectiveness of a weight reduction program. Furthermore, patients with diabetes may benefit from the effects of exercise training to enhance cardiovascular function, lower blood pressure, and improve the lipid profile. A more detailed discussion of the effects of exercise training in older individuals is provided in Chapter 114.

Exercise training alone has not had consistent effects to improve circulating glucose levels in patients with diabetes mellitus. For all the reasons just indicated, exercise may be a useful adjunct to drug therapy and may well contribute to enhanced effectiveness of glucose-lowering agents. Given the high prevalence of coronary artery disease in older patients with diabetes mellitus, which may be asymptomatic or atypical in symptoms, it is important for such patients to have

medically supervised stress testing before entering any challenging exercise training program. An additional issue to consider in an older person is the potential for foot and joint injury with upright exercise such as jogging. Particular attention should be given to the foot examination in an older person prior to and during the course of exercise training. Finally, because of its effects to enhance glucose uptake by muscle, exercise training may contribute to risk for hypoglycemia in patients treated with hypoglycemic agents. Issues related to hypoglycemia in older patients with diabetes are discussed in more detail later in the section on “Hypoglycemia”.

### Noninsulin Agents

A growing number of medications other than insulin are available for hyperglycemia management of older adults with diabetes mellitus. Table 109-6 lists the available drugs and summarizes some of the dosage and mechanism of action information. As the different classes of drugs have different mechanisms of action, there is increasing opportunity to individualize therapy as more is learned about the heterogeneity of type 2 diabetes. All of these agents are effective in lowering glucose levels in clinical trials of patients with type 2 diabetes mellitus. Some of them may also assist in lowering glucose levels as an adjunct to insulin therapy in patients with type 1 diabetes. The effectiveness of these agents must be considered in relation to the treatment goal set for the patient. For example, these agents are frequently successful in achieving the basic goal of hyperglycemia management; that is, to achieve an average glucose level in the range

of 200 mg/dL and avoid the catabolic effects associated with very poor diabetes control. These drugs have been much less successful in achieving the goals of aggressive hyperglycemia therapy, that is, a Hgb A<sub>1C</sub> ≤7% and a fasting glucose level close to the normal range. In fact, even in carefully conducted clinical trials of relatively short duration, only a minority of patients with type 2 diabetes are able to achieve such rigorous goals for hyperglycemia management with one of these agents alone or even in combination. Thus, a therapeutic trial of one or more of these agents for older patients who have not achieved their goal for hyperglycemia management with lifestyle modifications in diet and exercise is warranted. Such therapeutic trials should be instituted over a limited time frame without losing sight of the overall therapeutic goal. For the substantial number of patients for whom such a trial does not successfully achieve or maintain the treatment goal, both the patient and health provider team should be prepared to move forward to a more aggressive regimen including treatment with insulin.

**Sulfonylurea Drugs** Sulfonylurea drugs have been on the market for many years and have been historically the predominant oral agents used in the elderly diabetes population. As first-generation sulfonylureas are rarely used, Table 109-6 only includes second-generation agents. Because of their long history, there is a substantial body of knowledge about the mechanism of action and side-effect profile of sulfonylureas. Their primary mechanism of action is to enhance insulin secretion by the beta cells of the endocrine pancreas. Indeed, there is a sulfonylurea receptor on pancreatic beta cells that is closely

**TABLE 109-6**

#### Drugs (Other Than Insulin) for the Management of Hyperglycemia

GENERIC NAME	BRAND NAME	USUAL DAILY DOSE	MECHANISM OF ACTION
Sulfonylureas (Second Generation)			Enhance insulin secretion
Glimepiride	Amaryl	1–8 mg once	
Glipizide	Glucotrol	10–20 mg once or divided	
Glipizide, sustained release	Glucotrol XL	5–20 mg once or divided	
Glyburide	Diabeta, Micronase	2.5–20 mg once or divided	
Glyburide, micronized	Glynase	1.5–12 mg once or divided	
α-Glucosidase inhibitors			Decrease glucose absorption
Acarbose	Precose	25–100 mg tid	
Miglitol	Glyset	25–100 mg tid	
Biguanide			Decrease hepatic glucose production
Metformin	Glucophage	1500–2550 mg divided	
Thiazolidinediones			Enhance insulin sensitivity
Pioglitazone	Actos	15–45 mg once	
Rosiglitazone	Avandia	2–8 mg once or divided	
Meglitinide			Enhance insulin secretion
Repaglinide	Prandin	0.5–2 mg tid (before meals)	
D-Phenylalanine Derivative			Enhance insulin secretion
Nateglinide	Starlix	60–120 mg tid (before meals)	
DPP-4 inhibitor			Inhibitor of DPP-4, which degrades native GLP-1
Sitagliptin	Januvia	100 mg once orally	
GLP-1 Analog			Enhance glucose-dependent insulin secretion Decrease glucagon secretion Slow gastric emptying
Exenatide	Byetta	5 mcg–10 mcg sq bid (before meals)	
Amylin Analog			Reduces postprandial glucose in conjunction with mealtime insulin
Pramlintide acetate	Symlin	Adjunct to mealtime insulin sq tid (before meals)	

DPP-4 = Dipeptidyl peptidase-4; GLP-1 = Glucagon like Paptide-1.

linked to the signaling mechanism for glucose-induced insulin secretion. There is also some evidence that sulfonylurea drug treatment can enhance sensitivity to insulin in peripheral tissues. While enhancement of insulin action may be a direct effect of sulfonylureas on peripheral tissues, it is more likely that improved sensitivity to insulin is secondary to lowering of glucose levels, as hyperglycemia per se appears to contribute to insulin resistance in patients with diabetes mellitus.

Sulfonylurea drugs have established a long record of safety, with hypoglycemia being the main side effect about which to be concerned. Conservative dosing is recommended for older people. Gliburide has been associated with hypoglycemia in older people; however, it is also the sulfonylurea most frequently prescribed and is somewhat more potent than the other agents. These drugs should not be used in patients with renal insufficiency or with significant liver disease, as they depend on the liver for metabolism and the kidney for excretion. Hyponatremia has also been observed as a complication in some patients. Because of similar risk with use of thiazide diuretics, the combination of thiazide and sulfonylurea drugs should be avoided if hyponatremia is a concern.

**$\alpha$ -Glucosidase Inhibitors** These agents work by inhibiting the key gastrointestinal (GI) enzyme responsible for breakdown of carbohydrates prior to absorption. They are particularly helpful to reduce postprandial increases of glucose levels and may be a useful adjunct to therapy with other agents. The major side effects are local to the GI tract (flatulence, diarrhea, abdominal pain) because these drugs are not absorbed to any significant degree. These agents may be useful and relatively safe in older people with fairly well-controlled diabetes. One can expect an approximate 0.5% decrease in hemoglobin A1c.

**Biguanide** Metformin appears to work primarily by suppressing hepatic glucose production. Increased basal hepatic glucose production is an important contributing factor to fasting hyperglycemia in patients with diabetes mellitus. The precise mechanism by which metformin affects the liver is unknown, and there is somewhat inconsistent evidence for a small effect of metformin to enhance peripheral sensitivity to insulin as well. The most common side effect of metformin is some GI discomfort, which in some patients can be associated with decreased appetite and modest weight loss. While some have viewed this as a potential benefit for a patient on a weight-reduction program, this effect needs to be balanced against the degree of symptoms and the appropriateness of decreased caloric intake and weight loss in a given individual. The biguanide class of drugs is also known to be associated with development of life-threatening lactic acidosis under some circumstances. Although this complication appears to be rare in patients using metformin, this drug should be avoided in situations that may put people at risk for development of lactic acidosis. The drug should not be used in patients with chronic congestive heart failure, and it should be withheld during acute hospitalization for any major illness that could result in decreased tissue perfusion as a precipitating factor for lactic acidosis. Metformin also should be avoided in patients with significant liver disease or renal insufficiency (a creatinine level  $\geq 1.5$  mg/dL in men and  $\geq 1.4$  mg/dL in women). Creatinine clearance should be measured in people 80 years of age and older if metformin treatment is considered.

**Thiazolidinediones** This class of drugs appears to work primarily by enhancing peripheral and hepatic sensitivity to insulin. This mecha-

nism of action complements that of the other drug classes available. As peripheral resistance to insulin is a key part of the metabolic syndrome that predisposes to development of diabetes, use of a drug that targets this abnormality is attractive. These drugs have been shown to have similar efficacy and adverse events in older adults. One disadvantage is economic, as this is one of the more expensive class of drugs available and widely used for treatment of diabetes. These drugs may cause fluid retention and so should not be used in patients with heart failure. Overall analyses of the effectiveness of the thiazolidinedione rosiglitazone to reduce cardiovascular events or mortality have been disappointing, with some analyses showing increased, rather than decreased rates. Thus, the role of these agents in improving outcomes remains controversial.

**Meglitinide** Repaglinide enhances insulin secretion, but by a mechanism that differs from the sulfonylureas. Repaglinide acts rapidly to enhance insulin secretion, and is designed to be used immediately before meals. It predominantly improved postprandial glucose levels, but also lowers fasting glucose. It is of moderate potency. Although there are no age differences in the pharmacokinetics of repaglinide, there is limited experience in older people. Repaglinide and gliburide achieved similar A1c lowering in one study of older people with type 2 diabetes, but less hypoglycemia with repaglinide. This agent should not be combined with gemfibrozil because of increased repaglinide levels.

**D-Phenylalanine Derivative** Nateglinide acts directly on pancreatic beta cells to rapidly stimulate insulin secretion. Because of the rapid onset and short duration of action, it was developed to address meal-time needs for insulin secretion. It is to be taken shortly before a meal at a standard dose of 120 mg, although a 60 mg dose is also available. No dose adjustments are necessary in older people. Because of the glucose level dependency of its effect on insulin secretion and its short duration of action, its use has been associated with a low rate of hypoglycemia when used alone or in combination with other agents such as metformin. There are currently no known drug interactions, and nateglinide can be used in patients with renal insufficiency.

**Dipeptidyl Peptidase-4 (DPP-4) Inhibition** The incretin hormones are intestinal hormones that are released as glucose levels increase with meals and cause glucose-dependent insulin secretion. Native incretin hormones (such as glucagon-like peptide-1 [GLP-1] and gastric inhibitory polypeptide [GIP]) have very short half-lives as they are degraded by the enzyme, dipeptidyl peptidase-4, and thus cannot be used for therapeutic treatment. Sitagliptin, which became available in 2006, inhibits DPP-4 and thus increases and prolongs the action of the incretin hormones. Sitagliptin is indicated for monotherapy or in combination with metformin or a thiazolidinedione. The recommended dosing is 100 mg by mouth daily, although 25 and 50 mg tablets are also available. This agent does not cause weight loss, but has few nonspecific side effects including nasopharyngitis and headache. No overall differences were noted in initial safety and efficacy studies including older people.

**Glucagon-like Peptide-1 (GLP-1) Analog** Exenatide, a GLP-1 analog, became available in 2005. Similar to native GLP-1, but used in pharmacologic amounts, exenatide causes enhanced glucose-dependent insulin secretion, suppresses glucagon secretion, slows gastric emptying, and reduces food intake and body weight.

Exenatide is initiated at 5 mcg per subcutaneous injection via dosing pen twice daily at any time within the 60-minute period before the morning and evening meals. The dose can be increased to 10 mcg twice daily after 1 month of therapy. Exenatide primarily improves postprandial hyperglycemia, but also causes modest decreases in fasting glucose. Exenatide is approved for adjunctive therapy in patients treated with sulfonylurea and/or metformin and/or thiazolidinedione who have not achieved adequate glycemic control. There is limited experience in older people. Initial studies included people in late middle age and early sixties. Side effects include nausea/vomiting and hypoglycemia (with sulfonylurea treatment). Precautions include severe renal impairment and GI disease.

**Combination Therapy** Combinations of these oral agents or a combination of one or more of these oral/injectable agents with insulin are theoretically attractive because of the different modes of action of the various classes of drugs. Thus, combination therapy addresses various aspects of the pathophysiology of hyperglycemia in diabetes, offering the possibility of synergism in therapeutic efficacy without synergism in toxicity. Overall, the effects of such combinations are additive.

For elderly patients, the logic of combination therapy must be balanced against incremental costs and incremental risks of side effects with each additional drug. Furthermore, the potential for polypharmacy for multiple coexisting conditions such as hypertension, hyperlipidemia, osteoarthritis, and coronary artery disease needs to be considered. The overall treatment goal for the patient must also be kept in mind. Adding a second or third oral or injectable agent without achieving the target goal of near normoglycemia can be an indication to proceed to use of insulin.

### Insulin Therapy

Use of insulin is required in patients with type 1 diabetes mellitus. Insulin is also often used in patients with type 2 diabetes either as a primary hypoglycemic agent or to maintain reasonable glucose control in the hospital setting during acute stressful illness or in the perioperative period when oral agents may be less acceptable or useful.

**Advantages of Insulin** There are now more than 75 years of clinical experience with use of insulin since its discovery in 1922 and the dramatic demonstration of its effectiveness to save lives of patients with type 1 diabetes in DKA. Many formulations of insulin with varying duration of action allow individualization of treatment plans. Insulin is the natural hormone that is deficient in relative or absolute terms in diabetes, so its use fits with the overall concept of hormone replacement for endocrine deficiency syndromes. Virtually all forms of insulin currently in use are identical to human insulin or with only slight molecular modifications, so the incidence of allergic reactions is very small. There are virtually no known drug interactions, at least from a pharmacokinetic point of view, and virtually no absolute contraindications to insulin use.

With appropriate dosage modification and monitoring of glucose levels, insulin can be used safely for patients with renal or hepatic insufficiency, patients unable to eat, and during major illness. Insulin itself is relatively inexpensive, although the overall program of insulin treatment, including frequent glucose monitoring, may become expensive. While appropriate insulin use can be a complex challenge, it encourages active self-care by the patient and/or care-

givers. Finally, and perhaps most important from the point of view of achieving treatment objectives, insulin can effectively lower glucose levels in virtually any patient and in sufficient dosage has at least the potential to normalize circulating glucose levels if the regimen intensity is sufficient.

**Disadvantages of Insulin** One disadvantage of insulin is that it requires injection to be effective. (Inhaled insulin became available in 2006, although it is not currently being marketed because of concerns about long-term pulmonary toxicity.) Injection may represent an insurmountable psychological barrier for a small number of patients. For others, insulin injections may not be feasible owing to functional limitations or insufficient caregiver support. Many older adults can, however, be trained to use insulin appropriately. Insulin is a potent agent and the dose must be carefully measured to minimize risk of hypoglycemia. Accidental overdosage is a risk. The most common issue to address with insulin management is risk for hypoglycemia, which is discussed in more detail later in the chapter in the section on “Hypoglycemia.”

**Insulin Regimens** A range of therapeutic options is available for insulin, which can make a treatment program complex. If, however, a basic hyperglycemia treatment program is the goal for the patient, this can often be achieved with a single injection a day of a long-acting insulin analog, or two injections of intermediate-acting insulin in a patient with type 2 diabetes. Patients with type 1 diabetes may need three or four injections a day with mixtures of intermediate-acting and short-acting insulins to achieve even a basic treatment goal. Some patients with type 2 diabetes can also achieve an aggressive management goal with one or two injections of intermediate-acting insulin per day as long as a sufficient overall dose is provided. Mixtures of short- and intermediate-acting insulin, as well as increased frequency of insulin dosing, may be needed to meet an aggressive treatment goal in some patients with type 2 diabetes.

Newer, modified insulin preparations may help to target therapy. Insulin glargine (Lantus) is modified to slow degradation. It has a stable time course of action over 24 hours, so can be given once daily for basal insulin replacement. Insulin glargine is a clear solution with no need to re-suspend, which is a major cause of variability in absorption of long-/intermediate-acting insulins. Clinical trial and pharmacokinetic data suggest that insulin glargine can improve management of diabetic patients with a low incidence of nocturnal hypoglycemia, no pronounced peak, a long duration of action, and little interpatient absorption variability. Insulin glargine can be dosed as 0.2 units/kg/day subcutaneously once daily or initiated at 10 units once daily and adjusted as needed. Insulin glargine cannot be mixed with any other insulin. Insulin detemir (Levemir) is now also available. Insulin detemir is highly bound to albumin, which delays its absorption from the subcutaneous space. Dosing can be initiated at 0.2 to 0.5 unit/kg/day (0.1 to 0.2 unit/kg/day for insulin naïve patients) with one injection daily in the evening or at bedtime. However, the lower dosage requires twice daily injection separated by 12 hours.

Insulin aspart (NovoLog) and insulin lispro (Humalog) were developed as agents with a very rapid onset of action and short duration. These insulins are used for injection just prior to meals and are less likely to result in postmeal hypoglycemia than longer-acting regular insulin. Insulin glulisin (Apidra) is a newer rapid-acting insulin, which can be given within 15 minutes before or within 20 minutes

after starting a meal. Thus a combination of once-daily insulin glargine plus premeal injections of short-acting insulin may be used for intensive insulin therapy, with potentially similar results as with use of a subcutaneous insulin pump system delivering a continuous basal insulin infusion plus bolus injections with meals. Indeed, intensive insulin therapy of elderly people with type 2 diabetes using either of these two regimens achieved an average hemoglobin A<sub>1C</sub> of 7% over a period of 1 year with minimal adverse effects.

**Amylin Analog: Adjunct to Mealtime Insulin Therapy** Amylin is cosecreted with insulin and is absent in type 1 diabetes and deficient in type 2 diabetes. Pramlintide acetate (Symlin) is an analog of amylin that overcomes the tendency of human amylin to aggregate and form insoluble particles. It reduces postprandial glucose in conjunction with mealtime insulin. It is used as an adjunct treatment in patients who use mealtime insulin therapy and have failed to achieve desired glucose control despite optimal insulin therapy with or without a concurrent sulfonylurea agent and/or metformin. Pramlintide is administered as a subcutaneous injection via an insulin syringe before each major meal, but cannot be mixed with insulin. Pramlintide and insulin should always be given as separate injections and at separate sites at least 2 inches apart. Mealtime insulin is reduced by 50% with initiation of pramlintide with tailored dose escalation for type 1 and type 2 diabetes based on side effect of nausea and glucose levels.

**Initiation of Insulin Therapy** In developing an insulin treatment regimen for an older adult, it is useful to keep in mind a target total dose range per 24 hours, even though the initial starting dose may be substantially lower. An estimate of 0.5 to 1.0 units per kilogram for a thin patient with type 1 diabetes and 1.0 to 2.0 units per kilogram for a typical type 2 diabetes patient with insulin resistance represent reasonable targets. Of course, there will be substantial variation among individuals in total dose needed, depending on the target treatment goal, patient adherence to lifestyle modification recommendations, degree of insulin resistance, and individual variation of insulin dose pharmacokinetic patterns. Thus, a low starting dose of a single injection of long-acting insulin 10 to 20 units daily, depending on the degree of obesity, is reasonable. Initiation of insulin treatment is usually done as an outpatient and in conjunction with a diabetes education program for the patient and family members.

Frequent follow-up should be provided initially to ensure that the treatment program is progressing smoothly and that hypoglycemia does not occur early on. Given the metabolic stability of most older patients with type 2 diabetes, there is no need to escalate the insulin dose rapidly. Doses can be adjusted in 2- to 5-unit increments every 3 to 5 days (or every 7 days for insulin glargine) while glucose levels are being monitored. Patients should be prepared from the outset to progress to at least two injections per day, although some patients may achieve the treatment goal with a single dose.

As insulin doses continue to be gradually adjusted upward, an obese patient with type 2 diabetes may need a total well in excess of 100 units per day to achieve an aggressive treatment goal. Also, as doses are increased, it makes sense to include a combination of short-acting insulin with intermediate-acting insulin to help cover meal-related increases of glucose levels.

As glucose levels are reduced, insulin sensitivity will likely improve owing to amelioration of the direct effects of hyperglycemia. Thus, an overweight older patient who appears relatively unresponsive to a moderate dose of insulin initially may begin to respond dramatically

to modest further increases of insulin dose. In fact, the patient may progress to having episodes of hypoglycemia even with reduction to a total insulin dose that previously was not very effective. It is apparent that close follow-up with the diabetes care team, careful attention to glucose monitoring, and coaching about symptoms of hypoglycemia are all critical to a successful treatment program. A suitably trained diabetes nurse educator can play a particularly critical role during this phase of treatment.

**Combination of Insulin and Oral Agents** Combination therapy of insulin with one or more oral agents has also been considered, although there are little data available specifically in older adults. One regimen is use of an evening or bedtime injection of a long-acting insulin such as glargine (Lantus) to target control of the fasting glucose level plus oral agents for daytime use. A comparison of several insulin regimens added to oral therapy of people with type 2 diabetes with mean age of 62 years found that less than 25% of patients achieved a stringent hemoglobin A<sub>1C</sub> target of 6.5%. The average hemoglobin A<sub>1C</sub> was a little lower with multiple injections of short-acting insulin than with a single injection of detemir insulin, but the rate of hypoglycemia was higher with multiple injections.

There are theoretical advantages to combining insulin with an agent that enhances insulin sensitivity in a patient with insulin resistance or with an agent that reduces meal-related glucose excursions. However, insulin regimens alone with dose adjustments can achieve remarkably similar control of hyperglycemia as combinations of lower doses of insulin with an oral agent. Given the minimal incremental cost of additional insulin to a patient already on insulin and the potential for adverse drug reaction with any addition of a therapeutic agent, the practical gain of such combination therapy remains unclear.

Another theoretical advantage of combination therapy is that lower doses of insulin can be used to achieve similar glycemic control. It has been argued that high doses of insulin may have adverse cardiovascular effects. Such concerns are based in part on epidemiologic studies demonstrating that (in people without diabetes) higher circulating insulin levels are associated with coronary artery disease. There is also some evidence for direct effects of insulin on the cardiovascular system, some of which might be detrimental. There are, however, no convincing data linking dose of insulin in patients with diabetes to adverse cardiovascular effects.

Another concern about using a high dose of insulin is the potential for weight gain with an intensive insulin treatment program. For patients for whom the indication for insulin is a period of substantial weight loss caused by decompensated diabetes, insulin therapy should be expected to cause weight gain back toward baseline with accompanying restoration of lean body mass. For other patients, it may be necessary to balance the potential risk of weight gain versus the benefit of substantial lowering of circulating glucose levels. In general, weight gain with insulin therapy is modest (in the range of a few kilograms) except for those individuals who have lost substantial weight prior to insulin therapy. By emphasizing and reinforcing lifestyle modifications as insulin therapy is instituted, substantial weight gain can generally be avoided.

### Follow-up Care

Diabetes mellitus is a chronic disease that requires long-term follow-up. Frequency and intensity of follow-up depend on the treatment

goal for the patient and the type of treatment program that the patient is on. At a minimum, a patient should annually have a dilated retinal examination by an ophthalmologist, screening for early nephropathy, a foot examination and testing for neuropathy, measurement of circulating lipids, reassessment of blood pressure and smoking status, and review of key aspects of diabetes self-management and education. Measurement of hemoglobin A1c is a very useful way of assessing overall diabetes control and should be performed every 3 to 4 months for most patients. At regular follow-up visits, which can vary from monthly to every 3 months depending on the patient's situation, body weight and blood pressure should be assessed, a review of lifestyle components of the treatment program should be carried out, home glucose monitoring data should be evaluated, interim health problems and psychosocial problems should be reviewed, and appropriate adjustments in the overall treatment plan should be made. For patients with type 1 diabetes or type 2 diabetes with an aggressive treatment goal or with multiple diabetes complications, participation by a specialized diabetes care team in the overall management program should be carefully considered.

## SPECIAL ISSUES

### Hypoglycemia

Hypoglycemia is the primary short-term risk of a hyperglycemia treatment program, particularly one that is targeted at achieving near-normal control of glucose levels. Multiple mechanisms exist to maintain adequate circulating glucose levels because glucose is a fuel particularly targeted to meet the needs of the brain and other tissues that are not dependent on insulin for glucose uptake. The major peripheral tissues, muscle and fat, have a glucose transport system that primarily depends on insulin for activation. Brain cells, however, have a different type of glucose transporter molecule that is continually expressed on the cell surface and does not depend on insulin for activation. Thus, when insulin levels are low, as after an overnight fast, the brain does not have to compete with other major tissues for access to glucose. This is in contrast to fat-related fuel such as free fatty acids and ketones, which have ready access to muscle and fat tissue and therefore are less available to the brain. Because of the brain's dependency on glucose as a fuel, it is particularly vulnerable to injury from hypoglycemia, a fact that must be carefully considered as the overall benefits and risks of a diabetes treatment program are reviewed. An older diabetic adult on a hypoglycemic agent must be counseled to carry glucose tablets or food at all times. An older adult on insulin therapy and their family or caregiver should be given a glucagon emergency kit and teaching on its use.

### Hypoglycemia Counterregulation

Table 109-7 lists factors that are important in recovery from hypoglycemia. The major source of endogenous glucose is the liver. The liver contributes to recovery from hypoglycemia by increasing glucose production under the influence of counterregulatory hormones. As the insulin effect fades during insulin-induced hypoglycemia, there is a decline in peripheral glucose uptake, preserving more circulating glucose for recovery. The degree of fall of glucose levels determines the magnitude of counterregulatory responses and

**TABLE 109-7**

#### Factors Affecting Recovery from Hypoglycemia

Hepatic glucose production
Glucose uptake by tissues
Degree of hypoglycemia
Wearing off of drug effect
Counterregulatory hormone responses
Behavioral responses

the speed with which normal glucose levels can be restored. Normally, there is a hierarchy of responses to hypoglycemia with release of counterregulatory hormones such as epinephrine and glucagon occurring before a patient becomes symptomatic and aware of hypoglycemia. The initial symptoms are caused by autonomic nervous system activation with tachycardia, nervousness, and a sweating response, all of which can alert the patient to the need to seek exogenous sources of glucose to facilitate recovery. Hunger is often a part of this behavioral response. However, as glucose levels fall lower and brain cell function becomes compromised, confusion, lethargy, and progression to coma can occur. Fortunately, the response to glucose administration is quick, and dramatic recovery normally occurs.

It is now recognized that the history of the glucose level that the brain is exposed to influences the counterregulatory response mechanisms, perhaps by affecting the brain glucose transport system. For example, there appears to be adaptation to chronic hyperglycemia in patients with diabetes, with resulting elevation of the glucose level at which counterregulatory responses begin to occur. Thus, a patient with diabetes may begin to develop symptoms of hypoglycemia at a glucose level in the range of 80 to 100 mg/dL, well above the symptomatic threshold in nondiabetic individuals of 50 to 60 mg/dL. Conversely, the brain appears to adapt to low glucose levels as well, with a shift downward of the glucose threshold for activation of counterregulatory responses. Prior exposure to hypoglycemia leads to diminished counterregulatory hormone responses. This can set up a vicious cycle by which patients are less able to counterregulate hypoglycemia and have more recurrent episodes. A key issue seems to be that as the glucose threshold for counterregulation drops, it becomes perilously close to glucose levels that can adversely affect brain function. Thus a patient may have a very narrow margin for error, proceeding from relatively normal function without symptoms to profound hypoglycemia and loss of consciousness. This so-called hypoglycemia unawareness syndrome is in part iatrogenic in origin and generally responds to strict avoidance of hypoglycemia.

### Hypoglycemia in Elderly Patients

Table 109-8 summarizes a number of risk factors for hypoglycemia in an older patient with diabetes. As counterregulatory hormone responses are important for both symptom recognition and hypoglycemia counterregulation, impairment of autonomic nervous system reflexes can contribute to risk for hypoglycemia. In addition to risk of the hypoglycemia unawareness syndrome, some older patients may have autonomic neuropathy because of longstanding diabetes or other causes, and many older patients are treated with antiadrenergic agents for cardiovascular diseases. For example,  $\beta$ -adrenergic blocking drugs can potentially interfere with counterregulation of

**TABLE 109-8****Risk Factors for Hypoglycemia in Older Diabetic Patients**

Impaired autonomic nervous system function
Diminished glucagon secretion
Poor or irregular nutrition
Cognitive disorder
Use of alcohol or other sedating agent
Polypharmacy
Kidney or liver failure

hypoglycemia. Given the substantial benefit of  $\beta$ -adrenergic blockade to patients with cardiovascular disease, a combination with hypoglycemic drug therapy should not be viewed as an absolute contraindication, but only as a concern to keep in mind and share with the patient.

Fortunately, the counterregulatory system is redundant. Glucose counterregulation can be maintained quite well as long as there is an adequate glucagon response even when the adrenergic nervous system is blocked. However, some patients may have impaired glucagon secretion as well, particularly patients with longstanding type 1 diabetes or those with diabetes caused by inflammatory disease of the exocrine pancreas. Patients who have relatively poor nutrition and an irregular meal pattern are at increased risk of hypoglycemia, in part because of inadequate maintenance of muscle and liver glycogen stores. Use of alcohol or a sedating agent should be avoided in patients receiving hypoglycemic agents, particularly if an aggressive treatment program is being pursued. Clearly, a cognitive disorder will interfere with recognition of hypoglycemia and possibly affect decisions about responding to hypoglycemia. Patients with underlying renal or hepatic insufficiency may have problems eliminating hypoglycemic agents, particularly an issue for sulfonylurea drugs. Insulin is partly cleared by the kidney, and the insulin dose must often be reduced substantially in patients with renal insufficiency. A patient with severe hepatic insufficiency may have difficulty mobilizing a counterregulatory increase of glucose production. Finally, any complex drug regimen may include agents that influence the pharmacokinetics of hypoglycemic agents, or counterregulatory or behavioral responses to hypoglycemia, and therefore should be an issue when considering risk for hypoglycemia.

Despite all of these issues and concerns, many older patients with diabetes can be treated aggressively with low risk for hypoglycemia. By providing a strong educational program focused on hypoglycemia recognition and treatment and considering the risk factors outlined in Table 109-8, severe hypoglycemia can generally be avoided. Only subtle alterations of hypoglycemia counterregulatory mechanisms have been identified in healthy older adults, and patients who are hyperglycemic actually have elevated thresholds for counterregulation. Patients with type 2 diabetes are at less risk for severe hypoglycemia than are intensively treated patients with type 1 diabetes.

### Hyperosmolar Coma and Diabetic Ketoacidosis

DKA and hyperosmolar coma are the extreme examples of impaired metabolism in patients with diabetes mellitus. DKA is relatively uncommon in older people, but it can occur in an older patient with

type 1 diabetes mellitus. As in younger people, the hallmarks of DKA are substantial hyperglycemia, hyperosmolality, and volume depletion, and the presence of systemic acidosis caused by marked elevation of ketoacids. Ketoacids result from metabolism of elevated free fatty acids released by lipolysis as a result of severe insulin deficiency. DKA can occur in a patient with type 1 diabetes when insulin is inappropriately discontinued, but in an older adult, this may be a result of a major underlying illness that interferes with the patient's self-care capability. In the setting of severe coexisting major illness in an older individual and decreased tissue perfusion, lactic acidosis may occur in the setting of hyperglycemia. It is important to document the presence of significant ketonemia to ensure that DKA is contributing to the systemic acidosis observed. Treatment of DKA should focus on immediate insulin replacement to inhibit lipolysis and reverse the ketoacidosis, vigorous replacement of fluids and salt to replace losses, and a thorough evaluation to identify underlying illness. Careful monitoring is required to ensure response and particularly to monitor the cardiovascular system for signs of failure.

Hyperosmolar coma, which occurs primarily in older people, is characterized by marked hyperglycemia, hyperosmolality, severe volume depletion, and associated renal insufficiency. The mortality rate is high because there is often a severe underlying illness such as pneumonia or a cardiovascular accident. Metabolic acidosis is notably absent, or, if present, it is caused by lactic acid rather than ketoacids. The reason for failure to mobilize fatty acids despite severe insulin deficiency in these patients is unclear. While insulin should be provided as part of the initial therapy, the focus should be on volume and sodium replacement and on identification and intervention for major underlying illness. In fact, as volume status is corrected, in the presence of recovering renal function, glucose levels can fall precipitously. Therefore attention must be paid to avoidance of hypoglycemia.

### Diabetes in Long-Term Care

Diabetes mellitus is very common among nursing home residents. Because of the overall disease burden, degree of disability, and limited life expectancy of these patients, basic diabetes care should usually be the goal. As undernutrition may be a much more important health problem than obesity in this situation, diet therapy should focus on matching caloric intake to meet nutritional needs rather than restriction of calories. Furthermore, for a nursing home patient with limited remaining life expectancy, the priority should be to stimulate the patient's appetite and take advantage of opportunities for the patient to enjoy this aspect of life, rather than introduction of unnecessary dietary restrictions. Consistency of caloric intake is important for a patient treated with insulin and may be a particular challenge in a disabled nursing home resident.

Careful attention to skin and foot care is clearly important to avoid problems with healing and infection. Similarly, intensive exercise may not be appropriate for a nursing home resident. Efforts should focus on constructive leisure time activity. Given the staff support available, reliable insulin treatment should be available for a nursing home patient, and nursing home staff can also carry out glucose monitoring as needed. Staff needs to be trained to recognize symptoms of hypoglycemia, carry out testing as appropriate, and provide rapid intervention when hypoglycemia is present. In nursing home patients already at high risk for developing urinary

tract infection, diabetes may increase this risk because of bladder dysfunction secondary to autonomic neuropathy. Particular attention should be paid to keeping the bladder free of infection and carrying out intermittent catheterization as needed.

# Dyslipoproteinemia

Leslie I. Katzel ■ Jacob Blumenthal ■ John D. Sorkin ■ Andrew P. Goldberg

## DEFINITION

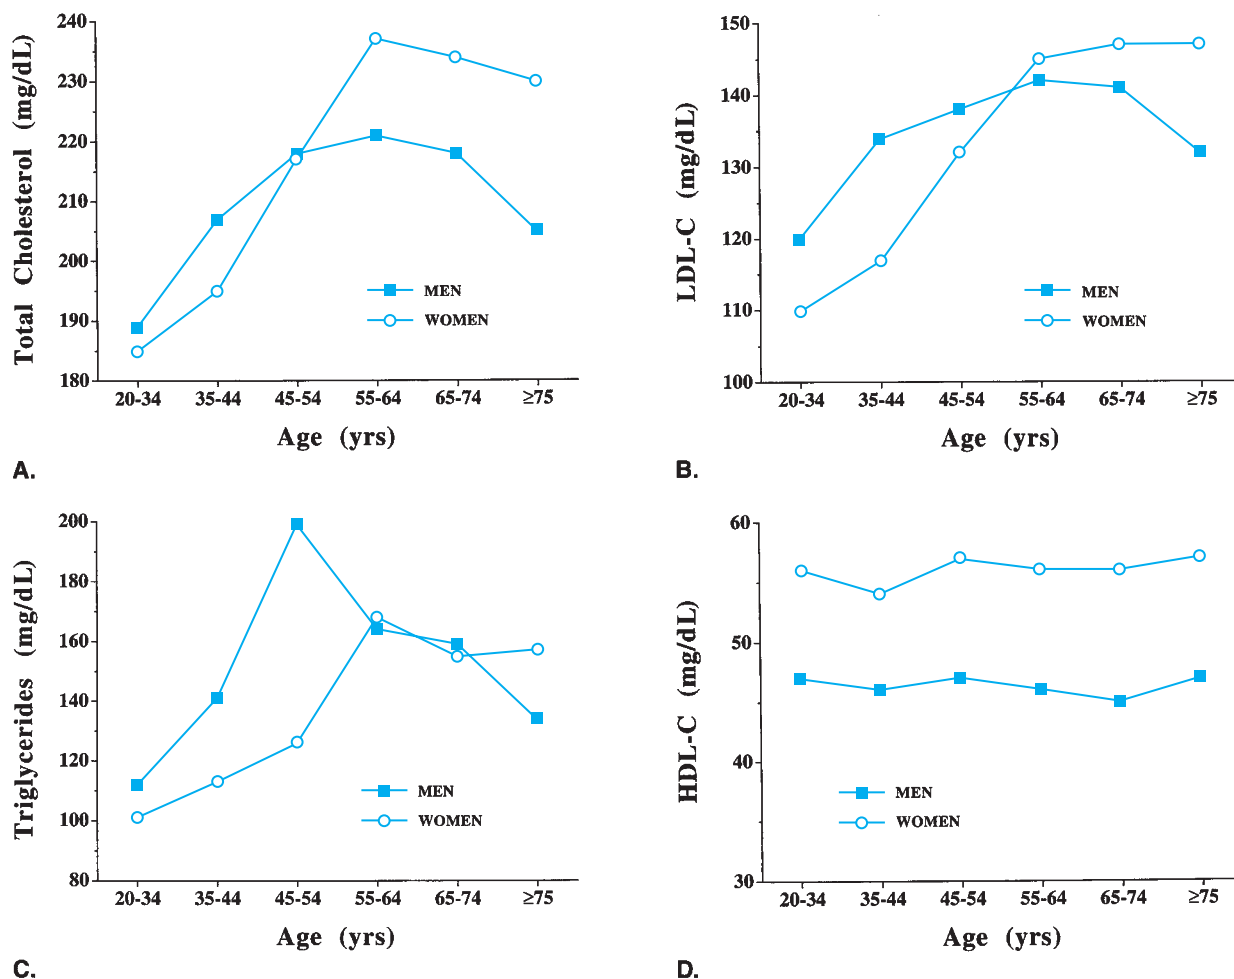

Dyslipoproteinemia, also referred to as dyslipidemia, encompasses a range of disorders of lipoprotein lipid metabolism that include both abnormally high and low lipoprotein concentrations, as well as abnormalities in the composition of these lipoprotein particles. Dyslipoproteinemias are clinically important because of their role in the pathogenesis of cardiovascular disease (CVD), which includes coronary artery disease (CAD), cerebrovascular disease, peripheral vascular disease, and renal disease. Thus the term dyslipoproteinemia is broader than the term hyperlipidemia, which focuses solely on the concentrations of the lipoproteins.

There is considerable evidence that dyslipoproteinemia is a risk factor for CVD in adults aged 60 to 80 years, with an expanding body of literature demonstrating dyslipoproteinemia as a risk factor for people older than 80 years of age. The consensus guidelines for the management of dyslipidemia are continually being reevaluated. Over the past several years, National Cholesterol Education Program (NCEP) Adult Treatment Panel (ATP) consensus guidelines have made the target lipoprotein concentrations more stringent for individuals with CVD. These guidelines have in turn led to more stringent recommendations for patients with CVD equivalents such as diabetes mellitus and renal disease, and for individuals with multiple CVD risk factors who are at increased risk for CVD events. Epidemiologic and clinical trial data suggest that the optimal concentration for low-density lipoprotein cholesterol (LDL-C) maybe <100 mg/dL, or even as low as 70 mg/dL for some high-risk patients. Similarly, the optimal concentration for high-density lipoprotein cholesterol (HDL-C) maybe >60 mg/dL. As discussed below, triglyceride, cholesterol, and LDL-C levels tend to rise with increasing age, before falling late in the sixth decade. HDL-C decreases at puberty and then is relatively constant across the age-span until the age of 70 years when it may increase (Figure 110-1). As a result, a majority of older individuals could be classified as having

undesirable lipoprotein lipid concentrations and are candidates for lifestyle intervention and potentially for pharmacological therapy if their concentrations exceed treatment cut points. The changes in the treatment guidelines are reflected in secular changes in prescribing patterns of drugs to treat hyperlipidemia, as the number of older adults on cholesterol-lowering medications has quadrupled over the past 15 years. In 2002, more than 30% of Medicare patients between the ages of 65 and 84 years were prescribed a statin for cholesterol reduction.

Many older individuals have metabolic abnormalities that promote atherosclerosis, but are not routinely measured. These risk factors include elevated lipoprotein (a) [Lp (a)], elevated apolipoprotein (apo) B, small dense LDL particles (the atherogenic LDL pattern B phenotype), oxidized LDL, apo E4 genotype, insulin, high-sensitivity C-reactive protein (hsCRP), homocysteine, and other markers of inflammation. These biomarkers provide incremental benefit in predicting CVD risk beyond the routine measures that are included in the Framingham Risk score. The role of genetic analyses in the assessment of CVD risk is an evolving field of research. It is also becoming increasingly clear that the measurement of structural markers of arterial vulnerability (carotid intimal-medial thickness, assessment of coronary artery calcium among others) and functional markers of arterial vulnerability (brachial artery reactivity assessment of endothelial function, arterial stiffness, and ankle-brachial blood pressure index [ABI]), similarly provide incremental benefit in predicting CVD risk in elderly people and help identify older individuals who might benefit from risk factor intervention.

Given the high prevalence of physical inactivity, hypertension and type 2 diabetes (T2DM) in the elderly, the geriatrician must have a firm understanding of the pathogenesis and treatment of disorders of lipoprotein metabolism in the geriatric population. This chapter reviews the epidemiology and mechanisms underlying age-associated changes in lipoprotein lipid concentrations, evidence that hyperlipidemia is a risk factor for coronary heart

**FIGURE 110-1.** Time-series analyses of lipid concentrations in U.S. adults aged 20–75+ yr. Data are from the NHANES surveys of 1976–1980, 1988–1994, and 1999–2002 (<http://www.cdc.gov/nchs/nhanes.htm>). NHANES data are a representative sample of the civilian, noninstitutionalized population. Age groups are indicated on the abscissa, lipid concentrations in mg/dL on the ordinate. Each age group contains mean lipid concentrations obtained at three time points. Over 26 yr of follow-up, LDL cholesterol concentrations have dropped in men and women. There is more variability in the patterns of change for HDL (data not shown) and triglycerides; however overall over the last 26 yr, triglyceride concentrations have generally increased. Data represent values for all races combined. Concentrations are expressed as arithmetic means for LDL cholesterol and geometric means for triglycerides. (Data adapted from Carroll MD, Lacher DA, Sorlie PD, et al. Trends in serum lipids and lipoproteins of adults, 1960–2002. *JAMA*. 2005;294:1773–1781.)

disease (CHD) in the elderly population, and controversies regarding the screening and treatment of hyperlipidemia in elderly patients.

## PATHOPHYSIOLOGY

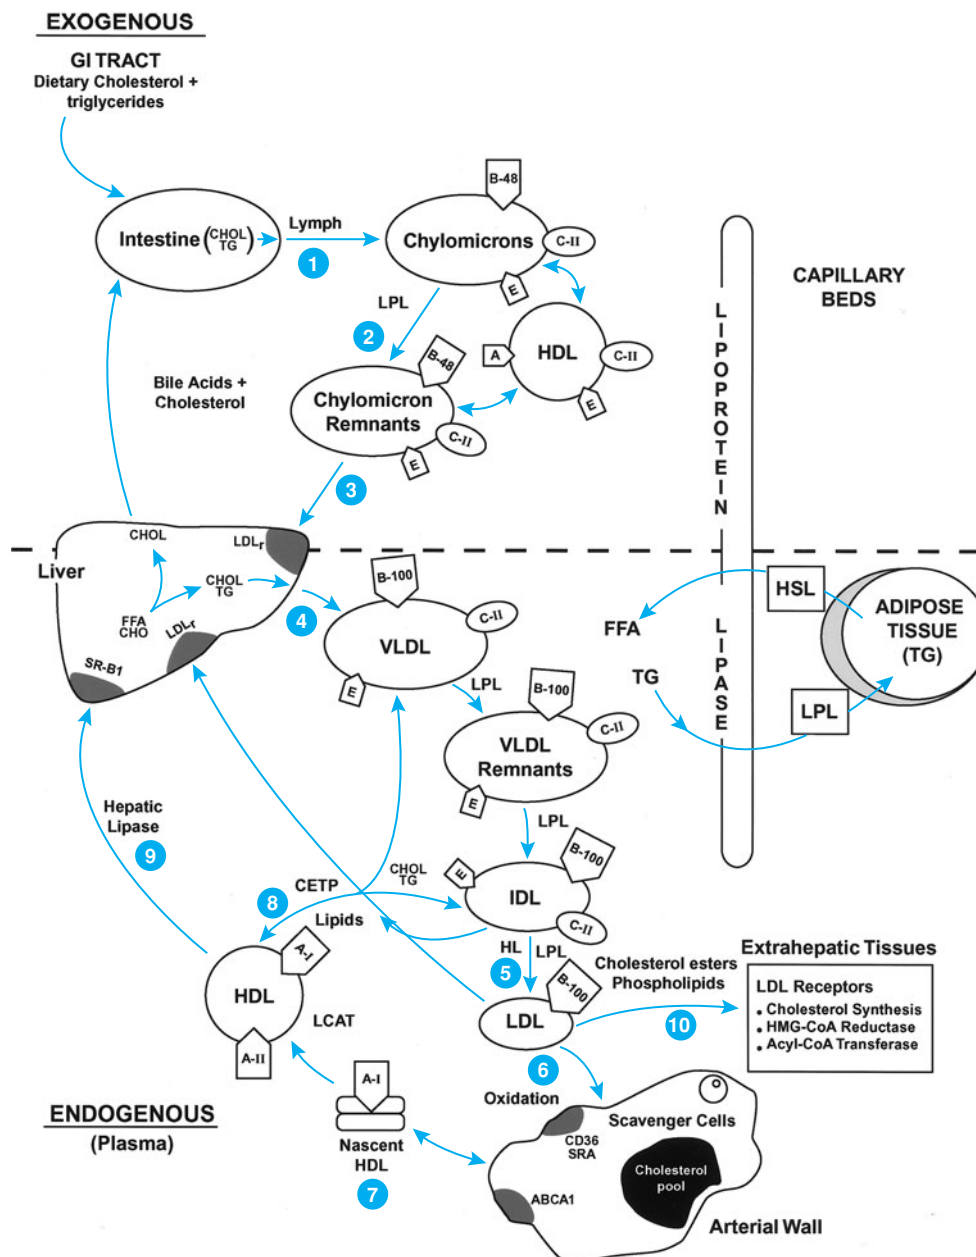

### Overview of Lipoprotein Subclasses and Lipoprotein Metabolism

Triglycerides (TG) and cholesterol of exogenous (dietary) and endogenous origin are transported in the blood stream as part of lipoprotein particles. These lipoprotein particles contain TG, cholesterol, cholesterol esters, phospholipids, and apolipoproteins (apo). Historically, the lipoprotein particles in the plasma have been classified on the basis of their density or by their electrophoretic mobility. Using ultracentrifugation, five major classes of plasma lipoproteins can be identified in ascending order of density: chylomicrons, very low-density lipoproteins (VLDL), intermediate density lipoproteins

(IDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL). The major classes of lipoproteins comprise subpopulations of lipoproteins that differ in composition, metabolic function, and atherogenic potential.

Lipoprotein metabolism involves the absorption of exogenous dietary fat from the GI tract, and the endogenous synthesis and secretion of triglyceride-rich lipoproteins by the liver. The physiological regulation of this process provides an understanding of the pathogenesis of atherosclerosis as the metabolic mechanisms by which therapies can target key regulatory sites to reduce CHD risk. In summarizing this process, we highlight a few key regulatory sites of normal and abnormal metabolic regulation and their consequences (Figure 110-2).

The major inherited forms of dyslipoproteinemia, and strategies for drug and dietary treatments for hyperlipidemia should be directed at these key regulatory sites of lipoprotein metabolism. Increased knowledge of the metabolic regulation of the lipoprotein subclasses by enzymes, cofactors, and transfer proteins, and various receptors has provided a framework for the understanding of pathogenesis of disorders of lipoprotein metabolism and their treatment.

**FIGURE 110-2.** Schematic overview of the Apo B containing lipoproteins. Lipids in the diet are hydrolyzed in the small intestine, and the resultant fatty acids and monoglycerides are repackaged with apo B-48 into TG-enriched chylomicron particles by the intestinal enterocytes and secreted into the lymphatics (1). Dietary chylomicrons bypass the liver and enter the plasma via the thoracic duct. They acquire apo E and C-II from HDL, and are hydrolyzed by lipoprotein lipase (LPL) to smaller TG-depleted, cholesterol-rich chylomicron remnants (2). These remnants are taken up by the liver primarily by the LDL receptor-related protein receptor (LDL-R) and degraded, affecting endogenous TG synthesis and secretion (3). Endogenous TG is synthesized in the liver from carbohydrate and free fatty acid (FFA, derived from adipocyte hydrolysis by hormone-sensitive lipase) precursors assembled in the Golgi with apo B-100, E, C-II, C-III, and secreted as triglyceride-rich very low-density lipoproteins (VLDL-TG) (4). VLDL-TG are hydrolyzed by LPL to VLDL remnants and IDL, which are taken up by scavenger cells or apo E-specific hepatic receptors and degraded in the liver. VLDL remnants are removed irreversibly or hydrolyzed further by LPL and hepatic lipase to cholesterol-rich LDL particles (5). LDL has its cholesterol removed from plasma by the LDL receptor or oxidized and taken up by CD36 scavenger receptors on macrophages to generate an intracellular cholesterol pool. The hydrolysis of TG from VLDL-TG by LPL also generates free cholesterol, and phospholipids (PL), substrates for lecithin cholesterol acyl transferase (LCAT). Nascent HDL interacts with the ATP-binding cassette transporter-1 (ABCA1) on peripheral lymphocytes to remove excess cholesterol from cells and then binds with apo A-I, the principal activator of LCAT, to esterify cholesterol forming large, spherical cholesterol-ester-rich HDL<sub>2</sub> particles (6). [Thus apo A-I and the ABCA1 transporter play critical roles in the formation of HDL and reverse cholesterol transport.] Cholesterol is transported back to the liver directly by HDL or via transfer to apo CII containing VLDL or IDL by the cholesterol ester transfer protein (CETP). Hepatic lipase stimulates HDL-C uptake by the hepatic scavenger class B type 1 receptor (SR-B1) (7). [Cholesterol is also synthesized endogenously from acetate precursors, regulated by the enzyme HMG-CoA reductase. The accumulation of intracellular free cholesterol suppresses endogenous cholesterol synthesis by inhibiting HMG-CoA reductase, the rate-limiting enzyme in cholesterol synthesis, stimulates cholesterol reesterification by acyl-CoA: cholesterol transferase, and downregulates LDL receptor synthesis (8).] However, if there is excess VLDL-TG production or dietary fat intake, CETP exchanges cholesterol from HDL with TG from VLDL, raising the TG and lowering the cholesterol composition of HDL (9). Hepatic lipase hydrolyzes HDL TG and phospholipid, converting HDL<sub>2</sub> back to smaller HDL<sub>3</sub> particles, reducing the efficient clearance of cholesterol from cells. Cholesterol can then be resecreted from the liver on VLDL, increasing endogenous LDL synthesis, excreted directly into the bile, or converted to bile acids for reabsorption (enterohepatic circulation) or excretion in stool and bile (10).

These disorders arise either from accelerated synthesis, decreased degradation of the lipoproteins, or both. The primary dyslipoproteinemias can be caused by biochemical defects resulting from single-gene mutations or can be caused by polygenetic or multifactorial causes. Secondary dyslipidemias, caused by systemic disorders such as obesity, diabetes, hypothyroidism, renal and liver disease, are more common in the elderly population.

Age, environmental factors, diet, and other lifestyle factors affect the phenotypic expression of both the single-gene and polygenetic disorders. The prevailing dogma is that dyslipidemias that arise from the single-gene mutations have both an earlier age of onset and clinical manifestations of atherosclerosis at a younger age than the polygenetic disorders. For example, individuals with familial hypercholesterolemia, both the homozygous and heterozygote genotypes, can be identified in childhood. Familial combined hyperlipidemia might not be phenotypically manifest until after puberty, and is usually clinically and biochemically diagnosed in the fourth decade. Familial hypertriglyceridemia and other disorders associated with increased TG production and decreased clearance may not become clinically apparent until middle age when age-associated increases in adiposity, physical inactivity, and the development of insulin resistance enhance the expression of the metabolic defects. Most older individuals presenting to the geriatrician with hypercholesterolemia have multifactorial disorders. Age-associated increases in adiposity, decreased fitness, decreased number or function of the LDL receptor, and hormonal changes associated with menopause act in concert with polygenetic factors to raise LDL-C concentrations in older age. Similarly, the interaction of genetic, lifestyle, and environmental factors increase the age-associated prevalence of atherogenic LDL pattern B phenotype. Early detection and treatment of hyperlipidemia is critical for primary and secondary prevention of CHD in the elderly.

### Mechanisms Underlying the Age-Associated Changes in Lipids

A number of mechanisms have been proposed to account for the age-related changes in lipoprotein concentrations, particularly change in LDL-C concentration. These mechanisms include age-related increases in dietary fat content and adiposity, declines in physical activity and physical fitness, and decreases in the number and function of the hepatic LDL receptor.

#### Changes in Diet

Age-associated changes in dietary content are reviewed in Chapter 38. In men in the Baltimore Longitudinal Study of Aging (BLSA), total caloric intake, cholesterol intake, the percent of calories obtained from fat, and the percent of calories obtained from saturated fat declined with age. Such age-associated changes in dietary content would be expected to result in lower levels of total and LDL-C, a result that is opposite to the commonly observed age-associated increase in these parameters. Others have reported changes in the distribution of energy consumed in older adults with a larger relative contribution of calories consumed at breakfast and snacks, with fewer calories consumed at lunch and dinner. The increased snacking may result in a greater portion of calories from sweets and carbo-

hydrates. It is well recognized that low total energy consumption is associated with inactivity, deconditioning, sarcopenia, and frailty.

### Total and Visceral Adiposity

The prevalence of obesity increases with aging, with a preferential accumulation of fat in visceral abdominal sites. These changes are associated with hyperinsulinemia, which predisposes older adults to develop glucose intolerance, type 2 diabetes, and other metabolic risk factors for CHD. The Italian Longitudinal Study on Aging showed higher insulin concentration was associated with low HDL-C and apo AI concentrations, higher TG and glucose concentrations, hypertension, and higher body mass index (BMI), but not high total or LDL-C in a cohort of 5632 people aged 65 to 84 years. Among the subjects with diabetes, TG concentration was higher but HDL-C concentration did not differ across insulin quartiles; however, total and LDL-C concentrations were lower and white blood cell count higher in women with diabetes with high insulin concentrations.

The prevalence of metabolic syndrome increases with age. There is an ongoing controversy as to the utility of the metabolic syndrome as a disease construct (also see the “Special Issues” section at the end of the chapter). A joint statement in 2005 from the American Diabetes Association and the European Association for the Study of Diabetes noted that the metabolic syndrome is imprecisely defined, there is a lack of consensus on the underlying pathophysiology, and there is little evidence that the metabolic syndrome denotes greater CVD risk per se than the sum of its parts (low HDL-C, hypertension, glucose intolerance, hypertriglyceridemia, increased waist circumference). Longitudinal follow-up and the assessment of mortality will determine the relationship of hyperinsulinemia and the metabolic syndrome to CHD risk.

### Physical Fitness (also see Chapter 114)

Regular physical activity has a significant impact on plasma lipoprotein concentrations. Older athletes have higher HDL-C, lower TG, and LDL-C concentrations than age-matched sedentary counterparts, and the concentrations are often similar to those seen in younger adults. The interpretation of these cross-sectional comparisons is confounded by differences in body composition, as the trained subjects are significantly leaner than the sedentary population. The differences in obesity contribute the most to the difference in TG and HDL-C concentrations between older athletes and their sedentary counterparts, while the differences in maximal aerobic capacity ( $VO_2$  max) account for a small percentage of the variance in these lipoproteins. Current physical activity guidelines from the Centers for Disease Control and American College of Sports Medicine recommend that older adults participate in moderate-intensity aerobic activities 3 to 5 days a week for at least 30 minutes each session, daily stretching for flexibility, and strength-building activities 2 to 3 days per week (see Chapter 114). These guidelines are based on experimental and epidemiologic data that energy expenditure and metabolic responses to exercise training reduce lipoprotein lipid, insulin-glucose, and blood pressure associated CVD risk, and directly affect CVD mortality. Vigorous exercise improves cardiovascular fitness indexed as  $VO_2$  max, reduces visceral adiposity, and has salutary effects on lipid profiles, insulin sensitivity, glucose

metabolism, and blood pressure, thereby reducing major components and risk associated with the metabolic syndrome.

### Lipoprotein Synthetic and Catabolic Rates

A number of studies have examined the metabolism of LDL in young and older subjects. Miller pooled data on the fractional catabolic rate of LDL apo B from four groups of subjects; normal men, normal women, individuals with heterozygous familial hypercholesterolemia, and in individuals with hypercholesterolemia. In these four groups the LDL apo B fractional catabolic rate decreased with age, whereas the LDL production rate did not change with age. The age-related rise in LDL was attributed to an acquired defect in the LDL receptor function. Similar findings subsequently were reported by Ericson, who suggested that there might be an age-associated reduction in hepatic LDL receptor expression. Kinetic studies with isotopes suggest that the age-associated increase in VLDL apo B-100 is caused by an increased rate of production, whereas the age-associated increase in LDL apo-B 100 is caused by increased residency time. Matthan and colleagues determined that decreased clearance of TG-rich lipoprotein and of LDL contributed to the increase in TG and LDL in postmenopausal women, rather than increased production of these particles. These studies did not control for differences in body composition and physical activity among age groups, factors which may elevate plasma-free fatty acid concentrations, glucose, and insulin concentrations in the older subjects and result in a raise in hepatic production of TG. We would contend that many of the purported age-related changes in lipoprotein concentrations reflect interactions between primary age-related changes in LDL metabolism and the effects of obesity, physical inactivity, diet, and other lifestyle habits, or secondary aging.

## EPIDEMIOLOGY

### Coronary Heart Disease

CHD remains the leading cause of death in older men and women. Despite secular declines in mortality rates from CHD, since 1950, as a result of the aging of the population since 1950, the number of CHD deaths in the United States has actually increased in people 65 to 74 years of age, and has more than doubled in those older than age 75 years. It is estimated that almost 16 million adults in the United States have prevalent CHD and 5.6 million have had a stroke. Based on National Health and Nutrition Examination Survey (NHANES) data, 23% of men and 15% of women aged 60 to 79 years have prevalent CHD. For those aged 80 years and older, 33% of men and 22% of women have prevalent CHD. However, these numbers severely understate the burden of CHD in the older adult population because much of the disease is clinically silent. Electron beam tomography, a noninvasive technique to detect subclinical coronary artery calcification, as indicator of atherosclerotic plaque burden and CHD, showed that two-thirds of the people older than 65 years of age in the Cardiovascular Health Study had either subclinical atherosclerotic disease or clinically apparent CHD. According to American Heart Association statistics, in 2004, 83% of the deaths from CHD and 88% of deaths from stroke occur in peo-

ple older than 65 years of age. Furthermore, the projected growth of the population older than 80 years of age by 2030 suggests there will be a huge increase in the burden of disease from CHD and CVD. Many of these deaths and some of this burden maybe preventable (see “Prevention” later in the chapter).

### Age-Associated Changes in Lipids

Many cross-sectional studies have examined age-associated changes in lipoprotein concentrations in both men and women. Unfortunately cross-sectional studies alone cannot distinguish changes caused by biological aging from those caused by lifestyle and those caused by disease. To do this longitudinal studies are needed. Knowledge of longitudinal changes in lipoproteins is limited because of the inherent difficulties in following cohorts of individuals over extended periods of time, and methodologies that limited widespread measurement of HDL-C and apolipoproteins prior to the mid-1970s. The window of opportunity to perform longitudinal studies of the natural history of lipoprotein changes with aging has closed, as treatment of clinically apparent dyslipidemia is standard clinical practice. In general, the cross-sectional studies demonstrate that total cholesterol, LDL-C, and TG concentrations increase in both men and women from the third to seventh or eighth decades of life, with a more pronounced increase in LDL-C concentration in women and important changes in women around the menopause. These increases in total cholesterol, LDL-C, and TG in general parallel changes in body composition seen with aging.

Typically, there is a decline in LDL-C and total cholesterol concentration in oldest age cohorts. For example, in NHANES III of 1988–1991, total cholesterol concentrations were on average 189 mg/dL in men aged 20 to 34 years and 221 mg/dL for men aged 55 to 64 years, but down to 205 mg/dL for men older than the age of 75 years. In the Honolulu Heart Study, total cholesterol levels were 8% lower in men older than age 85 years, as compared to men aged 71 to 74 years. This decline in cholesterol levels in the population older than age 75 years could reflect selective mortality, or be caused by changes in body composition, coexistent comorbid diseases, and poor nutrition. Indeed, longitudinal change in body weight over an 8-year period of time was an independent predictor of changes in total cholesterol, LDL-C, and HDL-C in older men and women in Rancho Bernardo, California.

The overall pattern of change in total cholesterol profiles across the age span in women is similar to that for men, but on average is 20 to 30 mg/dL above men from age 55 to 75 years. In NHANES III, 39% of women and 22% of men aged 65 to 74 years had a total cholesterol concentration above 240 mg/dL. However, the implications of “elevated” cholesterol in elderly people are not as straightforward as in younger age groups. In a subgroup of men aged 71 to 93 years from the Honolulu Heart Study, the age-adjusted incidence rates of coronary heart disease exhibited a significant U-shaped relationship with both total cholesterol and LDL.

In addition to the changes in the concentration of LDL, there are age-related changes in the LDL subclass population distribution that affect the atherogenicity and susceptibility of LDL to oxidation. The prevalence of individuals with a predominance of small, dense apo B-enriched LDL particles increases with age. In women, there are marked changes in lipoprotein concentrations and composition associated with menopause. In the Framingham Offspring Study,

postmenopausal women had 16% higher values of total cholesterol, 62% higher TG, 23% higher LDL-C, and smaller LDL particles than premenopausal women. These changes in LDL composition adversely impact CAD risk, and are not detected by routine methods for measurement of lipoproteins.

There are also changes in HDL-C concentrations across the age span in both men and women. In men at puberty, there is a drop in HDL concentrations. The HDL-C concentration then remains fairly constant until the sixth or seventh decade of life, at which point there maybe an increase in the HDL-C concentration. This increase in HDL-C concentrations at older age noted in the cross-sectional studies also maybe the result of selective morbidity and mortality, as opposed to true age-associated changes in HDL metabolism. However, some studies have found lower HDL-C concentrations in postmenopausal women. Analogous to LDL, there are also compositional changes in the HDL subfractions associated with menopause that may increase CHD risk.

Based on ATP III guidelines, the marked age-associated increase in the prevalence of hypercholesterolemia (60% of men and 77% of women older than 65 years of age with total cholesterol > 200 mg/dL) make millions of older adults candidates for lifestyle intervention. Millions of older individuals with prevalent CHD, CHD equivalents (diabetes, stroke, peripheral vascular disease, chronic kidney disease), or with multiple risk factors for CHD events also are candidates for cholesterol lowering-drugs. Controversies on whom to treat and the target criteria are discussed in greater detail later in the chapter. As discussed in the next section, an increasingly informed and proactive older population, and changes in professional opinion toward ever more aggressive therapy for hyperlipidemia are reflected in the large number of elderly people prescribed HMG-CoA reductase inhibitors (statins).

## SECULAR CHANGES IN LIPOPROTEIN LIPID CONCENTRATIONS AND PRESCRIBING PATTERNS

### Secular Changes in Lipoprotein Lipid Concentrations

There have been substantial changes in lipoprotein lipid concentrations in the U.S. population over the past four decades (Figure 110-1). NHANES data demonstrates that from 1960 to 2002, secular changes in diet, increased use of lipid-lowering medications, and other factors resulted in lower mean total cholesterol concentration across the age span in both men and women. The greatest declines have occurred in the older populations. There was no change in mean HDL-C and a trend for an increase in TG. The increase in the proportion of adults using lipid-lowering medication, particularly in older age groups, likely contributed to the decreases in total and LDL-C concentration, while the heightened prevalence of obesity in the U.S. population probably contributed to the increase in plasma TG levels.

The secular decline in cholesterol concentration maybe accelerating. A retrospective analysis of data from nearly 80 million LDL-C tests performed at Quest laboratories across the United States from 2001 through 2004 for adult patients aged 20 years and older demonstrated that the average serum LDL-C concentration declined from 124 mg/dL at the beginning of 2001 to 112 mg/dL at the end of 2004. The decline in average LDL-C concentration was ob-

served across all age groups, but was most pronounced for tests performed on older patients. The decrease was greatest (approximately 13%) for people aged 70 years and older and least pronounced (approximately 7%) for the 20-to-39-year age range. These analyses were not adjusted for medication usage or disease, and patients referred for assessment of their lipoprotein lipids may not be representative of the general population.

This decline in cholesterol concentration could have a significant impact on CVD morbidity and mortality. Conversely, secular changes resulting in an increased prevalence of obesity may worsen the manifestations of the metabolic syndrome, i.e., raise TG concentration, lower HDL-C concentration, and shift the distribution of HDL and LDL lipoprotein particle distribution toward smaller, denser, more atherogenic particles, worsen insulin resistance, and raise blood pressure. Therefore, LDL-C concentration alone maybe misleading as in these older people there will be more LDL particles for any cholesterol concentration if the LDL particles are small and dense. Such changes may require a change in the approach to the identification and treatment of dyslipoproteinemia toward therapies that modify both the concentration and composition of HDL and LDL, and reduce the high number of apo B and dense LDL particles, as well as treat other components of the metabolic syndrome. Combination therapy of LDL-lowering drugs such as HMG-CoA reductase inhibitors with niacin, cholesterol absorption inhibitors (ezetimibe), or fibrates in combination with insulin sensitizers to reduce insulin resistance, glucose, and plasma triglyceride maybe required to achieve lipid-lowering targets (see "Management" later in the chapter.).

### Secular Changes in HMG-CoA Reductase Inhibitor (Statin) Prescription Patterns

In 1997, fewer than 12% of the 38 million Medicare beneficiaries (4.4 million persons) used at least one statin. By 2002, roughly 27% of the 41 million Medicare beneficiaries (11 million individuals) used the drugs. The 2005 U.S. Agency for Healthcare Research and Quality (AHRQ) statistics (<http://www.meps.ahrq.gov/mepsweb>) indicates that statin use doubled between 1997 and 2002 in the Medicare recipients older than 65 years of age. The statistics from AHRQ's Medical Expenditure Panel Survey do not include Medicare patients in nursing homes or other institutional settings. When examined by age category, about 31% of those 65 to 74 years of age and 30% aged 75 to 84 years used a statin in 2002, but only 12% of the beneficiaries were older than 85 years.

Despite the large increase in number of prescriptions, many feel that statin therapy is underutilized. A study by Ko of elderly residents in Ontario demonstrated that paradoxically, older individuals with the highest cardiovascular risk and risk for death were the least likely to be prescribed statins. This was because of a largely sharp age-related decline in the prescribing of statins. This problem of underuse of statins is further compounded by patient noncompliance. Concerns about adverse side effects may also deter health care providers from prescribing these medications to the elderly. However, concerns about side effects are not supported by the available data, as a meta-analysis of 35 randomized controlled trials and examination of Medicare data bases demonstrate that statins as a class are safe with a risk of transaminase elevation in about 4/1000 patients and a risk of fatal rhabdomyolysis of about 0.15 per 1 million statin prescriptions (the risk was 12-fold higher in the now withdrawn

cerivastatin). Contrary to some clinical observations, the rate of myalgias (5%) and creatine kinase elevations (1%) in the meta-analysis was similar to placebo. Concerns about statins causing an increased risk of cancer are probably unfounded, as epidemiological data suggest that statins may actually reduce the rates of several cancers. Of note, the protective effects of statin therapy may go beyond simple lipoprotein reduction to include possible anti-inflammatory, antioxidant, and antithrombotic effects, as well as effects on nitric oxide metabolism. Several studies are currently underway addressing the benefits of statins with a variety of comorbid medical conditions including congestive heart failure, cerebrovascular disease, type 2 diabetes, and aortic stenosis.

## LIPOPROTEINS AS RISK FACTORS FOR CORONARY HEART DISEASE

Many case-control and prospective studies examining lipoprotein risk factors for atherosclerosis have focused on the impact of the traditional lipoprotein risk factors, that is, total cholesterol, LDL-C, and HDL-C. There is also substantial evidence that many older individuals have abnormalities in lipoprotein metabolism that are not detected by routine lipid profiles. These dyslipidemic syndromes include the apoE4 genotype, elevated levels of Lp(a), and the atherogenic LDL pattern B phenotype. These disorders of lipoprotein metabolism are more common than familial heterozygous hypercholesterolemia and familial multiple lipoprotein hyperlipidemia in both the general population and CHD patients, and may play major roles in the pathogenesis of CHD in older individuals. In this section, the evidence that dyslipidemia is a risk factor for CHD in the elderly population is reviewed.

### Elevated Total and LDL-C Concentrations

There is convincing evidence that elevated levels of total cholesterol and of LDL-C increase the risk for CHD in middle-aged men. The evidence supporting elevated levels of LDL-C as a risk factor for CHD in the elderly population, particularly elderly women, is mixed. In pooled data presented at a National Heart, Lung, and Blood Institute (NHLBI) conference, in 21 of 24 studies of men aged 65 years and older, the relative risk was  $>1.00$  for total cholesterol concentrations  $>240$  mg/dL, as compared to cholesterol levels  $<200$  mg/dL. The pooled relative risk was 1.32. By comparison, for women aged 65 years and older, in 10 of 16 studies, the relative risk was  $>1.00$  for cholesterol  $>240$  mg/dL, as compared to cholesterol levels  $<200$  mg/dL. The pooled relative risk was 1.12. Although statistically significant, the relative risk for CHD in older individuals with hypercholesterolemia is lower than the relative risk observed in studies of men younger than 65 years of age.

There are many factors that may account for the disparities between the studies that have examined the relationship between cholesterol levels and CHD in the elderly. One explanation maybe a nonlinear relationship between cholesterol levels, CHD events, and total mortality, that is, a J- or U-shaped curve. In this situation, individuals with the highest or lowest cholesterol levels are at increased risk for CHD, as compared to those with intermediate levels. Another confounder in the association between cholesterol levels and CHD outcomes in the elderly person is that cholesterol levels measured at a given time may not accurately reflect the lifelong average

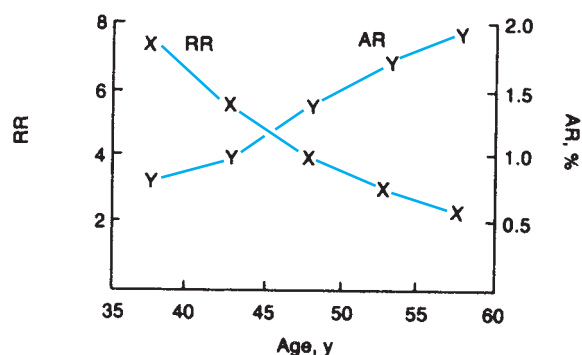

exposure to plasma cholesterol, leading to spurious conclusions. For example, at age 70 years, the measured total cholesterol level maybe 220 mg/dL, whereas the average cholesterol level over the adult life span could have been 180 or 250 mg/dL. As a result, longitudinal studies that examine both the baseline cholesterol level and its change over time are needed to provide insight into the predictive values of cholesterol levels for subsequent CHD and all-cause mortality in the elderly population. For example, in a Finnish 30-year longitudinal study, there was a U-shaped relationship between the change in cholesterol level and coronary and all-cause mortality. The authors concluded that this U-shaped relationship may confound the association of cholesterol with CHD risk in the elderly. A potential way out of this conundrum is to focus on LDL cholesterol as advocated by the ATP III guidelines. Not only is this more closely linked to CVD, but increasing clinical trial data tie improvements in LDL-C to those in CHD clinical endpoints (see below).

The majority of studies report data on the relative risk of hypercholesterolemia for CHD morbidity and mortality. However, some investigators suggest that the attributable risk is a more useful parameter for making clinical decisions regarding treatment of hypercholesterolemia in the elderly. In this context, attributable risk is the difference in the CHD mortality rate in subjects with a high lipid concentration and the CHD mortality rate in subjects with a lower or desirable lipid concentration. Attributable risk provides an estimate of the degree to which cause-specific mortality (in this case CHD mortality) would be lowered if the putative risk factor were lowered to a normal level. Unlike relative risk, attributable risk is very sensitive to the underlying mortality rate in “normals”, that is, the mortality rate in subjects with normal or desirable cholesterol levels. The MRFIT data permits an analysis of how the relative and attributable risks of hypercholesterolemia for CHD mortality vary with age. In MRFIT, the relative risk for CHD mortality for a man in the upper quintile of the population declined from over 7 in men aged 35 to 39 years to 2 for men aged 55 to 59 years (Figure 110-3). However, as a result of age-associated increases in the CHD death rate in men with “normal” cholesterol, the attributable risk for CHD in the upper versus lowest quintile increased progressively with age, from 0.7% for men aged 35 to 39 years compared to 1.9% for men aged 55 to 59 years. As a result of the age-related increase in the attributable risk for hypercholesterolemia, there maybe substantial public health benefit, i.e., the ability to prevent a large numbers of deaths by treating hypercholesterolemia in the elderly. Furthermore, as discussed in the Management section of this chapter, the number of subjects who have to be treated to prevent one death or the inverse of the attributable risk is substantially lower in older than in younger adults. Thus, pharmacologic interventions to decrease morbidity and mortality from CHD maybe more cost-effective in older compared to younger people.

### Reduced Concentrations of HDL-C

A preponderance of studies demonstrate that measurement of HDL-C provides additional information on risk for CHD and stroke in the elderly. In the Framingham Study, 4- and 12-year follow-up data demonstrate inverse relationships between HDL-C concentrations and CHD incidence. In Framingham men 50 to 79 years of age, the relative risk for all-cause mortality in men with an HDL-C  $<35$  mg/dL compared to those whose HDL-C  $>54$  mg/dL was 1.9 and risk of CHD mortality was 4.1. In women, the relative

**FIGURE 110-3.** The effect of age on the relative and attributable risk of hypercholesterolemia for CHD death in patients of the Multiple Risk Factor Intervention Trial (MRFIT). Although the relative risk (RR) for CHD death for individuals with hypercholesterolemia declines with aging, because of age-associated increases in the absolute death rate from CHD, the attributable risk (AR) for CHD in the upper versus lowest quintile increased progressively with age. (From Malenka DJ, Baron JA. Cholesterol and Coronary Heart Disease. The importance of patient-specific attributable risk. *Arch Intern Med.* 1988;148:2247–2252.)

risk for all-cause mortality was 1.5 and the risk for CHD mortality was 3.1 (HDL-C < 45 mg/dL vs. > 69 mg/dL). In data from three Established Population for the Epidemiologic Study of the Elderly (EPESE) sites, subjects aged 71 to 80 years in the lowest HDL-C category (<35 mg/dL) were four times more likely to die from CHD than those with HDL-C above 60 mg/dL. A 10-year prospective study of lipid risk factors for CHD in 989 older subjects in Marshfield, Wisconsin, showed that survival among men was associated with higher HDL-C and a lower total cholesterol/HDL ratio. However, there was no relationship between any of the lipid concentrations and all-cause mortality in women older than 65 years of age. There was a 1.24-fold increased risk of having peripheral arterial disease and a 1.36 risk of having a stroke for a 10 mg/dL decrement of HDL-C in older men and women, after controlling for other risk factors. Therapy with gemfibrozil increased HDL-C and reduced the risk of stroke in older men with prevalent CHD. These findings support the use of measurement of HDL-C along with total cholesterol to predict CHD risk in older individuals.

Measurement of apo A-I concentration, the main apolipoprotein constituent of HDL, or of apo B 100 (see next section), the primary apolipoprotein of LDL, or a combination of the two might provide superior discriminatory power than measurement of HDL-C and LDL-C in predicting CVD morbidity and mortality in older adults. In Swedish men aged 77 years who participated in the Uppsala Longitudinal Study of adult men, men in the first, second, and third quartiles of apo A-I values had a relative risk of subsequent death of 10.2, 5.0, and 3.0 compared to the quartile with the highest apo A-I concentration. In older (>70 years) patients with diabetes, apo B concentration and the ratio of apo B to apo A-I predicted CHD events independent of LDL-C.

The association between low HDL concentration and CHD has accelerated the development of pharmacological treatments to raise HDL-C. Inhibition of cholesteryl ester transfer protein (CETP) is one strategy to raise HDL-C concentration, and initial studies with torcetrapib, a potent inhibitor of CETP, showed 60% increases in HDL accompanied by reductions in LDL-C beyond that that seen with atorvastatin. Unfortunately, a large-scale randomized clinical trial of torcetrapib was stopped prematurely because the torcetrapib

plus atorvastatin group had a substantially higher mortality rate than the group that received only atorvastatin. Increased rates of heart failure, angina, hypertension, and coronary revascularization were also seen in the torcetrapib group. It is unclear whether these adverse results are restricted to this particular CETP inhibitor or to the entire class of CETP inhibitors.

### Atherogenic LDL Pattern B Phenotype

LDL comprise a spectrum of heterogeneous particles that differ in size, chemical composition, and density. The LDL subpopulations differ in their metabolism and in their propensity for promoting atherosclerosis. There are two general phenotypic patterns of LDL particles distribution: individuals who have a predominance of large, buoyant LDL particles have the LDL pattern A phenotype, and those with a predominance of small, dense LDL particles have the LDL pattern B phenotype. Individuals with the LDL pattern B typically have other lipoprotein abnormalities, including mildly elevated TG and reduced HDL-C concentration, as well as hypertension, leading some to believe that the LDL B phenotype is a biochemical marker for the metabolic syndrome. Each of the metabolic components of the LDL pattern B phenotype promotes atherosclerosis, thus the term atherogenic LDL pattern B phenotype. Direct assessment of LDL size and LDL subclass distribution requires use of techniques such as gradient gel electrophoresis, density gradient ultracentrifugation, ultracentrifugation, and nuclear magnetic resonance, not routinely employed in clinical practice. Apo B concentration can be measured by most laboratories and provides an estimate of the total number of circulating LDL particles. Apo B levels tend to be higher in LDL pattern B and the ratio of LDL-C to apo B provides an indirect estimate of LDL particle size and number.

Most, but not all studies, demonstrate an association between LDL pattern B and increased risk for prevalent CHD and subclinical manifestations of atherosclerosis detected by assessment of carotid intima media thickness. In the Physicians' Health Survey, LDL pattern B was prospectively associated with a threefold increased risk of CHD, independent of total cholesterol, HDL, and body mass index. The prevalence of the atherogenic LDL pattern B phenotype increases markedly with age. Studies by Austin et al. demonstrated that the prevalence increases from 10% to 15% in young men to 30% to 35% in middle-aged men, and from 5% to 10% in young women to 15% to 25% in postmenopausal women. Several investigators propose that the atherogenic LDL pattern B phenotype maybe the most common abnormality in lipoprotein metabolism that predisposes to CHD. The NCEP III guidelines recognize small, dense LDL as a CVD risk factor.

The etiology of LDL pattern B is multifactorial. Family studies suggest that LDL pattern B is inherited as a Mendelian-dominant or polygenetic trait that interacts with other genes to increase apo B production. The phenotypic expression of the pattern is affected by age, visceral obesity, diet, sedentary lifestyle, and the presence of type 2 diabetes. Several studies link LDL pattern B to a number of genetic loci but there is no consensus on which of these, if any, is responsible for the syndrome.

If a preponderance of small LDL particles is harmful, one can hypothesize that individuals with larger, more buoyant LDL particles (LDL pattern A) would be less likely to have CVD and have greater longevity. In case-control studies, individuals with exceptional longevity (mean age 98 years) and their offspring have significantly

larger HDL and LDL particle sizes than control families. The phenotype of larger LDL particles was associated with a lower prevalence of hypertension, CVD, metabolic syndrome, and increased homozygosity for the I405V variant in the CETP gene. These findings suggest that lipoprotein particle size is associated with longevity.

There is substantial evidence that individuals with the LDL pattern B have a different metabolic response to drug and dietary interventions than those with the “normal” LDL pattern A phenotype. Subjects with LDL patterns B and A had differential lipoprotein lipid responses to dietary interventions, exercise, weight loss, and therapy with statins, nicotinic acid, bile acid-binding resins, and fibrates. Certain classes of drugs appear more effective at lowering the concentration of the small, dense LDL particles than other drugs, and reductions in the concentration of these particles is associated with decreased CAD progression or regression in several studies that measured plaque size using angiography. In the St. Thomas’ Atherosclerosis Regression Study (STARS) comparing usual care, intervention with lipid-lowering diet and lipid lowering diet + cholestyramine, small dense LDL was significantly reduced in the groups showing regression, and dense LDL concentration during the trial was the best predictor of arteriographic outcome with those with the lowest treated levels of dense LDL having the greatest regression. Similarly, in the Helsinki Heart Study (HHS), the subset of subjects having an elevated TG concentration and low HDL-C, that is, patients who presumably had LDL pattern B, received substantial clinical benefit from gemfibrozil. These findings have important implications for clinical practice.

Because statins lower the concentration of all LDL subclasses, their net effect on LDL subclass distribution or mean size of the LDL particles maybe only moderate. However, different statins have differential effect on the LDL subclass distribution. Pravastatin and simvastatin have a limited ability to modifying particle size and their subclasses while fluvastatin and atorvastatin seem to be much more effective. Rosuvastatin seems to be the most potent in altering particle size toward a less atherogenic profile. The clinician must realize that lipid-lowering drugs have differential effects on the lipoprotein subclasses that are not detected by routine measurements of TG, LDL-C, and HDL-C and could affect plaque regression. Advances in technology may make measurement of the lipoprotein subfractions and apolipoproteins part of the routine lipoprotein profile. Until that time, measurement of apo B concentrations and the LDL-C to apo B ratio can be used as surrogate markers for LDL particle size. This ratio can then be used to select drugs that target the patient’s underlying metabolic abnormalities. However, until large-scale clinical trials comparing the effect of the different statins on morbidity and mortality in older individuals with different LDL subclass distributions and apolipoprotein profiles are performed, we will not know if the theoretical advantages of those medications particularly effective in decreasing dense LDL subfraction concentration result in improved clinical outcomes.

### Apolipoprotein E4 Allele

Apolipoprotein E is a constituent of chylomicrons, VLDL, and HDL, and modulates the metabolism of the apo B-containing lipoproteins. The gene that codes for apo E is polymorphic, with single amino acid substitutions that result in three common alleles designated 2, 3, and 4. These alleles encode 3 common isoforms, E2, E3, E4, that determine the six common apo E genotypes E2/2,

2/3, 2/4, 3/3, 4/3, and 4/4. The relative frequencies of the 2, 3, and 4 alleles in adult populations are approximately 8%, 78%, and 14% respectively. There are a number of studies that demonstrate that LDL-C concentrations are in part determined by the apo E gene locus. Individuals with the apo E2/3 genotype on average have LDL concentrations 20% lower than the common apo E3/3 genotype, whereas subjects with apo E4/3 have LDL-C concentrations 10% higher than apo E3/3. In addition, some individuals with apo E2/2 genotype have defective clearance of lipid remnants (dysbetalipoproteinemia, type III hyperlipidemia). The apo E genotype may also influence HDL concentrations, but the effect appears to be modified by gene–gene interactions with other loci (CETP, cholesterol 7- $\alpha$ -hydroxylase [CYP7A1], and others), as well as exercise and dietary factors.

A number of studies show that the apo 4 allele is a risk factor for CHD. In the Framingham Offspring Study, apo E4 was a determinant of CHD risk independent of age, sex, hypertension, cigarette use, obesity, diabetes, or the concentrations of LDL-C and HDL-C. The odds ratio for CHD in men heterozygotic for apo E4 compared to men without any copy of the 4 allele was 1.53, while in women it was 1.99. The 4 allele also is associated with increased mortality and decreased survival into older age; thus, the frequency of the 4 allele is lower in older compared to younger populations. In one cross-sectional study, the 4 allele declined progressively across the age span: 0.198 in young adults to 0.116 in nonagenarian. Similarly, in another study, the frequency of the 4 allele was lower in older women (0.098) compared to younger women (0.122), whereas the allele frequency of 2 was higher and associated with lower total and LDL-C concentrations in the older cohort.

These cross-sectional studies are supported by results of longitudinal studies. In older Finnish men (mean age at entry 72 years), the death rate from CHD over 5 years of follow-up of men with the 4 allele was double that of men with the other apo E genotypes. In the BLSA, in multivariate analyses, apo E4 was an independent predictor of coronary events (relative risk of 2.9) in middle-aged and older men over 20 years of longitudinal follow-up. These studies strongly support selective mortality as the cause for the progressive decrease in the prevalence of apo E4 in older populations. Conversely, a number of studies indicate that the 2 allele promotes longevity, possibly through an association with lower concentration of apo B-containing lipoproteins. The apo E genotype may also affect the metabolic response to statin therapy. It is not known whether lifestyle or pharmacologic interventions specifically targeted at older individuals with the 4 allele would reduce death from CHD and all-cause mortality.

Given its prevalence, the 4 allele maybe the most common genetic lipid abnormality associated with CHD. The mechanism underlying the increased CHD in individuals carrying the 4 allele is not known with certainty, but is in part caused by changes in LDL and TG-rich remnant metabolism. Patients with the 4 allele tend to have lower HDL-C and higher TG concentrations than individuals with the common apo E3/3 genotype. In addition to being a genetic risk factor for CHD, there is an association between the 4 allele and Alzheimer’s disease, stroke, and Parkinson’s disease. Understanding the mechanisms by which apo E polymorphisms modulate risk for atherosclerosis, mortality, and morbidity, and the affects of apo E on the brain and lipoprotein metabolism may shed light on the role of environmental change, lifestyle, and genetics on longevity. Ethical issues related to genetic screening, employment, and health insurance

will need to be addressed prior to widespread measurement and treatment based on the apo E genotype in clinical practice.

### Elevated Lipoprotein (a)

Lipoprotein (a) is a cholesterol-rich lipoprotein particle similar to LDL in which apolipoprotein (a) is covalently bonded to apo B. The genetic locus for apolipoprotein (a) is polymorphic and there are a large number of genetically determined isoforms of Lp(a). Genetic studies indicate that Lp(a) concentration is highly heritable, and one study estimated that 98% of the variance in Lp(a) concentration could be explained by the Apolipoprotein (a) locus. As a result, Lp(a) concentration is essentially constant across the life span. The pathogenicity of Lp(a) is attributed in part to the strong homology of apolipoprotein (a) and plasminogen, thereby providing a link between atherosclerosis and thrombosis. The Atherosclerosis Risk in Communities (ARIC) study showed that over a 10-year period, Lp(a) along with LDL-C, HDL-C, HDL<sub>3</sub>-C, and TG concentrations were independent predictors of CHD events in middle-aged subjects, whereas apo B, apo A-I, and HDL<sub>2</sub>-C were not. Lp(a) concentration was higher in subjects who developed CHD, but added only a small predictive value to that provided by LDL-C, HDL-C, and TG, and was not a predictor in black men. In a cohort of 5732 subjects aged 70 to 82 years enrolled in the prospective study of pravastatin in the elderly at risk PROSPER study, Lp(a) concentration was associated with a small increased risk of vascular disease over a period of 3 years. Niacin lowers the Lp(a) concentration, but other lipid-lowering drugs, such as resins and fibrates, have minimal effects. There are contradictory reports of the effects of statins and estrogen replacement therapy on Lp(a) concentrations.

Knowledge of a patient's Lp(a) concentration might provide the clinician with additional insight into the patient's risk for CHD, complementing the information provided by the standard lipoprotein profile. Unfortunately, there is no universally accepted standardization program for Lp(a) assays, thus limiting its utility because of the lack of reproducibility and reliability of measurement.

### Summary

Despite impressive advances in our understanding of the pathogenesis of atherosclerosis, there are several ongoing questions to be resolved concerning the lipoprotein risk factors for CHD in the elderly population: (1) Do lipoprotein subfractions (Lp(a), LDL, HDL) predict CHD morbidity and mortality, as well as total mortality? (2) Should the interpretation of a given lipoprotein concentration take into account the age of the patient? (3) Does longitudinal measurement of lipoprotein concentrations improve prediction of CHD? (4) Would genetic screening for high CHD risk-associated polymorphisms identify individuals for whom early therapy might reduce CHD risk and prolong survival? and (5) What role should the noninvasive measurements of atherosclerotic plaque or calcium score have in the assessment of cardiovascular risk and treatment?

### INTERVENTION TRIALS

Multiple clinical trials have assessed the effect of lowering LDL-C concentration on CHD and total mortality, and are summarized in Table 110-1. These studies demonstrate that treatment of hyper-

cholesterolemia in high-risk older adults aged 65 to 80 years with statins reduces CHD death rates. Collectively, these intervention studies support the use of statins in older individuals below the age of 80 years, particularly in those with prevalent CHD or CHD equivalents. Definitive evidence supporting treatment for those 80 years old and older is limited, and the ATP III recommends using good clinical judgment.

### PRESENTATION

Dyslipoproteinemia is often diagnosed in asymptomatic individuals as part of a routine health maintenance evaluation for individuals with other risk factors for CVD. The primary clinical manifestations of dyslipoproteinemia are those related to symptomatic CVD. Physical findings directly related to dyslipidemia are relatively infrequent in elderly patients and include the development of yellowish nodules of fat, xanthomas or xanthelasmas, in the skin beneath eyes (xanthelasma palpebrarum), or overlying elbows, knees, and tendons.

Moderate elevations of TG may lead to fatty liver and pancreatitis and higher levels are linked to eruptive xanthomas over the trunk, back, elbows, buttocks, knees, hands, and feet. Severe hypertriglyceridemia (>2000 mg/dL) can give retinal arteries and veins a creamy white appearance (lipemia retinalis). Some forms of hyperlipidemia can lead to an enlarged liver and spleen, manifesting in discomfort or tenderness in the upper abdomen, and patients with the rare dysbetalipoproteinemia can have palmar and tuberous xanthomas.

### EVALUATION

The NCEP recommends that all patients older than 20 years of age undergo lipid testing at least every 5 years. There is no defined upper age limit for this testing. The ATP III guidelines recommend a more comprehensive assessment, including measurements of fasting total cholesterol, LDL-C, HDL-C, and TG. If any of these concentrations are abnormal, the physician should evaluate the patient for causes of secondary dyslipidemia. These secondary causes include obesity, diabetes mellitus, hypothyroidism, obstructive liver disease (primary biliary cirrhosis, etc), nephrotic syndrome, chronic renal failure, the use of certain drugs (see "Special Issues" section at the end of the chapter), alcohol consumption, and smoking. The measurement of thyroid function is of particular importance in older subjects, as clinically silent hypothyroidism may occur with associated secondary dyslipidemia. In patients referred to a lipid clinic for hyperlipidemia, 3% had overt hypothyroidism and 4% had subclinical hypothyroidism.

The screening of older individuals, particularly those without overt CVD for dyslipoproteinemia, and the treatment of hyperlipidemia in older individuals remain controversial because of the paucity of data in older patients >80 years and in ethnic minority populations. The arguments for and against the treatment of hyperlipidemia in elderly patients are summarized in Table 110-2. The reader is referred to the May 2005 issue of the *Journal of Gerontology* for further discussion of the pros and cons of pharmacological therapy and interpretation of the NCEP III guidelines in the elderly population.

The foregoing arguments need to be viewed in the context of several secular changes. First, all the published screening guidelines

TABLE 110-1

## Summary of Randomized Clinical Trials of Treatment of Dyslipidemia

TRIAL	POPULATION		INTERVENTION	OUTCOME	
	Characteristics	n		LDL	Comments
Scandinavian Simvastatin Survival Study (4S)	h/o Angina/MI TC 5.5–8mmol/L TG < 2.5 mmol/L	4444 ♂/♀ aged 50–75 yr	Dietary counseling ± Simvastatin (20 mg titrated to TC response)	25% reduction	Significantly reduced major coronary events and mortality—similarly in those younger than and 65 yr or older in age; 43% reduction in CHD mortality for those aged 65 yr or older
Pravastatin Limitations of Atherosclerosis in the Coronary Arteries (PLAC I)	h/o CAD and 130 ≤ LDL < 190 despite an AHA step I diet	408 ♂/♀ aged 50–75 yr	40 mg Pravastatin versus Placebo	28% reduction	Significantly reduced progression of atherosclerosis as well as incidence of coronary events—similarly in those younger than and 65 yr or older in age
Pravastatin, Lipids, and Atherosclerosis in the Carotid Arteries (PLAC II)	h/o CAD + diet-resistant elevated LDL	151 ♂/♀ aged 50–75 yr	Pravastatin (20 mg titrated to LDL response) versus Placebo	28% reduction	
Cholesterol and Recurrent Events (CARE)	h/o MI and baseline TC < 240, 115 < LDL < 175, TG < 350 mg/dL	4159 ♂/♀ aged 21–75 yr	40 mg Pravastatin versus Placebo	32% reduction	Reduced major coronary events and stroke in those 65–75 yr
West of Scotland Coronary Prevention Study (WOSCOPS)	LDL ≥ 154 despite dietary therapy, no h/o MI	6595 ♂ aged 45–64 yr	40 mg Pravastatin versus Placebo	26% reduction	Reduced cardiac endpoints to a greater extent, 31%, than would be predicted by its reduction of LDL-C
Medical Research Council/British Heart Foundation Heart Protection Study (HPS)	h/o DM, PVD, or CHD	20,536 ♂/♀ aged 40–80 yr	40 mg Simvastatin versus Placebo	44% reduction	Significant benefit on major vascular events irrespective of initial cholesterol levels and proportional across the age span
Prospective Study of Pravastatin in the Elderly at Risk (PROSPER)	h/o vascular disease or at high risk for CHD caused by HTN, smoking, or DM	5804 ♂/♀ aged 70–82 yr	40 mg Pravastatin versus Placebo	34% reduction	Significant reductions in major coronary events by 15%; no effect on stroke
The Reversal of Atherosclerosis with Aggressive Lipid Lowering (REVERSAL)	CAD and 125 < LDL < 210 after washout period	651 ♂/♀ aged 30–75 yr	40 mg of Pravastatin versus 80 mg of Atorvastatin	Pravastatin → 27% reduction Atorvastatin → 47% reduction	Both decreased atheroma volume. Greater benefit from Atorvastatin seen only among older individuals
Treating to New Targets (TNT)	Clinically evident CHD	10001 ♂/♀ aged 35–75 yr	Atorvastatin 10 mg versus 80 mg/day	35% reduction with 10 mg; additional 20% with 80 mg	Significantly greater reductions in the composite end point of death from CHD, nonfatal MI, resuscitation after cardiac arrest and stroke
Long-Term Intervention with Pravastatin in Ischemic Disease (LIPID)	h/o MI or hospitalization for USA and 155 < TC < 271	9014 ♂/♀ aged 31–75 yr	Dietary counseling ± 40 mg Pravastatin	18% reduction	Significantly reduced mortality by 21% as well as cardiovascular outcomes (MI death from CHD, stroke, coronary revascularization) with similar relative effects in older and younger patients
Pravastatin or Atorvastatin Evaluation and Infection Therapy (PROVE IT-TIMI22)	Recently hospitalized for ACS, TC ≤ 240	4162 ♂/♀ mean age 58 ± 11 yr	400 mg Gatifloxacin + 40 mg Pravastatin or 80 mg Atorvastatin	Pravastatin → 10% Atorvastatin → 42% reduction	Lower risk of recurrent MI or vascular death
Study Assessing Goals in the Elderly (SAGE)	Patients with CHD with evidence of ischemia on ambulatory monitoring	893 ♂/♀ aged 65–85 yr	80 mg Atorvastatin versus 40 mg Pravastatin	Pravastatin → 32% Atorvastatin → 56% reduction	Substantial reduction in ischemic burden on ambulatory monitoring in both groups, lower all cause mortality in Atorvastatin versus Simvastatin

**TABLE 110-2****Considerations of Factors For and Against Treatment of Hyperlipidemia in the Elderly Patient****Factors favoring treatment of hyperlipidemia**

- CHD is the most common cause of death in old age
- Attributable risk increases with age
- Atherosclerosis is pathologically indistinguishable in elderly and middle-aged persons
- Hypolipidemic drugs appear to be as efficacious in elderly persons as in middle-aged persons
- Numerous clinical trials of lipid-lowering therapy found substantial reductions in cardiac morbidity and mortality in people age 65–80 yr

**Factors against treatment of hyperlipidemia**

- Lack of evidence that primary or secondary prevention decreases CHD morbidity and mortality in individuals older than age 80 yr.
- Drug side effects maybe greater
- There maybe a lag time (2 yr) between the initiation of therapy and the reduction of morbidity and mortality from CHD
- Cost for elderly persons on fixed incomes with limited insurance
- The presence of other multiple comorbid diseases might limit life span or the quality of life
- Polypharmacy and risk of drug side effects

assume that the clinician is faced with a de novo decision of whether the elderly patient should be screened for hyperlipidemia, when most of these individuals have had prior evaluations in middle-age or earlier. Indeed, cholesterol profiles are routinely obtained as part of the automated battery of laboratory tests in patients admitted to the hospital, and widespread cholesterol screening has occurred over the past 25 years. Thus most older individuals, particularly those at risk or with CVD, have already had multiple measurements of their lipid concentrations. Therefore, whether or not to screen de novo is often a moot point.

Second, given secular increases in the use of hypolipidemic drugs for both the primary and secondary prevention of CHD in middle-aged and older individuals, an increasing number of older patients presenting to the geriatrician will already be on lipid-lowering medications. For these patients, the geriatrician will have to decide on the appropriateness of continuing therapy. It will be difficult to discontinue medications in older patients with overt CVD and in those with multiple risk factors for CVD, unless there are compelling reasons.

Third, there is growing emphasis on maintaining or increasing functional independence and quality of life in the elderly. The prevention of coronary or vascular events that contribute to disability in the elderly must be factored into any decision related to the screening and treatment of hypercholesterolemia in the elderly. Some of the pharmacologic agents appear to have beneficial effects independent of their lipid-lowering effects. For example, statins may have antioxidant properties and have been associated with improvement in endothelial function, improved nitric oxide metabolism, and reduced inflammation. Some cross-sectional and epidemiological studies suggest that statin users have a lower prevalence of Alzheimer's disease than nonstatin users. Two completed studies demonstrate that the decline in cognitive function in older adults is significantly slower in patients treated with statins than in control groups. However, more recent randomized clinical

trials do not demonstrate that statins cause a reduction in the incidence of Alzheimer's disease. Thus, some clinicians will place older patients on statins hoping for the secondary (pleiotropic) benefits despite a lack of convincing evidence that the therapy will be efficacious.

Fourth, the results of the PROSPER, HPS, and other studies (see Table 110-1) support the use of pharmacological interventions for the secondary prevention of CVD in older individuals up to the age of 80 years. We know of no definitive data demonstrating a lack of effectiveness among older individuals (>80 years). Delaying evidence-based preventive therapy while awaiting definitive studies maybe untenable in those living independently despite the cost.

Finally, the question of when and in which patients to pharmacologically intervene will be influenced by the development of new pharmacologic agents that target the underlying mechanisms of CVD. A multitude of new agents are currently in development and are undergoing clinical trials. New agents, including inhibitors of microsomal triglyceride transfer protein (MTP) that decrease the secretion of apo B containing proteins by the liver, may play a role, either alone or in combination, in the treatment of dyslipoproteinemia.

**MANAGEMENT****Risk-Stratified Approach to Lipid Treatment**

The approach to the management of hyperlipidemia in older persons (men  $\geq$  65 years; women  $\geq$  75 years) was extensively modified in the NCEP ATP III Report in 2001, and updated again in 2004. This report recommends the calculation of the Framingham Risk Score (<http://hp2010.nhlbihin.net/atpiii/riskcalc.htm>) as the primary means of identifying older persons at increased risk for coronary events. Based on the overall Framingham Risk Score, people are stratified into four main risk categories: high-risk, moderately high-risk, moderate risk, and low risk, with a portion of the high-risk patients being designated as very high risk. There are different treatment recommendations and therapeutic goals for the different risk categories with the most aggressive therapy directed at patients with the highest risk. Table 110-3 summarizes the ATP III updated risk categories.

Older people who have no risk factors other than their age with an absolute 10-year risk <10% are considered at low-risk. There is considerable controversy concerning the management of hyperlipidemia in older individuals who have no risk factors other than their age. For individuals in this risk category, the LDL-C goal is <160 mg/dL. According to the update, the absolute benefits for people at the lower levels of risk are less clear-cut and the recent clinical trials do not suggest a modification of treatment goals and cut points. The ATP III update emphasizes that therapeutic lifestyle changes, that is, diets low in saturated and *trans* fat, increased physical activity, and weight control are advocated for lowering cholesterol concentrations. The ATP III guidelines for pharmacological treatment in people at low risk have not changed the LDL concentration at which drug therapy should be considered, i.e.,  $\geq$ 160 mg/dL. However, many clinicians have taken a more aggressive therapeutic approach in older individuals in this category and have begun lipid-lowering therapy with statins to reduce LDL-C below 100 mg/dL.

TABLE 110-3

## ATP III LDL-C Goals and Cut Points for TLC and Drug Therapy in Different Risk Categories and Proposed Modifications Based on Clinical Trial Evidence

RISK CATEGORY	LDL-C GOAL	INITIATE TLC	CONSIDER DRUG THERAPY*
High risk: CHD <sup>†</sup> or CHD risk equivalents <sup>‡</sup> (10-yr risk >20%)	<100 mg/dL (optional goal: <70 mg/dL) <sup>§</sup>	≥100 mg/dL <sup>¶</sup>	≥100 mg/dL** (<100 mg/dL: consider drug options)*
Moderately high risk: 2+ risk factors <sup>‡</sup> (10-yr risk 10–20%) <sup>††</sup>	<130 mg/dL <sup>‡‡</sup>	≥130 mg/dL <sup>§</sup>	≥130 mg/dL (100–129 mg/dL; consider drug options) <sup>§§</sup>
Moderate risk: 2+ risk factors <sup>¶¶</sup> (10-yr risk <10%) <sup>††</sup>	<130 mg/dL	≥130 mg/dL	≥160 mg/dL
Lower risk: 0–1 risk factor <sup>***</sup>	<160 mg/dL	≥160 mg/dL	≥190 mg/dL (160–189 mg/dL: LDL-lowering drug optional)

\*When LDL-lowering drug therapy is employed, it is advised that intensity of therapy be sufficient to achieve at least a 30% to 40% reduction in LDL-C concentrations.

<sup>†</sup>CHD includes history of myocardial infarction, unstable angina, stable angina, coronary artery procedures (angioplasty or bypass surgery), or evidence of clinically significant myocardial ischemia.

<sup>‡</sup>CHD risk equivalents include clinical manifestations of noncoronary forms of atherosclerotic disease [peripheral arterial disease, abdominal aortic aneurysm, and carotid artery disease [transient ischemic attacks or stroke of carotid origin or >50% obstruction of a carotid artery]], diabetes, and 2+ risk factors with 10-yr risk for hard CHD >20%.

<sup>§</sup>Very high risk favors the optional LDL-C goal of <70 mg/dL, and in patients with high triglycerides, non-HDL-C <100 mg/dL.

<sup>¶</sup>Any person at high risk or moderately high risk who has lifestyle-related risk factors (e.g., obesity, physical inactivity, elevated triglyceride, low HDL-C, or metabolic syndrome) is a candidate for therapeutic lifestyle changes to modify these risk factors regardless of LDL-C concentration.

\*\*If baseline LDL-C is <100 mg/dL, institution of an LDL-lowering drug is a therapeutic option on the basis of available clinical trial results. If a high-risk person has high triglycerides or low HDL-C, combining a fibrate or nicotinic acid with an LDL-lowering drug can be considered.

<sup>††</sup> Electronic 10-yr risk calculators are available at [www.nhlbi.nih.gov/guidelines/cholesterol](http://www.nhlbi.nih.gov/guidelines/cholesterol).

<sup>‡‡</sup> Optional LDL-C goal <100 mg/dL.

<sup>§§</sup> For moderately high-risk persons, when LDL-C concentration is 100 to 129 mg/dL, at baseline or on lifestyle therapy, initiation of an LDL-lowering drug to achieve an LDL-C concentration <100 mg/dL is a therapeutic option on the basis of available clinical trial results.

<sup>¶¶</sup> Risk factors include cigarette smoking, hypertension (BP ≥140/90 mm Hg or on antihypertensive medication), low HDL-C (<40 mg/dL), family history of premature CHD (CHD in male first-degree relative <55 yr of age; CHD in female first-degree relative <65 yr of age), and age (men ≥45 yr; women ≥55 yr).

\*\*\*Almost all people with zero or 1 risk factor have a 10-yr risk <10%, and 10-yr risk assessment in people with zero or 1 risk factor is thus not necessary.

From Grundy SM, Cleeman JI, Merz CN, et al.; Coordinating Committee of the National Cholesterol Education Program. Implications of recent clinical trials for the National Cholesterol Education Program Adult Treatment Panel III guidelines. *Arterioscler Thromb Vasc Biol.* 2004;24(8):e149–e161.

It is important to recognize that the relative risk of hyperlipidemia for CHD is lower in the elderly than in younger people because of competing causes of mortality and cumulative effects of comorbid diseases. However, because of both the high absolute risk in the elderly and the high attributable risk for CHD events, a given therapeutic treatment such as statin therapy will prevent a greater number of events in older than in younger people. Based on CARE (Cholesterol and Recurrent Events) data, Lewis and colleagues estimated that 225 cardiac events would be prevented for every 1000 older (>65 years) CHD patients with baseline cholesterol concentration <240 mg/dL treated with statin therapy for 5 years compared to 121 events prevented in younger patients. Twenty-seven fatal CHD events would be prevented per 1000 patients older than 65 years of age treated for 5 years with a statin. By contrast, only 11 fatal CHD events would be prevented in a comparable number of younger people with CHD treated for the same period of time. ATP III estimates that the number needed to treat (NNT) with statin therapy at age 65 years with the aim of preventing CHD events at age 80 years is only 10 for a 65-year-old person with a 10-year risk for hard CHD endpoint of 10%. The NNT for 65-year-old patient with a 20% 10-year risk for hard CHD endpoint is 5. Thus, the elderly with CHD and those with multiple risk factors would be expected to particularly benefit from pharmacologic therapy because of their high absolute and attributable risk.

There are a number of limitations to applying the Framingham Risk Score to older adults. Factors that increase the short-term risk for CHD are well known. However, the effect of risk factors on long-term risk are less clear, particularly at older ages because of the competing risks for non-CHD death. The usefulness of blood-based biomarkers beyond a standard lipid panel (e.g., LDL particle size, insulin, high sensitivity CRP, homocysteine, apolipoproteins,

etc.) and structural markers of subclinical diseases (such as extent of coronary atherosclerosis using the surrogate marker of coronary artery calcium assessed by computed tomography (CT) scan, increased carotid artery intima medial thickness) to guide therapy needs further evaluation in the elderly population.

### Therapeutic Lifestyle Intervention

Diets reduced in saturated fat and cholesterol and increased in fiber and complex carbohydrate content, weight loss, and regular aerobic exercise (Therapeutic Lifestyle Changes) are widely advocated for the initial treatment of hyperlipidemia. To reduce LDL-C, the American Heart Association and the American Diabetes Association recommend the following dietary composition: saturated fats should be <7% of energy intake; dietary cholesterol should be <200 mg/day; intake of *trans*-unsaturated fatty acids should be <1% of energy intake; total energy intake should be adjusted to achieve body-weight goals; total dietary fat should be moderated (25–35% of total calories) and should consist mainly of monounsaturated or polyunsaturated fat; dietary fiber should be >14 g per calories consumed; salt intake should be 1200 to 2300 mg/day; and alcohol intake should be moderate (limited to 1 drink per day in women and 2 drinks in men).

In obese individuals, moderate weight loss in combination with aerobic exercise will decrease total cholesterol and LDL-C concentrations by 10% to 15%, increase HDL-C by 15%, improve glucose tolerance, and lower blood pressure. Moreover, the lipid lowering response to lifestyle interventions is related to the initial lipoprotein profiles and probably selected gene polymorphisms. Individuals with the highest baseline cholesterol concentrations show the greatest improvements with weight loss and AHA diet interventions. However, the beneficial effects of low fat diets in reducing total and LDL-C

concentrations maybe tempered by reductions in HDL-C. Without concomitant weight loss, the ratio of LDL-C to HDL-C may actually increase, not decrease when individuals are placed on diets low in saturated fat and cholesterol. This suggests that high carbohydrate diets might not be optimal for older women in whom HDL-C concentrations are a major determinant of CHD risk, but the beneficial effects of reduced atherogenic LDL-C concentrations may outweigh any putative harmful effects of reductions in HDL-C. The addition of monounsaturated fats to the diet may prevent declines in HDL-C.

Increased physical activity is often advocated as a means to reduce CVD risk factors. However, the majority of this benefit is likely because of the accompanying weight loss. Weight loss and aerobic exercise results in improved lipoprotein concentrations (as well as glucose tolerance and blood pressure) in middle-aged and older women and men, whereas aerobic training without weight loss yields substantially less beneficial effects. Nonetheless, a complete lifestyle intervention of achieving and maintaining optimal weight in conjunction with aerobic activity is likely to lead to the greatest improvements in CVD risk factors as well as maximize the long-term maintenance of these improvements. We advocate lifestyle interventions consisting of the AHA Step I diet, moderate weight loss, and daily moderate intensity exercise for 30 min/d in older individuals with overt manifestations of atherosclerosis, or in higher risk asymptomatic individuals with multiple CHD risk factors.

## Pharmacological Therapy

In many older patients with hyperlipidemia at risk for CHD, therapeutic lifestyle intervention does not effectively lower LDL-C to within the target range. Several classes of drugs are available to treat hyperlipidemia. The commonly used lipid-lowering agents, their anticipated therapeutic effects, and side effects are summarized in [Table 110-4](#). We briefly review their mechanism of action below.

The clinician should consult package inserts and other pharmacologic resources to obtain the most up-to-date information before prescribing these medications. A large number of nutraceuticals and dietary supplements are also employed to improve lipoprotein profiles. Their use is beyond the scope of this chapter. For many older adults, monotherapy with a statin can safely achieve LDL-C target goals.

### HMG-CoA Reductase Inhibitors (Statins)

Statins inhibit hepatic HMG-CoA reductase, the enzyme catalyzing the rate-limiting step in hepatic cholesterol synthesis, thereby reducing cholesterol production. This has several effects: upregulation of LDL receptors by hepatocytes and consequent increased removal of apo E- and B-containing lipoproteins from the circulation and a reduction in the synthesis and secretion of lipoproteins from the liver. Statins lower LDL-C and increase the removal and reduce the secretion of remnant particles, that is, VLDL and IDL (non-HDL-C). Therefore statins are effective in treating patients who have an elevation of both LDL-C and TG.

### Fibrates

The fibrates decrease the production of VLDL and increase the clearance of triglyceride-rich lipoproteins. The latter is mediated by the peroxisome proliferator-activated receptor (PPAR)- $\alpha$  and by

an increase in lipoprotein lipase, a key enzyme in the clearance of TG-enriched particles. Fibrates also increase HDL-C and apo A-I. Fibrates are indicated in the treatment of patients with high TG and low HDL-C.

### Bile Acid Sequestrants

Bile acid resins are generally considered second-line agents for the treatment of hypercholesterolemia. The bile acid sequestrants bind bile acids in the intestine, which reduces the enterohepatic recirculation of bile acids. This promotes the upregulation of the enzyme 7- $\alpha$  hydroxylase and the conversion of more cholesterol in the hepatocyte into bile acids. This decreases the cholesterol content in the hepatocyte, which enhances LDL-receptor expression. This leads to increased clearance of LDL and VLDL remnants from the circulation. However, this also results in an increased synthesis of cholesterol by the liver, thereby partially negating the LDL-C-lowering effects of the sequestrants. Caution is indicated in the use of the resins in patients with elevated TG as the resins may increase hepatic VLDL production, thereby raising TG levels.

### Nicotinic Acid (niacin)

Nicotinic acid inhibits lipoprotein synthesis and decreases the production of VLDL particles by the liver. It inhibits the peripheral mobilization of free fatty acids, thus reducing hepatic synthesis of TG and the secretion of VLDL, reducing the number of LDL particles. Nicotinic acid increases the production of apo A-I, thereby raising HDL-C.

### Ezetimibe

Ezetimibe is an inhibitor of intestinal cholesterol absorption. It reduces the amount of biliary and dietary cholesterol delivered to the liver and reduces the cholesterol content of atherogenic particles remnant particles, VLDL, and LDL. The reduced delivery of intestinal cholesterol to the liver increases hepatic LDL receptor activity and increases clearance of circulating LDL. Current clinical trials question the added CHD preventive value of adding ezetimibe to statin therapy.

## PREVENTION

The risk-based algorithms of ATP-III and Framingham Risk Score focus on 10-year risk. Age has a substantial effect on predicting absolute risk, and many elderly patients exceed thresholds for treatment solely based on their age. Estimation of lifetime risk may provide a more useful conceptual framework for the primary prevention of CVD. In the Framingham Heart Study, among men free of prevalent CHD at age 50 years, the lifetime risk of developing CHD was 52%, with an estimated 39% lifetime risk in women. Factors associated with survival to age 85 years included female gender, lower total cholesterol, lower systolic blood pressure, better glucose tolerance, not smoking, and higher education levels. At the age 50 years, the lifetime risk for men with optimal CHD risk profile for developing CHD was 5% versus 69% of men with two or more risk factors. In women, those with optimal CHD risk profile had an 8% risk versus 50% risk in women with two or more risk factors. Median survival

TABLE 110-4

## Pharmacological Therapy for Hyperlipidemia

Drug Class	Dose	Anticipated Effect	Comment
<b>Statins (HMG CoA reductase inhibitors)</b>			
Lovastatin	20–80 mg/day, take with evening meal, take bid if >20 mg/day	40 mg reduces LDL by 31%	Statins remain the drugs of first choice for lowering LDL. For the statins, for every doubling above the standard dose one can expect ~6% decrease in LDL. Changes in HDL-C are usually modest, in the 5–10% range, and not consistently dose-related; increases in HDL-C are greater in patients with low HDL-C and elevated triglycerides. Statins are very safe: 95% of patients can tolerate them; 5% cannot. Common side effects include headache, upset stomach, fatigue, flu-like symptoms, and myalgia. One or both liver transaminases maybe elevated to more than three times the upper limit of normal in 0.5% (with starting doses) to as high as 2.5% (with high doses) in a dose-dependent manner. Myopathy defined as muscle symptoms (muscle weakness, aches, or soreness) plus CK >10 times the upper limit of normal is seen in 2–4 patients per 1000. Statins have moderate TG-lowering in the range of 10–35%; reduction is dependent on the baseline TG concentration (the higher the baseline concentration, the greater the reduction) and the dose of the statin; the reduction in TG is greatest with the more potent statins.
Pravastatin	10–80 mg/day, take at bedtime	40 mg reduces LDL by 34%	
Simvastatin	5–80 mg/day	20–40 mg reduces LDL 35–41%	
Fluvastatin	20–80 mg/day, 80 mg SR, take bid if >40 mg/day	40–80 mg reduces LDL 25–35%	
Atorvastatin	10–80 mg/day	10 mg reduces LDL by 31%	
Rosuvastatin	5–40 mg/day	5–10 mg reduces LDL by 39–45%	
<b>Cholesterol absorption inhibitors</b>			
Ezetimibe	10 mg/day	When used in monotherapy reduces LDL by 15–20%, additive effect when used with statin	Avoid use with cyclosporine, gemfibrozil; increased transaminases when used in combination with statin. Current clinical trials question the added CHD preventive value of adding ezetimibe to statin therapy.
<b>Bile acid sequestrants</b>			
Cholestyramine	2–8 g bid with max of 24 g/d	LDL-C reduced in dose dependent manner, range of 15–30%. Resins may raise TG although this side effect appears to be less with colesevelam	Mix with water, take before meals. Serious side effects for these sequestrants include fecal impaction and a variety of GI symptoms; medications may also lead to a deficiency of fat-soluble vitamins and loss of calcium in the urine. Extensive drug–drug interactions (consult pharmacist).
Colestipol	5–30 g/d divided qd to qid		Take other drugs >1 h before or 4 h after colestipol.
Colesevelam	625 mg tabs, take 6–7 tabs PO qd		May reduce dose and take BID if combined with a HMG Co-A reductase inhibitor; take with meals.
<b>Nicotinic acid</b>			
Niacin (immediate, sustained, and extended release)	Regular release form 1.5–3 g/d divided bid or tid, extended release 1–2 g PO QHS	Reduces LDL by 15–25%. Niacin is the most effective drug available for raising HDL-C. 1 gm/d can raise HDL by 25%	Unfortunately there are substantial prostaglandin-mediated side effects including cutaneous flushing, headache, warm sensation, and pruritus; other side effects include hyperpigmentation, acanthosis nigricans, dry skin, nausea, vomiting, diarrhea, and myositis. ASA 325 mg taken before dose may decrease flushing; need to monitor liver function, glucose and uric acid; extended release also sold in combination with lovastatin.
<b>Fibrates</b>			
Gemfibrozil	600 mg bid 30 min before morning and evening meal	Reduce TG by 25–50%, raise HDL by 15–25% with variable effect on LDL, range –5% to –20%. Can raise LDL in some patients	Drug class of choice for high TG, low HDL. Side effects include myositis, stomach upset, sun sensitivity, gallstones, irregular heartbeat, and liver damage. Contraindicated with ezetimibe/simvastatin; multiple other drug interactions (consult pharmacist).
Fenofibrate	Start 48 mg PO qd with max of 145 mg PO qd		Consider decreasing dose if lipids fall well below target; monitor CBC and LFTs periodically.
Clofibrate	1000 mg bid	Lowers LDL and HDL, rarely used	Clinical trials in 1970s and 1980s showed an increase in all-cause mortality, death from heart disease stroke and cancer in patients with clofibrate; Use is reserved for patients who fail other therapies; used for type III, IV, and V hyperlipidemia.

Data from multiple sources including Grundy SM, Cleeman JI, Merz CN, et al.; Coordinating Committee of the National Cholesterol Education Program. Implications of recent clinical trials for the National Cholesterol Education Program Adult Treatment Panel III guidelines. *Arterioscler Thromb Vasc Biol.* 2004;24(8):e149–e161; McKenney JM. Selecting successful lipid-lowering treatments. <http://www.lipidsonline.org/slides/slides>.

was >11 years longer and 8 years longer, respectively, in men and women with optimal CHD risk factors. This suggests that there are impressive long-term benefits from optimal control of CVD risk factors.

The use of pharmacologic therapy to prevent CVD in older adults without prevalent CHD (true primary prevention of CVD) remains controversial (see review by Abramson). There is little clinical trial data to support statin therapy in older adults without prevalent CHD. Our position is that lifestyle intervention, particularly exercise training combined with weight loss, is beneficial to improve quality of life and function in older adults and should be universally recommended. Weight loss and medical nutrition therapy is particularly beneficial in individuals with the metabolic syndrome. The restriction of saturated fats, *trans*-unsaturated fats, and the inclusion of increased dietary fiber are recommended to improve lipids. Some would also advocate increasing monounsaturated and polyunsaturated fat in the diet and increased intake of omega three oils. For primary prevention of CVD in older adults, the horse is already out of the barn; about three quarters of older adults on statins are taking them for primary prevention. We advocate the noninvasive assessment of structural markers of arterial vulnerability (carotid intimal-medial thickness, assessment of coronary artery calcium) and functional markers of arterial vulnerability to identify older adults with evidence of subclinical disease who may particularly benefit from aggressive pharmacologic intervention. We recognize that a lack of standardization of these measures, paucity of clinical trial data supporting their use in primary prevention in older adults, and costs associated with these tests and subsequent evaluations for abnormal findings and incidental findings may limit their clinical utility.

## SPECIAL ISSUES

### Secondary Dyslipidemias Caused By Medications

A number of medications commonly used in older adults can adversely affect lipid profiles. Although diuretics and beta-blockers can adversely affect serum lipids, the beneficial effects of these medications on blood pressure outweigh their adverse effects. The effect of steroid hormones on lipoprotein lipids varies with the drug, dose, and route of administration. In general, anabolic steroids lower HDL-C and have a variable effect on LDL-C. The effects of progestins vary greatly depending on their androgenicity, and estrogens can cause hypertriglyceridemia. Glucocorticoids raise HDL-C, TG, and LDL-C. Retinoids increase TG and LDL-C and also reduce HDL-C. Interferons can cause hypertriglyceridemia. Medications used to prevent rejection following organ transplantation such as cyclosporine and CellCept (mycophenolate mofetil) can also cause dyslipidemia that may result in accelerated atherosclerosis. Antiretroviral therapy for human immunodeficiency virus (HIV), particularly protease inhibitors, can cause dyslipidemia characterized by elevated TG and LDL-C and other metabolic abnormalities (lipodystrophy syndrome) that increase risk for atherosclerosis.

### Diabetic Dyslipoproteinemia and Metabolic Syndrome

Type 2 diabetes mellitus is a common condition in older adults and is a substantial risk for CVD (see Chapter 109). Diabetes is now

considered a CAD equivalent for setting treatment goals because of the high long-term risk for the development of CAD, as well as increased risk for CVD events and subsequent morbidity and complications. Thus, older diabetes patients should have lipid, blood pressure and other CAD risk factors aggressively treated to target levels prescribed for patients with documented CAD. Furthermore, glucose toxicity affects coronary risk in older people with diabetes, and hyperglycemia is associated with a heightened incidence of silent ischemia during exercise stress testing.

Type 2 diabetes is commonly associated with dyslipidemia, characterized by hypertriglyceridemia, reduced HDL-C, a predominance of small-dense LDL particles, increased concentrations of apo B, and the accumulation of cholesterol-rich remnant particles, especially postprandially. The treatment of hyperlipidemia in T2DM is effective in reducing cardiovascular endpoints. Studies using statins (e.g., Heart Protection Study, 4S Study, Collaborative Atorvastatin Diabetes Study) all showed substantial 25% to 30% reductions in coronary events. However, most patients with T2DM have elevated TG and low HDL-C, lipoprotein lipids that are only modestly affected by statins. The results of the HHS, Veterans Affairs High Density Lipoprotein Intervention Trial (VA-HIT), the Bezafibrate Infarction Prevention Study (BIP), and the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) studies were inconsistent. Several additional large-scale clinical trials are underway to further examine the effects of lipid-lowering therapy on CVD events in diabetes. Pending their outcomes, we recommend statins to reduce total and LDL-C and raise HDL-C; however, when lifestyle changes and statins do not increase HDL-C to goal, we suggest the addition of niacin. Fenofibrate effectively lowers triglyceride and raises HDL-C in persons with hypertriglyceridemia, but we do not recommend combined therapy with statins because of the increased risk for myopathy in elderly patients.

There is a strong association between T2DM and manifestations of the metabolic syndrome, a constellation of risk factors associated with central obesity that cluster and promote accelerated atherosclerosis and vascular complications. Described originally in 1988 by Reaven to include insulin resistance, glucose intolerance, hyperinsulinemia, increased TG, decreased HDL-C, and hypertension, many now consider inflammation, microalbuminuria, small dense LDL particles, dysfibrinolysis and coagulopathy, nonalcoholic fatty liver disease, and central adiposity to components of the syndrome. However, the NCEP, World Health Organization, and International Diabetes Federation criteria define multiple phenotypes based on cutoffs for blood pressure, glucose, waist circumference, HDL, and TG levels. Three of the components, hyperglycemia, high TG, and large waist, have variable associations with vascular events and are more closely predictive of T2DM. Furthermore, the metabolic syndrome criteria do not include LDL-C, cigarette smoking, or age, three important risk factors for vascular events. In addition, no underlying metabolic cause seems pathogenic for this syndrome, as there are many subjects with the syndrome who are not insulin-resistant. The notion that cut points for various risk factors are predictors of vascular events does not align itself with the dogma that risk factors have a linear and progressive association with CVD. Until there is greater uniformity and agreement on the components and cut points for the metabolic syndrome that define CVD risk, there is no clear rationale to cluster the vascular risk factors when prescribing treatment. As obesity approaches epidemic proportions in western society, the prevalence of T2DM will likely increase proportionately. We

advocate aggressive risk factor modification that includes therapeutic lifestyle changes and physical activity to modify obesity, as well as pharmacological interventions for each component of the metabolic syndrome as indicated. Future advances in pharmacogenetics and therapeutics are likely to produce novel therapies for T2DM and the metabolic syndrome.

## Hypocholesterolemia

The prevalence of hypocholesterolemia (typically defined as total cholesterol concentrations <160 mg/dL, sixth percentile Multiple Risk Factor Intervention Trial (MRFIT)), increases with age. A “J”-shaped relationship between cholesterol and mortality is reported in some studies, suggesting that hypocholesterolemic individuals are at increased risk of death. Any examination of the association between low cholesterol and morbidity or mortality can be confounded by the presence of active or subclinical/occult disease, such as chronic infection and inflammation, cancer, chronic involuntary weight loss, diabetes, and chronic obstructive pulmonary disorder (COPD). These diseases may either suppress hepatic cholesterol synthesis or accelerate cholesterol catabolism. This bias potentially can be eliminated by the longitudinal analysis of cohort data after excluding individuals with early deaths (who may have had an undiagnosed disease). Such studies, in a variety of populations, have revealed correlations of low cholesterol with nutritional and functional status, as well as mini-mental examination scores.

Data from the Framingham cohort reveals a relationship between total cholesterol and both coronary heart disease and all-cause mortality that is positive until around the seventh decade of life, when the relationships start to become negative. Biologically plausible mechanisms linking low total cholesterol to death include alterations in cell membrane structure and function, abnormalities in steroid hormone metabolism, and fat-soluble vitamin deficiencies. In data pooled from 19 cohort studies, men and women with cholesterol concentrations <160 mg/dL were at a 40% to 50% higher risk for noncardiovascular deaths that occurred more than 5 years after baseline measurement than individuals with cholesterol concentrations of 200–239 mg/dL.

Low normal cholesterol concentrations and declining cholesterol concentrations maybe markers for increased morbidity and mortality, even in apparently healthy community-dwelling older people. In the Honolulu Heart Study, persistence of low cholesterol concentrations over 20 years was associated with increased risk of death. In that study, the earlier in life that the patients exhibited hypocholesterolemia, the greater the risk of death. In an attempt to clarify whether low cholesterol was a consequence of disease, or a result of some genetic or lifestyle factor, Iribarren et al. studied the relationship between the 6-year trend in total cholesterol and subsequent 16-year mortality, and found that declining total cholesterol levels were associated with an increased rate of both disease-specific and all-cause mortality: 30% higher among those with a decline from the middle to the lowest tertile. These findings raise questions about whether it is advisable to lower cholesterol concentrations below 180 mg/dL (4.65 mmol/L) in elderly people.

In evaluating an older patient with hypocholesterolemia, the geriatrician must consider both the pattern of change of cholesterol concentrations over time and their relationship with other diseases and events. Hypocholesterolemia maybe a marker for occult malignancy and other diseases that result in increased morbidity and mortality.

Unfortunately, there are no firm guidelines for the evaluation of patients with hypocholesterolemia. Some advocate the performance of routine cancer evaluations in otherwise healthy community-dwelling individuals with hypocholesterolemia, while others favor either more or less aggressive evaluation. Randomized clinical trials are needed to determine the efficacy of aggressive nutritional intervention in older patients with hypocholesterolemia.

## Management of Dyslipidemia in the Nursing Home Setting

The management of dyslipidemia in extended care facilities remains controversial. There is limited data on the value of treating elevated cholesterol in this situation. In a retrospective cohort study utilizing the Health Care Financing Administration's Minimum Data Set, nursing home residents with an active clinical diagnosis of CVD on statins were 31% less likely to have died at 1 year after adjusting for a broad variety of potential confounders than similar nonusers. In that study, there was no significant effect of treatment on declining physical function. A low-cholesterol diet had no effect on cardiovascular or overall mortality among a broad group of institutionalized individuals. On the other hand, precipitously declining cholesterol is linked to a greater than sixfold adjusted relative odds for death compared to nursing home residents with stable or increasing cholesterol. Therefore, based on the limited available data, we do not advocate the routine treatment of hypercholesterolemia in debilitated nursing home patients, but rather suggest good clinical judgment in identifying patients in whom the potential benefit outweighs the risks of drug toxicity and treatment costs.

## HYPERPARATHYROIDISM

### Background and Epidemiology

Hyperparathyroidism is a common disorder of calcium, phosphorus, and bone metabolism caused by increased circulating levels of parathyroid hormone (PTH). This disease is important to geriatricians because it occurs with increasing frequency in older patients. Widespread use of multiphasic biochemical screening tests led to an increase in the incidence of cases of primary hyperparathyroidism. In the population in Olmstead County, Minnesota, which is served by the Mayo Clinic, the annual incidence rose from 16 per 100 000 people before 1978 to a peak of 112 per 100 000 people 7 years later, then the rate declined. Now such screening tests are used less frequently and the incidence has fallen to 4 per 100 000 people. It is not clear why the incidence of hyperparathyroidism is decreasing, but it is postulated that there is a decreased exposure to ionizing radiation, or better supplementation with vitamin D.

Primary hyperparathyroidism may occur at any age but is found most commonly between the ages of 40 and 65 years. The incidence is approximately 1 per 1000. The disease affects women more than men by almost 2:1, and in women, this usually occurs in the first decade after menopause. In the United States, approximately 80% of patients with primary hyperparathyroidism have no signs or symptoms that are referable to their disease. With the development of sophisticated and specific technologies during the past 15 years, it has become feasible to evaluate patients with asymptomatic primary hyperparathyroidism in ways that have helped to establish prudent guidelines for surgical or medical management.

In hyperparathyroidism, PTH is inappropriately secreted by single or multiple glands in the presence of increased serum calcium levels. The disease is considered primary when autonomous hypersecretion of PTH is caused by a single adenoma, diffuse hyperplasia,

multiple adenomas, or, rarely, a parathyroid carcinoma. Secondary hyperparathyroidism occurs when there is a prolonged hypocalcemic stimulus, as in cases of vitamin D deficiency or chronic renal failure. Tertiary hyperparathyroidism occurs in patients with chronic secondary hyperparathyroidism who develop autonomous hypersecretion of PTH and hypercalcemia, e.g., patients who undergo successful kidney transplants. This chapter focuses on primary hyperparathyroidism only.

### Etiology and Pathology

The etiology of primary hyperparathyroidism is unknown. When calcium is infused into hypercalcemic hyperparathyroid patients, there is a failure to suppress the PTH levels. Furthermore, when cells from hyperparathyroid glands are incubated in vitro, higher levels of ionized calcium in the medium are required to suppress PTH release than are required to suppress PTH release from cells from normal glands. These data suggest that, in part, the abnormality occurring in the parathyroid gland is an elevation of the set point at which ionized calcium levels suppress PTH release. The receptor that is responsible for calcium-sensing in parathyroid glands has been cloned; it is a guanosine triphosphate (GTP)-binding protein that has a seven-amino-acid transmembrane domain. Mutations in this receptor are rare in primary hyperparathyroidism.

In most cases of hyperparathyroidism, no etiologic agent can be identified; these represent sporadic cases. Previous neck exposure to ionizing radiation is associated with an increased incidence of hyperparathyroidism. Lithium, when used for therapy of bipolar disorders, is associated with hypercalcemia and increased PTH levels in up to 10% of patients. Thiazide diuretics can cause hypercalcemia, but the persistence of hypercalcemia 6 weeks after stopping a thiazide usually means the agent has unmasked primary hyperparathyroidism. A few causes of hyperparathyroidism, usually parathyroid hyperplasia, are familial disorders that have an autosomal dominant

mode of transmission, such as (1) familial hyperparathyroidism, (2) multiple endocrine neoplasia type I (Werner's syndrome: hyperparathyroidism, islet cell tumors, and pituitary tumors), and (3) multiple endocrine neoplasia type II (Sipple's syndrome: medullary carcinoma of the thyroid, pheochromocytoma, and hyperparathyroidism). Only rarely does hyperparathyroidism occur in multiple endocrine neoplasia type IIB or III (medullary carcinoma of the thyroid, pheochromocytoma, mucosal neuromas, and marfanoid body habitus).

The pathologic abnormality in the parathyroid gland(s) may be an adenoma, four-gland hyperplasia, multiple adenomas, or carcinoma. Single adenomas cause 80% of the cases of hyperparathyroidism. Hyperplasia of all four glands is found in 15% of cases; parathyroid carcinomas and multiple adenomas comprise the remainder. Determining whether a single gland is an adenoma or chief cell hyperplasia is often difficult to ascertain by histologic features alone, so the gross pathology seen at operation is necessary to classify the disease. An adenoma is diagnosed when only one abnormal gland is found (all other glands are normal). Chief cell hyperplasia is diagnosed when more than one abnormal gland is found. Controversy currently exists regarding whether it is possible to have multiple adenomas. In several studies, enlargement of only two glands was documented, with the remaining two being normal. A rarer form of parathyroid hyperplasia is called "water-clear cell" hyperplasia, in which large, membrane-lined vesicles fill the cytoplasm. Finally, parathyroid carcinoma is diagnosed by finding mitotic figures in the gland or finding capsular or vascular invasion in pathological specimens obtained during surgery.

## Signs and Symptoms

Patients with primary hyperparathyroidism can present with a varying spectrum of signs and symptoms ranging from a total lack of symptoms to acute hypercalcemic crisis. The diagnosis is most frequently made by routine calcium measurements with multichannel screening chemistries in a patient with either no symptoms or only weakness or easy fatigability. Acute hypercalcemic crisis is now a rare form of presentation.

Osteitis fibrosa cystica, with radiographic features of osteopenia, subperiosteal bone resorption, brown tumors, bone cysts, and "salt and pepper" skull, is rare. Patients with hyperparathyroidism show evidence of increased bone remodeling on bone biopsy, with increased amounts of osteoid surface and eroded surface when compared to normal subjects. However, dynamic parameters of bone remodeling show that the mineral apposition rate is unchanged. Although radiographic evidence of hyperparathyroid bone disease in hand films—with subperiosteal resorption and loss of the distal tuft of the phalanges—is rare in cases of primary hyperparathyroidism now, it is found in patients with secondary hyperparathyroidism from chronic renal failure.

Because osteoporosis is such a major health problem in older patients, attention has been directed at determining PTH's effect upon bone mass. With improved techniques to measure bone mass, it is possible to assess changes in both trabecular and cortical bone envelopes. Several early cross-sectional studies suggested that hyperparathyroid subjects have decreased amounts of trabecular bone in the vertebrae. More recent work shows that cortical bone as measured in the forearm or femur is reduced in the affected patients. Thus, elevated levels of PTH seem to have different effects upon cortical

bone. Four studies suggest that patients with hyperparathyroidism have an increase in vertebral compression fractures, but one study found no evidence of an increased incidence of vertebral fractures. A study in Sweden of more than 1800 patients reported no increase in hip fractures in women with hyperparathyroidism, but there was an increase in hip fractures in men.

Nephrolithiasis occurs in 20% of hyperparathyroid patients. Of patients with kidney stones, approximately 5% have hyperparathyroidism. PTH causes a proximal renal tubular acidosis, increasing bicarbonate loss and decreasing hydrogen ion excretion, as well as lowering the phosphate reabsorption threshold. These changes cause a hyperchloremic metabolic acidosis, and 30% of patients will be hypophosphatemic. Hyperparathyroidism can cause nephrocalcinosis and a subsequent decline in the glomerular filtration rate. Hypercalcemia can lead to nephrogenic diabetes insipidus because the renal tubule becomes unresponsive to the action of antidiuretic hormone. Asymptomatic patients with primary hyperparathyroidism have defects in their ability to concentrate urine.

Most other signs and symptoms of hyperparathyroidism can be attributed to the resultant hypercalcemia or, more specifically, the elevated ionized calcium level. *Gastrointestinal* (GI) disorders include anorexia, nausea, vomiting, and constipation. Peptic ulcer disease occurs with increased frequency, and, rarely, it may be the first clue to a multiple endocrine neoplasia type I syndrome (hyperparathyroidism, islet cell tumors, especially gastrinoma, and, finally, pituitary tumors). Pancreatitis can also occur or be exacerbated by the hypercalcemia. *Central nervous system* disorders include impaired cognition, recent memory loss, anosmia, depression, lethargy, and coma. Thus, hypercalcemia and hyperparathyroidism are rare but important considerations in the differential diagnosis of depression and dementia in the elderly. *Neuromuscular* disturbances include a proximal weakness, more prominent in lower than in upper extremities. Many patients complain of malaise and fatigue. Rarely, pruritus can be caused by metastatic calcification in the skin. *Articular* disturbances include pseudogout from calcium pyrophosphate crystal deposition in articular cartilage, calcific tendinitis, and chondrocalcinosis. The main *cardiovascular* disturbance is an increased frequency of hypertension. Stefenelli et al. report that patients with surgically confirmed primary hyperparathyroidism showed a high incidence of left ventricular hypertrophy (82%) and aortic and/or mitral valve calcifications (46% and 39%, respectively). At 41 months after successful parathyroidectomy, there was regression of the left ventricular hypertrophy. Further studies are needed to confirm and expand upon these observations.

Physical signs are unusual in hyperparathyroidism. Soft-tissue calcification can cause pseudogout or cutaneous calcification. When present in the eye, deposits of calcium phosphate crystals can cause conjunctivitis. In the cornea, band keratopathy (a vertical line of calcium phosphate deposition parallel to and within the ocular limbus) is best appreciated with a slit lamp examination. Enlarged parathyroid glands are difficult to palpate in the neck; generally, when a nodule is found in the neck of a suspected hyperparathyroid patient, it represents thyroid rather than parathyroid tissue.

## Diagnosis

Primary hyperparathyroidism is diagnosed by elevated serum calcium levels and, frequently, associated hypophosphatemia, without any other apparent disease or drug causing the abnormalities. The

serum calcium should be measured fasting on several occasions with minimal or no venous stasis. Techniques for measuring PTH have improved significantly, making it possible to diagnose hyperparathyroidism directly rather than by exclusion as had been done previously. Thus, to prove hyperparathyroidism, serum PTH levels should be measured directly. Early assays measured the carboxy terminal portion of PTH. Because this fragment is cleared by the kidney, the diagnosis of hypercalcemia in patients with renal insufficiency was confounded. With improvement in assay techniques for the intact PTH molecule, using immunoradiometric (IRMA) and immunochemiluminescent (ICMA) assays, it is possible to show PTH elevations in 90% of patients.

Most clinical PTH assays have been validated so that the laboratory provides a range reflecting previous experience with the assay and showing where the patient's PTH and serum calcium levels fall in relation to the laboratory's other cases of hyperparathyroidism. In most nonparathyroid causes of hypercalcemia, PTH levels are suppressed, except in the unusual case of a malignant neoplasm that produces PTH. As is discussed in the section on "Differential Diagnosis," malignancy-associated hypercalcemia is always a concern in the differential diagnosis of hypercalcemia, but neoplasms that are actually proved to produce active PTH are unusual, most such cases being renal, pancreatic, ovarian, or hepatic carcinomas. In such instances, the PTH-related peptide secreted by the tumor does not usually cross-react with PTH of parathyroid origin in the immunoassays employed in most laboratories.

Serum phosphate levels maybe low in hyperparathyroidism, but they can be normal, especially if there is renal impairment. Although PTH does cause phosphaturia, other factors such as dietary intake and time of day may affect renal phosphate handling. Furthermore, patients with malignancy-associated hypercalcemia can have a decrease in the renal phosphate reabsorption threshold from hypercalcemia per se or from the tumor-derived peptides, which produce the hypercalcemia. Other serum electrolyte abnormalities, such as elevated chloride, low bicarbonate, and low magnesium levels, are not specific enough to be of diagnostic value. Both an elevated serum alkaline phosphatase level and increased urinary hydroxyproline level suggest significant skeletal involvement from hyperparathyroidism.

Patients who are being evaluated for hyperparathyroidism should have a 24-hour urine calcium and creatinine excretion measured. Patients with a calcium:creatinine ratio of 0.1 may have familial hypercalcemic hypocalcemia, a hereditary disorder with normal PTH levels that does not require surgery. It is caused by an inactivating mutation of the calcium-sensing receptor.

Routine use of preoperative localization of abnormal parathyroid tissue in hyperparathyroidism should not be part of the diagnostic evaluation because noninvasive imaging techniques require further development before being valid for such application. Some centers are evaluating the use of technetium-99m sestamibi scans or ultrasonography, but they should not be used routinely in evaluating patients for parathyroidectomy. Arteriography and selective venous catheterization looking for "stepped-up" levels is a technically difficult procedure and should be performed by experienced hands only when hyperparathyroidism persists after a failed neck exploration.

## Differential Diagnosis

The differential diagnosis of hyperparathyroidism is that of hypercalcemia, which can be caused by a diverse group of diseases and drugs

**TABLE 111-1**

### Differential Diagnosis of Hypercalcemia

Primary hyperparathyroidism
Solitary adenoma
Hyperplasia
Multiple endocrine neoplasia
Malignancy-associated hypercalcemia
Local osteolytic hypercalcemia
Humoral hypercalcemia of malignancy
1,25(OH) <sub>2</sub> D-mediated hypercalcemia
Granulomatous disorders
Sarcoidosis
Berylliosis
Tuberculosis
Histoplasmosis
Coccidiomycosis
Candidiasis
Eosinophilic granuloma
Silicone implants
Medications
Vitamin D and A intoxication
Lithium
Thiazide diuretics
Estrogens/antiestrogens
Theophylline
Immobilization plus
Juvenile skeleton
Malignancy
Paget's disease of bone
Primary hyperparathyroidism
Renal failure
Milk alkali syndrome
Parenteral nutrition
Familial hypocalciuric hypercalcemia
Hypophosphatemia
Renal failure
Idiopathic hypercalcemia of infancy
Hyperthyroidism
Addison's disease
Hyperproteinemia

(Table 111-1). A major concern when hypercalcemia is encountered is whether it is caused by a neoplasm. The clinical setting must be considered. Most patients with malignancy-associated hypercalcemia have obvious neoplastic disease on thorough examination and routine diagnostic workup. Thus, a chest x-ray a mammogram, and a serum and urine protein electrophoresis should be ordered when evaluating hypercalcemia. Since primary hyperparathyroidism is a common disease in older women, an elderly female with hypercalcemia without obvious evidence of malignant disease will be more likely to have primary hyperparathyroidism than occult malignancy.

Familial hypocalciuria hypercalcemia (FHH) should be considered in an evaluation of hypercalcemia. Although uncommon, FHH can present with hypercalcemia, but there is usually a family history, reflecting an autosomal dominant mode of inheritance, and 24-hour urinary calcium:creatinine excretion ratio of 0.1 is highly suggestive.

At present, no adverse effects of the hypercalcemia have been reported from affected kindreds under supervision, and parathyroidectomy does not alter the hypercalcemia.

Drugs that cause hypercalcemia, such as thiazide diuretics and calcium supplements, can be excluded by withdrawing them for 4 weeks and making sure that serum calcium levels return to normal. Hypercalcemia caused by vitamin D intoxication can be diagnosed by measuring 25-hydroxyvitamin D levels and finding a level above 120 ng/mL. Hypercalcemia can be found in sarcoidosis, tuberculosis, and chronic fungal infections. The mechanism in all these diseases is believed to be increased production of 1,25-dihydroxyvitamin D by the granulomatous tissue, which causes increased calcium absorption from the GI tract. Other diseases causing hypercalcemia, such as hyperthyroidism, adrenal insufficiency, and vitamin D intoxication, should be diagnosed by their historical or clinical features.

## Therapy

Treatment of hyperparathyroidism depends upon the way in which the patient presents to the physician. Because most cases are asymptomatic at presentation, no immediate therapy is usually necessary and a thorough diagnostic evaluation can be undertaken. When the patient presents with a hypercalcemic crisis (e.g., obtunded with serum calcium levels of greater than 12 mg/dL), management of the hypercalcemia must take precedence over diagnostic studies. Most hypercalcemic patients are dehydrated and may require several liters of parenteral fluids to lower the serum calcium into the 11.0 mg/dL range. Once hydration has been reestablished and the patient is stable, further decisions about therapy can be made.

At this time, there is no effective medical therapy for primary hyperparathyroidism. Beta-blockers, estrogen therapy in postmenopausal women, phosphate supplementation with potassium phosphate (Neutra-Phos-K), etidronate disodium (Didronel), or oral cellulose phosphate with dietary calcium restriction may lower serum calcium levels, while other aspects of the disease may progress. The second-generation bisphosphonates, alendronate, and risedronate can lower serum calcium levels, but long-term studies are needed to document their effect on the disease and whether they alter fracture rates. A new class of drug, calcimimetic agents, is under study. Calcimimetics activate the calcium sensing receptor in the parathyroid gland and inhibit PTH secretion. A long active calcimimetic agent, cinacalcet, is now approved by the Food and Drug Administration (FDA) for the treatment of secondary hyperparathyroidism with renal failure and for hypercalcemia from parathyroid cancer. This agent is not approved for the treatment of primary hyperparathyroidism, but early results suggest it may help control serum calcium levels. Therefore, long-term management of hyperparathyroidism must involve a decision about whether to intervene surgically or to follow the patient until there is an indication for surgery.

Because many cases of hyperparathyroidism are asymptomatic and without any potential complications of the disease at diagnosis, immediate surgery is not necessary, and some patients may never need an operation. A National Institutes of Health (NIH) consensus conference points out that because surgery is the only effective therapy for this disorder, the patient and the physician must realize that meticulous, long-term follow-up is necessary. Understanding of long-term complications is incomplete, and no

study has randomized asymptomatic patients to surgery or medical follow-up.

There are indications for surgery in asymptomatic patients with primary hyperparathyroidism: (1) markedly elevated serum calcium (above 12.0 mg/dL); (2) history of life-threatening hypercalcemia; (3) reduced creatinine clearance (below 30% for age-matched normals); (4) nephrolithiasis; (5) markedly elevated 24-hour urinary calcium excretion (above 400 mg); and (6) reduced bone mass as measured by direct measurement (more than 2 standard deviations below age-matched normals). Surgery should be considered strongly in the following circumstances: (1) the patient desires surgery; (2) meticulous, long-term follow-ups are unlikely; (3) coexistent illness complicates management; and (4) the patient is young (younger than age 50 years). After successful surgery, recovery is rapid. Serum calcium levels normalize within hours to several days. There is a 90% reduction in recurrent renal stones in patients with nephrolithiasis. Bone mass also improves after surgery; patient can gain 12% to 20% of their femoral or lumbar density respectively in 4 years.

Patients with serum calcium levels below 11.0 mg/dL and no other evidence of disease maybe safely followed. There is agreement that malaise and fatigue are associated with hyperparathyroidism, but no prospective studies are available to show that these complaints improve with surgery. This is also true for neuropsychiatric disturbances in patients with serum calcium levels below 11.0 mg/dL. At present, no markers are available in lieu of direct measurements to suggest who will lose bone, develop nephrolithiasis, or have a decline in glomerular filtration rate. Therefore, patients with asymptomatic hyperparathyroidism require close follow-up; in addition, they should be educated about the signs and symptoms of hypercalcemia. Vitamin D deficiency can cause secondary hyperparathyroidism and patients with primary hyperparathyroidism may also be vitamin D-deficient. When vitamin D deficiency is found, patients should be given 400 IU of vitamin D daily. These patients should have yearly serum measurements of calcium and creatinine, determination of creatinine clearance, and yearly kidney-ureter-bladder radiography searching for nephrolithiasis. Most experts believe that bone mass measurements (spine, hip, and possibly radius) should be followed annually for 2 to 3 years until stable. Thus, if physician and patient decide not to operate for hyperparathyroidism, education and long-term follow-up are necessary.

For patients who require surgery, the most important aspect is referral to a surgeon who is experienced in neck dissections and identification of parathyroid glands. With an experienced surgeon, parathyroidectomy is usually not a major procedure unless the sternum must be split to find a substernal gland. All four glands should be identified and biopsied for histologic confirmation. Because 80% of the cases of hyperparathyroidism are caused by a single adenoma, removal of the offending gland is curative. When hyperplasia is identified, most surgeons remove 3.5 glands, marking the remaining portion of gland so it can be identified if necessary in the future. Transplantation of parathyroid tissue into the forearm after removal of all of the glands from the neck is used by some surgeons, especially when they anticipate removing more tissue should hyperplasia become a problem at a later time (e.g., with chronic renal failure).

Postoperatively, patients should be watched closely for 72 hours for signs of hypocalcemia. Nervousness, tingling, and a positive Chvostek or Trousseau sign may indicate hypocalcemia, which should be confirmed by total or ionized serum calcium levels. Many

patients have transient hypocalcemia, and additional calcium should be given only if the level is below 8 mg/dL. Intravenous calcium as the chloride or gluconate salt maybe given for several days, but persistent hypocalcemia requires oral calcium in a dose of 1000 to 1200 mg daily. If hypocalcemia is severe, 1, 25-dihydroxyvitamin D (calcitriol) can be added at 0.5 to 1  $\mu\text{g}/\text{day}$  in doses divided every 12 hours. Because calcitriol can cause hypercalcemia and hypercalciuria, serum and urine levels must be monitored. Patients who have developed hypocalcemia from skeletal uptake of calcium and phosphorus with healing of osteitis fibrosa cystica ("hungry bones") have normal or low serum phosphorus levels. This complication is currently rare because of early detection of the disease; treatment with calcium supplements and calcitriol can be necessary for up to 3 months. Permanent hypoparathyroidism is a rare complication of parathyroidectomy (when performed by experienced surgeons), but it can occur. Hypocalcemia with persistent hyperphosphatemia postoperatively suggests hypoparathyroidism. This can occur transiently from bruising of the glands as they are identified and biopsied at surgery, so follow-up is required to determine whether parathyroid function returns over time. Finally, hyperparathyroid patients can have low serum magnesium levels, another cause of hypocalcemia. Thus, the serum magnesium level should be checked if hypocalcemia develops postoperatively. Because serum magnesium levels may not reflect tissue stores, patients should receive parenteral magnesium if a low normal level is found.

## PAGET'S DISEASE OF BONE

### Epidemiology

Paget's disease of bone is a focal disorder of accelerated skeletal remodeling, first described by Sir James Paget in 1877. In his original description, Paget described six patients with enlarged skulls, hearing loss, bowed extremities, and kyphotic spines. He called the disease osteitis deformans and proposed an inflammatory basis to the lesion, which he said led to the progressive deformity of the affected bones over the lifetime of an individual.

Paget's disease is a disease of older people. In the United States, the disease occurs in 1.8% of people older than 60 years of age. Its prevalence increases to 10% to 15% by the ninth decade of life. Paget's disease affects men and women equally. The disorder is rarely recognized before age 40 years of age. The incidence and severity of Paget's disease of bone appears to be declining in New Zealand, Great Britain, Spain, and the United States. At this time, there is no explanation for this decline in prevalence and severity.

A cohort of subjects from Rotterdam was evaluated with serum alkaline phosphatase levels and radiographs. Of the subjects who had an elevated serum alkaline phosphatase level with normal measures of other liver enzymes activities, 20% were diagnosed with Paget's disease. Of the patients with normal serum alkaline phosphatase levels, Paget's disease was found using radiographs in 2.3%. The population prevalence in Paget's disease in the Netherlands is 3.6%. Importantly, 84% of subjects with Paget's disease in this country have a normal serum alkaline phosphatase level.

There are clear geographic distributions of Paget's disease. The disorder is most prevalent in England, western Europe, the United

States, Australia, and New Zealand, but is uncommon in Scandinavia, China, Japan, and India.

### Etiology

Although the etiology of Paget's disease of bone is unknown, there are two hypotheses currently promulgated that are not mutually exclusive: one, a viral etiology, and the other, a genetic susceptibility. Since the early 1970s, studies have suggested that paramyxoviruses may have a role in this disorder. Studies also document familial clusters of Paget's disease, suggesting a genetic component to this disorder.

Several paramyxoviruses (measles virus, respiratory syncytial virus, and canine distemper virus) are postulated to play a role in the etiology of Paget's disease. This hypothesis was based on finding nucleocapsid-like structures and antigens in osteoclast nuclei and cytoplasm. In addition, measles virus messenger RNA was found in osteoclasts and mononuclear cell progenitors. However, no virus has been cultured from pagetic cells, and despite use of sensitive techniques, no direct evidence of any type of paramyxovirus RNA or of virus infection has been found. In three other skeletal disorders—osteopetrosis, pyknodysostosis, and osteoclastoma—nuclear inclusions bodies have been identified. Transgenic mice with measles virus nucleocapsid protein introduced into osteoclasts develop skeletal lesions similar to those found in patients with Paget's disease.

Increased interleukin-6 (IL-6) levels have been reported in bone marrow plasma and the peripheral blood of pagetic patients, and IL-6 increases osteoclast formation when added to normal marrow cells. Cytokines in the marrow microenvironment are postulated to influence the development of osteoclast precursors and thus limit the lesions to local sites once the initial lesion occurs. What is still unknown is how the initial lesion begins.

The hypothesis that Paget's disease has a genetic etiology is supported by work showing that 15% to 30% of patients have a positive family history of the disorder. In one study from Spain, 40% of pagetic patients had an affected first-degree relative. Some of the more severely affected patients have disease involving the pelvis, the spine, the proximal femurs, and the skull, and the disease appears at an earlier age. Some such patients have a family history of the disorder. There are seven chromosomes where Paget's disease associated loci have been identified (PDB1-7). One of the PDB associated genes has been identified: the SQSTM1 gene, which is located in the PDB 3 region on chromosome 5p35. The SQSTM1/p62 protein is a scaffold protein in the RANK signaling cascade, but the pathogenic mechanism regarding Paget's disease is unclear presently.

A current hypothesis is that patients in middle to late life who have a genetic predisposition to Paget's disease of bone develop a viral infection, which causes the disease to become manifest. Still unknown is why it involves particular areas of the skeleton and why the disease generally becomes manifest after the age of 60 years.

### Pathophysiology

Because Paget's disease of bone is a localized disorder of accelerated bone remodeling, it is useful to briefly review the normal bone remodeling process (also see Chapter 117). All areas of the skeleton must be remodeled throughout life to repair acquired microfractures and to strengthen parts of the skeleton placed under new or increased mechanical loads. The process begins when osteoclasts from bone

marrow colony-forming units of the macrophage lineage come to a surface that needs remodeling. They excavate a cavity 50  $\mu\text{m}$  in depth over a 2- to 4-week period and then undergo apoptosis. A new series of cells, osteoblasts, derived from bone marrow colony-forming units of fibroblast lineage, appear in the resorption cavity and fill it with layers of osteoid tissue known as *lamellae*. The cavity is filled with osteoid tissue and the osteoblast also form hydroxyapatite crystals on the collagen, which provides strength to the matrix. The process of bone remodeling is tightly coupled so that increases or decreases in rates of bone resorption are followed for an increase or decrease in bone formation. Through this coupling process, it is possible for most people to maintain their skeleton as a serviceable, lightweight frame throughout life. We now know that the coupling process is mediated by cytokines and growth factors released by osteoblasts and osteoclasts, which serve to control the remodeling process. The final common pathway for control of osteoclast differentiation and function is the receptor activation of NF- $\kappa$ B (RANK) receptor activator of NF- $\kappa$ B ligand (RANKL) and osteoprotegerin (OPG). The pathway with IL-6 and macrophage colony stimulating factor are major regulators of osteoclast differentiation and function.

In pagetic lesions, the primary abnormality is in the osteoclast. A major histologic feature is the increased number and size of the osteoclasts and their nuclei. Normal osteoclasts have 10 nuclei while osteoclasts from areas of the skeleton with Paget's disease have up to 100 nuclei. There is a compensatory increase in the number and size of the osteoblasts in the areas of increased remodeling activity, which leads to large amounts of new bone formation. The increased rate of bone turnover disrupts the normal lamellar pattern of the osteoid tissue and results in immature woven or mosaic bone. This bone has increased amounts of fibrosis and vascularity as well as enlarged haversian canals. Thus, although the bone appears denser radiographically, it is more subject to fracture, can bow with weight bearing, and, especially in the skull, can enlarge as long as the remodeling activity is increased.

### Clinical Manifestations

Patients with Paget's disease of bone present with a wide array of symptoms. Depending upon the clinical setting, 70% to 90% of patients with Paget's disease will have no symptoms. In a tertiary referral practice, 20% to 30% of patients will have symptoms. In contrast, in a primary care practice, only 10% of patients with the disease may have related symptoms. Many patients have the diagnosis made incidentally when an elevated serum alkaline phosphatase level is found on a multiphasic chemistry screening panel or radiography is performed that shows an asymptomatic bone lesion. The disease may affect any bone and can be monostotic or polyostotic. Symptoms depend on the bone(s) and the part of the bone involved as well as the activity of the bone remodeling. Many patients with radiographic evidence of Paget's disease have no symptoms.

The most commonly affected bones are the pelvis, lumbar spine, the skull, and proximal femurs. All areas of the skeleton can be affected by the disease. In patients with symptomatic Paget's disease, bone pain can be mild to severe. The pain is usually not related to physical activity. The pain can be variously described as dull aching, burning, or boring in nature. Acute pain may develop as a consequence of a pathologic fracture in an affected bone. Bone pain may also arise from increased vascularity or from stretching of the periosteum caused by the increased amount of new bone from the

**FIGURE 111-1.** Left anteroposterior tibia and fibula radiograph from a 78-yr-old woman with Paget's disease of bone involving the tibia. At the proximal portion of the tibia are staples from a failed osteotomy 25 yr before. Note the lateral bowing of the tibia. There is the characteristic increase in cortical bone size from the abnormal remodeling process. In the distal portion of the tibia is seen the advancing lytic disease front, sometimes called a blade-of-grass lesion.

disorganized bone remodeling. Periarticular pain maybe the presenting symptom in 50% of cases and is an important diagnostic problem because Paget's disease commonly affects bone around major joints such as the hip and knee, as well as those of the spine, with narrowing of the joint spaces and formation of osteophytes.

Bowing of weight-bearing bone is another common feature, occurring most commonly in the femur, tibia, humerus, and ulna (Figure 111-1). The bowing seen in the femur and tibia is often associated with stress fractures on the convex surface of the bowed bone (Figure 111-2). Bone deformity alters force transmission through the adjacent joint causing premature loss of articular cartilage and secondary osteoarthritis especially in the hip and knee. In addition to deformities, the affected bone can enlarge. Degenerative arthritis in joints contiguous to pagetic lesions causes juxta-articular enlargement and altered subchondral bone support. Patients also develop osteoarthritis in unaffected knees as a result of favoring the nonpagetic knee. Protrusion acetabuli occurs in some patients with disease involving the ilium (Figure 111-3).

Neurologic complications reflect the predilection of the disease to affect the axial skeleton. Disease in the skull can cause nonspecific headaches, possibly from increased blood flow. Patients with skull involvement can develop deafness. Pagetic involvement of the temporal bone can cause conductive hearing loss. Involvement of the cochlea results in mixed sensory and conductive deafness.

**FIGURE 111-2.** Right proximal femur and pelvis radiograph of a 68-yr-old man with Paget's disease of bone involving both the femur and ilium. The angle of the femoral neck and femur are decreased as the bone is less strong, a coxae vera deformity. Also note the lateral bowing of the femur with the stress fractures on the convex side of the femur.

Occasionally, the optic or trigeminal nerves may be involved, resulting in visual loss or tic douloureux. Skull deformity may result in enlargement of the vault, with a characteristic appearance particularly of the forehead (frontal bossing) or of the maxilla (leontiasis osseum). Basilar invagination of the skull can cause symptoms from internal hydrocephalus or long tract signs from brainstem compression. Bone enlargement of vertebrae can cause spinal stenosis, resulting in spinal radiculopathy or cauda equina syndrome. Increased blood flow to the highly vascular pagetic bone has been postulated to provoke a

**FIGURE 111-3.** Anteroposterior pelvis radiograph from a 72-yr-old man with Paget's disease of bone involving the entire pelvis. Femurs are not involved with Paget's disease, but the right side of the pelvis has marked protrusion acetabuli.

“steal syndrome.” In this situation, blood is shunted away from the neural elements, exacerbating the neurologic symptoms and signs accompanying the stenosis.

Pagetic bone fractures more easily because it is formed more rapidly than normal bone. In addition to incomplete fissure fractures on convex surfaces of bowed long bones, complete transverse fracture can occur with minimal trauma (Figure 111-4). These fractures are called chalk stick fractures because the bone breaks evenly as a piece of chalk would, rather than with jagged fragments as normal bone does. Such fractures also have a higher rate of nonunion, between 10% and 40%, occurring most commonly in the femur.

A serious but rare complication of Paget's disease (less than 0.1% of affected patients) is the development of malignant neoplasms. Osteosarcomas, chondrosarcomas, fibrosarcomas, and tumors of mixed histologic characteristics may develop, almost always in a preexisting pagetic lesion. Primary giant cell tumors and secondary spread of other cancers to existing pagetic lesions also occurs. When malignant neoplasms occur, they are very aggressive and unless the neoplasm can be removed totally (usually limb amputation), the disease is rapidly fatal. At present, there are no data showing that treatment of Paget's disease of bone reduces the occurrence of malignant neoplasms.

With high rates of bone remodeling, some patients with Paget's disease can develop nephrolithiasis. Occasionally, when patients with active polyostotic disease must be put in bed, for example, after a fracture, they can develop hypercalcemia and hypercalciuria. When this occurs, antiresorptive agents must be initiated on an emergent basis to reduce calcium release from bone resorption. Hyperuricemia and gout are reported to occur in patients with Paget's disease of bone. It is unclear whether abnormal purine metabolism is caused by the elevated bone remodeling or whether gout and Paget's disease are just two common diseases occurring in the same patient.

High-output cardiac failure has been reported to occur in patients with Paget's disease. Generally, patients have more than one third of their skeleton involved with bone turnover lesions; however, documented occurrences are rare.

A series of fibrosing or inflammatory disorders are reported to occur with Paget's disease: Dupuytren's contractures, Peyronie's disease, and Hashimoto's thyroiditis. Whether these inflammatory/fibrotic disorders are only associated with Paget's disease or in some fashion caused by the release of cytokines from the areas of increased turnover awaits further study. Angioid streaks and peripapillary chorioretinal atrophy are associated with Paget's disease of the bone but are more frequently seen with pseudoxanthoma elasticum, another connective tissue disease.

### Diagnosis

All patients with Paget's disease of bone should receive a thorough history and physical examination. Because 30% to 70% of patients have the diagnosis made serendipitously, it may be necessary to reevaluate the patient, seeking symptoms and signs of the disease. All patients with Paget's disease should have a total-body bone scan using a technetium-labeled bisphosphonate. Areas of rapidly remodeling bone will appear as hot spots and this technique is the most sensitive method for localizing pagetic areas. Areas that are hot on bone scan should then have radiographs to confirm the presence of abnormal remodeling. Radiographs of painful or deformed bones are usually diagnostic, showing the characteristic mixed appearance of

**FIGURE 111-4.** A series of left anteroposterior tibial radiographs from a 74-yr-old man with Paget's disease of bone in the left tibia. (A) The patient's tenth fracture; note chalk stick nature. The fracture did not heal with casting over 6 months. (B) The patient underwent tibial straightening with two osteotomies. He also wore an Ilizarov external fixation device for 1 yr and received 6 months of alendronate 40 mg daily. (C) The left tibia is much straighter. The patient now walks with a clamshell leg brace.

areas of lysis from increased osteoclastic resorption with sclerotic areas from excessive osteoblastic bone formation as well as cortical thickening. In the early stages of the disease, the changes may be predominantly lytic with flame-shaped resorption fronts in long bones or osteoporosis circumscripta in the skull. A characteristic appearance that distinguishes Paget's disease from other conditions radiographically is the increased size and diameter of affected bones, particularly those of the spine or shafts of long bones. If spinal stenosis, hydrocephalus, or brainstem compression from basilar skull invagination is suspected, computed tomography (CT) or magnetic resonance imaging (MRI) scans may be necessary to confirm these diagnoses.

Measurement of a serum alkaline phosphatase level is the most useful biochemical test for Paget's disease. This enzyme is located in the plasma membrane of osteoblasts, and levels are elevated above the normal range in 90% of affected patients. Alkaline phosphatase activity reflects the number and functional state of osteoblasts in patients with the disease. The serum level of alkaline phosphatase correlates roughly with the extent of skeletal involvement as established by radionuclide bone scans. Serial determinations of alkaline phosphatase provide useful, simple, and inexpensive biochemical indices of skeletal activity. Serum alkaline phosphatase levels do vary from day to day, so that for a change in levels to represent a change in disease activity or a response to therapy, the level should increase or decrease by 25% to be clinically significant. Because 10% of patients with Paget's disease have normal serum alkaline phosphatase levels, it can be helpful to measure bone specific alkaline phosphatase. This isoenzyme of alkaline phosphatase can be elevated when total alkaline phosphatase levels are normal and can also be useful in patients with coexisting liver disease. Measurement of serum osteocalcin level, a vitamin K-dependent protein made by osteoblasts, has not been useful in diagnosing or following patients with Paget's disease.

Increased bone resorption is the initial abnormality in Paget's disease. Bone resorptive activity can be assessed by measuring serum levels of collagen breakdown products, C-telopeptide or N-telopeptide. These collagen fragments can also be measured in urine specimens and creatinine should be assessed concomitantly. Markers of bone resorption change within 1 day to 1 week after the initiation of therapy for Paget's disease while it may take 1 to 2 months before serum alkaline phosphatase levels show a response to therapy. Once a diagnosis of Paget's disease has been made and the extent of the bone involvement quantitated, only serum alkaline phosphatase levels need to be followed. In some patients, bone pain can reoccur after successful suppression or disease activity with therapy. When this occurs, and serum alkaline phosphatase levels are normal, measurement of urinary levels of pyridinoline cross-links or *n*-telopeptide levels can show an increase in bone resorption activity.

Table 111-2 lists the diseases that should enter into the differential diagnosis of Paget's disease. These diseases can be categorized as either causing an elevated serum alkaline phosphatase level or causing a radiographic lesion similar to Paget's disease.

In most cases, the diagnosis of Paget's disease is not difficult. An asymptomatic or symptomatic bone lesion with an elevated serum alkaline phosphatase level can be easily resolved with the clinician and a radiologist. Occasionally, the author has seen an isolated skeletal lesion in the ilium or in a vertebral body that may not have the classical radiographic appearance of Paget's disease and the markers of bone turnover; serum alkaline phosphatase, urinary pyridinoline cross-links, or *n*-telopeptide levels are all normal. In these cases, a closed or open bone biopsy is necessary to rule out a neoplasm. Rarely, a patient with Paget's disease of bone may develop a metastasis from another cancer that is in a preexisting pagetic lesion. The author saw a man whose first recurrence of an adenocarcinoma from his lung primary appeared 2 years after resection of the primary lesion as a bone metastasis to an area of Paget's disease in his ilium.

**TABLE 111-2****Differential Diagnosis of Paget's Disease of Bone**

Causes of elevated serum bone alkaline phosphatase level
Metastatic neoplasm to the skeleton
Osteomalacia
Hyperparathyroidism with osteitis fibrosa cystica
Idiopathic hyperphosphatasia
Causes of skeletal lesions with similar radiographic appearance
Metastatic neoplasm to the skeleton
Vertebral hemangioma
Fibrous dysplasia
Chronic osteomyelitis
Metaphyseal dysplasia (Engelmann's disease)
Familial expansile osteolysis
Sternocostal clavicular hyperostosis

Data from Crisp AJ. Paget's disease of bone. In: Maddison PJ et al., eds. *Oxford Textbook of Rheumatology*. Oxford: Oxford University Press; 1993:1025.

Finally, fibrous dysplasia can cause diagnostic confusion with Paget's disease because the lesion appears hot on bone scan. An experienced skeletal radiologist or a bone biopsy maybe required to clarify this diagnosis.

## Therapy

As with any chronic disease, patient education about Paget's disease is the first and most important aspect of disease management is education of the patient about their illness. The Paget Foundation for Paget's Disease of Bone and Related Disorders, 120 Wall Street, New York, NY 10007, is helpful in providing information to patients and health care professionals, the Web site is <http://www.paget.org/>.

With current knowledge, not all patients with Paget's disease require treatment. In some cases, the symptoms that cause the patient to seek medical care are caused by an associated disorder. Thus, careful consideration of the symptoms and the physical and radiographic findings are necessary to determine whether treatment of the Paget's disease is indicated.

Patients with bone pain from associated osteoarthritis should be treated with aspirin, acetaminophen, or nonsteroid anti-inflammatory agents (NSAIDs). Because many patients are elderly, care should be taken to avoid renal and GI toxicity from NSAIDs. Some patients with severe joint destruction from Paget's disease who are not candidates for joint replacement may require narcotics to control their pain.

Patients who develop deformities or gait disturbances from their Paget's disease should be evaluated to correct or improve these impairments. A cane can be a very important therapeutic device for patients with disease in the pelvis or lower extremities. If the patient has a leg-length deformity, our group tries to correct the deformity with a shoe lift to 50% of the leg length discrepancy over 3 to 4 months. When this has been accomplished, the patients find they ambulate better. Patients with hearing impairments should be referred to an audiologist. When patients have maxillary or mandibular disease, they should be evaluated by a dentist.

Patients should be followed, once they are stable, semiannually or annually. An alkaline phosphatase should be checked annually, and radiographs performed when symptoms indicate a change in the disease.

**TABLE 111-3****Indications for Treatment of Paget's Disease of Bone**

- Symptoms caused by metabolically active Paget's disease
- In a patient planning to undergo elective surgery on a pagetic site
- Hypercalcemia with prolonged immobilization
- To decrease local progression and reduce the risk of future complications even in asymptomatic patient

Data from Siris ES, et al. Indications for treatment and review of current therapies medical management of Paget's disease of bones. *J Bone Miner Res*. 2006;21(2): P94-P98.

The ultimate goal of therapy for Paget's disease is to restore bone remodeling to normal levels so that all new bone formed is normal. At present, all available therapies only control the abnormal remodeling rates and do not cure the disease.

Two classes of drugs—bisphosphonates and calcitonin—are available to treat Paget's disease. Although both of these types of drugs control the increased bone remodeling by inhibiting bone resorption, bisphosphonates are more effective in controlling the increased remodeling rates. Now, calcitonin therapy is used when patients are allergic to bisphosphonates. A number of randomized controlled clinical trials have shown that bisphosphonates can improve the pain associated with Paget's disease of bone. [Table 111-3](#) lists current recommendations for the types of patients who should receive therapy. Although no controlled clinical trials have been performed to support the second, third, and fourth points of the guidelines, such trials may never be performed. The recommendations are generally accepted by experts who treat large numbers of patients.

The development of potent "second and third generations" bisphosphonates has made these agents the drugs of choice for the treatment of Paget's disease. Bisphosphonates are analogs of inorganic pyrophosphate. Pyrophosphate binds avidly to the surface of the calcium phosphate mineral phase of bone and modulates the rate and extent of mineralization. Bisphosphonates have a carbon atom substituted for the oxygen atom in pyrophosphate. Bisphosphonates bind to bone mineral but are resistant to hydrolysis. Different side chains on the central carbon atom confer different activities to bisphosphonates. Bisphosphonates bind to bone mineral and are potent inhibitors of osteoclasts. The earliest bisphosphonate etidronate inhibited osteoclast activity, but it also impaired bone mineralization. Prolonged use of etidronate was associated with the development of osteomalacia.

There are now six bisphosphonates approved for the treatment of Paget's disease in the United States: alendronate, risedronate, tiludronate, pamidronate, etidronate, and zoledronic acid. Alendronate is given in doses of 40 mg daily for 6 months. More than 60% of patients who receive this drug normalize their serum alkaline phosphatase levels. Orally administered alendronate cause GI disturbances in 17% of patients; in some, esophagitis can be severe enough to cause discontinuation of the drug. Risedronate is given at a dose of 30 mg orally for 60 days. At this dose, 70% of patients experience normalization of their alkaline phosphatase levels. Although esophagitis can occur with risedronate, it is believed to occur less frequently than with alendronate.

A clinical trial of patients with Paget's disease of bone compared the effects of risedronate, 30 mg daily for 60 days versus intravenous zoledronic acid 5 mg in a single dose. The alkaline phosphatase levels were maintained within the normal range in the vast majority

of patients treated with zoledronic acid, whereas patients treated with risedronate had an increase in their mean alkaline phosphatase level over a 2-year period. Thus, the advantage of the most potent bisphosphonate in normalizing and maintaining serum alkaline phosphatase levels over a 2-year period is apparent from this work.

Tiludronate is more potent than etidronate, but less potent than alendronate or pamidronate. It is given 400 mg orally for 3 months. This regimen is well-tolerated and will normalize alkaline phosphatase levels in 40% of patients. Pamidronate is another second-generation bisphosphonate that has been used in Europe for 15 years, but is approved in the United States only as an intravenous preparation. The approved regimen is 30 mg intravenously over 4 hours on 3 consecutive days. A second course of pamidronate may be administered as needed. The advantage of pamidronate is that it can be given intravenously and thus GI toxicity is avoided.

There are several caveats when using nitrogen containing bisphosphonates. These agents are potent and require the person not be hypocalcemic or have a vitamin D deficiency. Rarely these drugs can cause an iritis and if they have, they should be avoided and the nonnitrogen containing bisphosphonates, etidronate or tiludronate, should be used. Patients receiving this class of drugs, especially intravenous pamidronate and zoledronic acid, should be instructed that they may experience an acute phase response within 96 hours after their dose of drug. This acute phase response can be managed with acetaminophen, aspirin, or ibuprofen taken for 72–96 hours post-dose. Finally, patients should be made aware of the risk, although it is small, associated with bisphosphonate-associated osteonecrosis of the jaw. It has been described in three patients treated with bisphosphonate for their Paget's disease of bone. However, in the three reported cases, the patients received more than the recommended dose to treat their disease.

Calcitonin is a safe treatment for Paget's disease. Salmon calcitonin must be administered subcutaneously, usually daily at first, and after 1 to 2 months, it is given three times a week. Calcitonin can normalize bone turnover indices in mild cases of Paget's disease, but it is clearly not as potent an antiresorptive agent as the bisphosphonates are. Usually, the biochemical response is partial, with about a two thirds reduction in serum alkaline phosphatase levels. In approximately 20% of patients, resistance to chronic salmon calcitonin develops after a successful initial treatment period. Neutralizing antibodies develop to calcitonin, but it is not clear whether these antibodies are responsible for the resistance. Side effects occur in approximately 20% of patients treated with either salmon calcitonin. These include nausea, facial flushing, and polyuria. Nasal salmon calcitonin is approved by the FDA for treatment of postmenopausal osteoporosis. It is not recommended for use in Paget's disease because only 40% of the drug is absorbed from the nasal mucosa, and, thus, does not provide a high enough dose of medication. If calcitonin is discontinued, exacerbation of biochemical abnormalities and symptoms usually occurs in 1 year.

Resistance to bisphosphonate is described but is poorly understood. Patients who receive salmon calcitonin, etidronate, and pamidronate have all been reported to have less reduction in their serum alkaline phosphatase levels or a more rapid return to an elevated alkaline phosphatase level after subsequent doses of bisphosphonate. The exact mechanism for this is not known. What is known is however that it is possible to switch the patients to a more potent bisphosphonate and with such therapy have reduction or normalization of alkaline phosphatase levels.

Plicamycin and gallium nitrate are two other drugs that have been used to treat Paget's disease. Both are approved for use in the treatment of hypercalcemia of malignancy and are effective antiresorptive agents. They are not approved by the FDA for use in Paget's disease and have been supplanted by the more effective second-generation bisphosphonates.

Patients with Paget's disease may need emergency or elective orthopedic surgical procedures because of complications of their Paget's disease. Fractures may require open reduction and internal fixation. Before any operative orthopedic procedure, it is desirable to reduce the remodeling activity to reduce excessive blood loss. Such a reduction in remodeling activity can be obtained with intravenous pamidronate or calcitonin if the surgery is emergent. Oral bisphosphonates may be used if the procedure is elective. A goal of this form of therapy is to reduce alkaline phosphatase levels to normal. Surgery for spinal stenosis can be effective in relieving symptoms, but most experts suggest a course of bisphosphonates or calcitonin to try to improve symptoms before undertaking a decompression procedure. Total joint replacement especially for the hip is a highly effective way to control pain and improve mobility in patients with advanced Paget's disease and degenerative arthritis of the femur or ilium. Tibial osteotomy is effective in relieving knee pain in patients who have severe tibial bowing if the associated osteoarthritis is not too severe. An external fixation device (Ilizarov) has been used in patients with tibial Paget's disease, which allows an osteotomy to be performed and then gradual changes in external pressure to be used to straighten the bowed tibia or to allow a nonunion fracture to heal (see Figure 111-4). When any orthopedic procedure is performed, it is important to maintain the patient on antiresorptive medication after surgery so that prostheses will not loosen with accelerated remodeling or straightened limbs will not rebow.

## ACKNOWLEDGMENTS

The author appreciates the help of Monica L. Harris in preparation of this chapter. Support for this work came from the VA Medical Research Service, AG11268 from NIA, and RR-30 from the Division of Research Resources, General Clinical Research Centers Program, NIH.

# Aging of the Muscles and Joints

*Richard F. Loeser, Jr. ■ Osvaldo Delbono*

Aging-related changes present in the tissues that make up the musculoskeletal system contribute to a number of common chronic conditions seen in older adults. In fact, musculoskeletal disease is the most common cause of chronic disability in people older than age 65 years. This is attributable both to the prevalence of diseases affecting the musculoskeletal system and the central role of the musculoskeletal system in physical function. Despite the prevalence of musculoskeletal disease, however, there is still much to learn about the pathogenesis of these diseases, including the role of aging in their development.

A number of diverse tissues, including muscle, tendon, ligament, cartilage, and bone comprise the musculoskeletal system; aging-related changes, as well as changes secondary to disuse, have been noted to occur in all of these. As in other systems, it is often difficult to separate aging from disuse from disease. Because the musculoskeletal tissues must function in concert for normal joint motion and thereby appropriate movement to occur, it is easy to see why physical function so commonly declines with age. However, it is also clear that regular submaximal stress to the musculoskeletal system through exercise can prevent or slow the age-related decline in physical function as well as improve function of diseased tissues.

There are a number of age-related changes common to tissues of the musculoskeletal system, which have also been noted in other tissues within the body (Table 112-1). Because of the relatively slow turnover rate of cells and matrix components in musculoskeletal tissues, aging-related changes such as the accumulation of advanced glycation end-products (AGEs) in matrix proteins and oxidative damage to cell and matrix components can have particularly profound effects on the aging musculoskeletal system. This chapter reviews aging in each of the major components of the musculoskeletal system including cartilage, muscle, ligaments and tendons, and intervertebral disks. Although bone is a key player in the musculoskeletal system, aging changes in this tissue are discussed in more detail in Chapter 117.

## ARTICULAR CARTILAGE

### Normal Structure and Function

Articular cartilage is the tissue present on the ends of bones that comprise diarthrodial joints (Figure 112-1). This cartilage serves to provide a smooth surface with a very low coefficient of friction necessary for rapid, painless, and smooth joint motion. During joint motion, the opposing cartilage surfaces, separated by a thin layer of viscous and slippery synovial fluid, easily glide over each other. In addition to providing a form of lubrication for the joint surface, the synovial fluid also provides a large portion of the nutrition for the articular cartilage, which is an avascular and aneural tissue.

When a load is placed across the joint surface, such as occurs in the knee joint during ambulation, the thin gel-like cartilage is compressed. Compression of the cartilage helps to distribute the load evenly to the underlying bone, where force can be absorbed. Cartilage is too thin to absorb any substantial amount of force itself. Rather, the force of joint loading is absorbed by the muscle and bone associated with the loaded joint. This concept is relevant to the pathogenesis of diseases occurring in weight-bearing joints. If changes occur in muscle or bone that limit their ability to absorb mechanical loads, then the articular cartilage may experience abnormal stresses, which could adversely affect the tissue. Loading of the articular cartilage in the knee is also modulated by the presence of the medial and lateral menisci, which absorb approximately 50% of the load placed on the tibiofemoral regions. Damage to a meniscus can therefore significantly increase the load placed on the cartilage.

Complete compression of cartilage during joint motion is resisted by forces within the tissue generated primarily by the highly negatively charged proteoglycans. Proteoglycans are composed of a core protein to which are attached chains of glycosaminoglycans containing negatively charged sulfate groups. In articular cartilage,

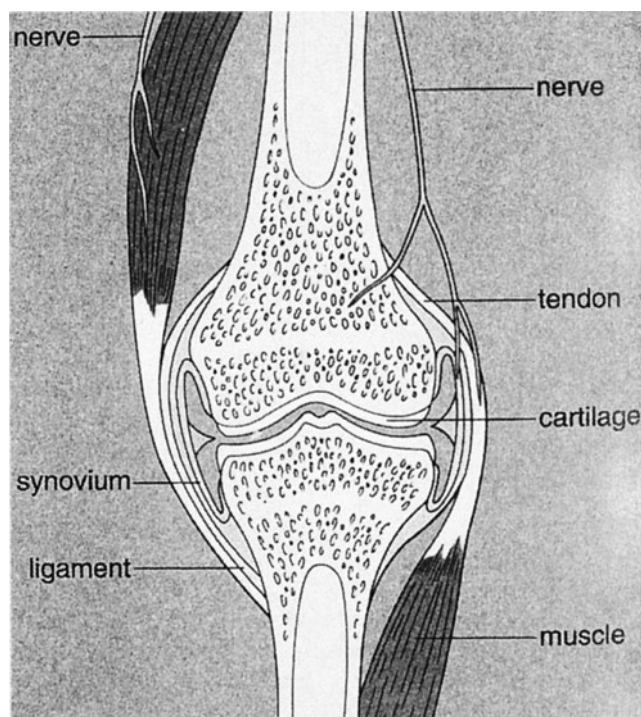

**TABLE 112-1****General Mechanisms of Musculoskeletal Tissue Aging**

Accumulation of modified and degraded extracellular matrix components
Increased collagen cross-linking by advanced glycation endproducts
Decreased numbers of mesenchymal stem cells to replace lost cells
Decreased mitogenic response to injury
Decreased synthetic capacity in response to growth factor stimulation

a large proteoglycan called aggrecan is present. Aggrecan is bound at its amino-terminus to a long strand of hyaluronic acid. Many aggrecan molecules are bound to a single strand of hyaluronic acid to form a large complex that is quite hydrophilic. Cartilage is approximately 70% to 75% water, and much of this water is bound to the negatively charged groups on proteoglycans, forming a gel-like substance. Water is partially extruded from the cartilage matrix during compression, resulting in exposure of negative charges that, as they are brought closer together, resist further compression. As the force is released, the proteoglycans reexpand, and water is drawn back into the cartilage bringing along nutrients from the synovial fluid. The role of joint motion in providing cartilage nutrition may be very relevant to changes occurring in cartilage with disuse.

In addition to proteoglycans, a number of other matrix proteins are responsible for the physical properties of cartilage, including several types of collagen (predominantly types II, VI, IX, and XI) and glycoproteins (including fibronectin and cartilage oligomeric protein). Collagen is quite abundant in cartilage, comprising about

**FIGURE 112-1.** Components of the musculoskeletal system that comprise the joint include bone, cartilage, muscle, tendon, ligament, synovium, and meniscus (not shown). Note that the nerve supply to the joint does not include cartilage, and, therefore, age- or disease-related changes in cartilage are not directly responsible for joint pain. (Reproduced with permission from Bullough PG. *Atlas of Orthopedic Pathology*, 4th ed. New York, New York: Gower Medical Publishing; 2004:9.4.)

half of the dry weight of the tissue. The majority of the collagen in cartilage is type II collagen. Type II collagen forms long fibrils that provide the tensile strength of the tissue, while the proteoglycans provide the resiliency. The collagen fibers appear to hold aggrecan complexes in place and prevent the proteoglycan gel from complete expansion, which results in the generation of swelling or osmotic pressure within the tissue. Thus, in normal cartilage, the osmotic pressure generated by proteoglycans is balanced by the tensile force provided by the collagen fibrils. The nonfibrillar collagens and the other matrix proteins in cartilage are thought to be involved in the organization and maintenance of the collagen fibrillar network, in structural interactions between collagen and proteoglycans, and in mediating interactions between the chondrocytes and the extracellular matrix (ECM).

### Regulation of Cartilage Matrix Turnover

Chondrocytes, the only cells present in cartilage, control the composition and organization of the cartilaginous matrix through the synthesis and degradation of selected ECM components. Together, the processes of synthesis and degradation result in ECM repair and remodeling. From studies performed in a number of tissues, including cartilage, it is becoming clear that ECM proteins can bind to cell surface receptors such as the integrin family of receptors, which, along with growth factors and cytokines, send signals to the cell to regulate matrix synthesis and degradation.

Several different types of enzymes capable of degrading cartilage ECM proteins are produced by chondrocytes, including the metalloproteinases, serine proteases such as elastase, and the cathepsins. The matrix metalloproteinases (MMPs) are prominent players in mediating cartilage catabolism. These include collagenases (MMP-1, MMP-8, and MMP-13), which cleave fibrillar collagens, the gelatinases (MMP-2 and MMP-9), which degrade denatured collagen, and stromelysin (MMP-3), which degrades proteoglycans. Other important MMPs in cartilage are the membrane-type (MT-MMPs), the ADAMs (a disintegrin and a metalloproteinase) and the ADAMTSs (a disintegrin and a metalloproteinase with a thrombospondin motif). The MT-MMPs are bound to the chondrocyte surface through transmembrane domains and can serve to activate other MMPs at the cell surface. An ADAM found in cartilage is ADAM-17, also known as tumor necrosis factor- $\alpha$ -converting enzyme (TACE), which functions to cleave tumor necrosis factor (TNF)- $\alpha$  to an active form. The ADAMTSs use the thrombospondin motif to interact with proteoglycans that can serve as substrates for these enzymes. ADAMTS-4 and ADAMTS-5 are aggrecanases that cleave the large proteoglycan aggrecan. The activity of the MMPs in cartilage is controlled in part by proteins called tissue inhibitors of metalloproteinase (TIMP). There is evidence for a reduction in the levels of TIMPs relative to the increased levels of MMPs in osteoarthritic (OA) cartilage.

A number of growth factors and cytokines are present in cartilage. These serve to regulate anabolic and catabolic processes involved in repair and remodeling (Table 112-2). In general, growth factors stimulate matrix synthesis, whereas the inflammatory cytokines inhibit synthesis and stimulate degradation. Insulin-like growth factor-1 (IGF-1), transforming growth factor- $\beta$  (TGF- $\beta$ ), and osteogenic protein-1 (OP-1) appear to play a prominent role in regulating adult articular cartilage metabolism. They are expressed in cartilage and act in a paracrine and autocrine fashion to stimulate cartilage matrix

**TABLE 112-2****Major Growth Factors and Cytokines Active in Cartilage**

GROWTH FACTORS/CYTOKINES	ACTIVE
IGF-1	Promotes cell survival, stimulates matrix synthesis
OP-1 (BMP-7)	Stimulates matrix synthesis, inhibits some catabolic pathways
TGF- $\beta$	Mitogenic, stimulates matrix synthesis, stimulates chondro-osteophyte production
bFGF	Mitogenic, stimulates matrix synthesis, potentiates IL-1-induced protease release, may be more important in fetal and growth plate cartilage than adult
IL-1 $\beta$	Inhibits matrix synthesis and stimulates matrix degradation
TNF- $\alpha$	Similar to IL-1 $\beta$
LIF	Stimulates matrix degradation
IL-6	Inhibits proteoglycan synthesis
IL-8	Neutrophil chemoattractant
MCP-1	Monocyte chemoattractant; stimulates MMP production

synthesis as well as inhibit cytokine-stimulated matrix degradation. IGF-1 also appears to promote chondrocyte survival in conjunction with signals from the matrix. As discussed later in this chapter, there is growing evidence that chondrocytes from older individuals are less responsive to growth factor stimulation than those from younger persons. This could contribute to aging-related changes in the tissue, as well as to disease progression with age.

The mitogenic properties of growth factors noted in cell culture studies may not be relevant to normal adult cartilage homeostasis *in vivo*. In the normal tissue, adult articular chondrocytes do not appear to proliferate or do so at such low rates that proliferating cells are not detected. Chondrocytes, however, are not postmitotic cells. When removed from cartilage by enzymatic digestion of the tissue and placed in cell culture, human chondrocytes can proliferate. Proliferation of chondrocytes *in situ* occurs during the development of OA, when the presence of clusters or “clones” of chondrocytes is a common pathologic finding. These clusters of cells are thought to represent an attempt at repair of damaged and lost tissue (Figure 112-2).

Normal articular cartilage in the adult contains fully differentiated cells and does not appear to contain its own source of undifferentiated mesenchymal cells available to repair or replace damaged or lost tissue. However, mesenchymal stem cells capable of differentiating into chondrocytes are present in the bone marrow, synovium, adipose tissue and periosteum. Current research is trying to use these cells for repair of cartilaginous lesions because endogenous repair responses in cartilage are inadequate to replace significant amounts of lost matrix, particularly after damage to the collagen network has occurred. The potential role of aging in the failed repair response in cartilage is discussed in the following sections.

## AGE-RELATED CHANGES IN CARTILAGE

### Changes in Cartilage Structure and Matrix Composition

A number of studies have examined age-related changes in articular cartilage by using tissue collected from various animal species or

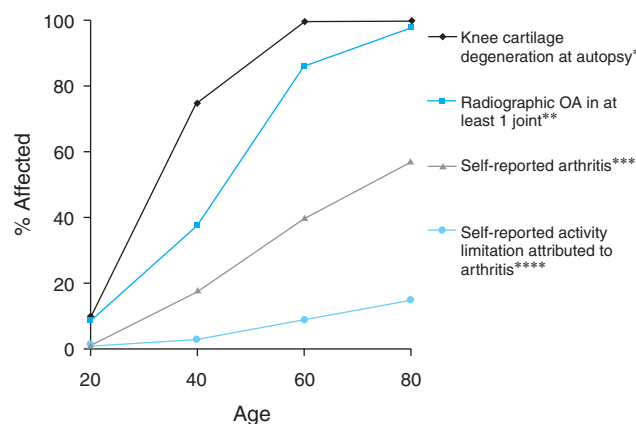

**FIGURE 112-2.** Normal (A) and osteoarthritic (B) cartilage. These sections from monkey knee joints are stained with toluidine blue, which binds to the negatively charged proteoglycans that are abundant in cartilage. In the osteoarthritic tissue, there is a loss of cartilage matrix staining, resulting from loss of proteoglycans. Other changes include fibrillation and cleft formation, presence of chondrocyte clusters, and a marked thickening of the subchondral bone. (Photographs are courtesy of Dr. Cathy S. Carlson.)

human tissues obtained either at autopsy or from surgical specimens. When surgical specimens are studied, they usually are obtained from subjects undergoing hip or knee replacement surgery for arthritis, in which case the tissue is taken from grossly normal appearing areas but may not be truly normal. Tissues have also been obtained during hip replacement surgery after femoral neck fracture, which is usually associated with osteoporosis. In these cases, the cartilage is felt more likely to be normal because osteoporosis and OA tend to occur in different patient populations, although this is not always true.

Problems in interpreting the results of cartilage aging studies include translating the biology from lower species of animals to humans and separating disease effects from aging effects. In addition, a number of changes have been reported to occur in cartilage when comparing immature versus middle-aged animals. These changes are probably best considered to be developmentally related rather than aging-related. With the above caveats in mind, there do appear to be a number of changes occurring in cartilage that can be related to aging and, importantly, many of the aging-related changes can be contrasted to changes seen in disease (Table 112-3).

Structurally, fibrillation of the articular cartilage surface becomes more prevalent with age, particularly in the knee joint on the vertical ridge of the patella and in the tibiofemoral areas not covered by the menisci. These changes could represent the presence of early OA, although other pathologic changes of OA are not always present and it is most often asymptomatic. Morphologic changes become more common and more extensive with advancing age (Figure 112-3). Similar to the articular cartilage, age-related changes in the menisci have also been noted. Recent studies that have examined the knee joints of older adults using magnetic resonance imaging have noted that damage to the meniscus is strongly associated with damage to the articular cartilage in the same area and meniscal damage predicts further cartilage loss. This work highlights the importance of the meniscus to the normal function of the knee joint. Since the peripheral areas of the menisci contain nerve fibers, they may also be a source of pain in people with OA.

There appears to be a slight decline in the number of chondrocytes present in cartilage with age. Early studies of cartilage from

**FIGURE 112-3.** Effect of age on the prevalence of arthritis. \*Knee cartilage degeneration at autopsy is the prevalence of significant histological changes of degeneration. \*\*Radiographic evidence of OA (Kellgren and Lawrence Grade 2 or greater) present in at least one joint site (hands, feet, spine, knees, and hips) in a population survey in northern England. \*\*\*Self-reported arthritis and \*\*\*\*activity limitation attributable to arthritis derived from the National Health Interview Survey—US, 1989–1991. the femoral head noted a 30% fall in cell density between the ages of 30 and 100 years. But more recent studies of knee joints have noted much lower cell loss with normal aging in the range of 1% to 2%. Cartilage from older individuals has also been noted to have microcracks in the calcified layer. The significance of these cracks is not clear, but if they extend to the underlying subchondral bone, they could provide a mechanism for the exchange of cytokines and growth factors between the two tissues; and if vascular invasion occurs, they could mediate remodeling of subchondral bone, which is a characteristic feature of OA.

A consistent biochemical finding in cartilage is an age-related decrease in hydration. A decrease in hydration could explain evidence obtained from magnetic resonance imaging of knee joints showing that some thinning of knee cartilage occurs with age, particularly at the femoral surface, which is more evident in women than men. The decrease in cartilage hydration is likely related to changes with age in the proteoglycans that bind the majority of the water in cartilage. The total proteoglycan content does not appear to change significantly, instead changes in proteoglycan structure have been reported that could affect its biophysical properties. Aggrecan molecules become smaller with age and are structurally altered as the result of proteolytic modification in the core protein as well as changes in the length and abundance of the attached glycosaminoglycan chains. Hyaluronic acid, to which the aggrecan molecules bind to form large aggregates, is also decreased in size with age. In addition, proteolysis of the aggrecan core protein between the G1 and G2 domains results in increased levels of molecules bound to hyaluronic acid that contain only the G1 region and therefore lack the remainder of the aggrecan molecule necessary for normal function. The half-life for the free binding region is calculated to be as long as 25 years, consistent with its accumulation in cartilage with aging. By occupying and competing for space on the hyaluronic acid strands, the bound G1 domains may reduce the number of newly synthesized aggrecan molecules bound to hyaluronic acid.

As with proteoglycans, there does not appear to be a significant reduction in the total amount of collagen present in cartilage with

**FIGURE 112-4.** Age-related accumulation of advanced glycation end-products in cartilage. Pentosidine levels were measured in cartilage samples from 36 donors clustered into 10-year age intervals. Results shown are mean  $\pm$  SEM (standard error of mean). (Reproduced with permission from DeGroot et al. Age-related decrease in proteoglycan synthesis of human articular chondrocytes: The role of nonenzymatic glycation. *Arthritis Rheum.* 1999;42:1003.)

age. However, important changes in collagen structure and function have been noted. The collagen network appears to become stiffer with age. The increased collagen stiffness is thought to be a result of increased collagen cross-linking. There is evidence for nonenzymatic glycosylation in cartilage from older adults that result in the formation of pentosidine residues that can cross-link collagen molecules. An age-related accumulation of AGEs has been noted in cartilage (Figure 112-4). Pentosidine and other AGEs have been found in collagen, as well as in aggrecan. The accumulation of pentosidine is reported to be greater in collagen than aggrecan because of the exceptionally long half-life of collagen in cartilage, which is calculated to be approximately 117 years.

In addition to increased cross-linking from the accumulation of advanced glycation end products, collagen fibril diameter tends to increase with age, and this may also contribute to changes in collagen stiffness. Increased collagen network stiffness could contribute to the decrease in hydration, as stiffer collagen would tend to cause greater proteoglycan compression and thereby push out more water from the matrix. Biomechanical studies suggest that the stiffer network is more prone to fatigue failure. With age there is a decrease in the tensile strength of cartilage as well as a decrease in overall tensile stiffness. Therefore, age-related changes in the overall composition of the cartilage matrix result in a tissue that is less capable of handling mechanical stress.

In addition to changes in type II collagen and aggrecan, age-related changes in several of the other less-abundant cartilage matrix

proteins have been reported. These include a decrease in type IX collagen, a protein that may be important in holding together adjacent collagen fibers and an increase in link protein, the protein that helps bind aggrecan molecules to hyaluronic acid. While link protein is increased with age, it also appears to undergo proteolytic modification with age that could affect its function.

### Aging and Chondrocyte Function

Changes in the proliferative and synthetic capacity of chondrocytes with age have been noted. There is evidence for an age-related decreased mitogenic response to serum and growth factor stimulation. There is also evidence for telomere shortening in chondrocytes isolated from older adults but it is not clear if telomere dysfunction is the cause of the reduced mitogenic response. In addition, a reduction in proteoglycan and protein synthesis in response to growth factor stimulation has been seen in cartilage from older animals, including nonhuman primates. Likewise, decreased proteoglycan synthesis in response to serum stimulation has been noted in human cartilage from older adults. In the human samples, the decreased serum response correlated with the presence of advanced glycation end-products. Other studies also suggest that a decline in cell signaling in response to growth factors is responsible for the decreased mitogenic and synthetic responses.

A reduction in response to growth factor stimulation with age, disease, or both, could be significant in the development of OA, where catabolic processes are greater than anabolic. In addition, there appears to be an age-related increase in the ability of catabolic factors, including the cytokine interleukin-1 $\beta$  (IL-1 $\beta$ ) and a fibronectin matrix fragment, to stimulate MMP production by chondrocytes. These age-related changes could contribute to the anabolic–catabolic imbalance that has been observed in OA.

An age-related finding in cartilage, which is also observed in many other soft tissues, is an increased prevalence of crystals and calcification. It is difficult to determine the relative effects of age and disease on cartilage calcification. Calcification or crystal formation within cartilage is a common feature of OA, particularly in advanced disease and, like OA, age is the strongest risk factor for the development of crystal-associated arthritis. Cartilage from older individuals often contains crystals composed of calcium pyrophosphate dihydrate or hydroxyapatite. Studies with animal tissues show that the increase in the formation of calcium pyrophosphate crystals may be caused by an age-related increase in the activity of transglutaminase, an enzyme that is involved in the biomineralization process. Also chondrocytes from older individuals produce more inorganic pyrophosphate in response to TGF- $\beta$  stimulation, despite a decreased proliferative response to this and other growth factors.

### Potential Role of Oxidative Stress in Cartilage Aging

The free radical theory of aging dates back to the 1950s and there is now a large body of evidence that oxidative damage can occur with aging in multiple tissues including musculoskeletal tissues. Oxidative damage in aging cartilage has been detected using antibodies to nitrotyrosine, which recognize a modification occurring after the reaction of protein tyrosine residues with the free-radical peroxynitrite generated from nitric oxide reacting with superoxide. In addition, age-related oxidative stress in human articular chondrocytes has been detected by measuring the ratio of intracellular oxidized to reduced

glutathione. A reduction in levels of antioxidant enzymes with aging may contribute to an increase in oxidative stress and damage. As discussed further below, an increased level of reactive oxygen species (ROS) in aging chondrocytes could be important to the age-related increase in OA.

## AGING AND THE DEVELOPMENT OF OSTEOARTHRITIS

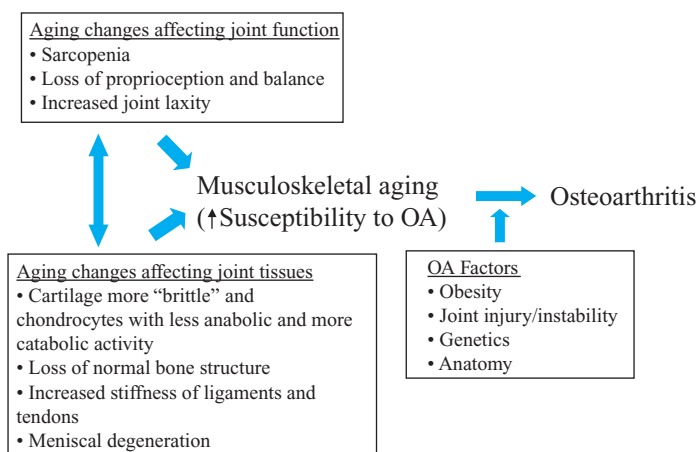

### Aging as a Risk Factor for OA

OA is a disease process that usually develops slowly over a long period and becomes manifest in the later years of life. OA is not seen clinically in children or adolescents and is rare in young adults, but becomes increasingly common in those older than age 55 years. In the Framingham cohort of subjects, radiographic knee OA was present in 27% of those aged 63 to 70 years and in 44% of those ages 80 years or older. A population survey in northern England that included x-rays of the hands, feet, spine, knees, and hips found evidence for radiographic OA in at least one joint in about 80% of the population by age 60 years (see Figure 112-3). Even so, not everyone develops OA with age; all joints are not equally affected by OA; and, perhaps most importantly, not every joint or every individual with radiographic or even pathologic evidence of the disease is symptomatic. In several studies, it has been found that only about 50% of people with radiographic OA are symptomatic.

Osteoarthritis appears to remain asymptomatic until sufficient damage occurs to structures capable of producing pain or results in changes in joint function. The percentage of people with symptoms increases with more severe radiographic disease and in particular people with bone marrow lesions noted on magnetic resonance imaging. These lesions appear in regions neighboring areas with the greatest cartilage loss and are associated with alignment abnormalities. An additional level of complexity is added by the physical, psychological, and sociological factors that contribute to the development of symptoms such as pain. The end result is a multifactorial, heterogeneous group of diseases in which symptoms do not always correlate with pathologic changes as visualized using methods such as plain radiographs.

Most likely the process leading to OA is initiated earlier in life under the influence of factors specific to each individual such as obesity, joint injury, abnormal joint anatomy, and genetically abnormal cartilage matrix proteins. These factors act by either directly altering the structure or metabolism of cartilage or bone or indirectly affecting the tissues by altering joint biomechanics. The changes noted in joint function and musculoskeletal tissues with age appear to increase the risk of developing OA and may contribute to progression of the disease. Abnormal effects on joint structure and function from one or more of the “OA factors” likely works in concert with aging to result in the development of the disease and to the expression of symptoms and disability (Figure 112-5).

As is the case with all diseases that are common in old age, osteoarthritis is really a group of diseases of various etiologies, resulting in common pathologic changes within diarthrodial joints. Pathologically, OA is characterized by changes in both cartilage and bone (see Figure 112-2). Fibrillation and loss of articular cartilage by degradation are accompanied by hypertrophic changes in the subchondral

**FIGURE 112-5.** Relationship between musculoskeletal aging and the development of osteoarthritis. Changes that affect joint structure and function with aging increase the susceptibility to developing osteoarthritis but additional factors (OA factors) are usually also present which lead to the development of symptomatic osteoarthritis.

bone, resulting in subchondral thickening and in osteophyte formation at joint margins. Like many of the changes seen in cartilage, the changes in bone appear to be in opposite directions when comparing aging and OA (see Table 112-3). Thickening of the subchondral bone is a consistent finding in OA, whereas decreasing bone mass is commonly seen with age, at least in cortical and particularly in trabecular bone.

However, studies of aging in bone have not specifically assessed the region of the subchondral bone. The subchondral bone can remodel in response to mechanical loading, and this bony remodeling may play an important role in the OA disease process. It has been hypothesized that thicker and stiffer subchondral bone would place additional stress on the overlying cartilage during joint loading, resulting in mechanical failure of the cartilage. There is much debate about whether OA actually starts with changes in the subchondral bone rather than in cartilage. The answer as to which comes first may depend on the circumstances by which OA has developed. The importance of the subchondral bone to the OA disease process has been emphasized by studies that show increased activity in this region, detected by technetium bone scans, can predict disease progression in OA. Likewise, the presence of bone marrow lesions on magnetic resonance imaging (MRI) is also a risk factor for progression.

There is evidence for some degree of synovial inflammation in most patients with symptomatic OA, although the amount of synovial inflammation varies. A study that examined synovial tissue removed at the time of knee replacement found that about one third of patients had mild synovitis, one third moderate, and one third severe, suggesting that synovitis may play a role in disease progression in a subset of patients.

### Contribution of Aging to the Anabolic and Catabolic Imbalance in OA

OA is often described as a “wear and tear” degenerative disease because the cartilage changes are most severe in the areas that receive the greatest mechanical stress. But the pathobiology of OA is much more complicated than either simple joint aging or wear and tear from repetitive use. Unlike an automobile part that can simply wear

out with time, the tissues that comprise the joint contain living and metabolically active cells. The cells themselves are responsible for the destruction of the cartilage, likely under the influence of biomechanical forces, as well as for dynamic processes involved in continual regeneration, repair, and remodeling.

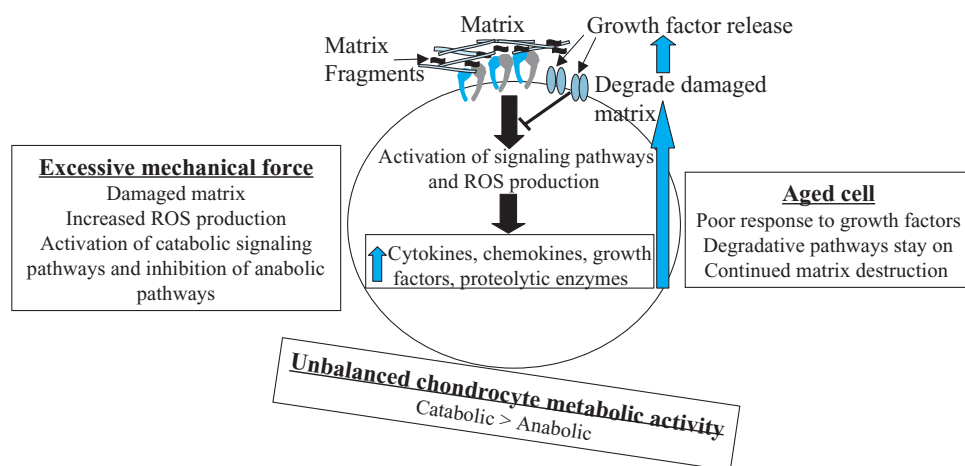

The cartilage changes found in OA appear to be caused by an imbalance between anabolic and catabolic activity. In OA, the chondrocytes are synthetically active, producing increased amounts of a number of matrix proteins, most likely as an attempt at repairing the damaged matrix. However, OA chondrocytes also produce increased amounts of degradative enzymes that overwhelm the repair response. Increased levels of several of the MMPs, including MMP-1, 2, 3, 9, and 13, as well as the aggrecanases (ADAMTS-4 and -5), have been noted in OA cartilage and appear to play a key role in matrix degradation. Matrix fragments, including hyaluronic acid fragments, collagen fragments, and fibronectin fragments, are produced as a result of the increased proteolytic activity and these fragments can in turn act on the cell to stimulate further matrix destruction. Cytokines, including IL-1, TNF- $\alpha$ , and others, are also increased in OA cartilage and contribute to the increased production of MMPs. Other factors associated with inflammation such as prostaglandins, nitric oxide, and ROS are also increased in OA cartilage. The increased local production of cytokines and inflammatory mediators in OA cartilage indicates that OA is really a process that involves cartilage inflammation.

Another characteristic of OA cartilage is the appearance of clusters of chondrocytes resulting from cell proliferation, thought to be part of the attempt at matrix repair. But areas practically devoid of cells can be seen adjacent to areas containing cell clusters. The overall number of cells in OA cartilage appears to decline, especially in the advanced stages of the disease. This decline is associated with the appearance of apoptotic chondrocytes, indicating that cell death is occurring, although significant cell death has not been confirmed at earlier stages of the disease. Therefore, it is not clear whether an imbalance between cell proliferation and death plays an important role

in the development of OA. If it does, then aging changes that reduce the proliferative capacity of the cells and changes which make the cells more susceptible to dying would contribute to the development of OA in older adults.

Similar to findings suggestive of a reduced response to growth factor stimulation with age in normal cartilage, studies indicate that chondrocytes from OA cartilage are also less responsive to growth factor stimulation. Lack of an anabolic response to IGF-I has been noted in several studies of OA chondrocytes. The decrease in response to IGF-I in OA may be related to increased levels of IGF-binding proteins, also noted in OA cartilage, which could decrease the amount of free IGF-1 available to bind to cell receptors. Although serum levels of IGF-1 decrease with age, there is no evidence that local levels in cartilage decrease. In fact, in OA cartilage levels of IGF-1 appear to be increased. If the cells maintain responsiveness to cytokines such as IL-1 while losing responsiveness to growth factors such as IGF-1, this could sway the balance of cartilage synthesis and degradation toward the catabolic side. This would be an important link between aging and the development of OA since an age-related resistance to growth factors such as IGF-1 would allow degradative pathways to stay on, which would normally be shut down by growth factors released from matrix stores (Figure 112-6).

The basic cellular mechanisms that explain how aging contributes to the development of OA are just beginning to be understood. One hypothesis being tested is that production of ROS leading to oxidative stress alters the normal signaling pathways in the cartilage such that catabolic signaling is favored over anabolic. ROS are produced by chondrocytes in response to stimuli by cytokines as well as matrix fragments and are required as secondary messengers in cell signaling. ROS may also be produced in response to matrix damage from mechanical stimulation. Excessive levels of ROS could interfere with anabolic signaling pathways such as the IGF-I pathway and in this way tip the balance of anabolic and catabolic signaling (see Figure 112-6). Restoring this balance represents an important goal for future OA therapies.

**FIGURE 112-6.** Theoretical model for pathways involved in cartilage destruction during the development of osteoarthritis. Excessive mechanical forces stimulate the chondrocyte directly or indirectly through signals generated by matrix damage including generation of matrix fragments. The resultant activation of signaling pathways, including ROS generation, results in increased production of cytokines, chemokines, and proteolytic enzymes. This catabolic response to injury serves to degrade the damaged matrix. Matrix degradation results in release of growth factors stored in the matrix, which would normally feedback on the cell and shut down the catabolic pathways. But aged chondrocytes have an insufficient response to growth factor stimulation resulting in continued matrix destruction from unbalanced catabolic and anabolic activity. ## SKELETAL MUSCLE

### Skeletal Muscle Structure and Function

All skeletal muscle is enclosed by a sheath of connective tissue called epimysium. Bundles of muscle fibers and individual contracting units of muscle fibers are surrounded by partitions of the connective tissue constituting the perimysium and the endomysium, respectively. Blood vessels, lymphatics, and nerves reach all the muscle compartments by way of these fibrous partitions. The connective tissue merges into stronger structures such as tendons, aponeuroses,

raphes, the reticular layer of dermis, or the periosteum that provide support for muscle insertion and contraction.

Matured single muscle fibers are long multinucleated and cylindrical units separated from other cells and surrounded by a membrane, the sarcolemma. Muscle fibers contain myofibrils made up of the contractile proteins myosin, actin, tropomyosin, and troponin and the structural supportive proteins actinin and titin. The particular spatial arrangement of the thick and thin contractile proteins is responsible for the characteristic cross-striations in skeletal muscle. Differences in the refractive index of the muscle fiber determine the alternation of light I band and dark A band (Figure 112-7). Z lines in the middle of the I bands are the limits of a sarcomere. The thick

**FIGURE 112-7.** Diagram of a skeletal muscle fiber illustrating the spatial arrangement of contractile proteins and surrounding membrane system. (Reproduced with permission from Cormack DH. *Ham's Histology*. 9th ed. Philadelphia: Lippincott, William and Wilkins; 1987:402.)

filaments are made up of myosin, whereas the thin filaments are made up of actin, tropomyosin, and troponin.

Myosin is an actin-binding protein provided with a catalytic site that hydrolyzes adenosine triphosphate (ATP), the source of energy for muscle contraction. Actin molecules polymerize in long, thin double-helix filaments, forming a groove where tropomyosin molecules are located. Troponin molecules are located at regular intervals along the tropomyosin molecules. Troponin has three components: troponin T binds the other components to tropomyosin, troponin I inhibits the interaction of myosin with actin, and troponin C contains the binding sites for calcium that initiate muscle contraction.

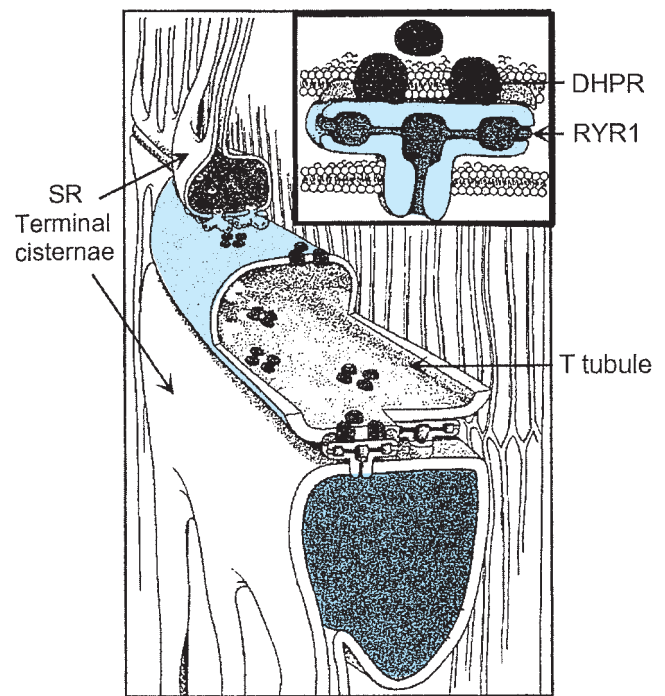

### Motor Unit

Lower spinal cord motor neurons provide a common pathway for transmitting neural impulses from upper motor levels of the central nervous system to the skeletal muscle. This information is directed to skeletal muscles via the ventral roots, peripheral nerves, and cranial nerves. Each motor neuron innervates muscle fibers within a single muscle and the motor neurons innervating a single muscle are grouped in the spinal cord, forming the motor neuron pool for that muscle. During development, polyinnervated muscles become innervated by a single motor neuron. Axonal branches establish synapses with multiple muscle fibers of a single muscle. The activation of a motor neuron brings all the muscle fibers to the mechanical threshold; therefore, a single motor neuron and its associated muscle fibers constitute the motor unit that is the smallest that can be activated to induce movement. On the basis of the speed of contraction, three types of motor units can be distinguished: fast-fatigable motor units, fatigue-resistant motor units, and slow-motor units that are in between the first two subtypes in terms of time to fatigue initiation. These differences in motor unit performance are based on physiological and biochemical characteristics of their constituent muscle fibers.

### Events in Muscle Contraction and Relaxation: Skeletal Muscle Excitation–Contraction Coupling

Skeletal muscle contraction is initiated by generation and conduction of action potentials by the motor neuron, release of acetylcholine at the motor end-plate, and binding to nicotinic acetylcholine receptors, and an increase in sodium and potassium conductance in the end-plate membrane. End-plate potentials at the muscle membrane lead to generation of action potentials and their conduction to the sarcolemmal infoldings (T-tubules).

The transduction of changes in sarcolemmal potential into elevations in intracellular calcium concentration is a key event that precedes muscle contraction. The muscle electromechanical transduction requires the participation of a protein located at the sarcolemmal T tubule, the dihydropyridine receptor (DHPR), in the early steps of this signal-transduction mechanism. The DHPR is a voltage-gated L-type  $\text{Ca}^{2+}$  channel (dihydropyridine-sensitive), and its activation evokes  $\text{Ca}^{2+}$  release from an intracellular store, the sarcoplasmic reticulum (SR) through ryanodine-sensitive calcium channels (RyR1) into the myoplasm. **Figure 112-8** illustrates the typical arrangement of DHPR and RyR at the skeletal muscle triadic junction. The functional consequence of alterations in the number, function, or interaction of these receptors is a reduction in the amount of intracellular calcium mobilization and in the development of force. Calcium is bound to troponin C, leading to formation

**FIGURE 112-8.** Schematic of the interaction between the dihydropyridine receptor (DHPR) and ryanodine receptor (RyR1) and their location at the sarcolemmal tubular system and sarcoplasmic reticulum terminal cisternae, respectively. (Redrawn from Block BA, Imagawa T, Campbell KP, Franzini-Armstrong C. Structural evidence for direct interaction between the molecular components of the transverse tubule/sarcoplasmic reticulum junction in skeletal muscle. *J Cell Biol.* 1988 Dec;107(6 Pt 2):2587–2600; Brandt NR, Caswell AH, Wen SR, Talvenheimo JA. Molecular interactions of the junctional foot protein and dihydropyridine receptor in skeletal muscle triads. *J Membr Biol.* 1990 Feb;113(3):237–251; Wagenknecht T, Grassucci R, Frank J, Saito A, Inui M, Fleischer S. Three-dimensional architecture of the calcium channel/foot structure of sarcoplasmic reticulum. *Nature.* 1989 Mar 9;338(6211):167–170.)

of cross-linkages between actin and myosin and sliding of thin on thick filaments, which produces shortening. Muscle relaxes as a result of calcium pumping back to the SR, release of calcium from troponin, and cessation of interaction between actin and myosin filaments.

### Muscle Fiber Subtypes and Types of Contraction

Muscle fiber types can be determined using immunostaining or the adenosine triphosphatase (ATPase) stain based on the pH dependence of myosin ATPase activity, which relates closely to antigenic differences in myosin between fast- and slow-twitch muscles. Muscle fibers are classified by histochemical identification into type I and type II (A, B, and C) (**Table 112-4**), and into fast- and slow-twitch based on their contractile properties in response to brief stimulation (action potential). Fast-twitch fibers (type II, glycolytic, white) contract for less than 10 ms and are primarily concerned with fine, precise, and rapid movements. Slow-twitch fibers (type I, oxidative, red) exhibit twitch durations up to 100 ms and are involved in strong, gross, and sustained movements. Muscle fibers are integrated into motor units and are classified into fast-fatigable, fast-fatigue-resistant, and slow motor units according to their speed of contraction, maximum tension generated, and degree of fatigue.

TABLE 112-4

## Histochemical Classification of Muscle Fibers

MUSCLE FIBER SUBTYPES	FUNCTIONAL AND HISTOCHEMICAL CHARACTERISTICS	ATPASE SAINAIN		
		PH 9.4	pH 4.6	pH 4.2
Type I	Slow twitch, oxidative	Light	Dark	Dark
Type IIA	Fast twitch, oxidativelyglycolytic	Dark	Light	Light
Type IIB	Fast twitch, glycolytic	Dark	Dark	Dark
Type IIC	Fetal	Dark	Dark	Dark

## NEURAL CONTROL OF MUSCLE CONTRACTION

Several factors regulate muscle contraction, including innervation of muscle fibers. Alterations in innervation state leads to changes in gene expression of proteins involved in excitation–contraction (EC) coupling, ultimately resulting in EC coupling differences. During development, muscle fibers are innervated by spinal cord motor neurons. Fiber type is determined by interaction with different subpopulations of these motor neurons that activate contraction at different rates, ranging from 10 Hz (slow-twitch) to 100 Hz (fast-twitch fatigue-resistant) or 150 Hz (fast-twitch fatigue-sensitive). Interaction with motor neurons and induction of activity determines more than just fiber type. Depolarization of myotubes in culture triggers the appearance of dihydropyridine binding sites, suggesting that the induction of muscle activity during innervation induces DHPR expression.

Experimental denervation in fast-twitch muscle fibers, such as extensor digitorum longus (EDL), results in alterations in EC coupling. Denervated EDL fibers exhibit alterations indicative of reduced number or reduced functional DHPRs. Additionally, denervation affects DHPR function in other ways, slowing both DHPR activation and inactivation. Denervation also affects RyR1 function and expression. Morphological evidence from denervated EDL muscles shows a reduction in the number of “indentations” in SR terminal cisternae membranes. These indentations are the RyR1 feet at triad junctions. Accordingly, following denervation, RyR1 mRNA transcript levels have been shown to decrease.

DHPR in skeletal muscle is dependent upon the presence of RyR1 to function properly. Dyspedic myotubes, which do not express RyR1s as a result of a mutation, display drastically reduced DHPR function compared to normal myotubes. When dyspedic myotubes are transfected to express RyR1, DHPR function returns to normal levels. This evidence may indicate that denervation-induced reduction of DHPR expression may result from loss of innervation-driven gene expression, RyR1-driven DHPR gene expression, or a combination of both.

Although denervation removes nerve electrical influence from muscle, evidence indicates that electrical activity of a nerve is not the only controlling factor in muscle gene expression. Chronic blockade of nerve action potentials by infusion of tetrodotoxin, a specific sodium channel-blocker, without compromising axonal transport and nerve–muscle contact, increases expression of DHPR and RyR mRNA expression 4.5- and 2.5-fold, respectively. Accordingly, expression of both proteins was increased by 50% after 10 days of treatment with these agents. Muscle contraction analysis after elim-

inating axonal transport with a colchicine-containing cuff on the sciatic nerve in animal models indicate that alterations in EC coupling mechanisms may explain the decline in specific force.

While decreases in motor neuron electrical activation of and axonal delivery to skeletal muscle effect changes in gene expression, increases in nerve activity also causes changes in adult muscle gene expression. These changes are generally characterized by a fast-to-slow switch in myosin and  $\text{Ca}^{2+}$  ATPase isoforms. A 12-week endurance training program in rats, an activity that can lead to fast-to-slow transformations in muscle, was shown to increase DHPR expression as much as 60% in EDL muscles. Another method of increasing muscle activity, surgical ablation of synergistic muscles to induce hypertrophy of the plantaris muscle in rats, causes no change in DHPR or RyR1 expression in this predominately fast-twitch skeletal muscle. The possibility exists that the “protocol” used to increase activity plays an important role in regulating gene expression: endurance exercise training allows for long quiescent recovery periods between bouts of increased activity, while chronic low-frequency stimulation does not; and mechanical loading of muscle that induces hypertrophy apparently differs from these two protocols altogether.

In a rodent model, decreases in muscle activity without compromise of nerve–muscle interaction can be induced by mechanical unloading of muscle through the use of hindlimb unweighting. Hindlimb unloading is generally characterized by a slow-to-fast transition in fiber type, as evidenced by the increase in fast  $\text{Ca}^{2+}$  ATPase and myosin isoforms, as well as the speed of the unloaded muscle fiber shortening. This leads to marked atrophy of slow-twitch soleus muscles, but increases in DHPR mRNA and DHPR and RyR protein expression in the same soleus muscles. These results, taken together, indicate that electrical activity of the nerve, the pattern of nerve activation, axonal delivery of trophic factors to the muscle, muscle fiber type, fiber type transition direction (i.e., fast-to-slow or slow-to-fast), and type of muscle activity (i.e., endurance vs. strength training) are all variables that exist in tenuous balance to regulate muscle gene expression.

## MECHANISMS UNDERLYING SKELETAL MUSCLE WEAKNESS IN OLD AGE

Age-related decreases in skeletal muscle mass and quality contribute to physical disability and loss of independence in the elderly population. In addition to decreased muscle mass, aging muscle is characterized by decreases in contractile force or weakness that have been reported to occur with age in several mammalian species including humans. Age-related weakness may be associated with fatigue, weakness discerned as an absolute decrease in muscle force, and fatigue as a progressive decline in force with prolonged physical activity. Muscle weakness is associated with limitations in activities of daily living, such as climbing stairs or rising from a chair, that lead to loss of independence. Muscle weakness is a risk factor for falling and also increases the risk for fractures resulting from a fall. Reduced heat and cold tolerance, impaired glucose homeostasis, and obesity have been also related to aging skeletal muscle. Decline in muscle performance with aging has been quantified in both untrained and highly trained individuals. These studies showed that although the individuals with higher levels of physical activity were stronger, the rate of decrease in the level of muscle performance in both groups was similar. These results suggest that age-related deficits are largely

  - C. Age-related vasculopathy

inevitable and decreases in physical activity further contribute to this process.

Despite the importance of muscle strength in preventing disability, the biological mechanisms responsible for these phenomena are poorly understood. Cellular and molecular aspects have been explored both in human and more extensively in animal models of aging. The conclusions included in this section arise from investigations in human and nonhuman aging skeletal muscle. Factors that determine skeletal muscle impairment with aging can be divided into four groups: (1) neurogenic, (2) myogenic, (3) a combination of neural and muscular alterations, and (4) general mechanisms that involve skeletal muscle (Table 112-5).

### Neurogenic Mechanisms of Skeletal Muscle Impairment with Aging

Neurogenic mechanisms of decline in muscle function with age include reduction in the number and/or size of spinal cord motor neurons, alterations in axonal flow, and the neuromuscular junction. Each of these factors, individually or in combination, leads to chronic muscle denervation and motor unit remodeling. Some older persons present electromyographic evidence of muscle denervation suggestive of motor neuron alterations. These patients never develop classical amyotrophic diseases (e.g., amyotrophic lateral sclerosis). Muscle denervation is associated with reinnervation, as demonstrated by the presence of muscle fiber grouping in histologic sections. Cycles of muscle denervation associated with reinnervation lead to motor unit remodeling.

The functional significance of motor unit remodeling still needs to be determined. The relative histologic areas corresponding to fast- and slow-twitch muscle fibers change with age, becoming predominantly slow muscle fibers. Age-related remodeling of motor units appears to involve denervation of fast muscle fibers with reinnervation by axonal sprouting from slow fibers. Therefore, motor

unit remodeling leads to changes in fiber-type distribution in mixed fiber-type muscles.

Reinnervation of muscle fibers tends to compensate for denervation; however, a net loss of fibers across age has been detected. This obviously occurs when the rate of muscle fiber denervation surpasses the rate of axonal sprouting and reinnervation. Indirect studies show a decrease in the total number of fast-motor units and enlargement of the remaining motor units with age. Direct neuronal counting shows a reduction in the number and/or size of ventral spinal motor neurons at the cervical or lumbar regions with aging. Whether alterations in motor neuron, nerve terminal, or axonal transport account for muscle denervation is not clear.

Studies on conduction velocity in peripheral nerves do not show significant changes with aging. This would suggest that alterations in myelin or severe reductions in nerve axonal composition do not occur with age. Although denervation has been suggested as a contributing factor to aging skeletal muscle, the extension of denervation in individual muscles and its effect on human muscles remain to be determined. In addition, it is becoming apparent that denervation does not explain a significant deficit in specific maximum isometric tetanic force (muscle force normalized to cross-sectional area) recorded in aged skeletal muscles. Also, decreases in the number of spinal cord motor neurons occur after the eighth decade, when the loss in muscle mass and strength is already well established.

### Myogenic Mechanisms of Skeletal Muscle Impairment with Aging

Primary muscular or myogenic factors refer to a group of alterations including contraction-induced injury and alterations in muscle signal transduction (trophic factor/hormone resistance). The phenomenon of contraction-induced injury is related to increased mechanical frailty and decline in muscle restorative capacity with age. Muscles from older individuals or animals become injured when undergoing lengthening contractions. Also, older muscles recover more slowly and do not exhibit complete recovery when compared with those in younger controls. Eccentric contraction injury has also been demonstrated in older individuals. Insulin and IGF-1 resistance in aging skeletal muscle have been reported. The influence of weight and physical activity on trophic factor/hormone resistance are currently under investigation.

### Combined Neurogenic–Muscular Mechanism

Combined mechanisms include muscle unloading and EC uncoupling. Muscle unloading associated with sedentary lifestyle is a major determinant of muscle atrophy in the elderly population. The decrease in physical activity is a combined process in which the lower the nerve activation, the lower the muscle contraction. This process leads subsequently to muscle atrophy. However, not all the motor units within a muscle seem to be affected to the same extent. Predominant atrophy of type II fibers has been reported in aging muscles from rodents; however, the clinical significance of this finding is uncertain because there are very few type IIB fibers in human muscles.

Alterations with age in muscle fiber signal transduction such as sarcolemmal excitation–SR calcium release uncoupling and impaired IGF-1-dependent modulation of muscle calcium channels have been demonstrated. Studies in muscle fibers deprived of

sarcolemma (skinned muscle fibers) demonstrated that the force generated per unit cross-sectional area does not differ in adult and old mice during isometric contractions. These results suggest that muscle atrophy does not explain entirely the age-related decline in muscle strength. A deficit in specific contractile force (force normalized to muscle cross-sectional area) in aging skeletal muscle has been described in the literature. However, the significance of this finding in terms of the etiology and therapeutics of the age-related decline in muscle force has not been sufficiently investigated.

The deficit in specific force is a widespread phenomenon involving fast- and slow-twitch fibers in different muscles. Several mechanisms have been postulated to explain the skeletal muscle weakness associated with aging. However, it is not known whether the loss of specific and absolute force share common mechanisms. It appears that the age-related impairment in muscle force is only partially explained by the loss in muscle mass. Therefore, both the loss in specific and absolute forces contributes to the muscle weakness measured in the elderly and in animal models of aging.

Successful interventions aimed at counteracting age-associated functional deficits will require better insight into the mechanisms underlying the decline in muscle-specific force. Alterations in several mechanisms of signal transduction operate in aging skeletal muscles. Two of these mechanisms in particular are directly involved in development of muscle force: excitation-induced elevations in intracellular calcium and energy conversion from ATP into a mechanical response. It seems that changes in phosphorus metabolites involved in energy transduction (phosphocreatine, adenosine diphosphate [ADP], and ATP) and myosin isoforms do not change with aging. However, alterations in EC coupling have been demonstrated in human quadriceps.

Physiologic activation of the muscle membrane elicits elevations in intracellular  $\text{Ca}^{2+}$  that, in turn, induce muscle contraction by interaction with contractile proteins. Impairments in the mechanism of transduction of muscle activation into intracellular  $\text{Ca}^{2+}$  mobilization lead to decreases in muscle tension, clinically manifested as muscle weakness. The basic mechanism underlying EC uncoupling with aging is a molecular unlinkage between the two calcium channels, one that functions at the external membrane (sarcolemma) as a voltage-sensor, the other mediates calcium release from intracellular stores (SR). Alterations in EC coupling result from significant changes in either the number or regulation of these molecules, or both.

### General Mechanisms of Aging that Involve Skeletal Muscle

General mechanisms that may adversely affect skeletal muscle directly or indirectly are oxidative DNA damage, mitochondrial DNA (mtDNA) mutations, and age-related vasculopathy. Superoxide radical and hydrogen peroxide that are continuously produced in aerobic cells undergo metal ion-catalyzed conversion into hydroxyl radicals. These hydroxyl radicals can cause oxidative damage, which, in turn, may be related to the development of mutations in mtDNA. Mitochondrial DNA mutations are associated with ischemic heart disease, late-onset diabetes, Parkinson's disease, Alzheimer's disease, and aging. The accumulation of damage to mtDNA by oxidation may be the basis for defects in oxidative phosphorylation capacity with age. A decline in oxidative phosphorylation capacity would be-

come symptomatic when tissue energetics fall below the threshold required for optimal organ function.

A group of factors that deserve attention are subclinical inflammation, vascular pathology, and muscle perfusion. Subclinical inflammation has been suggested as a mechanism for loss in muscle mass and weakness in the elderly, often called sarcopenia. Such inflammation-related loss may be mediated by tissue increases in  $\text{TNF-}\alpha$ , IL-6, IL-1 $\alpha$ , and/or IL-1 $\beta$ . Some evidence suggests that subclinical inflammation may contribute to the debilitating muscle atrophy associated with congestive heart failure, renal failure, or rheumatoid arthritis. In the extreme, this may lead to cachexia, generalized loss of muscle as well as fat mass, aggravated by the anorexia associated with starvation, acquired immunodeficiency syndrome, or advanced cancer. Thus, the involuntary decline in muscle mass characteristic of old age may represent a continuation in degree and rate of development with inflammation, subclinical or clinical, as an important mediating mechanism. The existence of an altered capillary bed in aging skeletal muscle is controversial at the present time. Reduced or increased numbers of capillaries have been reported in the literature, but less is known about muscle perfusion in physiologic conditions.

### CLINICAL AND EXPERIMENTAL INTERVENTIONS AIMED AT DELAYING OR PREVENTING AGE-ASSOCIATED CHANGES IN SKELETAL MUSCLE COMPOSITION AND FUNCTION

We are just beginning to identify the specific changes in muscle with age. Withdrawal of anabolic stimuli to skeletal muscle, including decline in estrogen/androgen, growth hormone, insulin, or IGF-1 may lead to both loss in muscle mass and impairment in the intrinsic capacity of the muscle fiber to generate force. A key question to be addressed at this time in studies of both muscle and cartilage is: does a cell-signaling impairment with aging result from tissue resistance to trophic factors? Increasing evidence supports this concept. However, understanding this process requires further insight into a more general phenomenon, the role of trophic factors in mature tissue maintenance and restoration.

In healthy individuals, deficiency with aging in spontaneous and stimulated growth hormone secretion, as well as circulating IGF-1 and IGF-binding protein-3 levels, is associated with decreased lean body mass, decreased protein synthesis, and increased percent body fat. Administration of recombinant human growth hormone or growth hormone secretagogues improves nitrogen balance, increases lean body mass, and decreases body fat in older people with low IGF-1 levels. However, the effects on muscle strength do not seem to be proportional to the improvement in muscle mass with such replacements.

IGF-1 is a peptide structurally related to proinsulin, which has a primary role in promoting skeletal muscle differentiation and growth. In skeletal muscle, IGF-1 potentiates calcium current through L-type calcium channels in adult fibers but not in muscles from aging mammals, probably because of IGF-1 resistance. Using a transgenic mouse model overexpressing IGF-1 in skeletal muscle, increases in the number of DHPR have been reported. IGF-1 also has an effect on muscle mass, inducing hypertrophy in transgenic models or preventing atrophy in aging rodents. Virally mediated overexpression of IGF-1 in muscle prevents the age-related loss in

type IIB fibers and contractile force in rodents. In summary, IGF-1 prevents EC uncoupling, changes in fiber type composition, and loss in absolute and specific force. One of the main stumbling blocks for IGF-1 application to human therapeutics is the need to design a strategy for safe delivery of IGF-1 in a sustained fashion.

Caloric restriction has beneficial effects on skeletal muscle structure and function. Transcriptional patterns of tissues from calorie-restricted animals, analyzed by DNA microarrays, suggest that calorie restriction retards the aging process by reducing endogenous damage and by inducing metabolic shifts associated with specific transcriptional profiles. Caloric restriction delayed the decline of gastrocnemius muscle mass and reduced the age-related loss of hindlimb skeletal muscle mass in rodents. Caloric reduction has been found to reduce the rate of age-related skeletal muscle mass loss in soleus, anterior tibialis, EDL, and hindlimb muscle of rats. The secondary or delayed onset injury induced by the free radicals in EDL muscle was alleviated by treatment with a free radical scavenger, polyethylene glycol–superoxide dismutase. Furthermore, 50% caloric restriction initiated at 17 months of age preserved the fiber number and fiber type composition in the vastus lateralis muscle of the aged rat. Our laboratory has demonstrated that calorie restriction prevents significantly age-dependent decrease in rat EDL and soleus muscles and the expression of proteins that play a crucial role in EC coupling. Whether this effect is recorded exclusively on muscle, motor neuron, or both was uncertain until recently when it was demonstrated that food restriction decreases motor neuronal loss with advancing age in the rat. Only sparse information about effects of calorie restriction on humans is available. Calorie restriction increases muscle mitochondrial biogenesis in healthy humans and reduces plasma endothelin-1 concentration, improving consequently obesity-induced endothelial dysfunction. The effect of calorie restriction on human skeletal muscle is currently unknown. Results from a human clinical trial (Comprehensive Assessment of Long-Term Effects of Reducing Intake of Energy [CALERIE]) sponsored by the National Institute on Aging will provide some clues on the effectiveness of this intervention on age-related diseases, and perhaps muscle changes with age.

Exercise is clearly one of the most effective interventions in reducing muscle impairment in the elderly. Exercise interventions such as resistance training are being used in an attempt to restore muscle force in the elderly. Strength training in sedentary young and sedentary older individuals improves muscle force, improves metabolic capacities, increases glycogen storage, and enhances oxidative enzyme activity. Aerobic training involving high-repetition, low-intensity muscle contractions leads to minimal strength gain when compared to the low-repetition, high-intensity stimulus of resistance training in which both strengthening as well as endurance activities are included. Further studies on the use of trophic factors and on the use of specific exercise interventions are needed to determine the best means of preventing or reversing the decline in muscle function with age.

## TENDONS AND LIGAMENTS

Tendons and ligaments are composed of dense connective tissue that has a high content of fibrillar collagen to provide tensile strength. Tendons attach muscle to bone, while ligaments attach bone to bone. The integrity of these attachments is important for normal joint function. Ligaments serve to stabilize the joints, and tendons

transmit the forces of muscle contraction to bone. There appears to be a general decline in joint range of motion with age that may be related, at least in part, to changes in tendons and ligaments.

The percent reduction in range of motion varies with the joint studied and is greatly influenced by both disuse and disease. In general, declines in the range of 20% to 25% have been reported. In addition to effects on joint motion, aging-related changes in tendons and ligaments may contribute to the development of injuries to these structures, resulting in conditions ranging from tendonitis to tendon and ligament tears or rupture. Although these injuries certainly occur in younger individuals, the amount of trauma required to produce them is reduced with age. In addition, ligamentous ruptures from injuries in younger individuals can predispose the affected joint to the development of OA later in life as a result from joint instability, altering joint biomechanics.

Biomechanical studies reveal that the strength of tendons and ligaments and their insertions to bone are reduced with age. In one study, it took approximately one third less loading to cause failure of the anterior cruciate ligament attachment in cadaver knees from individuals aged 60 to 97 years, as compared with a younger group of individuals aged 22 to 35 years. A twofold decrease in the strength of the anterior longitudinal ligament of the spine has also been noted in subjects between the ages of 21 and 79 years in cadaver studies.

Shoulder problems are quite common in older adults and may be related to aging changes in the rotator cuff tendons. Changes with age including calcification, microtears, and fibrovascular proliferation have been reported in the region where the tendons attach to bone. These changes would result in a weakening in the attachment, predisposing the tissue to injury after minor trauma.

Biochemical studies of aging in tendons and ligaments have been limited but have shown changes with age, some of which are similar to changes noted in cartilage. Like cartilage, the tensile strength of these tissues depends on the collagen fibers, although the primary fibrillar collagen is type I rather than the type II found in cartilage. There is no clear evidence that collagen content in ligaments or tendons changes with age, but changes in cross-linking have been reported with the appearance of nonreducible cross-links with age, including cross-links formed by nonenzymatic glycation. Increased cross-linking may cause increased stiffness of the collagen and make it more prone to fatigue failure. Like cartilage, there appears to be a decrease in the water content of tendons and ligaments with age, but there is little information on changes in proteoglycans that, if altered, could explain the reduced water content as discussed earlier with respect to cartilage proteoglycans.

## INTERVERTEBRAL DISKS

Imaging studies of normal subjects without recent back pain, as well as morphologic studies of autopsy material, show that disk degeneration increases directly with age, with at least some degree of degeneration universally present by the sixth decade of life. Because the presence of disk degeneration does not correlate well with symptoms of pain, it is often difficult to determine the clinical significance of these findings. Magnetic resonance imaging evidence of disk bulging and herniation increases with age but is often asymptomatic. On the other hand, disk herniation associated with extrusion of disk material is more likely to be associated with symptoms, particularly if the disk material extends beyond the posterior longitudinal ligament. It

is also generally agreed that degenerative changes in the intervertebral disks likely contribute to a variety of conditions seen in older adults, including osteoarthritis, spondylosis, and spinal stenosis.

The intervertebral disks consist of an outer fibrous ring of dense connective tissue referred to as the annulus fibrosus and an inner gel-like material called the nucleus pulposus. The annulus fibrosus is composed of approximately 70% collagen by dry weight, whereas the nucleus pulposus is approximately 20% collagen and 50% proteoglycan. The superior and inferior boundaries of the disks are formed by end-plates consisting of a thin layer of cortical bone covered by hyaline cartilage that directly connects with the vertebral bodies. Aging changes occur within all these regions but are probably most pronounced in the nucleus pulposus.

The most common age-related change in the disk is dehydration. There is a marked decrease in water content, particularly in the nucleus pulposus, which becomes fibrotic, and, starting in young adults, contains fissures and cracks. Tears also become common in the outer annulus in young adults. These can lead to disk herniation, which has a peak incidence at about 40 to 50 years of age. With advancing age, the nucleus pulposus becomes more dehydrated and less likely to herniate. The decrease in water content is likely related to a decrease in proteoglycans in the nucleus pulposus as well as an increase in collagen cross-linking which, by making the collagen network stiffer, allows for less expansion of the proteoglycans. Similar to articular cartilage, there is evidence that increased collagen cross-linking with age is caused by the accumulation of advanced glycation end-products.

Many of the age-related changes noted in intervertebral disks are thought to be attributable to a decline in the diffusion of nutrients to the disc cells. Cells in the nucleus pulposus derive their nutrition by diffusion from vessels in the outside layers of the annulus and from the vertebral end plates. There appears to be a decline in the number of vessels in these regions with age, a disease which can be made worse by conditions including atherosclerotic vascular diseases and diabetes. There is a dramatic decline in the number of viable cells in the nucleus pulposus with age. This is associated with evidence of apoptotic cell death, likely because of the lack of nutrients.

Apoptotic cell death has also been noted in the end-plates. These structures become increasingly calcified with age. This contributes to the development of sclerosis. Because the facet joints of the spine are intimately linked with the end-plates and the disks, the age-related changes in these structures contribute significantly to the development of osteoarthritic changes in the spine. Degenerative disk disease accompanied by vertebral osteophytosis results in spondylosis, which, when severe, can cause spinal stenosis.

There is still much that is not known about aging in the intervertebral disks as well as in cartilage, muscle, ligaments, and tendons. It is necessary to continue to try to separate normal aging from changes in these tissues that lead to disease so that appropriate interventions can be designed to prevent and treat musculoskeletal disease in older adults.

# Biomechanics of Mobility

*James A. Ashton-Miller* ■ *Neil B. Alexander*

## PREVALENCE OF MOBILITY PROBLEMS AMONG OLDER ADULTS

Problems with mobility in older adults are common. In the United States, among noninstitutionalized persons 65 years and older, approximately 13% have difficulty in performing activities of daily living. Approximately 9% have difficulty with bathing, 8% have difficulty with walking, and 6% have difficulty with bed or chair transfers. The rate at which these problems occur increases progressively after the age of 65 years and climbs sharply after the age of 80 years, so that, for example, more than 34% of noninstitutionalized persons who are 85 years or older have mobility problems.

## AGE AND GENDER DIFFERENCES IN FALLS AND FALL-RELATED INJURY RATES

Perhaps the most serious problem of mobility impairment is the tendency of older adults to fall and to be injured by falls. Death rates from falls per 100,000 persons in 1999 were 9.1 for those between 65 and 74 years, 31.7 for those between 75 and 84 years, and 109.7 for those 85 years or older. For comparison, in those aged 75 years and older, the death rate from falls (67.9 per 100,000) is more than double that from motor vehicle accidents (29.8 per 100,000). Falls and fall injuries are of substantial concern because of their frequency and because of their physical, psychological, and social consequences. Even a fall that does not result in injury can have a substantially adverse effect on an older person's self-confidence, mobility, and independence. Indeed, fear of falling, which can accompany decreased mobility, can lead to decreased physical activity outside and avoidance of social activities because of the possibility of embarrassment as well as injury in connection with a fall.

Older females are substantially more prone to fall and to be injured in a fall than are older males. Three studies of rates of falls, involving more than 4500 adults ages 65 years or older, found those rates to range from 137 to 690 falls per 1000 persons per year, with older females falling from 1.3 to 2.2 times more often than older males. Three studies of rates of fall injuries requiring medical attention, involving more than 38,000 adults, found that fall injuries leading to hospital admission or death occurred in males and females at rates per 1000 persons per year of 1.88 and 0.83, respectively, for those aged 20 to 29 years and increased steadily with age to 6.97 and 15.58, respectively, for those aged 70 to 79 years. Correspondingly, female-to-male ratios of these serious fall injury rates increased with age from 0.44 to 2.24.

In 1996, there were 340,000 hip fractures requiring hospital admission. The direct medical and other costs for the injury have been estimated as being at least \$16,300 in the first year following the injury. With current trends, approximately 500,000 hip fractures are expected to occur in the year 2040, with an associated total annual cost of \$240 billion. Most hip fractures occur in old adults, and more than 95% of those hip fractures result from a fall; the remainder fracture spontaneously during a physically stressful activity or prior to the fall.

Hip fractures can be devastating, particularly in older women. In 1998, there were 863 hip fractures per 100,000 adults older than 65 years (1056 and 593 per 100,000 in women and men, respectively), with the highest rate in white women 85 years and older (2690 hip fractures per 100,000). Approximately 20% of women who fracture their hip do not survive the first year after fracture, and another 20% do not regain the ability to walk unassisted. The incidence of hip fractures rises much faster with age than that of falls. This increase in hip fractures with age is not fully accounted for by increases in the number of falls or decreases in bone mass of the hip with age. Therefore, other factors must increase susceptibility to hip fractures. The biomechanics of the fall arrest responses are likely to be among these factors. More than 85% of wrist fractures involve

falls. The incidence of wrist fractures rises from the age of 50 to 65 years and then reaches a plateau after the age of 65 years, but why this occurs is not yet known.

Most falls (78.3%) in those 65 years and older occur in or within the immediate vicinity of the home. Much is known about the epidemiology of falls, but little is known about the mechanisms responsible for the remarkable increase with aging in falls and fall-related injury rates. Diagnosis of specific diseases does not discriminate elderly fallers from elderly nonfallers. Individual risk factors for falls may be grouped into intrinsic and extrinsic factors. Intrinsic factors include decreased level of physical activity, cognitive impairment, depression, visual deficits, sensory and strength deficits in the lower limbs, previous stroke, dizziness, medications, abnormal balance and gait, use of assistive devices, and age more than 80 years. Extrinsic factors include environmental factors including stairs and obstacles in the gait path that can cause trips or slips. The presence of multiple risk factors substantially increases the risk of a fall. Little is known about the changes with age in impending fall response biomechanics that must, in part, be responsible for the rate changes. For example, tripping is commonly self-reported by older persons as a cause of falls: In a 1-year study of 1042 persons greater than 65 years of age, tripping was reported to be the cause of the fall in 53% of the 356 falls that were documented. Whatever the underlying neurological and physiological mechanisms, responses to trips are ultimately expressed in terms of biomechanical factors.

### Fall-Related Injury Biomechanics

There probably are a number of factors that determine whether a fall will result in an injury: the initial conditions under which the fall begins, the biomechanics of the response during the fall, the passive and active mechanisms for dissipating energy on impact with the ground or other surfaces, and the proneness to injury of the hard and soft tissues that are impacted. However, the biomechanics of fall arrests and of fall-related injuries have received little attention. Clear need exists to examine them, in order to improve assessments of risk and programs for both intervention and prevention.

### The Biomechanics of Hip Fractures

The risk of bony fracture has been defined by Hayes and colleagues as the ratio of the magnitude of the force applied to the bone divided by the force necessary to cause fracture. A fall from standing height directly onto the greater trochanter carries a 21-fold higher risk for hip fracture than landing on another body part. This is because the loss in potential energy associated with such a fall is an order of magnitude greater than the average energy required to fracture the proximal femur in elderly cadaver specimens. Hence, falls in a lateral direction, which carry a higher risk for landing on the hip than other directions, must be avoided if possible. This is particularly true in an individual with reduced bone mineral density and reduced body mass index. Reductions in the latter are associated with less soft tissue over the hip to dissipate the impact energy. Hip pad protectors can be effective in reducing the risk of hip fracture in frail ambulatory elderly. By diverting the impact energy to adjacent tissues, the impact force on the hip may be more than halved. However, patient compliance has been problematic because the pads are uncomfort-

**FIGURE 113-1.** Example of the measured wrist impact force plotted versus time for one hand in four consecutive forward falls onto both arms for a young subject weighing 620 N. The subject fell onto a lightly padded surface from a shoulder height of 1 m. Note that (1) the time-to-peak force is less than any upper extremity neuromuscular reflex, rendering reflexes unable to protect the wrist, and (2) the magnitude of the peak impact force on one hand exceeds as much as one body weight for a brief time in two of the four trials, mainly as a result of the ground arresting the downward momentum of the upper extremity over a relatively short distance. (Data from DeGoede KM, Ashton-Miller JA: Fall arrest strategy affects peak hand impact force in a forward fall. *J Biomech.* 2002;35:843.)

able to sleep with and the garment in which they are located can impede dressing and undressing.

### The Biomechanics of Wrist Fracture

Once a fall is initiated, fall arrests have two post initiation phases: a preimpact phase and an impact phase. In a fall from standing height, the preimpact phase lasts approximately 0.7 seconds as the body falls to the ground. The impact phase lasts only tens of milliseconds for structures near the impact site (Figure 113-1) to a few tenths of a second at more proximal body sites further from impact. Thus, for structures near the impact site, like the hands and elbows in a forward fall, short- and long-loop neuromuscular reflexes are simply too long to be able to alter the fall arrest strategy during the impact phase.

The hands and arms are commonly used to protect the head and torso during a fall. The factors that determine the risk of Colles fracture, the most common upper extremity fall-related injury, are the height of the fall and the compliance of the surface. Moreover, at impact, the relative velocity of the hand as it strikes the surface, the elbow flexion angle, the angle of the lower arm with respect to the ground, and, of course, forearm bone mineral density status play a role. There is almost always time for older women or men to deploy their upper extremities in the event of a fall. But our research shows that a fall by an older woman from 25 cm or more onto a stiff surface, when landing with a straight arm, will almost certainly break the wrist. However, falling onto a slightly flexed arm will reduce this risk, although triceps and shoulder muscle strength is required to prevent the elbow from buckling. If the elbow buckles then the head, face, and cervical spine are placed at risk of injury. This justifies encouraging elderly people to maintain extensor muscle strength in the upper extremities so that they can better protect themselves in a fall.

## AGE CHANGES IN COMPONENTS OF BIOMECHANICAL CAPABILITY

The biomechanical factors that underlie mobility impairments among older adults in general, and falling and fall injuries in particular, are not well understood. To come to that understanding, examination of the changes in biomechanical capabilities that occur with natural aging and with disease is merited. This section discusses the changes that occur in myoelectric latencies, reaction times, proprioception, joint ranges of motion (ROM), and muscular strengths and the rapid development of those strengths.

### Myoelectric Latencies

The myoelectric latency or premotor time is the delay from a test stimulus cue to the onset of the first measurable change in myoelectric activity in a muscle. Myoelectric activity refers to the electrical signals sent through the nerves to initiate or modify the muscle contraction process. At the latency time, the muscle will not have yet developed any significant contractile force or, if already contracted, changed that force. Myoelectric latencies typically range from 30 to 50 milliseconds for myotatic reflexes involving the muscle spindles, 50 to 80 milliseconds when cerebellar or cortex neural pathways are involved, 80 to 120 milliseconds when afferent receptors and higher motor centers are involved, and 120 to 180 milliseconds for volitional actions.

### Reaction Times

The term “reaction time” refers to the delay from a stimulus signaling a needed reaction to making a movement or developing a force. Reaction time is longer than myoelectric latency because it includes both the myoelectric latency and the finite time required for a muscle to develop or change its force magnitude after myoelectric activity begins. This additional time interval is called the motor time.

Researchers define reaction time in different ways. For example, in studies of postural control, reaction time is often defined as the delay between stimulus onset and the first measurable change in the forces exerted by the feet on the floor support. This reaction force is usually measured with an instrumented force plate. This force development reaction time incorporates the myoelectric latency and the motor time required for the muscles to contract in order to alter the body configuration enough to change the support force. This happens with little discernible foot movement or limb-segment acceleration. Reaction time has also been defined to be the delay from stimulus onset until the first detectable acceleration of a body segment. This might be termed segment acceleration reaction time. Reaction time has also been defined as the delay from stimulus onset until a limb has been moved to a target. This movement-to-target reaction time incorporates myoelectric latencies, body-segment acceleration reaction times, and body-segment movement times. Movement reaction times depend on how far body segments have to be moved. Reaction times also depend on how many choices a subject has in responding to a cue. Simple reaction times are those exhibited when no choices are given to the subject. Choice reaction times are those exhibited when the subject must decide between two or more courses of action, depending on which of two or more cues is presented. Choice reac-

tion time increases in proportion to the logarithm of the number of choices to be made. Choice reaction times are, therefore, considerably longer than simple reaction times. A speed-accuracy tradeoff is also found in reaction time measurements. As the accuracy requirement of the task is increased, reaction time increases. These differing definitions of reaction time and differing circumstances in which it is measured make it difficult to compare results from different studies of reaction times. Meaningful data on group differences in reaction times seem best obtained by comparing those times among different groups performing the same task, with the reaction time measure defined in the same way among the different groups.

### Age and Gender Group Differences in Latencies and Reaction Times

Many studies report statistically significant age differences, but not gender differences, among healthy adults in myoelectric latencies. Myoelectric latencies are typically 10 to 20 milliseconds longer in healthy old than in young adults.

Age systematically increases force development reaction times. Older, compared with younger, adults require perhaps 10 to 30 milliseconds longer to volitionally develop from rest modest levels of ankle torque or to begin to take a step upon loss of balance. Systematic age differences in movement-to-target reaction times are often found. These increase on the order of 2 milliseconds per age decade between the second and 10th decades. Age differences increase when subjects are not warned several seconds in advance of the cue that it is imminent. Much larger increases with age occur in choice reaction times than in simple reaction times. For example, in 10-choice button pushing tasks, where choices were identified by letter or color or both, choice reaction times increased 27% to 86% more in subjects aged 65 to 72 years compared with those aged 18 to 33 years. No notable gender differences in reaction times have been reported.

### Biomechanical Effects of Age Differences in Latencies and Reaction Times Are Minor

Despite these statistically significant age differences, of 10 to 20 milliseconds in latencies and of 15 to 30 milliseconds in some reaction times, these seem seldom critical to mobility function. Even rapid responses in time-critical situations take place during perhaps 200 to 500 milliseconds, so these latency and reaction time differences compared with the task execution times are not large. For example, among healthy older adults, the time required to fully contract a muscle is on the order of 400 milliseconds. The time to lift a foot in order to take a quick step is on the order of 200 to 400 milliseconds. Adults need warning times on the order of 400 to 500 milliseconds to be able to stop before reaching or to turn away from obstacles that come suddenly to attention.

Reaction times, which include muscle latencies, are task and strategy dependent. These are modifiable by central command. Reaction times of older adults are not always slower than those of young. Moreover, reaction times do not necessarily predict performance on complex mobility tasks. For example, one of our studies found that simple reaction times in lifting a foot immediately upon a visual cue did not predict how well the same young or older subjects could avoid stepping on a suddenly appearing obstacle during level gait. In fact,

age-group differences in simple reaction times were substantially larger than age-group differences in the response times needed to avoid the obstacles successfully.

### Proprioception

*Proprioception* describes awareness of body-segment positions and orientations. Relatively few studies have examined changes with aging in proprioception. One study found joint position sense in the knee to deteriorate with age. Joint angles could be reproduced to within 2 degrees by 20-year-olds, but only to within 6 degrees by 80-year-olds. Twenty-year-olds could detect passive joint motions of 4 degrees, but 80-year-olds could detect only motions larger than 7 degrees. Other studies have found no major decline with age in motion perception in finger and toe joints but have found declines with aging in sensing vibration. Proprioceptive acuity at a joint is significantly better when muscles at the joint are active than when these are passive. Proprioceptive thresholds during weight bearing are at least an order of magnitude lower than those typically reported during non-weight-bearing tests. Recent studies exploring the effect of age on thresholds for sensing ankle rotations show that healthy adults can sense quite small rotations in the sagittal and frontal planes under the weight-bearing conditions of upright stance. The probability of successful detection of rotation increases with increasing magnitude and speed of imposed foot rotation. A 10-fold reduction in the angular threshold was observed on increasing the speed of rotation from 0.1 to 2.5 degrees per second, but thresholds did not further reduce at higher speeds. In healthy adults between the third and eighth decades, age, rotation angle, and rotation speed also significantly affected the threshold for sensing the direction of foot rotation. Threshold angles were three to four times larger in older females than in younger females.

Individuals with central or peripheral proprioceptive impairments can exhibit articular pathology. Examples include Charcot changes occurring in the upper or lower extremities owing to central nervous system damage by syringomyelia over several levels of the spinal cord and changes in the foot or ankle owing to lower extremity peripheral neuropathy often associated with diabetes. Indeed it is prudent to warn older diabetic patients planning an exercise program about the risk of developing Charcot feet if they try to return to activities requiring the feet to impact the ground in order to abruptly change direction (i.e., racquet sports or running), since they simply may not feel compression fractures of the bones comprising the arches of the feet. These can lead to skin breakdown, thereby increasing the risk for serious infection and even amputation.

Peripheral neuropathy increases the proprioceptive threshold at the ankle nearly fivefold compared with age-matched healthy controls. This increased threshold adversely affects postural stability and raises the risk of obstacle contact during gait, suggesting one mechanism that might underlie the 20-fold increase in fall risk and the 6-fold increase in fall-induced fractures that these patients have.

### Joint ROM

Body joint ROM have generally been found to diminish with age, but not all findings are consistent. For example, studies have reported approximately a 20% decline between ages 45 and 70 years in hip rotation and 10% declines in wrist and shoulder ROM. Compar-

isons of the ROM of lower extremity joints for young and middle-aged adults with those for older adults showed declines ranging from negligible to 57%. At the age of 79 years, one-fifth of a large group of subjects had restricted knee joint motion and two-thirds had restricted hip joint motion. Among more than 3000 blue-collar workers with ages ranging from 20 to 60 years, a 25% decline with age was found in ability to bend to the side and a 45% decline in shoulder motion. Declines of 25% to 50% have been found in various ROM of the lumbar spine between ages of 20 to 80 years. However, a comparison between two groups with mean ages of approximately 65 and 80 years found no significant differences in 28 different joint ROM. At least one study suggests that passive or active stretching exercises can increase hip extension ROM in young adults by 8 to 17 degrees, and another study suggested that exercises with a focus on stretching improve spine flexibility in older adults.

The effects of decreased ROM on abilities to perform activities of daily living are not well understood in young or old adults. One study of adults with arthritis found that the ability to move around in one's environment correlated well with ROM in knee flexion, the ability to bend down correlated with hip flexion ROM, and the abilities in activities requiring use of hands and arms correlated well with ROM of the upper extremities. Another study found that restricted knee motion in 79-year-olds correlated with disability in entering public transport vehicles but that ROM impairment did not generally associate with commitment to institutional care. A third study found the majority of a group of 134 people aged 79 years to have enough spinal mobility to perform common activities of daily living.

### Muscle Strength and Power

The loss of strength with age, even in healthy and physically active older adults (Table 113-1), has long been recognized. Isometric strengths peak at approximately the age of 25 years and then decline. The loss is approximately one-third by the age of 65 years. Isometric strength is more reliably measured, and considerably greater values are recorded, when the patient exerts force on a fixed force transducer, rather than one held by an examiner. To express the strength developed about the joint in units of torque, the force (in Newtons) developed by the limb segment against a force-measuring transducer is multiplied by its lever arm (in meters) about the joint being tested. Muscle strength about a joint is, therefore, expressed in torque units (i.e., Nm), and these torque units can be normalized by body size (i.e., body height \* body weight) to facilitate gender or age comparisons. Dominant limb strengths are typically approximately 10% greater than nondominant strengths. It has long been recognized that mean strengths of female adults of any age are on the order of one-third lower than those of male adults (see Table 113-1). However, when those strengths are normalized by body size, then the difference may no longer be significant. Reports of strength values vary widely because these depend on many factors, for example substantially on whether subjects have impairments or experience pain or discomfort during testing, at which joint angles, whether under isometric or constant velocity conditions, and, at constant velocity, whether muscle shortening or lengthening is occurring. As an example, maximum knee extensor torque in healthy individuals decreases by 14%, 23%, 41%, and 53% of isometric values at joint rotation speeds of 30, 60, 90, and 180 degrees/s, respectively. Isokinetic

dynamometers do not measure maximum torque or power accurately at speeds above 180 degrees/s because of substantial measurement artifacts.

The strength capacity needed at the very start of a recovery movement can best be measured by isometric strength. For the hip flexor muscles, which are needed to recover balance after tripping by swinging a leg forward rapidly and placing the foot on the ground ahead of the center of gravity, maximum hip flexor torque decreases linearly with increasing hip flexion angle, as a result of muscle shortening, and additionally with increasing hip flexion speed. So, given the typical bell-shaped hip flexion angular velocity versus time curve for a recovery step, it is the maximum power developed about the relevant joint that best predicts the fastest velocity that can be achieved mid-swing and, therefore, length of the recovery step. Since power is defined as the product of torque times angular velocity, high hip flexion power values would be attained by being able to develop a large torque about the joint at a high rotational velocity. Maximum power usually occurs in a shortening muscle at approximately one-third of the maximum movement velocity.

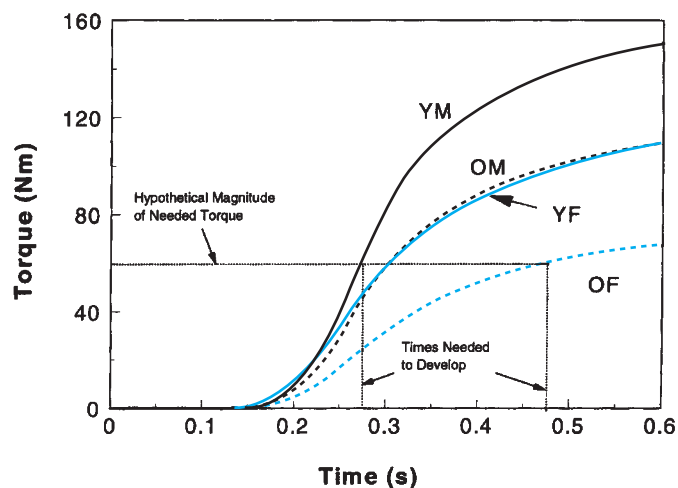

A prevalent casual belief is that many of the mobility impairments that arise in the elderly are caused by declines in muscular strength. This belief warrants careful consideration. Studies described subsequently suggest that the joint torques needed to maintain postural

balance and even to rise from a chair are often well below the joint torque strengths that healthy older adults have available.

The decline with aging in the ability of muscles to produce power is perhaps well illustrated by records of elite athletic performances. In short-distance races, male elite runners more than 70 years old run approximately one-third slower than do elite young adult male athletes. In long-distance races, male elite runners more than 70 years old run approximately half as fast as elite young adult male athletes. By that age the maximum extensor muscle power that can be developed about the knee, for example, has declined by approximately 40%.

Age-related changes in muscle morphology and physiology help to explain these changes. Older adults are particularly prone to loss of isometric strength as well as torque at high velocities because of the irreversible loss of the largest (and fastest) motor units with age. Fast/slow muscle fiber innervation ratios also seem to change with age. By contrast, the maximum speed of unloaded shortening for specific muscle fiber types does not decrease significantly with aging. The reduction in muscle power reduction with age may also be caused by systemic factors, such as declines in cardiopulmonary function. It is thus likely that, in order to maintain muscle function in older adults, the focus should be on the assessment and training of both muscle power and strength.

## Plantarflexion

**FIGURE 113-2.** Age and gender differences in rapid development of ankle plantarflexor torque. The subjects tested were healthy young and older (Y, O) females and males (F, M). Time is measured from a light flash cue signaling the subjects to push against a pedal as hard and as fast as possible. The four subject groups exhibited nearly the same mean reaction times, approximately 160 milliseconds. However, the mean time needed to develop a given magnitude of torque varied substantially among the four age/gender groups. For example, were a plantarflexion torque of 60 Nm required to regain balance upon the initiation of a fall, YM would need approximately 275 milliseconds to develop that torque, and OF would need approximately 475 milliseconds. (Data from Thelen DG et al: *Effects of age on rapid ankle torque development.* *J Gerontol Med Sci.* 1996;51A:M226.)

### Rapid Development of Joint Torque Strengths

Upon a substantial perturbation of standing balance, as already noted, fewer than 500 milliseconds are often available for the critical initial phase of balance restoration, yet 300 to 400 milliseconds can be required to develop maximum joint torques. Even older adults who are healthy and physically active have diminished abilities to develop large joint torques rapidly, compared with young adults. Moreover, older females have lower torque development rates than do older males. For example, in one study, the mean total time required to develop 60 Nm of ankle plantarflexion torque, when subjects were asked to develop maximum torque as fast as possible, was 311 milliseconds in young adult females and 472 milliseconds, or 161 milliseconds (52%) longer in older females. Corresponding times for males were 270 and 313 milliseconds (16% longer), respectively (Figure 113-2). Maximum rate of torque development tends to correlate highly with maximum voluntary torque strength, with correlation coefficients on the order of 0.8. Owing to slowing in peak rate of joint torque development abilities, capacities of even healthy old adults to recover balance or to carry out other time-critical actions that require moderate-to-substantial strengths, such as those required to avoid obstacles that come suddenly to attention, may be considerably reduced.

### Source of Age Differences in Rapid Strength Development

Measurements of myoelectric signals in ankle dorsiflexor and plantarflexor muscles during rapid isometric and isokinetic exertions

have been used to explore the extent to which this age-related slowing in rapid torque development might be attributed to neural factors, that is, those processes that precede the initiation of muscle contraction. In one study, latency times, muscle activation rates, and myoelectric activity levels of agonistic and antagonistic muscles were quantified. There were few marked age differences in the latencies or in the onset rates or magnitudes of agonistic or antagonistic muscles activities during maximum isometric and during isokinetic exertions. Myoelectric latency times were statistically associated with age, but, in the mean, these were only approximately 10 to 25 milliseconds longer in the old. Given the outcomes of this study, the differences observed in rapid torque development abilities in healthy elderly compared with healthy young adults seem largely because of differences in muscle contraction mechanisms once contraction is initiated, rather than to differences in the speeds of stimulus sensing or central processing of motor commands or to differences in the muscle recruitment decisions that precede contraction initiation.

### AGE DIFFERENCES IN PERFORMANCE OF SIMPLE MOBILITY TASKS

To reach a better understanding of the biomechanical mechanisms that underlie mobility impairments in general, and falling and fall injuries in particular, attention to how the changes in biomechanical capabilities that occur with natural aging and with disease affect the performance of individual mobility tasks is merited. This section discusses age differences in performance of common mobility tasks, such as walking; turning, rising from chairs, beds, and floors; and regaining standing balance when it is disturbed.

Age-related declines in mobility task performances are seen in tasks that are physically and/or cognitively very challenging long before any declines are seen in tasks easily performed. Physical and cognitive capacities can decrease substantially without leading to any impairment if task performance demands are modest because these do not tax the functional reserve. Once capacity falls to a point at which task demand begins to equal capacity, performance ability begins to decline substantially. In healthy adults, the consequences of a decrement in capacity are unlikely to be seen in performances of easy tasks but are likely to be seen in performances of demanding tasks, accompanied, perhaps, by compensatory changes in performance strategies.

### Assessment of Mobility Function

Mobility does associate with decrements in biomechanical variables. For example, in a recent study of community-dwelling older adults, self-reported difficulty with chair rise, ascending and descending stairs, and fast walking was found to be associated with a reduction of isometric knee extensor strength capacity below 3 Nm per kg body weight. A number of performance-based test batteries have been developed to globally assess a patient's mobility function, including that in changing positions, controlling upright posture, and walking. These batteries are designed to detect clinically significant changes that might, for example, place an individual at risk of falls or of developing mobility disability. Not all of these batteries are sensitive to the subtle age-related changes in performance found among healthy adults. Some do not include tasks that are sufficiently

demanding. Others use rating systems that are not quantitative enough. Such batteries serve well for assessing more impaired older adults, but healthy older adults can often perform without difficulty all of the tasks the batteries include. Batteries are available that can elicit subtle age-related effects. These rate performance sensitively enough and include tasks with sufficient demand; for example, in one test patients are asked if health problems or physical impairments have resulted in adaptation in the way daily tasks are performed, to test the ability to balance on one leg for 10 seconds, and to measure average gait speed relative to a 0.5 m/s standard. For example, if patients have altered the way they perform daily tasks, cannot balance for 10 seconds on one foot, and walk at less than 0.5 m/s, then their risk of developing mobility disability in the next 18 months is more than 55%. A recent review of fall risk assessment measures showed that certain measures showed good sensitivity and specificity in acute care settings (e.g., “STRATIFY” and “Fall Risk Assessment Tool”), others performed well in extended care settings (e.g., “Morse Fall Scale” and “Timed Up and Go Test”), while yet others performed best in outpatient settings (e.g., “Elderly Fall Screening Test” and Timed Up and Go Test).

### Ascribing Functional Decline Fully to Insufficient Motivation, Activity, or Training is Questionable

Performance records of elite older athletes suggest that physical inactivity, lack of motivation, and lack of training cannot fully explain functional decline in healthy older adults. Declines with age in physical performance abilities can be seen among even highly trained and highly motivated athletes. As already noted, top running speeds of short- and long-distance older elite runners are notably lower than those of young adult elite runners.

### Gait

Hippocrates once said that walking is man’s best medicine. We now know that gait speed is a powerful predictor of outcomes, including disease activity, mobility and activity of daily living (ADL) disabilities, institutionalization, and mortality. In older adults free of overt neurological, musculoskeletal, cardiorespiratory, or cognitive problems, comfortable gait speed declines minimally until approximately the age of 60 years and then declines by 1% to 2% per year through the age of 80 years; however, there is substantial variability among studies of age changes in comfortable gait speed (Figure 113-3). Speeds of less than 1.0 m/s, and 0.6 m/s in particular, have been suggested by Studenski and coworkers as identifying those at high risk of hospitalization and functional decline.

The causes of gait slowing with age are a subject of controversy. These may be multifactorial, including subtle age-related changes in joint stiffness, leg strength, and energy conservation strategies. Independently of age, comfortable walking speed associates nonlinearly with muscle strength (Figure 113-4) and maximum aerobic power. Much of the decline in speed has been attributed to reductions in step length. The earliest studies of gait in older adults found that men in their sixties demonstrated significantly shorter step and stride lengths and decreased ankle extension and pelvic rotation compared with younger males.

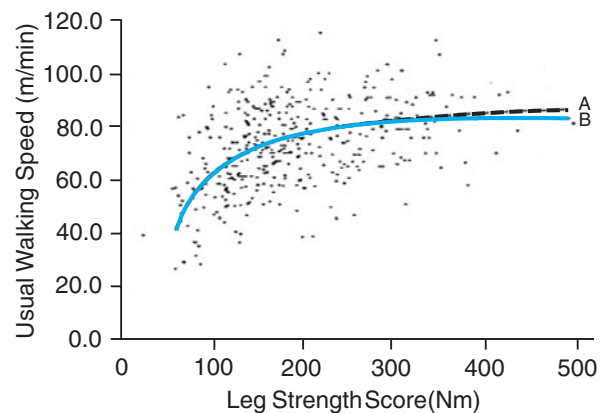

More recent studies have confirmed those findings, but not without exception. One found no significant age-group differences in step and stride lengths, velocity, or movements of the ankles, pelvis,

**FIGURE 113-3.** Age and gender differences in self-selected comfortable gait speeds. These data are graphed using those abstracted by Bohannon et al. (1996) from seven earlier literature reports. The mean speeds reported vary substantially. Nonetheless, the general trend is for comfortable gait speed to decline minimally until approximately the age of 60 yr and then to decline by 1% to 2% per yr through the age of 80 yr.

and total body mass center. Another concluded that increased variability in gait should not be regarded as a normal concomitant of old age. Still another found that among older adults, more than 40% of the variance in normal walking speed can be accounted for by differences in height, calf muscle strength, and the presence of health problems such as leg pain. A recent prospective study in older women showed that those with the poorest knee strength and balance scores were five times more likely to develop severe walking disability than those with normal function.

There is little evidence of an association between age-related reductions in stride length and gait speed and a tendency to fall. On the other hand, increased stride time variability is associated with a fivefold increase in the risk of falling.

**FIGURE 113-4.** Comfortable gait speed is nonlinearly related to leg muscle strength score in a population-based sample of over 400 adults between the age of 60 and 96 yr. The strength score was formed from the summed isokinetic right knee and ankle flexor and extensor muscle strengths. The regression curve represents the fit for an average age of 76 yr. [Data from Buchner DM et al: Evidence for a non-linear relationship between Leg Strength and Gait Speed. *Age and Ageing*. 1996;25:390.]

## Rising From Chairs, Beds, and Floors

The biomechanical demand of rising from a regular chair imposes the largest strength demands on the knee and hip extensor muscles: healthy older individuals are required to develop approximately 30% and 25% of their maximum knee and hip extensor strengths, respectively. It is instructive to think about how disease or impairments that affect muscle strength can affect the ability to rise from a chair. With bilateral symmetry in function and their young adult body weight, knee strength would have to be reduced by 70% before becoming inadequate. Thus, the healthy elderly have considerable functional reserve. However, if their body weight has doubled from their young adult weight, the older individual's knee strength would only have to fall 35% below age norms before knee extensor strength is inadequate to rise from a chair without arms. Likewise, a complete unilateral loss in knee extensor strength would mean that a healthy older individual could only tolerate a 35% loss in remaining knee strength before it becomes inadequate. In general, healthy older adults do rise more slowly than young adults, but the time differences for bed and chair rises are 2 seconds or less. When rising from the floor, age differences are larger, with older adults tending to take twice as long as young. Characteristic age-related changes in trunk, arm, and leg motions used to rise may account for these differences.

When rising from a chair, particularly without the use of hands for assistance, healthy old flex their necks, trunks, and legs and extend their thighs more than the young, resulting in a more anterior placement of their floor reaction force than young adults demonstrate. In one study of graded difficulty chair rise tasks, healthy young and older adults did not differ in the leg joint torques that they used to perform the series of tasks. Both young and older adults had enough strength to perform even the most challenging task. However, the old generally used a greater percentage of their available knee strength to rise from a chair, using near-maximum levels in challenging situations. Some of the older adults failed to rise when their postural control was challenged by a lowered seat and by a narrow foot support base. So, there are situations where older adults have adequate strength to rise from a chair but are limited by other factors, such as difficulty with postural control.

While rising from a bed, older adults, compared with young adults, tend to lengthen the time of contact of their arm with the bed surface. They are more likely to rotate and laterally flex their trunks, bear weight on their hip/gluteal area, and use their elbow to help pivot while rising. Declining trunk strength may account for some of these findings.

Many healthy older adults are unable to sit up in bed without the use of their hands. When rising from the floor, older adults tend to use key intermediate positions, such as getting to an all-fours position, in order to reduce the strength requirements and to enhance postural stability. In general, intermediate postures that reduce physical demands (e.g., knee extensor strength required) can be used as part of task-specific exercises to improve the ability to rise from the floor. Improvements as a result of these interventions, quantifiable biomechanically (such as increased momentum during the rise) and clinically (such as in time), are modest.

## Turning in a Confined Space

In bathrooms and kitchens it is often necessary to use the feet to turn through angles as much as 180 degrees as one moves from one

point to another. Falling while walking and turning has been shown to be 7.9 times more likely to result in hip fracture than falling while walking straight. In an effort to understand why turning is linked to such a high rate of injury, we have studied how age affects the kinematics of foot placement during turning by healthy young and older women. We found that subjects generally have a preferred direction of turning and that, in older women, the minimum foot separation distance during the turn was less when turning in the nonpreferred direction than in the preferred direction, raising the probability of foot-foot collisions, and hence a trip. The minimum foot separation distance during the turns was generally 55% more variable in the healthy older women than in young controls, despite the fact that they turned 20% more slowly.

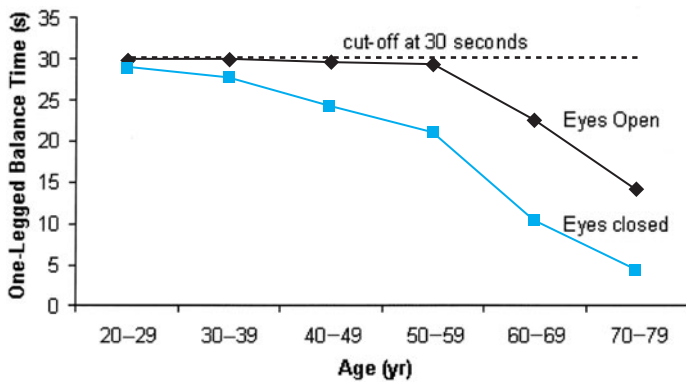

## Walking on Irregular Surfaces

There is often a need to cross irregular or uneven surfaces outside. Walking on an uneven or bumpy surface can pose a considerable challenge to an elderly person, as is evidenced by the fact that it is one of the two most frequent causes of falls in community-dwelling individuals. One of the first studies of gait on uneven surfaces compared subjects with age-related maculopathy against controls while walking across level, compliant, and uneven surfaces. Richardson and coworkers have shown that an irregular surface increases step width variability in healthy young and old controls and step time in peripheral neuropathic subjects who had to slow significantly on such surfaces. The irregular surface discriminated age and disease group differences in stepping pattern, as well as faller versus non-faller group differences better than did similar tests on a level surface. Application of bilateral ankle braces improved the step width variability in neuropathic patient walking on uneven surfaces.

## Restoration of Standing Posture after Modest Disturbance

There is evidence of deterioration in many of the sensorimotor systems underlying postural control, even in elderly populations without obvious signs of disease. However, aging alone does not account for the heterogeneity of postural control problems in the elderly. Moreover, responses to postural perturbations are task and perturbation specific, so that a single assessment technique may not serve as a true indicator of the overall integrity of the balance control system.

Reports of age effects on sway while standing generally show sway to increase with age during adulthood, but not without exception. Age-related changes in postural control in healthy adults are minimal through the age of 70 years under situations of low task demand. Examples of low-demand tasks are standing on two feet with eyes open, or maintaining stance when it is perturbed by modest movements of the support surface or by gentle backward pushes. When task demand increases, age-group differences in postural control abilities become more apparent. For example, when a sway response no longer suffices to recover balance in the face of a perturbation, young adults tend to resort to a single step, whereas older adults tend to employ multiple steps in order to recover their balance. Task demand can be increased by decreasing visual input or by making the support surface more compliant. The most striking age-related differences often occur when several different demands are increased simultaneously. Studies have found that when both the support surface and the visual surround were rotated in phase

**FIGURE 113-5.** Age differences in ability to stand on one leg. Healthy adults were asked to balance on one leg for up to 30 seconds, with eyes open and then with eyes closed. The y-axis shows the time until balance was lost. Difficulty in performing the eyes open task did not arise until after the age of 50 yr, but when the eyes were closed, even the younger subjects had some difficulty. The older subjects had substantial difficulty with both tasks. (Data from Bohannon RW et al: *Decrease in timed balance scores with aging. Phys Ther.* 1984;64:1067.)

with body sway, 50% of older adults lost their balance on their first attempt to maintain stance, compared with 9% of younger controls. There is evidence that the age-group differences may increase after the age of 70 years. The mean time for standing on one leg with eyes open before losing balance for 20- to 29-year-olds was at least twice as long as that for 70- to 79-year-olds and nearly seven times longer with eyes closed. In contrast, mean stance time for 60- to 69-year-olds compared with 20- to 29-year-olds was only 20% less with eyes open and only three times less with eyes closed (Figure 113-5).

It is not known why these changes with age occur in postural control abilities. One-leg stance time differences might result from reduced ankle joint lateral muscle strength or endurance, increased muscle latency times, decreased cutaneous or joint proprioception, or decreased willingness to allow the center of the floor reaction to deviate from the center of the foot support area. Only a few studies to date have analyzed whole-body response biomechanics or even the body-segment motions that are used or the joint torques developed in response to postural disturbances. Those that have report that the required motions and torques are generally modest compared with the literature-reported capacities of healthy old adults.

### Cognitive and Other Psychological Factors

Cognitive demand relative to cognitive capacity substantially influences physical task performance. As mobility task complexity increases, so do the cognitive demands placed on the individual. The need to perform two tasks simultaneously or to divide attention degrades performances of healthy elderly significantly more than for healthy young. For example, in a study of abilities to step over suddenly appearing obstacles while walking, the attention of groups of healthy young and older adults was divided by having them simultaneously respond in two reaction time tasks. Both young and old adults had a significantly increased risk of obstacle contact while negotiating obstacles when their attention was divided, but attention division diminished obstacle avoidance abilities of the old significantly more than it did in the young. These results suggest that

diminished abilities to respond to physical hazards present in the environment when attention is directed elsewhere may partially account for high rates of falls among the elderly. As an example, relative to controls, fallers tend to prematurely transfer their gaze from an obstacle that they are about to cross.

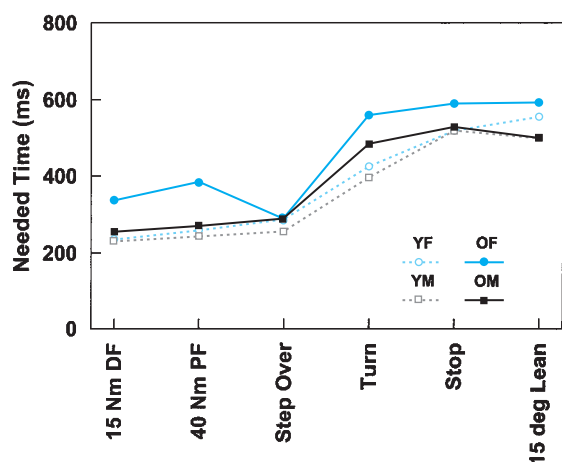

In our studies of relationships between neuropsychological status and physical performance, relatively minimal associations have been found in performance of simple tasks, such as in assessments of proprioception, joint ROM, and strengths. With tasks of increasing complexity, such as in chair rise, ambulation, and postural maintenance, visual attention abilities and psychomotor speed were found to be good predictors of performance. In performance of mobility tasks of substantial complexity, such as avoiding obstacles when attention is divided or stepping accurately under adverse conditions, measures of problem-solving ability and mental flexibility, along with psychomotor speed and attention, become performance predictors. These capacities include elements of executive control, an area of cognitive function increasingly recognized as critical to control of gait and fall avoidance. We have found that when embedding aspects of executive control into a walking task, such as the trails tests of visuomotor processing, older adults, particularly those with executive function impairment, perform more poorly.

Difficulties in walking seem to relate to cognitive impairment. Demented older adults have significantly shorter step lengths, lower frequencies of stepping, more step-to-step variability, and lower gait speed. Gait abnormalities in nondemented older adults can predict future occurrence of dementia, particularly vascular dementia. Difficulties in concurrent performance of cognitive and mobility tasks, such as a verbal task while walking, have been proposed as risk factors for falls. An extreme example, when the individual stops walking while talking, appears relevant only in those with significantly impaired gait or cognition. These findings reflect the inherent underlying cognitive demand in walking, particularly in those with already impaired gait. A geriatric rehabilitation program led to greater gains in walking speed in subjects with normal cognition than in those with impaired cognition. Moreover, walking speed appeared to be closely related to the ability to rise from a chair and to be a powerful predictor of patient placement upon discharge from the rehabilitation program. Of 116 older adults studied, none were able to live alone or even in a rest home if they were discharged with a walking speed of less than 0.15 m/s. Many frail elderly are aware of the difficulty of dividing one's attention while walking, as demonstrated by the ability of the simple but effective "Stops Walking When Talking Test" to predict impending falls in these patients.

### AGE DIFFERENCES IN PERFORMANCE OF TIME-CRITICAL MOBILITY TASKS

#### Times Needed for Quick Responses to Maintain or Recover Balance

As already noted, the time available in which to recover from a substantial disturbance of upright balance or to safely arrest a fall is often less than 1 second. For example, when walking forward at a speed of 1.3 m/s, the comfortable walking speed typically self-selected by healthy young and old adults, only 200 to 300 milliseconds may be available in which to make initial responses appropriate for balance

**FIGURE 113-6.** Summary of age and gender differences in times needed for various quick responses. Mean values across groups of healthy older females (OF), older males (OM), young females (YF), and young males (YM) of the times required for six different responses are shown. The responses are indicated by the horizontal axis labels. Each of the situations being responded to is further described in the text of this chapter. From left to right, the responses are the development of, respectively, (1) 15 Nm of ankle dorsiflexor flexor torque or (2) 40 Nm of ankle plantarflexor torque, as fast as possible; the achievement of a 50% rate of success in avoiding suddenly-appearing obstacles by, respectively, (3) stepping over the obstacle, (4) turning away before reaching the obstacle, or (5) stopping before reaching the obstacle; and (6) the replacement of the stepped foot on the ground when recovering balance by taking a single step up on sudden release from a 15-degree whole-body forward lean. The data points are connected by lines only to help distinguish the four subject groups.

recovery when tripping over an obstacle. If a large obstacle in the gait path, such as a moving vehicle, suddenly comes to attention 1 m ahead while walking at this speed, then a turnaway from the obstacle or a stop before reaching it would have to be accomplished within approximately 750 milliseconds. The term “time critical” is used here to refer to such situations. Differences in abilities to respond appropriately in at least some time-critical situations (Figure 113-6) may help explain age and gender differences in rates of falls and fall-related injuries.

## Studies of Time-Critical Obstacle Avoidance Tasks

### Avoiding Obstacles by Stepping over Them

The abilities of healthy and physically active young and older adults, who were walking forward at a speed of approximately 1.3 m/s, to step over an obstacle that suddenly appeared at seemingly random times and locations in front of them have been examined. The appearance of this obstacle was arranged to give the subjects available response times that varied from 200 to 450 milliseconds before they would have stepped on it. This task is a time-critical one, but because avoidance requires relatively minor changes in stepping pattern and relatively minor redistributions among segments of kinetic energies and forward momenta, the strength requirements of the task likely are modest. Few young or old could avoid obstacles if only 200 milliseconds were available. Most young and old reliably avoided obstacles that appeared so as to give 450 milliseconds warning time. Over all available response times used, the old had statistically significantly lower avoidance success rates than the young, but, in biomechanical

terms, it was estimated that they would have needed only 30 milliseconds more warning time to have the same success rates as the young. No significant gender differences in avoidance abilities were found.

### Avoiding Obstacles by Turning Away Before Reaching Them

In a study of abilities to make sudden turns to avoid previously unseen obstacles, healthy old adults were substantially less successful than young when available response times were short. For example, for an available response time of 450 milliseconds, mean success rates in completing the turn without colliding with the obstacle were 68% in young and 27% in older adults. Moreover, males had substantially better success rates for given available response times than did females in corresponding age groups. This task is a time-critical one. Avoidance requires complete arrest of forward momenta and quick development of lateral momentum, but relatively minor redistributions among segments of kinetic energies. Therefore, the strength requirements of the task likely are moderate.

### Avoiding Obstacles by Stopping Before Reaching Them

In a similar study of abilities to make sudden stops to avoid previously unseen obstacles, healthy old adults again were substantially less successful than young when available response times were short. For example, for an available response time of 525 milliseconds, mean success rates in stopping before passing forward of the obstacle were 58% for young females and male adults and 51% for older males, but only 23% for older females. This task is also a time-critical one. Avoidance requires complete arrest of forward momenta and total dissipation of body kinetic energy. Thus, the strength requirements of the task likely are substantial.

## Studies of Time-Critical Balance Recovery Tasks

Once a fall begins as a result of a trip, quick recovery of balance may be needed to avoid injury. In one set of studies by Grabiner and coworkers, forward falls were induced in healthy older adults by an unexpected trip or backward movement of the support surface. Factors associated with a failure to recover balance were one or more of the following: too short a recovery step, slower response time, greater trunk flexion angle at toe-off, greater trunk flexion velocity at recovery foot contact with the ground, and buckling of the recovery limb. In the case of an unexpected trip, Grabiner and colleagues have shown that there are two basic recovery strategies: a so-called “elevating” strategy and a “lowering” strategy. In the elevating strategy, the swing foot that is obstructed by the obstacle is directly lifted up and over the obstacle and then swung forward as quickly as possible as a (slightly delayed) recovery step. If it should prove difficult to disentangle the foot from the obstacle (thereby obviating use of the elevating strategy), then the subject can switch to a lowering strategy: the swing foot that is impeded by the obstacle is immediately placed onto the ground behind the obstacle to become the stance limb, as the contralateral foot is lifted up and over the obstacle and used for the recovery step. Using a computer simulation of a simple inverted pendulum model to represent the forward fall of the body following the trip, this team found that the recovery foot placement must occur before the inclination of the center of mass exceeds a critical angle of from 23 to 26 degrees from the vertical. In modeling

studies, a faster response time has been predicted to be more useful than a slower walking speed.

There is now evidence for two distinct phases of recovery from a trip in healthy adults: an early response and a later response. In the early response, a powerful stance limb plantarflexion moment and knee extensor and hip extensor moment are used to slow the forward angular momentum (and rotation) of the whole body around the point of obstacle contact, as well as torso flexion about the hip joint. The powerful plantarflexion moment helps to achieve this by orienting the ground reaction force in front of the whole-body center of mass. The resultant slowing of forward angular momentum allows more time for the necessary second part of the response: the powerful hip and knee flexor moment required to swing the recovery limb forward fast enough and far enough to land its foot in front of the onward traveling whole-body center of mass. Finally, as the recovery limb impacts the ground, sufficient resistance must be generated by its knee and hip extensor muscles to resist flexion buckling of the knee as the residual forward angular momentum of the body is attenuated. This resistance to buckling of the knee must come from the resistance of the knee extensor muscles to being forcibly lengthened. In other words, the knee extensor muscles must first be adequately activated, and then there must be sufficient knee extensor muscle mass to generate adequate elastic and viscous resistance to the sudden stretch of the knee extensor muscles. Inadequate activation or inadequate knee extensor muscle mass will mean that the task demands will exceed the capacity of the knee muscles to handle the challenge, the knee will then buckle and its owner will fall as the limb buckles under his/her weight.

Pijnappels and coworkers have shown that despite initial reactions not meaningfully slower, age adversely affects the ability of healthy individuals to generate an adequate stance limb ankle plantarflexor recovery response. This caused an age-related increase in failure to recover from a trip.

We have also studied the effect of age on the ability to recover from a forward fall by rapid step taking. Subjects were released from a forward-leaning position and instructed to regain standing balance by taking a single step forward. Lean angle was successively increased until a subject failed to regain balance as instructed. This task is a time-critical one, likely requiring the use of maximum strengths. The mean maximum lean angle from which older males could recover balance as instructed, 23.9 degrees, was significantly smaller than that for the young males, 32.5 degrees. Corresponding angles for the females were 16.2 and 30.7 degrees, but those numbers do not include five of the 10 older females who could not recover balance from even the smallest lean angle at which they were tested, approximately 13 degrees. Maximum lean angles were well correlated with the average forward step velocity and inversely correlated with the time required to unload the stepping foot, but were unrelated to myoelectric response latencies of  $\sim 70$  milliseconds in both young and elderly. A gender difference has been found in torques used for recovery of balance. None of the males needed to use their maximum ankle, knee, or hip torque capacities; but the young females used maximal hip flexion torques, and the older females used maximum plantarflexor, knee flexion, hip flexion, and extension torques.

The results suggest that reduced abilities of healthy older adults to recover from forward falls result from an inability to generate adequate stance limb extensor torques and sufficiently rapid body-segment movements, rather than from delayed initiation of response.

This means that future interventions should target muscle training designed to increase hip, knee, and ankle muscle strengths and powers in order for the subject to maintain agility by making sufficiently rapid recovery movements.

### Recovery from a Slip

An unexpected slip can be particularly challenging to recover from during gait. Healthy young subjects walking onto a level slippery floor attempt to correct an ongoing slip between 25% and 45% of stance phase (190–350 milliseconds after heel contact). In healthy young adults, the initial response to an unexpected slip is an early flexor synergy (starting at 146 milliseconds) in the muscles of the perturbed limb, presumably serving to limit how far the slipping foot slips; bilateral shoulder muscle activation (143 milliseconds) serving to produce bilateral arm elevation after approximately 288 milliseconds; and rapid protraction of the trailing swing foot onto the ground in order to rapidly enlarge the base of support rearward so as to be able to prevent a backward fall. This slows the acceleration of the whole-body center of mass by employing a flexor synergy in the trailing leg and decelerating the center of mass by using an extensor synergy of the leading leg. The trailing leg is rapidly placed back on the ground in order to provide a larger rearward base of support to decelerate the descending center of mass. Arm elevation movements help to dissipate forward momentum. After the first slip, healthy subjects exposed to successive slipping trials showed very rapid adaptation, with much less arm movement and more muscle cocontraction, often adopting a proactive “surfing” response whereby they slid forward on both feet.

The physical characteristics determining the potential for a slip as well as the required coefficient of friction (ratio of the shear to the normal foot forces) on slippery surfaces have been the subject of recent reviews. Redfern and coworkers have demonstrated on level floors and descending ramps that healthy subjects make significant proactive changes in gait (shorter stance phase duration, shorter normalized step lengths, and slower foot strike velocities) when anticipating the possibility for a slip. Properly corrected vision and good lighting can help foster such proactive strategies by elderly people.

### Mechanisms Underlying Age and Gender Differences in Performance of Time-Critical Tasks with High Strength Demands

Some of the studies discussed here suggest that the source of both age and gender differences in performance of tasks that both are time critical and have high strength requirements lies primarily in strengths and speeds of muscle contraction, rather than in sensory processing or motor planning abilities. As pointed out earlier in this chapter, studies of myoelectric latencies for rapid ankle torque development have found no significant gender group differences. These have found statistically significant age-group differences, but the differences in the mean latencies were only approximately 10 to 20 milliseconds, whereas the total times needed to develop near-maximum torques were on the order of 400 to 600 milliseconds. They showed that age-group differences in the use of cocontraction were not responsible for the age-group differences in torque development rates. Studies of mean reaction times have also found statistically significant age-group differences in those times. However,

those differences were only approximately 10 to 20 milliseconds, whereas the total response times ranged approximately from 400 to 800 milliseconds. No substantial gender differences were found in those reaction times. This suggests that, among healthy older compared with young adults and among females compared with males, differences in rapid torque development abilities, noted earlier in this chapter, and differences in performance of tasks that are both time critical and have high strength requirements seem largely because of differences in strengths and speeds of muscle contraction once contraction is initiated, rather than because of delays in initiating contraction.

The outcomes of the studies described, and those from other studies reported in the literature, suggest that healthy older compared with young adults, and healthy older females compared with older males, are more at risk of injury in tasks that both are time critical and have high strength requirements. Time-critical obstacle avoidance tasks involve rapid visual processing, rapid triggering of preplanned strategies, and rapid execution of movements, during which whole-body balance must be maintained. Among healthy adults, the times needed for the visual processing and response triggering phases are a few hundredths of a second longer for old than for young. In contrast, the times needed for movement execution are a few tenths of a second longer for old than for young. Almost exclusively because of these longer movement execution times, the warning times that older compared with younger adults need to perform successfully time-critical tasks with high strength requirements are a few tenths of a second longer. Although differences of a few tenths of a second in abilities to respond are not usually important, circumstances leading to needs for time-critical, high-strength responses probably combine at random. Sometimes, the consequence of needing a few tenths of a second longer to execute avoidance or recovery maneuvers may not be small, and that need, when circumstances combine unfavorably, may substantially lower the probability of regaining balance or avoiding a fall-related injury. The ability to perform these avoidance and recovery maneuvers usually involves stepping, and well-established clinical tests of these time-critical stepping responses do not yet exist. Tests of voluntary maximal distance and high-speed stepping are being evaluated.

## CONCLUSIONS

Research findings to date regarding the biomechanics of mobility among healthy older adults suggest the following:

1. In activities such as ambulation, chair and bed rise, and postural responses to small perturbations, performances of healthy older adults are often remarkably similar to those of the young. Age-group differences among healthy adults that seem biomechanically significant have been found in only certain kinds of tasks.
2. Age differences in performances of many tasks apparently seldom arise from limitations in joint ROM. Only a few physical tasks present substantial joint ROM requirements.
3. Similarly, those differences apparently arise only in some circumstances from limitations in joint torque strengths. The strength requirements of many daily tasks, excluding time-critical tasks requiring high strengths and certain kinds of transferring tasks, are modest compared with the available strengths of healthy old adults.

4. There are substantial age and gender differences in abilities to develop joint torques rapidly, but these differences generally seem to be of importance chiefly in performing time-critical tasks requiring high strengths and/or powers.

5. When significant age differences in responses have been found, those differences appeared seldom to depend in major ways on age differences in latencies or reaction times. Under many circumstances, the age differences that do exist in sensing and neural processing times are small compared with total response times.

6. In performing time-critical tasks requiring high strengths, for which major age differences arise, these presumably arise because of age differences in the muscle contraction physiology underlying the biomechanical response execution.

7. Cognitive and other psychological factors, such as risk-taking preferences, have a substantial role in mobility task performance.

8. Age-related declines in mobility function appear during performances of tasks that are physically and/or cognitively very challenging at much younger ages than these appear in tasks that are easily performed.

9. Gait tests performed on an irregular surface appear to discriminate age and disease effects better than gait tests conducted on a flat surface.

# Exercise: Physiological and Functional Effects

*Robert S. Schwartz* ■ *Wendy M. Kohrt*

## AGING, DISUSE, AND DISEASE

A common belief among the lay public, as well as among many health-care professionals, is that much of the disease and loss of function that commonly accompanies aging is inevitable and a result of the “aging process” itself. However, it has become clear that much of the physical decline and reduced physiological reserve previously blamed on aging is, in fact, caused by the complex interactions of true genetically determined aging, disease (often subtle or subclinical), disuse, and environmental exposure.

The myriad of possible interrelationships among these factors makes it difficult to ascribe specific causality for the loss of physical vigor or function. Thus, for example, preconceived societal notions about aging may predispose to greatly reduced expectations with regard to physical as well as mental performance. Such preconceptions may promote inactivity and disuse in women at an even earlier age than in men. With years of ensuing inactivity, disuse not only exaggerates and enhances any true age-related loss of endurance, strength, and flexibility, leading to further inactivity and disuse, but may also exacerbate previously subtle or subclinical diseases such as intra-abdominal obesity, glucose intolerance, osteopenia, hypertension, dyslipidemia, and coronary artery disease. These physiological disorders, the drugs used in their treatments, and the associated functional impairments and disability can, in turn, further limit activity and continue the vicious downhill spiral.

Physical activity level (and measured fitness) appears to be inversely related to the risk of mortality and is associated with a greater average life span (approximately 2 years in human studies). An inverse dose–response relationship has also been noted between physical activity and the risk of developing many important diseases (cardiovascular disease [CVD], stroke, hypertension, type 2 diabetes, osteoporosis, obesity, colon and breast cancer, anxiety, and depression). Many of these reports included older adults. Despite the clear advantages to physical activity, less than 40% of persons 65 years

and older meet the CDC recommendations for activity, and this percentage falls significantly further in older age groups.

This chapter reviews the physiological effects of aging and exercise training on the most common measures of physical fitness: (1) endurance or maximal aerobic exercise capacity, (2) skeletal muscle strength and power, and (3) body composition. Next, it investigates the theoretical relationship between fitness and functional status, reviewing the available, albeit somewhat limited, data on the effects of increased activity on functional performance. The chapter then reviews the effects of aging and activity on disorders commonly observed in geriatric patients. Last, the risks associated with exercising are discussed and some suggestions are made with respect to prescribing an exercise program for older individuals.

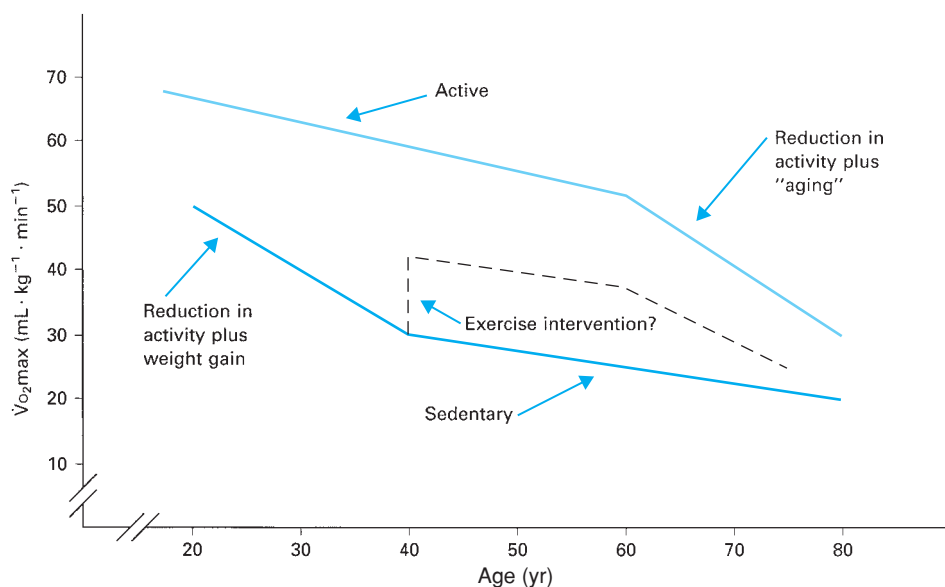

While we and others commonly discuss health benefits of “exercise training,” it is now abundantly clear that many benefits can be accrued simply through a more active (nonsedentary) lifestyle in the absence of formal “exercise training.” This concept may be especially helpful in trying to encourage older individuals who feel unable or unwilling to engage in formal exercise training but can and will increase their physical activity.

## AGING AND EXERCISE

### Endurance (Aerobic) Exercise Capacity

#### Aging-Associated Changes in Endurance Exercise Capacity

The best physiological measure of endurance work capacity is the amount of oxygen consumed at maximal exercise (maximal aerobic power or  $\text{VO}_{2\text{max}}$ ). Cross-sectional studies have repeatedly demonstrated a significant age-related decrement in  $\text{VO}_{2\text{max}}$  in both women and men. Together, these cross-sectional data suggest that exercise

**FIGURE 114-1.** Possible interindividual differences in the age-related decline in  $\text{VO}_{2\text{max}}$ . The possible effects of regular physical activity (or lack thereof) and the inevitable decline at advanced age are depicted. (Reproduced with permission from Buskirk ER, Hodgson JL, *Fed Proc.* 1987;46:1824.)

capacity declines by approximately 1% per year, when  $\text{VO}_{2\text{max}}$  is expressed as milliliters of oxygen consumed per minute per kilogram of body weight (e.g., mL/min/kg). Longitudinal data in this area are somewhat more confusing, probably owing to (1) variation in the initial level of fitness of the subject populations, (2) spontaneous modifications in activity level between test periods, (3) alterations in body weight and composition, and (4) intervening illness. It is possible that the data are further influenced by a nonlinear decline over time (Figure 114-1), with a more rapid decline in  $\text{VO}_{2\text{max}}$  in early adulthood in sedentary individuals followed by a less steep decline later in life. Longitudinal studies in both men and women demonstrate approximately a 0.5 mL/min/kg decline per year after a 4-year follow-up period. Almost half of this decrement could be accounted for by independent changes in adiposity and self-reported physical activity.

Both cross-sectional and longitudinal approaches have been used to determine whether habitual endurance training slows the age-related decline in  $\text{VO}_{2\text{max}}$ . Cross-sectional comparisons of younger and older endurance athletes and normally active controls indicate that the slope of the regression line for age-related decline in  $\text{VO}_{2\text{max}}$  is not as steep in athletes as in their more sedentary counterparts. In fact, these comparisons suggest that habitual exercise may attenuate the rate of decline in  $\text{VO}_{2\text{max}}$  with aging by up to 50% (0.5% vs. 1.0% per year). Longitudinal studies of older endurance-trained men, followed for more than 10 to 22 years, indicate that the slower decline in  $\text{VO}_{2\text{max}}$  occurs only in men who continue to train vigorously for competition. One study followed both sedentary and trained men, and the average rate of decline in  $\text{VO}_{2\text{max}}$  was higher in the athletes than in the nonathletes (−2.9% vs. −1.5% per year). When athletes were characterized by the level of exercise training they maintained, the rate of decline was −0.3% per year in those who trained vigorously, −2.6% per year in those who trained moderately, and −4.6% per year in the low-training group. However, even in the low-training group,  $\text{VO}_{2\text{max}}$  remained higher at follow-up (33.8 mL/min/kg; age 74 years) than in the sedentary controls (25.8 mL/min/kg; age 70 years). Thus, the higher fitness levels of active individuals may afford them protection later in life, by allowing them to remain above the threshold of exercise capacity necessary to remain functionally active.

### The Peripheral Components of Endurance Capacity

$\text{VO}_{2\text{max}}$  is equal to the product of maximal cardiac output ( $Q_{\text{max}}$ ) and the maximal ability of muscle to extract oxygen from the blood ( $a\text{-VO}_2$  difference) and, thus, is determined by both central (cardiovascular) and peripheral (primarily muscle) components. Studies have uniformly detected important changes in body composition associated with aging (see the following section on body composition), including increases in fat mass and decreases in fat-free mass (FFM) or lean body mass (LBM). Furthermore, with aging, muscle mass comprises a lesser percentage of what is usually measured as FFM. Several studies of carefully screened older subjects confirm that differences in FFM can explain some of the age-related differences in  $\text{VO}_{2\text{max}}$ . In a cross-sectional study of very healthy men and women, muscle mass, as reflected by 24-hour creatinine excretion, was found to decline 23% between ages 30 and 70 years. When normalized for this decrease in muscle mass, the slope of the decline in  $\text{VO}_{2\text{max}}$  with age flattened significantly, and the predicted age-related decline in  $\text{VO}_{2\text{max}}$  between the ages of 30 and 70 years was reduced in both men (39% vs. 18%) and women (30% vs. 14%). Approximately half of the original age-related decline in  $\text{VO}_{2\text{max}}$  could be explained by the age-associated loss of muscle mass. Other peripheral mechanisms might also account for some of the age-related decrement in  $\text{VO}_{2\text{max}}$  by attenuating the  $a\text{-VO}_2$  difference, including a reduced ability to direct blood flow to the working muscles or a diminished ability of muscle cells in older (inactive) individuals to use oxygen.

### The Central (Cardiovascular) Component of Endurance Capacity (See Chapter 74)

Declines in the central (cardiovascular) component of endurance capacity contribute substantially to the age-related reduction in  $\text{VO}_{2\text{max}}$ . In the absence of hypertension or coronary artery disease (clinical or asymptomatic), resting cardiac output, heart rate, and heart size are normal in older individuals. However, as illustrated in Figure 114-2, a number of age-related changes in resting cardiac function have been defined. These cardiovascular changes detected at rest in the elderly person are quite similar to those observed with hypertension. Indeed, it has been hypothesized that mild vascular

**FIGURE 114-2.** The interplay of vascular changes and adaptive cardiac changes that occur to varying degrees with aging in otherwise healthy individuals. (Reproduced with permission from Lakatta EG, *Eur Heart J.* 1990;11(suppl C):22.)

stiffness and ensuing subclinical hypertension may initiate this group of compensatory responses noted at rest.

As with most age-related abnormalities, alterations in cardiovascular physiology are most apparent and most clinically relevant during stress, such as physical exercise. In the setting of maximal exercise, striking differences between young and older individuals are apparent. By far the most salient and consistent is a marked decline in maximal heart rate with age. However, beyond this one finding, there is little agreement. While some studies suggest that most of the age-related decrement in  $\text{VO}_{2\text{max}}$  is explained by a decline in cardiac output, others detect little decrease in maximal cardiac output with age. In fact, the majority of studies now support the concept that diminished central responses to maximal exercise substantially contribute to the reduced  $\text{VO}_{2\text{max}}$  with aging. The degree to which this defect can be explained by a lower maximal heart rate or a reduced stroke volume response to exercise remains unclear.

## The Physiological Effects of Endurance Exercise Training

### Effects on $\text{VO}_{2\text{max}}$

Certain individuals (e.g., master athletes) can maintain a reasonably high endurance exercise capacity well into old age. It is now clear that the fitness response to an endurance training program in previously sedentary, healthy older individuals is comparable to that in younger subjects. Depending on the type and duration of exercise employed, the improvement in  $\text{VO}_{2\text{max}}$  typically varies between 10% and 30%, with similar responses in both men and women. Furthermore, when young and older subjects are trained in the same program at the same relative intensity, the relative increments in  $\text{VO}_{2\text{max}}$  are similar.

Healthy older individuals can tolerate carefully supervised endurance training at relatively intense levels (e.g., 85% of heart rate reserve;  $\text{HRR} = 0.85 [(\text{HR}_{\text{max}} - \text{HR}_{\text{rest}}) + \text{HR}_{\text{rest}}]$ ) with acceptable attrition rates and few, if any, significant injuries. Indeed, it appears that speed is a more important determinant of injury than the actual overall intensity of the exercise. However, few older individuals choose to maintain this rigorous training intensity on their own, and a clinically more salient question is whether qualitatively similar adaptive responses can occur with lower-intensity training. Although not all studies agree, it appears that cardiovascular improvement can be obtained with moderate-intensity programs, where subjects train at approximately 50% of heart rate reserve. In addition, metabolic improvements can occur with low- to moderate-intensity exercise that is maintained over a sufficient period of time (see below). New recommendations suggest that multiple short (10 min) bouts of exercise may be comparable to a single larger training session.

### Effects on Body Composition

As noted above, with aging there is a significant loss of FFM or LBM, mostly accounted for by a reduction in skeletal muscle mass. This decline has been estimated to be approximately 6% per decade between ages 30 and 80 years, although recent studies have suggested slower rates of decline. It is possible that the increasing prevalence of obesity has a “preserving” effect on LBM. Despite the loss of LBM with aging, body weight is sustained or increased as a result of the accumulation of adipose tissue. In fact, excess body fat is a stronger determinant of impaired physical function of older adults than is inadequate LBM. More importantly, with aging, fat is preferentially accumulated in a central distribution. This centralization of body fat seems to occur continuously with age (after puberty) in adult men, but, in women, a significant increase in central adiposity first occurs following menopause. This central distribution of adipose tissue mass is a major risk factor for many obesity- and age-related metabolic abnormalities and, in many studies, is independent of relative weight or other measures of obesity.

In cross-sectional studies comparing highly physically active older individuals with more sedentary controls, overall adiposity in the active group is consistently lower and, in fact, similar to younger individuals. This is true for both women and men, with the physically active groups having approximately 10% less body fat than sedentary controls. Furthermore, there is an inverse correlation between  $\text{VO}_{2\text{max}}$  and central adiposity, as defined by waist-to-hip ratio, within a population of healthy older men. However, relatively little difference in FFM or LBM has been observed in active, as compared to sedentary, healthy elderly persons. Therefore, even highly endurance-trained older individuals have significantly less LBM than do younger individuals.

Longitudinal endurance training studies in previously sedentary individuals support these cross-sectional findings. Endurance training has consistently produced small but significant decrements in percent body fat and overall fat mass in older men and women. In two studies, a loss of 2.5% body fat (1.5–3 kg of fat mass) followed a 6- to 12-month intensive endurance-training program in older subjects. Associated with this modest decrement in overall adiposity was a preferential decrease in the central distribution of fat. In fact, following endurance training in older men, there was a small fall in waist-to-hip ratio, but a 20% decline in intra-abdominal fat as measured by computed tomography. In contrast to the modest

but consistent decrements in adiposity, little or no change in overall FFM has been detected following endurance training in the elderly population, even when it is quite vigorous. The lack of improvement in overall FFM may be countered by significant changes in specific muscle groups. For example, cross-sectional mid-thigh muscle mass, measured by computed tomography, was found to increase by 10% in older men, despite no change in overall FFM. This finding suggests a redistribution of FFM with intensive endurance training in older men. The lack of accretion of FFM with endurance exercise in older individuals may reflect a reduced anabolic hormonal milieu, with lower levels of sex steroids, growth hormone, and insulin-like growth factor I.

Although highly trained athletes are leaner than less-active controls, the loss of weight or fat with endurance training is small when compared to dieting with caloric restriction. However, as noted above, the effects of exercise may be magnified by the preferential loss of central, and specifically intra-abdominal, fat with endurance training. Endurance training can increase the usually low resting metabolic rate in the elderly person by approximately 10%, even when corrected for any observed change in FFM. It should be noted that vigorous exercise in older subjects might be associated with a compensatory decrement in activity during nonexercising periods and, thus, no increment in overall energy expenditure. Concomitant exercise training was found to be associated with a lower rate of long-term recidivism in subjects participating in a dietary weight reduction program. Exercise may mitigate the drop in resting metabolic rate, lipolysis, and fat oxidation that usually accompany dietary caloric restriction, which would otherwise lead to rapid regain of lost weight. While there are fewer data available, it appears that strength training has many of the same effects of endurance training on adiposity.

A preliminary report of 10 days of continuous bed rest in healthy older subjects dramatizes the importance of activity and the tremendous costs of being sedentary. After even such a short period of time, healthy older subjects experienced a 30% reduction in muscle protein synthesis, a 1.5 kg loss of lean mass (most from the lower extremities), and a 16% decrement in lower extremity strength.

### Effects on Cardiac Function

Although cross-sectional studies suggest a significant age-related decline in cardiac output (see previous discussion), training status appears to positively affect this end point, with a greater maximal cardiac output found in well-trained older men and women when compared to matched sedentary controls. Most of the higher  $\text{VO}_{2\text{max}}$  in trained older individuals can be explained by their higher maximal cardiac output. In turn, a larger stroke volume explains the higher cardiac output, whereas no difference in maximal heart rate is detected between trained and untrained individuals. The relation between  $\text{VO}_{2\text{max}}$  and left ventricular performance seems to be linear over a wide range of fitness levels, suggesting that similar improvements could be expected with training, no matter what the initial fitness level.

Longitudinal studies of endurance training in previously sedentary older subjects have provided conflicting results on cardiac function. Initially, some found no improvement in estimated cardiac output following either low- or high-intensity endurance training. However, studies using more sensitive methods and more vigorous exercise training interventions provided evidence of enhanced left

ventricular systolic and diastolic function. There is some evidence for a sex- and age-specific difference in the left ventricular response to endurance training, with an improvement in diastolic function demonstrated in young and older men and possibly only in young women. Others have been unable to show significant differences in left ventricular diastolic filling dynamics between older trained and sedentary men, with both being reduced compared to young controls.

The finding in some studies that older women do not increase maximal cardiac output in response to endurance exercise training, but that older men and young women and men do, raises the question of whether estrogens could be involved in this adaptation. When older women, either on or not on estrogen-based hormone therapy, underwent a 20-week endurance exercise program of stationary cycling, both groups of women had similar increases in estimated cardiac output at peak exercise in response to training. This contradicts previous findings, but it should be noted that the methodology used to evaluate cardiac function was not as sophisticated in this study as in the others, which found that maximal cardiac output did not increase in older women not on hormone therapy. The role that estrogens play in the cardiovascular adaptations to exercise, therefore, remains uncertain.

### Effects on Endothelial Function

Vascular aging, including a decrease in large elastic artery compliance (increased stiffness) and vascular endothelial dysfunction, is a major independent risk factor for age-associated CVD in both women and men. In sedentary adults, arterial compliance and endothelial function decreases with advancing age even in the absence of clinical CVD. Cross-sectional studies demonstrate that the age-related loss of arterial compliance is attenuated in middle-aged and older endurance-trained men. Endurance training also mitigates the negative effects of estrogen deficiency on arterial compliance in postmenopausal women. Additionally, vascular endothelial function is preserved in endurance-trained men. Longitudinal studies demonstrate that short-term aerobic exercise programs (e.g., walking) can restore some of the age-associated loss of arterial compliance and completely restore endothelial function in previously sedentary middle-aged and older men. In previously sedentary postmenopausal women who chronically take hormone therapy, short-term aerobic exercise can restore arterial compliance to premenopausal levels.

## SKELETAL MUSCLE STRENGTH AND POWER

Strength can be defined as the maximum force exerted by a muscle, and power is the rate of force development. Strength and power are not determined by muscle mass alone but also by intact neurological function. Consequently, as discussed in more detail below, strength and power can be increased by improving muscular function (e.g., muscle cell hypertrophy) or by improving neurological function (e.g., learning).

Strength assessment depends on the conditions of measurement, specifically the speed of muscular contraction, whether the muscle is shortening (concentric) or lengthening (eccentric) during the contraction, and the conditions of mechanical leverage. Muscle strength can be measured during isometric, isotonic, or isokinetic contractile activity. Isometric strength is the force generated against a fixed

object, and isotonic strength is the force generated against a moving object (i.e., free weights and most resistance-exercise machines). Isokinetic strength also involves the generating force against a moving object, but, in this case, the speed of movement is controlled and constant. Muscle power can be determined simultaneously with the assessment of either isotonic or isokinetic strength by measuring the speed of movement.

### Aging-Associated Changes in Muscle Strength and Power

For more than 100 years, cross-sectional studies have demonstrated that strength declines with age. After peak strength is reached sometime around the age of 40 years, cross-sectional studies show approximately a 30% to 40% reduction in strength by the age of 80 years. Longitudinal studies suggest that the true rate of decline may be underestimated by the cross-sectional data. For example, a longitudinal study estimated a 60% loss of handgrip strength between ages 30 and 80 years, while a cross-sectional analysis of the same data estimated loss at only 40%. Strength loss appears even more rapid at greater ages. Longitudinal studies have found approximately a 10% to 25% loss in quadriceps strength within only 5 to 7 years in 70-year-old adults. In the majority of these studies, muscle power was not measured. However, there is growing evidence that the rate of decline in muscle power is even greater than the decline in strength. Measurements of muscle strength and power for more than 10 years in the Baltimore Longitudinal Study on Aging indicated that the decline in muscle power was approximately 10% greater than the decline in strength.

It is now clear that the decline in muscle power is a stronger determinant than muscle strength of physical functional status in old age. This is not surprising if the decline in power is, indeed, more pronounced than the decline in strength. Leg muscle power was reduced in older women prone to falling, as compared with nonfallers, and was a stronger predictor than strength of self-reported functional status in elderly women. These findings suggest that intervention strategies should be aimed not only at preserving muscle mass and strength with aging, but also muscle power.

### Muscle Mass

A close relationship exists between the size of a muscle, measured as cross-sectional area, and its ability to generate force. One would predict, then, that a 40% decline in muscle strength should be accompanied by a decline in muscle mass of a roughly equal amount—approximately 30% to 40%. This is the case, and, just as strength loss is more rapid at greater ages, loss of muscle mass is also reported as becoming more rapid with age. In laboratory animals, there is also an age-related decrease in muscle-specific force, which is the peak force per cross-sectional area. Single muscle fiber characteristics of tissue obtained from younger and older men and older women also indicate that the reduction in the capacity to generate force with aging is not solely a result of the reduction in fiber size or muscle mass and raise questions about how muscle fiber function and composition change with aging.

### Muscle Fibers

Skeletal muscle is comprised of groups of individual muscle fibers. These fibers contain myofibrils, which are, in turn, composed of a

number of myofilaments. The myofilaments contain the proteins actin and myosin and are arranged to form sarcomeres—the contractile units of muscle.

There are two major types of muscle fibers: slow twitch and fast twitch. Furthermore, there are at least three subtypes of fast-twitch fibers: a, b, and c. The fast-twitch fibers are variously referred to either as FTa, FTb, and FTc or as type 2a, type 2b, and type 2c. The slow-twitch fibers are referred to as ST or type 1 fibers. Type 1 fibers can sustain tension for long periods, are slow to fatigue, and have high oxidative (aerobic) capacity. Type 2 fibers can rapidly develop high tension, but only for short periods of time, and have high glycolytic (anaerobic) capacity. Types 2a, 2b, and 2c fibers all differ in their relative oxidative capacity.

The evidence that muscle mass decreases with aging is unequivocal. There is less certainty regarding the extent to which this is caused by a loss of muscle fibers versus a decrease in fiber size. There is a loss in the number of muscle fibers with age, but whether some fiber types are lost more rapidly with age remains controversial. Some evidence suggests that type 2 fibers are lost more rapidly than type 1 fibers. Opposing evidence suggests a more rapid reduction in type 2 fiber size with age but not a more rapid reduction in the total number of type 2 fibers. One factor that may contribute to the variation in these findings is the tremendous plasticity of skeletal muscle. Fiber cross-sectional area, and even the relative proportion of fiber types, may reflect the response to existing or recent physical activity patterns. That is, type 2 fiber loss and/or atrophy could be caused by an age-related change in activity patterns. As older adults perform fewer activities requiring rapid development of muscular force, they may have selective reduction in the type 2 fibers that are required for such activities.

### Motor Units

Muscle function depends on the coordinated activity of groups of muscle fibers and the motor neuron that innervates them, i.e., the motor unit. The motor neuron appears to control the size, contraction time, resistance to fatigue, and enzyme activity of the muscle fibers it innervates. Hence, neuronal mechanisms could account for many age-related changes in muscle fibers. There is growing evidence that the number of motor units decreases with age. This conclusion is supported by electromyographic studies that suggest a loss of functional motor neurons with age. Indeed, the loss of motor units may even exceed the loss of neurons.

### Muscle Quality

The concept that the quality as well as the quantity of muscle declines with aging has emerged in recent years, although there is no consensus regarding the factors that determine muscle quality or how it should be measured. It has been suggested that muscle quality encompasses many factors (e.g., structural composition, innervation, contractility, capillary density, fatigability, intramuscular fat content, protein metabolism, mitochondrial function, oxidative damage, and glucose metabolism). In general, there is an age-related deterioration in most factors that are thought to influence muscle quality. However, whether these are inevitable consequences of aging seems unlikely, as almost all respond favorably to increased physical activity.

### Disuse versus Aging

There is some epidemiological evidence that regular physical activity may prevent some of the age-related loss in strength. However, when activities are classified as to their expected effects on muscle strength, epidemiological studies have probably focused on a relatively narrow range of activity near the middle of the continuum. At one end of the continuum is bed rest. Bed rest is associated with a dramatic loss of strength—estimated as high as 1% to 5% per day. At the other end of the continuum is vigorous strengthening exercise (discussed below), which produces substantial gains in strength in older adults.

It is this perspective, integrating findings from studies of bed rest, epidemiology, and experimental interventions, that most clearly suggests that age-related losses in strength are mainly a result of age-related changes in physical activity. As a corollary, epidemiologic studies of adults with similar activity at all ages should show little or no loss in strength. Indeed, a cross-sectional study of workers at a machine shop showed no decline in grip strength between the ages of 20 and 60 years. But aging per se appears to have some role in loss of strength, as, at some point during life, strength will begin to decline despite continued activity patterns.

### The Physiological Effects of Strength Training

Strength training (resistance exercise) can be done in several ways. Unfortunately, at present there is no standard training program and little agreement on a preferred training method. In general, resistance exercise regimens typically involve either a high number of repetitions at a moderate level of resistance or a few repetitions at a high level of intensity. The former is aimed more at improving muscle endurance, while the latter is aimed more at increasing muscle strength. Analogous to the way in which strength can be measured, strength training can involve isometric, isotonic, or isokinetic exercises. The majority of equipment used for resistance training (i.e., free weights and machines) involves isotonic contractions. The relative level of intensity is usually based on the maximal weight that the subject can lift one time (the one-repetition maximum or 1RM).

Most resistance-training programs involve performing a prescribed number of sets (usually one to three) of each exercise, with a specific number of repetitions in each set, at a prescribed percentage of the 1RM. The number of repetitions that are performed depends on the relative intensity of each repetition. For example, at an intensity of 70% of the 1RM, people can typically perform 10 to 12 repetitions of an exercise, but at 80% of the 1RM usually only six to eight repetitions can be completed. When multiple sets of each exercise are performed, the relative intensity may be fixed for each set (e.g., 80%), increase with each set (70%, 80%, and 90%), or decrease with each set (90%, 80%, and 70%); whether one method is more effective is not certain. Once a subject can complete the proscribed number of repetitions in each set, a fresh prescription is written, based on a newly determined (higher) 1RM. New recommendations from the American College of Sports Medicine and the American Heart Association suggest one set of 10 to 15 repetitions for eight to 10 separate exercises on two nonconsecutive days should be undertaken by older adults.

In marked contrast to the effects of endurance exercise on vascular function and structure, the effects of chronic resistance training are less well studied and may be potentially detrimental. The age-related decrease in arterial compliance appears to be greater in resistance-

trained compared with age-matched sedentary men, and resistance training is associated with a lower rather than a higher arterial compliance in middle-aged men. Additionally, large elastic artery compliance decreased following a 4-month resistance-training program in young healthy men. The reasons for these observations are unclear. One likely explanation is that acute intermittent elevations in arterial blood pressure that occur during resistance training may produce increases in the smooth muscle content of the arterial wall and enhance the load-bearing properties of collagen and elastin. A second possibility is that the higher baseline sympathetic nervous system activity in resistance-trained individuals may reduce arterial compliance via greater sympathetic adrenergic vasoconstrictor tone. It is possible that the nature of the adaptive process of the arterial wall may be even greater in older adults because their arteries have already undergone some untoward changes owing to the aging process. When combined with an endurance training program, the potentially detrimental effects of resistance training on arterial compliance appear to be mitigated. The effects of resistance-training on age-associated changes in vascular endothelial function are presently unknown.

### Effect on Muscular Strength and Power

Historically, the majority of exercise intervention studies in older adults involved endurance exercise. More recently, there has been a dramatic increase in the number of resistance training studies. These have been primarily isotonic, fixed-resistance exercise programs lasting 2 to 6 months. Although almost all studies report that resistance training increases the strength of older adults, there is tremendous variability in the magnitude of the reported strength gains (from a few percent to almost 200%). A number of factors likely contribute to the variability, including the method of measuring strength, the duration of training, the exercise intensity, and baseline characteristics of the sample. Not surprisingly, the largest relative improvements in strength have been reported in frail elderly people in whom a small absolute increase in strength represents a large relative improvement because of their low starting strength levels. Progressive resistance training in older adults produces consistent enhancement in muscle strength, and some studies find functional improvements in areas such as gait speed, stair climb, and chair stand. However, there are few data of effects on disability measures.

A meta-analysis suggests that intensity of training is the most important factor affecting study results. Some studies used low- and moderate-intensity resistance training and reported only modest increases (10–25%) in strength. Other studies of healthy adults, physically unfit adults, and even frail adults have used more vigorous strength training, with resistance typically set at 80% of the 1RM. These studies report substantially larger strength gains (50–200%). Expressed in terms of the cross-sectional distribution of strength in the study samples, subjects improve from 1.0 to 3.5 standard deviations in strength over just a few months with these vigorous training protocols.

Duration of training also affects strength gain. Studies report weekly measurements of 1RMs, and strength continues to increase throughout the training interval, at least up to 6 months. Most studies of strengthening exercise fail to comment on the fact that their results show substantial variability in how older adults respond to strength training. The observed variability occurs despite the use of standard training protocols administered in supervised research settings. The causes of this observed variability remain to be explained.

Resistance training programs aimed at increasing muscular power feature fast concentric (“lift as fast as possible”) and slow eccentric movements (lower for 2–4 seconds), as opposed to equally paced concentric and eccentric movements (2 seconds for each phase) that are typical of strength training. High-velocity or high-power training increases muscular power and improves physical function in older adults beyond that of traditional strength training. However, the optimum training loads have yet to be elucidated and depend, in part, on the desired outcome. For example, greater improvements in standing balance were found with light (20% 1RM), compared to heavier (50–80% 1RM), load high-velocity training, whereas training with the heavier loads was associated with greater improvements in muscular endurance and strength. Longer duration (2 years), high-velocity training may also impart greater benefits to bone. Importantly, in a *supervised* setting and with careful pre-exercise medical screening, adverse event rates have been comparable to that of traditional strength training regimes.

### Physiological Mechanisms Explaining Gains in Strength with Exercise

Resistance exercise causes muscular hypertrophy in older adults, and muscle biopsies show hypertrophy of both type 1 and type 2 fibers. However, modest (10–20%) increases in fiber size or whole-muscle cross-sectional area have been reported to be accompanied by much larger (50–200%) increases in strength. This situation apparently violates the “rule” that muscle cross-sectional area is highly correlated with muscle strength. Actually, it is true in both older and younger adults that, after short-term strength training, there is a discrepancy between the increases in strength and muscle cross-sectional area. Some attribute the increase in strength that cannot be accounted for by hypertrophy as being caused by increased neural recruitment and discharge. In younger adults, the discrepancy appears to be transient, as highly trained individuals show the predicted ratio of strength to cross-sectional area. In older adults, it is unclear how the ratio of strength to cross-sectional area changes over the course of prolonged strength training. However, even very old individuals maintain the capability of increasing the synthesis rate of muscle contractile proteins in response to resistance exercise, suggesting that strength gains in elderly people are mediated both by neural mechanisms and by muscle hypertrophy.

### Exercise, Physical Activity, and Functional Limitations

The question “Can regular physical activity prevent and/or reverse functional limitations and disability in older adults?” is of great public health importance. In discussing this question, we adopt the terminology and framework of the Nagi model of disablement. In the model, etiologic factors (risk factors) include genetic, behavioral, and environmental factors. The effects of these factors on the disabling process can be measured at four distinct levels:

1. Measurements of disease or pathology are made at the cell and tissue level.
2. Measurements of physiological impairment (e.g., muscle strength and  $VO_{2max}$ ) are made at the organ and organ system level.
3. Measurements of functional limitations are made at the behavioral, whole-organism level. Measures of functional limitations range from assessing simple movements (e.g., pushing with the foot) to more complicated movements (e.g., ability to walk as

measured by gait speed) and to sequences of movement (e.g., ability to stand, walk, turn, and sit down).

4. Measurements of disability are made at the level of the interaction of the whole organism with the physical and social environment. For example, a person using a wheelchair has disabilities if stairs are the only means of getting inside and does not have disabilities if there is a ramp.

In this framework, risk factors cause disease, which causes physiological impairment, which causes functional limitations, which causes disability. (The model also includes the possibility of feedback loops and more complicated causal pathways.)

The discussion also makes a distinction between physical activity and exercise. Physical activity can be defined as any movement of the body produced by skeletal muscles that causes energy expenditure. Exercise is a subset of physical activity and can be defined as planned, structured, and repetitive body movement done specifically to improve fitness.

### Evidence That Exercise Improves Functional Limitations

It is intuitive that adults who remain physically active are less likely to experience problems in performing activities of daily life, such as climbing stairs, walking, gardening, and housework. In the framework of the Nagi model, physical inactivity (risk factor) causes muscle weakness and low  $VO_{2max}$  and other physiological impairments, which then cause functional limitations.

This intuition regarding the importance of physical activity in helping to maintain activities of daily life is supported by a number of important epidemiological studies. For example, in the Established Populations for Epidemiologic Studies of the Elderly, older adults who were physically active at the baseline examination were significantly less likely to experience mobility impairments during several years of follow-up. But the crucial issue is whether increasing physical activity levels in normally inactive older adults achieves the same health benefits found in naturally active older adults. A growing number of randomized trials address this issue. The emerging consensus is that exercise improves functional limitations in older adults. However, not all well-designed randomized trials show a beneficial effect of exercise. To illustrate how results vary among studies, consider the following randomized trials. A study of adults aged 75+ years, which compared resistance training and balance training, found that balance training, but not strength training, improved functional balance tasks. A study that compared strength training, aerobic training, and combined training found no effects of exercise on functional limitations. In a study of adults aged 68 to 85 years, walking exercise improved gait speed and SF-36 (Kidney Disease and Quality of Life Short Form 36 Health Survey) role physical scores, while aerobic movement and cycling exercises did not. In a study of older adults with knee osteoarthritis, aerobic exercise, and strengthening exercise caused similar, modest improvements in functional limitations for more than 18 months. Also, few studies have assessed whether regular physical activity (as opposed to exercise) affects functional limitations. This is important, as most adults who are sufficiently active according to public health guidelines do not also participate in regular, structured exercise programs.

The situation may be explained by the plausible argument that the effects of exercise on functional limitations should differ according to (1) type, frequency, duration, and intensity of exercise;

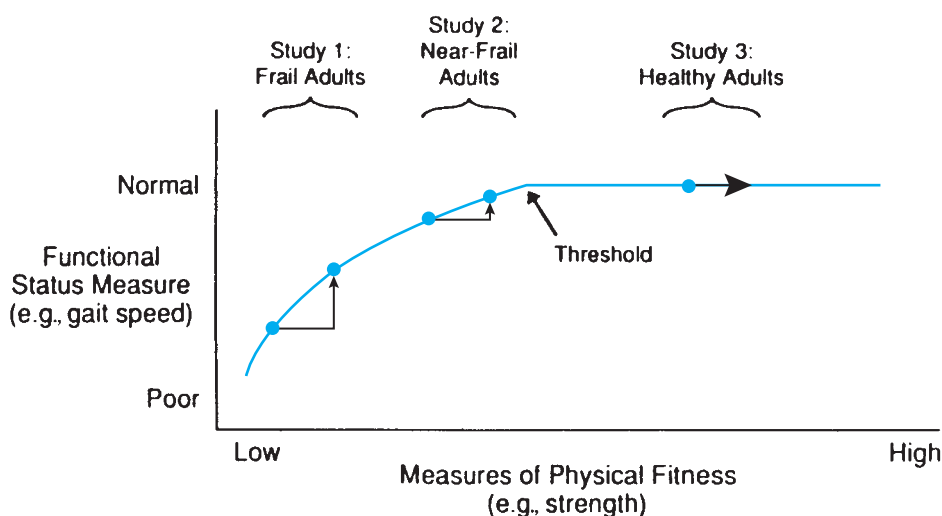

(2) the functional limitations of interest; (3) the method of measuring limitations; and (4) the target population. In particular, the effects of exercise on functional limitations should differ by target population because of a complicated, nonlinear relationship between physiological impairment and functional limitation. As noted above, high velocity training (power training) results in greater functional improvements than low velocity strength training in older adults. End points have included comprehensive performance-based functional assessment tests as well as tests of functional fitness. Power training also improves balance and slows contraction velocity at baseline, leading to balance improvement following the intervention.

### Nonlinear Relationship Between Physiological Impairment and Functional Limitation

Note that nonlinear relationships and thresholds are implicit in the Nagi model. Healthy humans have excess physiological capacity not tapped during most daily activities, so humans can lose a fair amount of physiological reserve before functional limitations occur. Recent epidemiological studies confirm a nonlinear relationship, for example, between leg strength and walking speed. This nonlinear relationship is actually intuitive. After all, if strength was linearly related to walking speed, highly trained weight lifters would walk ridiculously fast (16–30 km/h) because they are several times as strong as normal adults, who walk at around 5 to 8 km/h. That is, above a certain threshold level of adequate physiological reserve, function is normal; below the threshold, function is impaired (Figure 114-3). The exact shape of the curve depends on the task and the physiological capacity of interest. The figure may oversimplify the situation, because most tasks have multiple physiological determinants that may interact to affect behavioral ability.

To illustrate the concepts of thresholds, consider that in steady-state measures of oxygen consumption, walking on a level grade at 5 km/h requires 3.2 METs (1 MET = 3.5 mL O<sub>2</sub>/kg/min). With illness or inactivity, aerobic capacity falls below the level required for daily tasks. Because exercise can increase aerobic capacity, it should improve functional status when aerobic capacity is below the threshold needed for normal daily function. However, aerobic exercise would not affect ability to walk at 5 km/h in adults whose aerobic capacity already greatly exceeded 3.2 METs.

**FIGURE 114-3.** Theoretical relationship between physical fitness and functional status. The curvilinear relationship shows a threshold effect: above the threshold level of fitness, functional status is normal; below it, function is impaired. A curvilinear relationship implies that the benefit from exercise depends on the target group. Three hypothetical exercise studies are shown. Each study produces the same absolute improvement in fitness. In the frail adults of study 1, exercise produces a large improvement in functional status. In the healthy adults of study 3, no benefit is seen. Study 2 shows intermediate benefits. (Data from Buchner DM, et al. Evidence for a non-linear relationship between leg strength and gait speed. *Age Ageing*. 1996;25:386.)

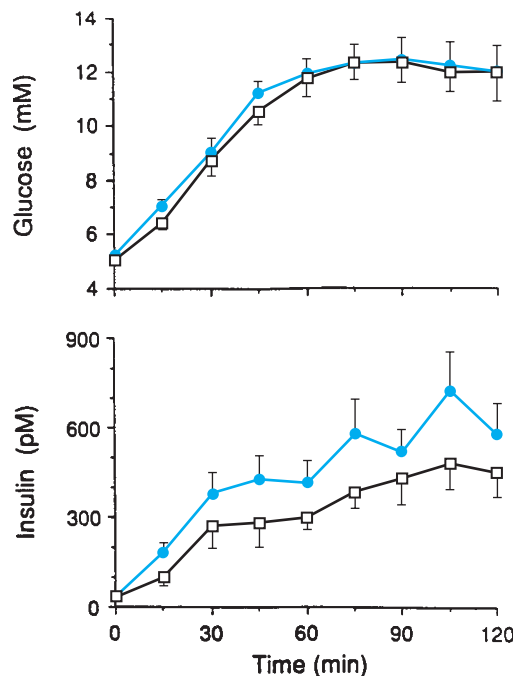

The implication of this model is that the effect of exercise on functional limitations depends on the target group. In frail adults with little or no physiological reserve, exercise theoretically produces a large improvement in function. In general, well-designed studies of exercise in frail adults report improvements in functional limitations with exercise. A randomized trial of 3 months of weight lifting in frail, very old nursing home residents found improvements in gait velocity and stair climbing. Even a 3-month supervised low-intensity exercise program produced a small improvement in physical performance in a group of frail older adults when compared to home-based flexibility training. Similarly, a 3-month task-specific resistance training program improved both the ability and the speed of bed and chair rises in a group of older patients living in a congregate care setting. In contrast, in healthy older adults, exercise would be expected to have much smaller effects on functional limitations, at least in basic activities of daily life. In general, the well-designed studies that do not report an effect of exercise training on functional limitations have enrolled relatively healthy older adults.

It follows that, if exercise has effects on functional limitations in healthy adults, effects will mainly occur with more difficult tasks, and a sensitive measurement tool may be required to ascertain the effects. One randomized trial of general exercise in healthy older adults suggests that this conclusion is true. The measurement used, the Continuous-Scale Physical Functional Performance, is sensitive to changes in functional limitations in the range of difficult tasks. In this study, there was a significant improvement in function noted in generally healthy older individuals following mixed endurance and strength exercise training.

## EXERCISE AND COMMON GERIATRIC DISORDERS

### Insulin Resistance and Glucose Intolerance

Aging is frequently associated with inactivity, increased adiposity, and a central distribution of fat. Because each of these potentially interrelated parameters can be associated with insulin resistance and glucose intolerance, the importance of aging alone has been unclear (see Chapter 109). Indeed, when secondary factors such as relative weight (e.g., body mass index [BMI]), central adiposity, and

**FIGURE 114-4.** Glucose and insulin responses after a 100-g oral glucose load in 13 older subjects before and after 6-month exercise training. Data points, means  $\pm$  standard error. (Reproduced with permission from Kahn SE, et al. *AM J Physiol.* 1990;258:E937.)

hypertension were statistically accounted for, age itself was not a significant independent determinant of the insulin resistance and/or glucose intolerance associated with “aging.”

Immobilization or inactivity is known to be associated with a decline in insulin sensitivity and glucose tolerance. An important effect of physical activity on glucose and insulin metabolism with age is supported by findings of normal or near-normal insulin sensitivity and glucose tolerance in physically well-trained older individuals. Prospective studies have investigated the effects of endurance exercise training on glucose and insulin metabolism in older individuals. For example, following a 6-month intensive endurance training program, no change in fasting glucose or the oral glucose response curve was observed (Figure 114-4). However, both fasting insulin and insulin response to the oral glucose challenge declined, suggesting improved insulin sensitivity. Although quantitative measurement demonstrated a 36% improvement in insulin sensitivity, the sensitivity of the older men remained 30% to 60% lower than that of normal young controls. Because the improvement in insulin sensitivity was balanced by a reciprocal change in insulin secretion, overall glucose tolerance was unchanged. While both endurance exercise and weight loss may reduce insulin resistance in nondiabetic obese men, only weight loss appears to improve oral glucose tolerance. Strength training in older subjects may similarly enhance insulin action.

There are limited data on the effect of endurance exercise training in older patients with type 2 diabetes mellitus. In one study of patients aged 55 to 75 years old, no improvement in either glycosylated hemoglobin or insulin sensitivity was found after 26 weeks of endurance training. It is now generally agreed that most of the metabolic effects of exercise training are transitory and that the observed changes are related more to the effects of repeated acute bouts of exercise rather than a more sustained training effect. A modest

(7%) decline in glycosylated hemoglobin was detected in patients with type 2 diabetes following a 3-month strength-training intervention.

One potentially important role for exercise is in the prevention of type 2 diabetes mellitus in at-risk subjects, such as those with a strong family history of type 2 diabetes, personal history of gestational diabetes, central obesity, impaired glucose tolerance, hyperinsulinemia, hypertension, metabolic syndrome, or a sedentary lifestyle. Large, long-term prospective studies have detected significant reductions in the transition to type 2 diabetes in subjects with impaired glucose treated with a lifestyle intervention (diet and exercise). The Diabetes Prevention Program followed more than 3000 nondiabetic individuals with impaired glucose tolerance randomized to placebo, metformin, or lifestyle treatment for an average of approximately 3 years. The incidence of developing type 2 diabetes was 11.0, 7.8, and 4.8 cases per 100 person-years in the placebo, metformin, and lifestyle groups, respectively. While both the metformin and the lifestyle groups reduced the incidence of type 2 diabetes compared to placebo, the incidence rate with lifestyle intervention was 39% lower than with the metformin intervention group. These impressive reductions in the incidence in type 2 diabetes with the lifestyle intervention occurred with an average of only 6 kg of weight loss and an increase in leisure-time activity of only 6 MET-hr/week. While this study was not specific to older individuals, approximately 16% of the subjects were older than 60 years. It is noteworthy that the lifestyle intervention was even more effective in the older subjects than in younger age groups.

A post hoc analysis of the Diabetes Prevention Program showed a similar effect of interventions on the incidence of new metabolic syndrome (ATP III criteria) with the biggest effect in the lifestyle group. Approximately 50% of the Diabetes Prevention Program subjects met criteria for metabolic syndrome at baseline. Of these, after 3 years of intervention, metabolic syndrome resolved in 38% of the lifestyle, 23% of metformin, and 18% of the placebo group. In a small study of obese (BMI  $\geq 30$ ) older (age  $\geq 65$  years) subjects randomized to a similar lifestyle or control intervention or a control group for 26 weeks, metabolic syndrome resolved in 66% of the lifestyle group compared to none in the control group.

Thus, it appears that endurance training in older individuals produces a response similar to that noted in younger subjects. Insulin sensitivity is improved, as reflected by a decline in plasma insulin levels. Glucose tolerance improves modestly in type 2 diabetic patients but little or not at all in older subjects with normal or impaired glucose tolerance. Although there are fewer data for strength training; the qualitative and quantitative responses appear to be similar. It is as yet unclear whether these changes are related indirectly to alterations in body fat, fat distribution, and/or FFM, or whether these are directly related to the training itself through changes in muscle capillary density or blood flow, fiber type, enzymes, or glucose transporters. Despite relatively unimpressive effects of exercise on overall adiposity or glucose tolerance, exercise-induced changes could be important in the long term, given the accumulating data linking insulin resistance and hyperinsulinemia to diabetes mellitus, hypertension, dyslipidemia, and atherosclerosis. Exercise may play a major role in the prevention or delay in the onset of type 2 diabetes in subjects who are at high risk of its development. The role of exercise in the treatment and prevention of type 2 diabetes is described in a position paper by the American College of Sports Medicine.

## Dyslipidemia

Dyslipidemia is common in the elderly population (see Chapter 110). Higher levels of physical activity are associated with less atherogenic lipoprotein profiles in cross-sectional studies in young and middle-aged individuals. Reduced plasma triglyceride (TG), very-low-density lipoprotein triglyceride concentrations, and higher high-density lipoprotein (HDL)-C, HDL<sub>2</sub>-C, and apolipoprotein A-I levels are consistently observed in trained subjects, when compared to sedentary controls. Of interest is the apparent lack of effect of physical activity on total and low-density lipoprotein cholesterol levels in many studies. However, in one prospective study in older adults (50–75 years), 6 months of endurance exercise positively affected low-density lipoprotein concentration and particle size, an effect that was independent of change in body fat. Neither cross-sectional nor intervention studies show a consistent effect of strength or strength training on lipoproteins.

In young and middle-aged individuals, there is a dose–response relationship between HDL-C and exercise for subjects running more than 10 miles/week but no effect for lower mileage. However, the duration and frequency of the training regimen may affect the relationship between exercise intensity and HDL-C. One study found no increase in HDL-C in older men and women who exercised vigorously or moderately for 1 year. After 2 years of participation, small but significant increments in HDL-C were noted at both exercise intensities. In fact, the increases were somewhat greater in the group that exercised more frequently (five vs. three times per week) at a lower intensity. Weight loss (or fat loss) may be necessary to attain an increase in HDL-C with exercise training, but intra-abdominal fat may be of particular importance in the increase in HDL-C with exercise. This small but metabolically important fat depot may be preferentially affected by exercise with little or no measurable loss of overall weight or adiposity.

There appears to be a difference in the effect of training on plasma lipoproteins between men and women, with women often demonstrating little or no improvement, especially with regard to HDL levels. The reason for this gender-related difference in response is not entirely clear but may relate to more favorable baseline lipoprotein concentrations in premenopausal women, or to differences in training effects on body composition or intra-abdominal fat depots between men and women.

## Hypertension

Drug treatment of hypertension in the elderly population produces long-term benefits, with reductions in stroke, atherosclerotic CVD, or both (see Chapter 81). Despite the known benefits of antihypertensive therapy, the side-effect profile of many drug therapies, especially in elderly people, has led to a resurgence of interest in non-pharmacological treatments (e.g., weight loss, low-sodium diet, and endurance exercise), especially in patients with mild-to-moderate hypertension. The majority of cross-sectional and cohort studies find modestly lower systolic and diastolic blood pressures (approximately 5–10 mm Hg) in active subjects, but the magnitude of the difference is dependent on the type and intensity of exercise, as well as the position in which the blood pressure was measured (with greater differences when the subject is supine). As a whole, studies suggest a greater exercise effect in older subjects and those with mild-to-moderate hypertension.

Two large prospective cohort studies demonstrated that both leisure-time activity and increased fitness, measured by  $\text{VO}_{2\text{max}}$  testing, were protective against the development of hypertension, with the effect being independent of age, obesity, and family history. In these studies, there tends to be a dose–response effect with the lowest risk of developing hypertension in the most active groups. In a cohort study of nearly 3000 middle-aged men and women, the relative risk of developing hypertension during the 10-year follow-up period was 1.7 in the least, as compared to the most, active group of men. A quantitatively similar but nonsignificant trend was noted for women. A 25-year follow-up of a prospective cohort study of men born in Malmo, Sweden, in 1914, found that hypertensive men who regularly exercised vigorously had an adjusted relative risk of 0.43 for total mortality and 0.33 for cardiovascular mortality.

Exercise intervention studies have frequently demonstrated small decrements in blood pressure after chronic endurance training. However, some of these had no true control group and are difficult to interpret given the well-known blood-pressure-lowering effect of participating in a study in control groups. A meta-analysis of 54 randomized controlled studies found a 3 to 4 mm Hg decline in both systolic and diastolic blood pressure with standard endurance training programs. While the number of studies comparing different intensities of exercise is small, it appears that the blood-pressure-lowering response to low- to moderate-intensity exercise is at least as good, if not superior, as that of more vigorous exercise. Indeed, even light T'ai Chi exercise can reduce blood pressure in sedentary older hypertensive patients. While older subjects with orthostatic hypotension must be careful of the hypotensive effect of an acute bout of strenuous exercise, chronic endurance exercise training may be useful in the treatment of patients predisposed to orthostatic dizziness and presyncope.

The blood-pressure-lowering effects of exercise are also found when ambulatory blood pressure monitoring is measured in older hypertensive patients, although it appears that most of the effect occurs during the daytime hours. Using ambulatory blood pressure monitoring, it appears that there is a positive relationship between blood pressure lowering (amount and duration) and the intensity of an acute bout of exercise.

There is, at present, no agreement on the possible etiology of any of the exercise-related effects on blood pressure in older individuals, although changes in body composition, fat distribution, sympathetic nervous system activity, and insulinemia have all been postulated. Both salt restriction and exercise have effects on arterial stiffness measures, with a threefold greater effect from salt restriction as compared to exercise. Weight loss alone or combined with exercise provides greater blood pressure lowering than exercise alone. Exercise also appears to restore the age-associated decline in cardiovagal baroreflex sensitivity in sedentary older subjects.

The available data on the effect of strength training on blood pressure are more limited, and at present there is no consensus. Excessive blood pressure elevations can be seen during high-intensity resistance training, especially if associated with Valsalva. However, with low- to moderate-intensity strength training and proper breathing techniques this is not a concern. Meta-analyses of randomized controlled trials of progressive-resistance-training effects on resting blood pressure revealed a 3 mm Hg drop in both systolic and diastolic blood pressure. Although less than found with endurance exercise, this degree of BP reduction has been associated with significant cardiovascular improvement. Despite the decline in resting BP

with strength training, several studies have detected worsening of arterial compliance. The clinical significance of such findings remains to be determined. As noted above, the positive effects of endurance exercise on vascular resistance and endothelial function may not also be associated with resistance training.

### Atherosclerotic CVD and Overall Mortality

An important effect of increased activity in reducing the risk of atherosclerotic CVD is supported by (1) population studies demonstrating a low prevalence of ischemic heart disease in extremely active societies, (2) retrospective studies comparing rates of heart disease in workers with active versus sedentary jobs, and (3) studies where activity mitigated the deleterious effects of a diet high in saturated fat and cholesterol in monkeys. Several large prospective cohort studies in humans also support this hypothesis. Paffenbarger's classic study of Harvard alumni found a greater than 50% reduction in the risk for heart attack in subjects expending more than 2000 kcal per week in leisure-time physical activity. Furthermore, it was present, not college, activity level that was inversely related to risk. Published multi-year follow-up studies of men who were middle aged at baseline confirm the importance of activity in protecting against CVD and reducing all-cause mortality. The 16-year follow-up of the Multiple Risk Factor Intervention study found excess CVD and all-cause mortality (29% and 22%, respectively) when comparing the least active (5 min of leisure-time physical activity per day) with those with light-to-moderate activity levels (23 min/d) and found no additional protection from more vigorous activity schedules. This study strongly supports the excess risks inherent with a sedentary lifestyle and suggests that even low-to-moderate activity can ameliorate much of this risk. The 20-year follow-up of the Goteborg Primary Prevention study evaluated both leisure- and workplace-related activity in men aged 47 to 55 years at baseline. They detected higher all-cause mortality in men with the greatest work-related activity, which was accounted for by smoking, alcohol, and occupational hazards. Leisure-time activity was associated with a relative risk of approximately 0.7 for both CVD and overall mortality when comparing the most and the least active groups. This protective effect of leisure-time activity was independent of other major risk factors. A 12-year follow-up of the Honolulu Heart study in 707 nonsmoking Japanese men living in Hawaii (ages 45–68 years at baseline) also noted a 50% increase in overall mortality in subjects who walked <1 mile/d, as compared to those who walked >1 mile/d. The cumulative all-cause mortality at 12 years in the group walking >2 miles/d (approximately 20%) was reached by the most sedentary group by 7 years of follow-up. At 12 years, the cumulative mortality in the sedentary group was twice that in the most active group (43/100 vs. 21/100).

Most of the older studies assessing the protection of activity against CVD and overall mortality were completed in male populations. Similar data have now been published in a 7-year follow-up of more than 40 000 postmenopausal women (ages 55–69 years at baseline). Those reporting regular physical activity had a relative risk of death of 0.77, as compared to those who reported none. While a dose–response effect was noted for increasing frequency of moderate activity, moderate activity as seldom as once a week was protective.

A study of nearly 16 000 healthy Finnish twins (ages 25–64 years at baseline) evaluated the effect of physical activity on mortal-

ity while controlling for possible hereditary influences. When subjects were classified as “conditioning” (six bouts of leisure-time exercise per month equivalent to 30 min of brisk walking), “sedentary” (no reported leisure-time activity), or “occasional exercisers” (the remainder), there was a significant trend for a reduced mortality risk with more vigorous exercise. In addition, when the total volume of exercise was estimated, there was also a trend toward a protective effect of increasing volumes of exercise. A 5% reduction in the hazard ratio was found for each quintile of increasing exercise volume. In twin pairs who were discordant for death during the follow-up period, the odds ratio for dying was 0.44 in the conditioning group and 0.66 in the occasional exercising group, when compared to the sedentary controls. When adjusted for smoking, occupation, and alcohol, these odds ratios did not quite reach significance, but the trend between the three activity categories remained significant.

While there is little argument about the positive effects of exercise on CVD and all-cause mortality, there remains some discrepancy about whether or not there is a threshold below which little protective effect is noted. It appears that the continuous inverse relationship between activity level and mortality is more easily detected when fitness level ( $VO_{2max}$ ) is used, rather than just a physical activity questionnaire. While activity questionnaires are clearly important in large population-based studies, these are more valid for either high-intensity activity or sedentary lifestyle and are less reliable for low or moderate levels of activity. In addition, it is possible that older studies that have used leisure-time physical activity questionnaires have consistently underestimated low-to-moderate levels of activity in women by failing to ascertain the activity involved in housework. Studies in older adults using quantitative methods to measure physical activity energy expenditure demonstrate an adjusted risk of all-cause mortality of 0.31 when the most active and least active tertiles are compared.

When fitness is used, not only is a continuous gradient of effect noted on mortality, but also the relative risk for mortality in the least-fit group (1.5 for men and 2.1 for women) is quite similar to the effect of smoking. Furthermore, when fitness level was measured at a mean interval of 5 years, an improvement in fitness (in a previously sedentary group) was associated with reduced mortality. For every minute increment in maximal treadmill time, there was an 8% decline in mortality risk. It should be noted that all of the above studies involved endurance exercise, and we are aware of no published studies assessing the relationship between CVD or all-cause mortality and strength training. The relationship between low cardiorespiratory fitness and CVD death was confirmed in an 11-year prospective follow-up of a cohort of nearly 1300 middle-aged Finnish men. Men in the low-fitness group ( $VO_{2max}$  <27.6 mL/kg or <8 METs) were threefold more likely to have a CVD-related death than the high-fitness group ( $VO_{2max}$  >37.1 mL/kg or >10.5 METs), when adjusted for age, smoking, and alcohol. This excess CVD death in the low-fitness group remained significant even when adjusted for lipids, diabetes, blood pressure, fasting insulin, and plasma fibrinogen. While there appeared to be a continuous effect of fitness on overall mortality, the major benefit seemed to occur for fitness levels above 9 METs. Low fitness was also found to be an important risk factor for non-CVD death, with a relative risk of 2.6, as compared to the high-fitness group. In this study, fitness was at least as good a predictor of both overall and CVD-related death as blood pressure, obesity, smoking, or diabetes.

In a study of fitness, obesity, and mortality, existing baseline CVD was the greatest predictor of overall mortality in the entire population, but low fitness conferred similar risk in the obese men.

## Arthritis

Arthritis is an important cause of functional impairment in older adults. A description of age-related changes in joint function and the impact of arthritis on function in older adults is given in Chapter 112. Despite concerns that exercise could be harmful to arthritis patients, several randomized controlled trials have demonstrated that exercise, even vigorous exercise, is beneficial in arthritis. These studies have enrolled both young and older adults and have included functional status outcomes. Exercise has included endurance training, such as riding a stationary bicycle, and strength training by using weights.

The exercise trials in arthritis patients report a 10% to 25% improvement in functional status outcomes. Improvements include faster gait, improved physical function performance, lower depression scores, less subjective pain, and less frequent use of pain medications. Improvements have persisted as long as 9 months after discharge from supervised exercise classes. As a group, these studies provide strong evidence of a beneficial effect of exercise on functional status in patients with mild-to-moderate arthritis (both rheumatoid and osteoarthritis). In one study, endurance and strength training were directly compared, and similar positive effects were found. In a recent study using this same population, both resistance (RR = 0.6) and endurance (RR = 0.53) exercise reduced the loss of activities of daily living.

## Osteoporosis

The decline in bone mineral density with age is well recognized (see Chapter 117), and there is an epidemic of osteoporotic fractures that affects women more than men and that primarily involves hip, vertebral, and wrist fractures. The extent to which the decline in bone mineral density with aging is a result of reduced physical activity is unknown.

The concept that mechanical loads are important to the integrity of the skeleton is more than 100 years old. Animal studies confirm the importance of mechanical strain to bone modeling and remodeling and have also identified the characteristics of loading forces that produce the greatest increase in bone mass. These studies demonstrated that (1) the osteogenic response to mechanical loading is optimized with relatively few repetitions of high-magnitude forces; (2) the application of force must be in a dynamic, rather than static, fashion; and (3) fast strain rates are more osteogenic than slow strain rates. Furthermore, the osteogenic response to mechanical loading is mediated locally in skeletal regions subjected to the strain, rather than systemically highlighting the need for exercises to specifically target regions of the skeleton at risk of fracture. Studies of laboratory animals suggest that bone cells lose sensitivity to mechanical loading after relatively few loading cycles. For example, four sets of 90 load applications per day was more osteogenic than one set of 360 loading cycles, and interposing an 8-hour recovery period between loading sessions resulted in a greater osteogenic response than when the recovery period was 0.5 hour. These concepts remain to be evaluated in humans. However, animal studies suggest that multiple short bouts of exercise per day may be more effective in preserving bone

health than a single, longer daily session. The concept of allowing bone to “rest” between loading cycles may also have implications for resistance training. For example, if the intent is to perform three sets of eight repetitions of several exercises, it might be of greater benefit to bone to perform one set of each exercise and then cycle back through for the second and third sets, rather than doing three consecutive sets of each exercise.

There are numerous cross-sectional studies of the effects of exercise on bone mass, comparing athletes who participate in different sports or physically active versus sedentary people. Interpretation of many of these studies is limited, because the area of bone density measurement frequently did not correspond to the bones that would be expected to receive the bulk of the mechanical stress from the given exercise. However, one well-conceived study found that the humerus in the dominant arm of tennis players had approximately 30% greater cortical bone thickness when compared to the nondominant arm. Other work suggests that the primary benefit of physical activity in adults may be to preserve, rather than increase, bone mass. Trabecular bone density was found to be roughly 5% to 10% higher in eumenorrheic runners when compared with eumenorrheic control women. Athletes who participate in muscle-building activities (e.g., weight lifting and body building) and in activities that involve jumping or vaulting (e.g., volleyball and gymnastics) also tend to have elevated bone mineral density. These data suggest that exercise in younger individuals may increase peak bone mass—an important negative risk factor for osteopenia later in life.

In postmenopausal women, exercise may increase bone mineral density by up to 5%, as compared to no-exercise controls, but average increases generally are only 1% to 3%. Although there are theoretical reasons why strength training may be a preferable intervention to increase bone mass, the magnitude of increase in bone mineral density in response to either resistance exercise or weight-bearing endurance exercise appears to be similar.

With the growing prevalence of obesity in the United States and other countries, it might be expected that the rate of osteoporosis will decline in the future. However, there are reasons why this may not occur. First, it is important to note that while low body weight is a risk factor for osteoporosis, increased body weight is not necessarily protective. In studies of overweight and mildly obese postmenopausal women, approximately one-third were osteopenic or osteoporotic. Second, the increased prevalence of overweight and obesity is likely to be accompanied by an increased prevalence of weight cycling (i.e., multiple cycles of weight loss and gain). Observational studies have found that women with a history of weight cycling have lower bone mineral density levels than noncyclers. Intervention studies have also found significant decreases in bone mineral density in response to modest weight loss (e.g., 5%) in postmenopausal women, even when calcium supplementation was provided and even when the weight loss was mediated by moderate-intensity exercise. It may be possible to prevent, or at least attenuate, bone loss during weight loss through the use of antiresorptive drugs.

There have been no randomized controlled intervention trials to evaluate the effectiveness of exercise to prevent fractures. However, results from prospective cohort studies, such as the Nurses' Health Study and the Study of Osteoporotic Fractures, suggest that the risk for hip fracture is reduced by ~50% in the most physically active quintile of the population. In evaluating just the potential benefit of walking activity, the Nurses' Health Study found a dose-response

benefit for both duration and speed of walking, such that more hours per week spent walking and fast walking speed conferred reduced fracture risk. Even hours per week spent standing was inversely related to hip fracture incidence. Perhaps most importantly, changes in physical activity for several years were related to hip fracture incidence in the expected manner: decreases in physical activity were associated increased risk and vice versa. Such findings suggest that any type of ambulatory physical activity may confer skeletal benefits and that increased physical activity should be advocated at any age as a strategy to reduce fracture risk.

Exercise may help to prevent fractures both by preserving bone mass and strength and by reducing the incidence of injurious falls. Of course, many factors contribute to risk for falling, including some that would be expected to improve in response to exercise (e.g., poor muscle strength) and some that would not (e.g., poor vision). Exercise interventions involving balance, leg strength, flexibility, and endurance training can reduce fall risk in community-dwelling older women and men. Such interventions have not proven effective in nursing home residents, but that may relate to the diverse causes of falls in that population.

## Cancer

Studies describing higher rates of cancer deaths in sedentary workers date back at least to the early 1960s, but these findings may have been skewed by greater alcohol and tobacco use in the higher-paid office workers. A more recent study demonstrated a dose–response relationship between fitness level and overall cancer death. In the 12-year follow-up of the Honolulu Heart Study, nearly one-third of the 208 deaths were from cancer. There was an inverse relationship between the daily distance walked and the risk of death from any cancer. The relative risk of cancer death was 2.4-fold greater in the sedentary group (<1 mile walked per day) when compared to the group walking >2 miles per day. At present, the most compelling data involve the relationship between activity and breast or colon cancer.

Both cohort and case–control studies in both men and women in a number of different ethnic populations have found a reduced relative risk of colon cancer when comparing the most to the least active groups, but the risk varies (range of relative risk, 0.4–0.9). In general, controlling for other cancer risks including tobacco, alcohol, age, obesity, and diet does not diminish the relationships. Evidence for a relationship between activity and rectal cancer appears to be substantially weaker. A negative result was reported from the Physicians Health study, where no level of reported physical activity was associated with a protection from colon cancer.

The risk for breast cancer has been linked to inactivity in 17 of 22 studies, with relative risks ranging from 0.20 to 0.89 when comparing the most active to the least active groups. These associations remain even after adjusting for potential confounding factors such as age, BMI, reproductive history, tobacco, and diet. The association holds for both pre- and postmenopausal women, although the risk factors for breast cancer in these two populations are felt to be different.

## Mood and Cognition

Subjects who exercise regularly consistently report an improved sense of well-being and reduced tension and anxiety. Indeed, similar re-

sponses occur acutely and persist for several hours after a single bout of exercise. Exercise can also ameliorate some of the symptoms of depression and anxiety. Cohort studies of endurance exercise have found a dose–response relationship between exercise at baseline and the development of depression at a later time point. One randomized controlled trial found that resistance training was also of benefit in a group of older depressed patients. In this study, the intensity of training was independently related to the decline in the Beck depression score.

Several studies have now documented a positive effect of exercise on cognition. A report of 19 000 subjects aged 70 to 81 years in the Nurses Health study found better cognitive test scores in subjects with higher levels of overall long-term physical activity or walking. Regular physical activity was also associated with less age-related cognitive decline. In another study of 1740 older adults, a hazard ratio of 0.62 was found for incident dementia after 6 years of follow-up in subjects who exercised at least three times per week compared to less active individuals. Intervention trials show a mixed pattern of effect of activity on cognition. A meta-analysis of 18 exercise intervention trials on nondemented subjects found a moderate positive effect, with the greatest effect found for executive control processes. Of interest, the effect was stronger with mixed training paradigms and in women. A meta-analysis of 12 exercise training studies in demented subjects showed a similar moderate positive effect. MRI studies have also demonstrated better frontal and parietal activation and greater frontal and superior temporal lobe volume after endurance exercise training.

The bases for the exercise-associated improvements in cognition are presently under considerable investigation in animal models, which suggest that elevations in brain-derived neurotrophic factor may underlie an increase in neurogenesis in exercised animals. Other work is investigating the potential role that obesity and insulin resistance may play in the development of cognitive decline in patients with type 2 diabetes mellitus and metabolic syndrome.

## Other Chronic Medical Disorders

While exercise rehabilitation has long been used in the treatment of patients with coronary artery disease, more recently, trials have begun to assess the effectiveness of exercise rehabilitation for the treatment of other common cardiovascular disorders. Exercise has also been found to provide improved functional outcomes in patients with peripheral arterial disease and claudication. In a randomized control trial, 6 months of endurance exercise improved distance walked until the onset of claudication (134%), distance to maximal claudication (77%), and walking economy (12%). More importantly, the daily physical activity in the trained group increased by almost 40%. While the most effective training appears to be walking, strength training may also provide some benefits.

Similarly, exercise rehabilitation has been shown effective in the treatment of some patients with congestive heart failure. Not only have increments in exercise duration and peak  $\text{VO}_{2\text{max}}$  been found in these patients, but there may also be some improvements in the skeletal muscle myopathy, which have been described in congestive heart failure patients. Patients with chronic obstructive lung disease have been shown to benefit from exercise training with the ability to do more absolute work, and also to sustain a constant submaximal workload for a longer duration and with a lower minute ventilation.

## RISKS ASSOCIATED WITH EXERCISE

Despite the recognition of exercise as a major public health objective for our entire population, there has been little systematic assessment of the health risks of exercise. This lack of information may be a result of the complex interplay of factors that may or may not predispose to injury: (1) host factors such as age, sex, fitness level, gait, balance, health status, and body weight; (2) exercise factors such as frequency, intensity, speed, duration, competition, and proper use of warm-up/cool-down periods; and (3) environmental factors such as surface, location, temperature, weather conditions, and use of proper supportive and protective equipment.

By far, the majority of injuries are caused by “overuse” and involve soft tissues. Approximately 10% of individuals (ages 16–65 years) participating in active sports or recreation reported having an injury within the last 4 weeks, with half of the incidents causing limitations in activity and 15% causing a hospital visit. Although the number of injuries might be expected to be reduced with less intensive and noncompetitive activity, it is also likely to be greater with increasing age. As noted previously, the speed of an activity may be a greater risk for injury than the intensity of the activity. Thus, fewer injuries would be expected from walking uphill as compared to jogging on a flat surface. Evidence also suggests that eccentric exercise (e.g., lowering a weight that has been lifted) may predispose to excess muscle injury. Patients with osteoporosis are at increased risk of fracture if they fall while exercising. Appropriate warm-up and cool-down periods, as well as emphasis on stretching and flexibility, are likely to be especially important in reducing soft-tissue injury in an older population.

A rigorous review of the potential exercise risks in an older population is outside the scope of this chapter, but two specific areas require comment. There is a significant transient increase in the risk of sudden death occurring during a bout of vigorous exercise, especially in previously sedentary individuals. However, the reduction in risk during the nonexercising period of the day more than makes up for the transient increase during exercise, producing an overall risk of sudden death in active men, which is 30% of that in sedentary men. These findings are supported by studies describing lower cardiovascular-related and overall mortality in active individuals. It should be emphasized that the relationship between the type, intensity, and duration of exercise and the reduction in cardiac risk remains unclear. The possible detrimental effects of resistance training on vascular function described above require additional investigation.

Exercise in older patients with diabetes mellitus also deserves additional comments. Careful attention to the possibility of both immediate and delayed episodes of exercise-induced hypoglycemia is critical, because of the sustained improvement in insulin sensitivity (24–48 hours) associated with vigorous exercise. Transient worsening of orthostatic hypotension can also occur following vigorous exercise, especially in hot weather. Meticulous foot care and supportive, well-fitted shoes are particularly critical for the exercising diabetic patient. Patients with proliferative retinopathy should avoid anaerobic (specifically isometric) exercise, such as power lifting, because of the increased ocular and systemic pressure occurring with the Valsalva maneuver. Diabetes is an important risk factor for ischemic heart disease, and its presence also puts the diabetic patient in a higher-risk category with respect to exercise-associated cardiovascular events.

## RECOMMENDATIONS

There is now ample evidence strongly supporting the beneficial effects of exercise in older individuals on several important health-related end points. It is also clear, however, that we still do not yet know enough about different types of exercise regimens to accurately prescribe a specific program that can be aimed at a specific disorder. Several large prospective cohort studies as well as smaller clinical trials have demonstrated a dose–response relationship between the intensity of exercise and the improvement in most outcome measures (blood pressure being one possible exception). This gradient of effect seems even clearer when fitness is substituted for physical activity. However, significant cardiovascular and metabolic improvements can be obtained when less-intense exercise is maintained over sufficiently long periods of time and that less-intense exercise regimens are generally more acceptable (especially to older individuals) and appear to make long-term compliance more likely. Low-intensity programs may be necessary in frail populations, such as those with stroke, congestive heart failure, and chronic lung disease, in which more intensive exercise is not tolerated. While multiple short bouts of exercise (at least 10 min each) may be effective in improving certain outcome measures, longer sessions remain preferable if these can be tolerated. A potential disadvantage of vigorous exercise in older individuals is that it may have little effect on total daily energy expenditure if overall activity during nonexercising periods is reduced.

After a thorough review of the types and amounts of exercise required for promotion of health and prevention of disease, a distinguished panel, representing the American College of Sports Medicine and the American Heart Association, published consensus recommendations for physical activity for adults and a separate report for older adults in 2007 (Table 114-1). While the reports are similar, the differences in the recommendations for older adults

**TABLE 114-1**

### Summary of Physical Activity Recommendations for Older Adults

1. Maintain a physically active lifestyle
2. Perform (a) moderate-intensity endurance activities a minimum of 30 min/d, 5 d/wk, (b) vigorous-intensity endurance activities a minimum of 20 min/d, 3 d/wk, or (c) a combination of moderate and vigorous activities
3. Perform 8–10 muscle strengthening activities that target all major muscle groups and require moderate to high effort (i.e., 10–15 repetitions) at least 2 d/wk
4. Perform activities that maintain or increase flexibility a minimum of 10 min/d, 2 d/wk
5. Perform activities that maintain or improve balance
6. Older adults with medical conditions for which physical activity is therapeutic should perform activities in a manner that is safe and effective for the conditions
7. Older adults who are not active at the recommended levels should increase physical activity level gradually. Many months of activity at less than recommended levels may be appropriate for some adults (e.g., those with low fitness) as they increase activity levels

Data from Nelson ME, et al. *Physical activity and public health in older adults: recommendations from the American College of Sports Medicine and the American Heart Association. Circulation. 2007;116:1094–1105.*

include (1) use of a relative scale of intensity, perceived effort, in place of an absolute measure of intensity in METs; (2) strength training exercise at a resistance that allows one set of 10 to 15 repetitions of eight to 10 different exercises; (3) inclusion of flexibility exercise; (4) balance exercise for those with a fall risk; and (5) use of a specific activity plan developed in consultation with a health-care provider, which can be tailored to specific chronic conditions and limitations, minimizes risk, and includes behavioral strategies to enhance adherence. The importance of reducing sedentary behavior and a gradual (stepwise) approach to increasing activity is stressed for all older adults.

For reasons of safety, in the past most experts recommended a pre-exercise assessment, including a complete history and physical examination, as well as an exercise stress test before vigorous exercise for all people older than 60 years. However, there are little data substantiating such a recommendation, and the significant cost of such an evaluation could greatly affect the practicality of using exercise as a public health measure and limit the participation of many older individuals in an exercise program. Furthermore, many older individuals have safely participated in community-based exercise programs for years with no such prior evaluation. New recommendations suggest that asymptomatic individuals who plan to exercise at moderate intensity do not need health-care provider screening before initiating an activity program. It is appropriate for patients to notify their physicians of their intent to begin an exercise program, because adjustments in medications or dosages may be necessary. The geriatric medicine axiom of “start low and go slow” should always be applied to beginning an activity program.

As discussed earlier, there are compelling reasons why an activity plan for older adults should also include activities that maintain and/or increase muscle strength. The Surgeon General’s report on physical activity affirmed the accumulating evidence of the health benefits of strength-developing exercises.

Changes in lifestyle are difficult to maintain at any age, and recidivism rates for exercise programs are high. This problem may be reduced by (1) careful attention to warm-up periods and slow progression in an effort to reduce early injuries, (2) enthusiastic leadership, (3) regular assessment of improvement with personalized feedback and praise, (4) spousal and family support for participation, (5) flexible goals (time rather than distance) set by the participant,

and (6) use of distraction techniques such as music. Because it is inevitable that a participant will, at some time, have a setback, it is important to provide strategies for coping with this stress at the beginning of any exercise program.

## INTRODUCTION

Mobility problems are pervasive in older adults. Mobility limitations affect personal independence, need for human help, and quality of life. Limited mobility predicts future health, function, and survival. Like other geriatric syndromes, mobility disorders are caused by diseases and impairments across many organ systems, so evaluation and management require multiple perspectives and disciplines. Health-care providers should be able to assess and treat mobility problems. They should be able to measure and interpret clinical indicators of mobility such as gait speed, the short physical performance battery, and the performance-oriented mobility assessment. They should know the physiological and biomechanical mechanisms underlying normal and abnormal mobility, the differential diagnosis of the causes of mobility disorders, and the approaches to management of mobility problems.

## DEFINITIONS AND METHODS OF CLASSIFICATION

### Defining Mobility

Mobility is the ability to move one's own body through space. Mobility requires force production and feedback control systems to navigate the mass of the body through a three-dimensional environment. Walking is the fundamental mobility task for human life. Mobility also includes a wide range of other important activities that require moving one's body, from turning over in bed to climbing stairs. Mobility tasks have an inherent hierarchical order based on the biomechanical and physiological demands made on the body. This orderedness is apparent in the developmental tasks of infancy and childhood, when mobility independence is first achieved. The simplest and first mobility task is turning over in bed, followed by

sitting upright, transfers from lying to sitting and from sitting to standing, locomotion with an increased base of support (like crawling or using a walker), to independent two legged walking, then more challenging tasks like ascending and descending stairs, running, climbing ladders, and sports.

Mobility disability is best defined within a conceptual framework such as that of disablement (Table 115-1). Disability is caused by pathologic processes that lead to organ system impairments and functional limitations. Disability causes handicap by limiting life roles such as work or caregiving. Disability in mobility occurs at the level of the whole person and is manifested by the inability to carry out normal mobility activities like bathing or shopping. Mobility disability is caused by functional limitations in walking, transferring, or climbing stairs, which are, in turn, caused by problems with strength, endurance, coordination, balance, and range of motion. These functional limitations can be caused by numerous pathological processes. Disablement can be modified by psychological, social, and environmental factors. Mobility disability can precipitate a cycle of negative consequences because it often leads to decreased activity, which in turn worsens functional limitations and causes organ system deconditioning, including muscle weakness, loss of joint range of motion, and poor cardiovascular endurance.

### Classification Methods for Mobility

Mobility classification is often driven by a tacit assumption of orderedness. No single current instrument assesses the full range of mobility from the lowest levels of rolling over in bed to the highest levels of endurance and coordination required for athletics or dance. Mobility assessment tools for older adults generally address one or more of the following three mobility levels: nonambulatory, ambulatory, and vigorous, corresponding broadly to Tinetti's levels of frail, transitional, and vigorous mobility status. Mobility levels are surprisingly stable. While day-to-day variability does occur, people in general tend to remain in one level or decline very gradually

**TABLE 115-1****Mobility Disability and the Disablement Process**

COMPONENT OF THE DISABLEMENT PROCESS	EXAMPLES RELATED TO MOBILITY DISABILITY
Pathological processes	Cardiopulmonary, neurological, and musculoskeletal conditions
Organ system impairments	Losses of strength, endurance, coordination, balance, and range of motion
Functional limitations	Problems with transfers, walking, and climbing stairs
Mobility disability	Dependence or difficulty with activities of daily living such as bathing or shopping
Handicap	Limitations in work, care giving

unless a major event has occurred. Within the nonambulatory level, there are important mobility skills that affect independence in personal care activities, care needs, and demand for human help; these activities include bed mobility, self transfer skills, and wheelchair mobility. Within the vigorous mobility level, the degree of fitness, as represented by the ability to perform demanding or challenging mobility activities, may be a useful indicator of the extent of “successful aging” and “physiological reserve.” As an indicator of the extent of physiological reserve, vigorous mobility status may be a marker of ability to tolerate physiologic stressors such as acute illness, surgery, or periods of reduced activity.

Mobility can be assessed by self-report, professional observation, or direct measurement. Instruments to assess mobility from all three perspectives have been developed (Table 115-2). Each has advantages and disadvantages. These tools have been used to estimate the population incidence and prevalence of mobility disorders, predict

**TABLE 115-2****Instruments Used to Screen and Classify Mobility**

INSTRUMENT TYPE	INSTRUMENT NAME, REFERENCES	ITEMS	RANGE	COMMENTS
Self-report	Rosow-Breslau SF-36 physical function	Walk ½ or ¼ mile and climb stairs 10 items, many directly related to mobility, from walk across a room to walk 1 mile	Ambulatory to vigorous Ambulatory to vigorous	Used as single items Score 0–100 U.S. adult mean 84.2 Older adult mean 52.0 Insensitive at lower levels of mobility
	Long-term care survey Mobility modifications	Walking inside and bed/chair transfers Self-report of changing the way one walks one-half mile or climbs stairs	Nonambulatory to ambulatory Ambulatory	Used as single items Used as single items
	Avlund mobility	Fatigue and need for help in six mobility activities from transfer to stairs and walking outside	Nonambulatory, ambulatory, and vigorous	Scores 0–6
Professional assessment	Barthel mobility items	Walking (or wheeling), transfers, and stairs	Nonambulatory, ambulatory, and vigorous	Mobility items integrated into total score
	Functional independence measure (FIM)	Transfers and locomotion (walk, wheelchair, and stairs)	Nonambulatory, ambulatory, and vigorous	Seven-level scoring of need for assistance with mobility items. Mobility items are integrated into total score
	Minimum Data Set (MDS)	Bed mobility, transfers, locomotion (includes wheelchair mobility), and walking	Nonambulatory to ambulatory	Used as single items
Performance	Short physical performance battery (SPPB)	Timed walk, chair rises, and tandem stands	Ambulatory	Score 0–12 Scores of 10–12, 7–9, and 4–6 associated with increasing risk of poor outcomes
	Gait speed	Timed walk, varying distances, instructions, and procedures	Ambulatory	Healthy older adult > 1.0 m/s Slow < 0.6 m/s Very slow < 0.4 m/s
	Timed up and go	Time to rise from chair, walk 10 feet, turn, walk back, and sit down	Ambulatory	< 10 s—normal < 20 s—able to move in community > 30 s—needs assistance for mobility
	6-min walk	Distance covered in 6 min	Ambulatory to vigorous	Healthy older adult mean > 500 m Older adults in assisted living < 300 m
	Health ABC	Walking endurance: 400 m walk time, distance in 2 min Expanded SPPB: longer tandem stands, one foot stand, and narrow walk time	Ambulatory to vigorous	Supplements SPPB by increasing discrimination among healthy older adults. Useful for persons with scores of 10–12 on SPPB score range 0–4

the consequences of mobility problems, screen patient populations, determine care needs, and reimburse services in rehabilitation settings. More detailed instruments have been developed specifically for sorting out causes and mechanisms. Detailed instruments will be discussed separately in the section on causes of mobility limitations. Mobility measures have varying strengths and limitations, depending on characteristics such as reliability and validity, respondent burden, feasibility and convenience of use, and assessor skill required. Self-report measures are the easiest type of measure to obtain when gathering data from large populations. Self-report measures have high face validity in that they reflect the opinion of the person themselves. Since self-report measures usually ask about a period of time, such as recent weeks or months, these are capable of reflecting fluctuating ability over time. Self-report measures can be limited by problems with reliability, accuracy, and nonresponse. Because these are usually ordinal scales, they lack ability to discriminate small but important differences. Professional report measures reflect the opinion of an experienced assessor, can integrate over time, and may be more feasible when an individual is considered an unreliable informant or is unable to cooperate with testing. Professional report is limited by the need for assessor experience and training and can be vulnerable to problems with interrater reliability unless extensive efforts to standardize assessment are made. Since professional reports are usually based on ordinal scales, ability to discriminate small but important differences might be limited. Mobility testing by measuring actual performance is somewhat more independent of opinion. Performance testing can produce very quantitative results, which discriminate small but important or subclinical differences. Performance measures are limited in that they require direct observation, subject cooperation, and standardization of instructions and procedures. These measure capability rather than actual daily mobility activities. The need for subject cooperation can lead to problems with nonresponse. Performance measures do not account well for short-term fluctuations over hours to weeks. Despite these limitations, performance testing may have direct applications in clinical settings because it can provide useful information and is brief and quantitative.

Psychological aspects of fear, mobility confidence, and activity avoidance can have great effect on mobility disability, separately or in combination with observable mobility limitations. Several instruments to assess psychological factors related to mobility disability have been developed (Table 115-3). Items from these scales might have use in the clinical setting.

## EPIDEMIOLOGY

### Prevalence

The epidemiology of mobility can be considered from the perspective of basic or higher-level mobility. Examples of basic mobility problems are getting around inside the house and transfers from bed or chair. Examples of higher-level mobility problems are getting around outside the house, ability to walk one-quarter or one-half mile, and ability to climb stairs. Basic mobility problems are uncommon in community-dwelling older persons but are very frequent in institutionalized older people. Among community-dwelling persons aged 65 years and older, approximately 5% are dependent in getting in and out of a chair or bed and 7.5% are dependent in getting around inside. Among institutionalized persons older than 65 years, approximately 80% are dependent in getting in and out of a chair or bed and getting around inside. Mobility disability increases dramatically with age; dependence in getting around inside increases from 5% of persons aged 65 to 74 years to 30% of persons aged 85+ years. Women tend to have higher rates of mobility disability than men and nonwhites than whites.

Approximately 13% of Americans older than 60 years report higher-level mobility problems in that they have difficulty going outside the home alone. There is a marked increase with age. There is also geographic variation; self-reported difficulty going outside the home alone is more common among older adults in the Southern United States. Higher-level mobility problems, defined as difficulty walking a quarter mile or climbing stairs, increase with age, are more common in women than in men, and appear to be decreasing during recent decades.

### Risk of Adverse Consequences Associated with Mobility Status

Mobility problems have serious consequences. Mobility status predicts mortality. Older people with difficulty walking 2 km (a little more than a mile) or climbing one flight of stairs are twice as likely to die during the next 8 years compared to those with no difficulty. Mortality risk is even higher among those who both have mobility difficulty and are physically inactive. Poor mobility performance, even in the absence of self-reported mobility limitations,

**TABLE 115-3**

#### Instruments to Assess Psychological Factors Related to Mobility

CONSTRUCT	INSTRUMENT/QUESTION	# ITEMS	POPULATION
Fear	Survey of Activities and Fear of Falling in the Elderly (SAFFE)	33	Community dwelling
	Fear	11	
	Activity	11	
	Activity restriction	11	Community and LTC
	Are you afraid of falling? (yes/no)	1	
	How would you rate your fear of falling? (five-point numerical rating 0–4)	1	
Self-efficacy/confidence	Falls Efficacy Scale (FES)*	10	Community dwelling, inpatients, and LTC
	Activities-specific Balance and Confidence Scale (ABC)	16	Community dwelling and patients
Avoidance	Has fear of falling made you avoid activities? (yes/no)	1	Community dwelling and LTC
	Modified SAFFE (mSAFFE)	17	Community dwelling

\*Several modified versions exist (revised FES, adapted FES, modified FES, and FES United Kingdom).

is an independent predictor of death and nursing home placement. In community-dwelling older adults, baseline physical performance score was associated with a twofold increase of death. Among persons who report no mobility problems, gait speed less than 1.0 m/s has been associated with an increased risk of death compared to a gait speed of more than 1.0 m/s. In another community-based population, 9-year mortality for older persons with gait speeds less than 0.6 m/s was 78% compared to 48% in persons with gait speed between 0.6 and 1.0 m/s and was 26% in persons with gait speeds more than 1.0 m/s. A change in gait speed of approximately 0.1 m/s (equivalent to approximately 0.2 miles per hour) or a change of one point in the SPPB or 20 m in a 6-minute walk test appears to be clinically important. Older persons who have a 0.1 m/s decline in gait speed over 1 year have a doubled risk of dying during the subsequent 5 years. Older persons who have a 0.1 m/s improvement in gait speed over 1 year have a 40% decreased risk of dying in the following 8 years.

Poor mobility performance is an independent predictor of future self-care difficulty and mobility disability. Among community-dwelling persons older than 70 years with no baseline self-care disability and no higher-level self-reported difficulty in ability to walk one-half mile and climb stairs, baseline physical performance score was a powerful predictor of incident disability in both activities of daily living and in higher-level mobility disability. Mobility self-report and performance have been shown to predict disability and mortality in older populations from numerous countries and cultures, including Mexican American, British, Italian, French, Dutch, Spanish, Scandinavian, Australian, Japanese, and Chinese.

Poor mobility performance is also an independent predictor of hospitalization and nursing home placement. In a population-based study of older adults who reported no disability at baseline, poor baseline physical performance score was associated with a twofold increased risk of hospitalization and more days in the hospital over the following four years. The increased hospitalization risk was independent of baseline health status. The increased risk was mostly associated with hospitalization for geriatric conditions, such as dementia, pressure ulcer, hip fractures, other fracture, pneumonia, and dehydration.

Mobility may be part of an underlying constellation of core factors that link multiple outcomes associated with aging. Poor mobility as measured by timed chair stands is one of four factors proposed to be common risk factors for geriatric syndromes, including incontinence, falls, and functional decline. Conversely, good mobility, along with good cognition and nutritional status, is an independent predictor of recovery of independence after a period of disability. Abnormalities of gait and slow gait speed have been found to precede the onset of cognitive decline and dementia. Slow and abnormal gait is a risk factor especially for vascular dementia. Among older adults, simultaneous abnormalities of mobility, cognition, and mood are more common than would be expected by chance, perhaps implying potential common underlying causes.

Severe mobility disability, sometimes called immobility, has widespread and devastating consequences. It accelerates impairments in multiple organ systems, including bone, muscle, heart, circulation, lung, skin, blood, bowel, kidney, nutrition, and metabolism. Loss of organ system function can be rapid and severe; muscle strength can decline by 1% to 5% per day of enforced bed rest. Skin breakdown and pressure ulcer start to occur after only hours of persistent and unrelieved pressure. Major consequences of clinical

significance include decreased plasma volume, orthostatic hypotension, accelerated loss of bone density, muscle weakness, decreased pulmonary ventilation, and constipation leading to fecal impaction. When even temporary bed rest is combined with the increased vulnerability of aging and acute illness, there is a marked increased risk of death, disability, and institutionalization.

## PATHOPHYSIOLOGY

The causes of mobility problems are complex. Unique and complementary etiologic perspectives can all contribute to a better understanding of mobility. Three perspectives are described here: epidemiological, biomechanical, and biomedical. Each has advantages and disadvantages for the clinician and the researcher.

### Epidemiological Perspective: Risk Factors

Epidemiological risk factors for the onset of higher-level mobility disability include demographics, health behaviors, psychological factors, and diseases. Demographic factors associated with increased risk include advancing age, lower income, and lower educational level. Behavior-related risk factors include current smoking, alcohol abstinence, low physical activity, high body mass index, and high waist circumference. Physical activity, a health behavior that is a key to mobility, is influenced by multiple psychological, social, and environmental factors. Common reasons given by older adults for limiting or avoiding physical activity include lack of an exercise companion, lack of interest, fatigue, fear of falling, weather, and safety. Self-reported conditions identified as major barriers to physical activity by older adults include arthritis and past injury. Psychological factors that influence mobility include negative attitudes toward aging, fear of falling, and poor emotional vitality. Self-reported conditions associated with increased risk of new higher-level mobility disability include baseline and incident heart attack and stroke, baseline hypertension, diabetes, angina, dyspnea, exertional leg pain and incident cancer, and hip fracture.

### Biomechanical Perspective: Direct Assessment of the Body in Motion

Age affects the biomechanics of walking. Normal gait can be defined in terms of the gait cycle with two main phases: stance and swing (Figure 115-1). A normal cycle begins with a push off from the forefoot, then a swing through and heel strike, timed tightly to be followed by the push off of the other leg. Normal gait has highly characteristic patterns of foot, ankle, knee, hip, pelvis, trunk, and arm motion. Gait biomechanics can also be viewed from the perspective of the pattern of steps (footprints) (Figure 115-2). Step length is the forward distance between two foot falls. Stride length is the distance covered by one foot until it falls again. Stride length is, therefore, twice the step length, assuming the step lengths are the same on both sides. Step width is the lateral distance between two foot falls. With age, gait speed slows, step length decreases, and the proportion of the gait cycle when both feet are in contact with the ground (double support time) increases. During gait, older people compared to young adults tend to have more thoracic kyphosis, more anterior pelvic tilt, increased hip flexion, and greater external rotation of the foot. Older people tend to generate less power about the ankle

Right Lower Extremity (LE)	Heel strike	Stance	Toe off	Swing
Ankle Joint:	Neutral position (90°)	Neutral position (90°)	Plantar flexion for push off	Dorsiflexion for foot clearance
Muscles:	Ankle dorsiflexors active to support position of ankle	Plantar flexor torque drives foot into floor, ankle dorsiflexors eccentrically active to slow foot	Plantar flexors active	Dorsiflexors active
Weight rolls from heel to toe				
Knee Joint:	Extended to prepare for weight bearing	Slight knee flexion (shock absorbing) progressing to full extension for stable weight bearing	Extension progressing to passive knee flexion to prepare for swing	Knee flexion for foot clearance progressing to passive extension for limb advancement
Muscles:	Initially, knee extensors (quadriceps) active then both quadriceps and hamstrings active for knee stabilization.	Quadriceps eccentrically active to decelerate knee flexion		Hamstrings and gastrocnemius active for knee flexion, relax for knee extension.
Hip Joint:	Hip flexed ~30°	Progressive hip extension	Hyperextension of the hip progressing to hip flexion	Hip flexing to advance limb
Muscles:	Hip extensors active for stability.	Hip extensors active initially. Hip abductors active to keep pelvis neutral.	Hip flexion initiated by hip adductors and hip flexors.	Hip adductors and flexors active for swing, hamstrings active to terminate swing.
Left LE*	Toe off	Swing	Heel strike	Stance
SUPPORT	Double support	Single support (right)	Double support	Single support (left)

\*Note: When the right LE is at heel strike, the left LE is approaching toe off and vice versa. When the right LE is in stance the left LE is in swing and vice versa.

FIGURE 115-1. Human walking.

Step length = the distance between two consecutive footprints on opposite sides of the body.  
 Stride length = the distance between two consecutive footprints on the same side of the body.  
 Step width = the distance between the outer most borders of two consecutive footprints.

Dark (black) footprints represent foot placement during walking.  
 Quick clinical inspection for approximation of normal gait:  
Step length = 1 step length between right and left steps (grey-dotted footprint).  
Step width = 1 foot width (grey-dotted footprint) between right and left steps

FIGURE 115-2. Step patterns in human walking.

A. Usual gait: right and left step lengths approximately equal.

B. Asymmetric gait (limp): right step length consistently shorter than left step length. All left step lengths approximately equal and all right step length approximately equal.

C. Variable gait: inconsistent right and left step lengths.

Red = left foot prints, Green = right foot prints

**FIGURE 115-3.** Gait patterns.

and use hip flexion to compensate more than young adults. Normal gait has a very regular spatial and temporal pattern. An irregular gait can be either regularly irregular, like a limp, or irregularly irregular, with no pattern at all (Figure 115-3). Irregularly irregular gait, often called gait variability, predicts falls and mobility disability.

Normal walking maximizes energy efficiency. When walking changes owing to biomechanical alterations caused by disease or aging, walking becomes more energy demanding. Normal walking also requires excellent control of balance and timing. When problems develop with balance and timing, the priority for safe walking may be to increase stability and support at the expense of losses of energy efficiency. Thus, many changes with aging increase the energy cost of walking and decrease gait efficiency.

A biomechanical perspective can be applied broadly to mobility and balance, based on the increasing biomechanical demand placed on the body in motion. Typically, tasks are considered more challenging as the base of support narrows and transfers of mass over the base become more demanding. Thus, difficulty increases from sitting to standing to walking, to climbing stairs, walking a line, or running. A biomechanical approach to postural alterations and body-segment movement abnormalities can be useful for identifying causes of, and solutions to, mobility problems. Specific abnormalities can be addressed by targeting rehabilitative programs, the type of assistive devices, or the design of environmental adaptations.

### Physiological Perspective: Using Organ System Impairment to Link Function and Disease

The causes of mobility limitation can be assessed from a physiological perspective. There are three main physiological components of mobility. These components include balance control (neurological

system), force production (cardiopulmonary and muscular systems), and structural support (skeletal system—bone and joints). Ferrucci has created a framework that identifies six main physiological subsystems of the ability to walk: central nervous system, perceptual system, peripheral nervous system, muscles, bones and joints, and energy production. Another way of organizing the systems that affect walking is to consider inputs and outputs. In this approach, the physiological elements of mobility can be assigned to three main components based on a sequence of information from sensory inputs to central processing to effector factors that carry out instructions from the brain. Sensory inputs include vision, vestibular function, and peripheral sensation. Central processing includes level of consciousness, integration of sensory inputs, coordinated timing of multiple segmental body motions, and postural reflexes. Effector-related factors include endurance, pain, speed of reaction, and flexibility.

There are several important emerging areas of knowledge related to our understanding of the physiological contributors to walking. Brain abnormalities found on magnetic resonance imaging (MRI) are associated with alterations in central processing and abnormal gait. Small vessel cerebrovascular disease in the absence of stroke and MRI findings of “white matter disease” or focal grey matter atrophy are associated with slower gait speed, even among high-functioning older adults. These MRI findings predict the onset of mobility disability. Such brain abnormalities have been found to concurrently affect mobility, cognition, and mood and may suggest a shared underlying cerebrovascular process. Another emerging area of knowledge is related to subclinical losses of dopaminergic transmission in the brain in the aged. These losses of dopaminergic function also contribute to altered mobility and may present clinically in patterns that differ from traditional Parkinson disease. Dopamine deficiency in the aged may be related to cerebrovascular disease. Loss of oxygen-carrying capacity because of anemia has been recognized as a potential contributor to mobility limitations, especially in Caucasians, perhaps owing to decreased endurance but also possibly because of chronic subclinical ischemic effects on the brain. Research on the link among cardiovascular risk factors, brain structural abnormalities, mobility, cognition, and mood is developing rapidly. In the future, it may be possible to refine these observations into diagnosable and possibly treatable disorders. It is possible that attention to cardiovascular risk factors might reduce the risk of developing some of these brain abnormalities and thus potentially reduce the incidence of mobility problems.

A physiological perspective on mobility helps define organ system impairments, which can be linked to treatable diseases, conditions, and pathological processes, as described by the disablement process in Table 115-1. A physiological perspective is also helpful when accounting for the multiple interacting health problems of many older adults. When more than one organ system that is important for mobility is impaired, the risk of mobility problems increases. Thus, mobility can be affected when one system is severely disrupted, when several are modestly disrupted or when many are mildly disrupted. A physiological perspective also helps account for the phenomenon of stress-induced disability. Organ systems have excess capacity, called physiological reserve. Losses of organ system function can be clinically unapparent because these are losses of unused reserve or because one system is compensating for another. Many subclinical physiological losses may not be recognized until stress is placed on the system by further physiological decline or by an unexpected high

demand on the system. When sufficient reserve is lost or a compensating organ system fails, mobility disability becomes overt. For example, when persons with many subclinical physiologic losses face an unexpected mobility demand, such as walking on ice at night, they may face a demand that is greater than their mobility capacity. Mobility reserve can now be assessed using recently developed tests. One way to challenge reserve is to perform simultaneous physical and cognitive tasks. Described as “dual tasks,” older individuals may deteriorate significantly when asked to walk and talk or walk and perform a mental calculation. Mobility tests that incorporate obstacles also assess reserve. Tests of gait variability may be another way to detect subclinical change in mobility.

A physiological perspective can help define interventions, based on the disablement structure described in Table 115-1. Treatments could be aimed at managing the underlying pathological conditions that are causing the impairment (e.g., improving cardiac ejection fraction through treatment of congestive heart failure), treating the impairments themselves (e.g., strength training), or creating compensations and adaptations at the level of functional limitations (such as using a cane). A physiological approach offers a constructive way to connect biomechanical and clinical mobility assessment to a biomedical model of diagnosis and treatment.

### Gait Speed as an Integrator of Multiple Approaches

Walking is the foundation of mobility, is influenced by biomechanical and physiological processes, and is a major driver of disability. Walking speed could be considered a “vital sign” in older adults. While there are several influences on measures of gait speed such as leg length, gender, or periods of acceleration and deceleration, in general gait speed can be interpreted clinically. Normal usual walking speed in the older adult should be at least 1 m/s. When measuring a fixed walk distance, this means that the time should be less than the distance in meters. For example, a 4-m walk speed should be less than 4 seconds. When measuring a fixed time, this means that the distance should be more than the time in seconds. For example, the distance walked in a 6-minute walk (360 seconds) should be more than 360 m. In a normal step frequency of walking (called the cadence), there are a little more than two steps per second or somewhat more than 120 steps per minute. With approximately two steps per second at a normal pace of 1 m/s, there is approximately 1 m or 20 inches in a step. Clinically, this translates into approximately two shoe lengths per step, or an imaginary “shoe” in between each step (Figure 115-2).

As a general rule, there are links among walking speed, energy expenditure, and disability. Energy expenditure can be measured in metabolic equivalents (METs). One MET is the energy requirement for lying in bed. Two METs is twice the energy requirement for lying in bed and is approximately the energy requirement for self-care activities. The usual energy cost in METs of walking at various speeds has been reported in miles per hour, and walking speed can be translated directly between meters per second and miles per hour. Therefore, the energy requirements in METs and the expected activity level can be associated with gait speed, as described in Table 115-4. This conversion table allows clinicians and researchers to approximate the functional status of individuals or populations based on any measure of gait speed. Using METs as a basis for function, one might be able to define a sequence of mobility capacities, as described in Table 115-5.

**TABLE 115-4**

#### Translating Walking Speed: Walking Speed, METS, and Function

WALKING SPEED				
m/s	mph	6-min Walk Distance (m)	METS	FUNCTION
0.67	1.5	240	<2	Self-care
0.89	2.0	320	2.5	Household activities
1.0	2.2	360	2.7	
1.11	2.5	400	3.0	Carry groceries and light yard work
1.33	3.0	480	3.5	Climb several flights of stairs

## EVALUATION

### Strategy for the Clinical Encounter

There are no established standards for the overall evaluation and treatment of mobility problems in older adults. Currently, the best approach is similar to the ones used for other geriatric syndromes. These approaches are all based on a biopsychosocial model that incorporates biomedical, rehabilitative, and psychosocial elements and a multidisciplinary team. The initial goal of assessment is to classify the mobility problem into one of three large groups: nonambulatory, ambulatory, or vigorous. For the person who presents in a wheelchair or bed, one can screen for ability to stand or walk with assistance. For ambulatory individuals, a quick sorting strategy is to observe gait. Since most gait parameters are highly interrelated, abnormal gait can be grossly distinguished from normal by a few simple characteristics like use of a gait aid, gait speed less than 1 m/s (or step length less than twice foot length), or step asymmetry. Persons with

**TABLE 115-5**

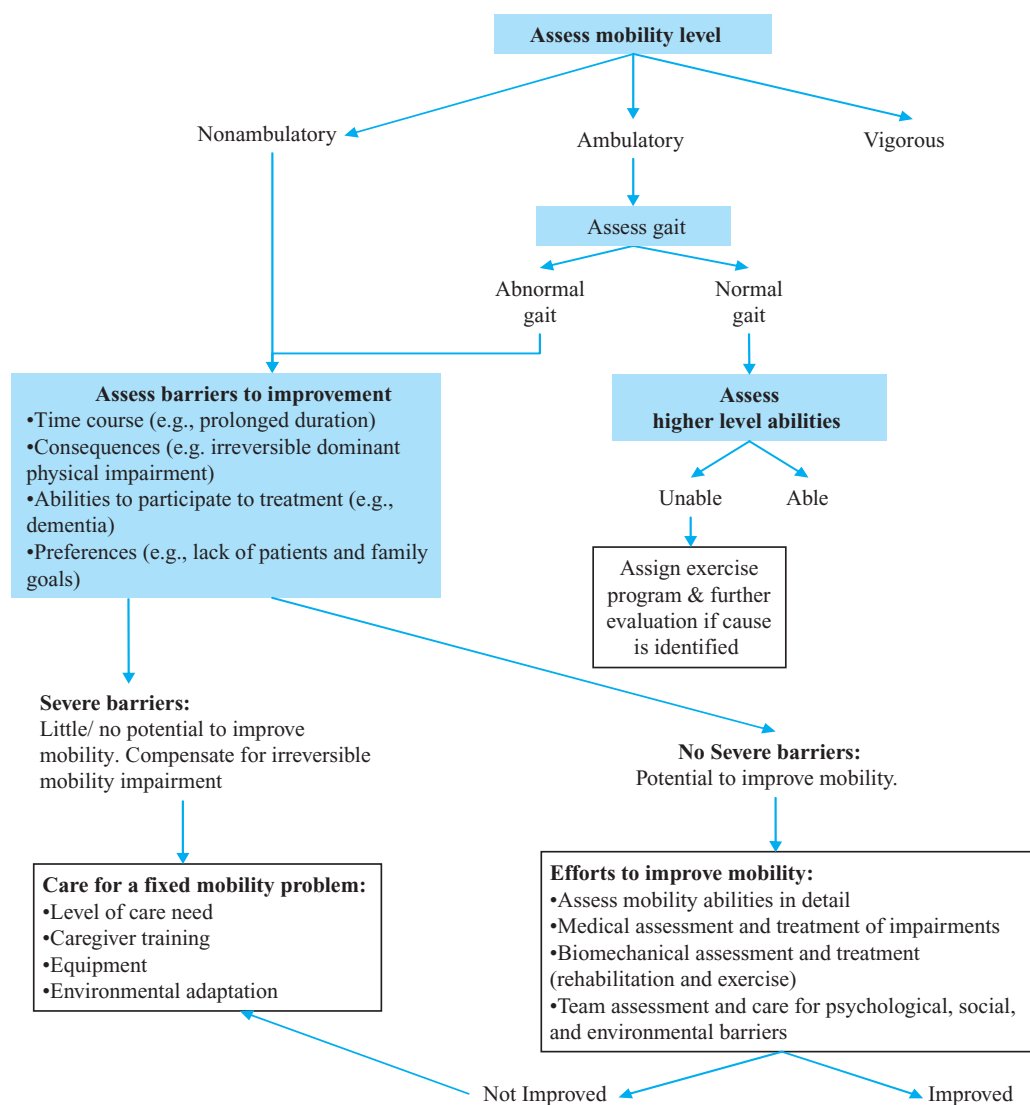

#### Example of a Seven-Level Classification of Mobility Based on Energy Expenditure

Level 1	Able to perform sustained physical activity for at least 30 min at a vigorous pace like running, jogging, and tennis. Greater than 4 METs, sustained activity
Level 2	Able to perform sustained physical activity for at least 60 min at a usual pace like walking one or more miles. 3.5–4 METs, sustained activity
Level 3	Able to perform physical activity at a usual pace for at least 15 min like walking one-half mile. 2.5–3.5 METs, limited duration of activity
Level 4	Physical activity limited. Able to walk one block. May have slowed gait speed. May use an assistive device like a cane to walk. 2.0–2.5 METs
Level 5	Physical activity limited. May have difficulty walking one block but able to walk across a room. May use assistive device like a cane or a walker. <2 METs
Level 6	Mobility severely limited. Requires wheelchair for indoor mobility. Transfers independently. 1.5 METs
Level 7	Mobility profoundly limited; requires assistance with transfers from chair or bed. 1 MET

normal gait can be assessed for higher level fitness by use of one or more screening tests for higher level abilities such as single foot stand for 30 seconds, ability to tandem walk or ability to walk more than 450 to 500 m in 6 minutes. Persons with normal walking but inability to perform higher level tasks might be good candidates for exercise programs for well elders or for further evaluation if the mobility change is recent or causing problems. Further assessment of the non ambulatory or for those with abnormal gait depends in part on the treatment goals. The team can select a basic strategy; either to try to improve mobility or to compensate for irreversible mobility loss (Figure 115-4). This decision is based on the time course of the mobility loss, the potential to reverse impairments, the ability of the patient to participate in treatment, and preferences of the patient. For example, a person with severe cognitive deficits or severe irreversible motor paralysis might be considered more appropriate for compensation than for interventions to improve mobility. Planning for compensation might target mobility care needs and resources. For the person considered to have potential for improving mobility, the major decisions are the timing and value of interventions directly on mobility (usually through exercise and rehabilitation) and on underlying impairments (usually through medical team care). In some cases, it is clear that a person requires medical intervention first. For

example, in a person with poorly controlled congestive heart failure, medical treatment for symptom control probably needs to occur prior to rehabilitation. In other cases, it can be difficult to predict if intervention on multiple impairments should occur before or during rehabilitation efforts. For example in a person with depression, low vision and peripheral neuropathy, one could intervene with rehabilitation and exercise simultaneously with vision correction and antidepressants or one could try to correct the impairments first. This decision is based in part on whether the impairments are felt to create significant barriers to the success of rehabilitation. One could argue that in the absence of obvious barriers, a “trial” of rehabilitation should be started. Treatment can be initiated for impairments that cause barriers along the way. Alternatively, one could argue that it is more efficient to eliminate barriers prior to starting therapy. Since the time and effort of comprehensive mobility assessment and rehabilitation are both substantial, it is a challenge to determine where to apply efficiencies. Older adults with mobility problems often have numerous impairments identified as part of comprehensive assessment (see Chapter 11), some of which may be barriers and some may not. The process is likely to be inefficient, and like comprehensive geriatric assessment, hard to use in routine clinical practice. To the extent that there are “high payoff” areas based on prevalence

**FIGURE 115-4.** A clinical strategy for assessment and management of mobility problems.

**TABLE 115-6****Brief Evaluation of Mobility Problems for Use in Primary Care**

SYSTEM	SYMPTOMS LIMITING WALKING	
	SYMPTOMS	CLINICAL FINDINGS
Cardiopulmonary (lung, heart, and blood)	Dyspnea and fatigue	FEV1, O <sub>2</sub> saturation with activity, hemoglobin, and ejection fraction
Neurological (frontal, motor, extrapyramidal, and peripheral)	Unsteady and hesitant	Tone, timed tapping, executive cognitive function, and peripheral sensation
Musculoskeletal (bones and joints, muscles)	Pain and stiffness	Knee, hip, low back range of motion, and pain Manual muscle tests and chair rise

or responsiveness to intervention, it may be possible to prioritize and streamline the process. In primary care, the provider can offer a screening and triage function by recognizing mobility disorders and assessing potential for intervention. [Table 115-6](#) gives examples of a quick system of assessment for symptoms and clinical findings based on the three main involved organ systems. The primary provider can identify and treat overt clinical impairments that can be detected quickly in the clinic, like weight-bearing pain caused by

osteoarthritis, or dyspnea caused by congestive heart failure. When the cause of the mobility problem is less obvious, a referral to multidisciplinary team for comprehensive mobility assessment can be considered. Since the potential causes range across many organ systems, this strategy might be more efficient than referral to several organ system based specialists. Since research into mobility problems is an active and high priority area in aging, in the future, efficient clinical practice and referral may be better informed by evidence.

The comprehensive approach to the clinical assessment of treatable causes of mobility is currently a specialized referral function that is resource intensive. Evaluation starts with the clinical assessment of the severity, course and consequences of mobility limitation, and the determination of potential to improve mobility. Mobility performance is assessed in more detail, including biomechanical aspects of functional limitations during movement. Potential contributing factors are identified based on physiological impairments, and evidence is sought for psychosocial and environmental influences.

### Clinical Assessment of Mobility Performance

In ambulatory patients, simple assessment of gait speed is a useful place to start. The gait speed can be used to estimate function as described above. Gait can be assessed in more detail from a biomechanical perspective ([Table 115-7](#)). Gait can be examined for general characteristics like path deviations, irregular or variable stepping, or a widened base of support and for altered motion of the component parts: trunk, arms, hip, knee, ankle, and foot. Mobility tasks can be examined for performance difficulty or altered movement patterns

**TABLE 115-7****Examples of a Biomechanical Assessment of Common Gait Abnormalities and Possible Causes**

GAIT ELEMENT	GAIT ABNORMALITY	POSSIBLE CAUSES	
<i>Body segments</i>			
Ankle and foot	Forefoot strikes floor simultaneously with initial heel contact (foot slap)	Weak ankle dorsiflexors and decreased proprioception	
	Initial contact is by forefoot	Leg length discrepancy, plantar flexion contracture, and painful heel	
	Heel and toe leave floor together during push off	Fixed ankle, weak plantar flexors, and painful forefoot	
	Forefoot drags during swing (foot drop)	Weak ankle dorsiflexors	
Knee	Tendency to roll from plantar to medial surface of the foot while walking	Weak lateral ankle stabilizers and varus knee deformity	
	Knee flexed at initial contact	Painful knee, weak knee extensors, leg length discrepancy, and knee flexion contracture	
Hip	Decreased knee extension during swing	Knee pain or decreased range	
	Hyperextension of the knee in stance	Weak knee extensors	
	Decreased hip flexion at initial contact	Weak hip flexors and decreased range of motion	
	Increased hip flexion during swing (steppage gait)	Compensation for foot drop	
	Decreased hip extension during late stance	Hip flexion contracture	
	Hip circumduction with lateral movement of entire limb	Weak hip flexors and inability to flex leg	
<i>Gait pattern</i>	Pelvis drops on one side, lateral instability when walking	Contralateral hip abductor or gluteus weakness	
	Excessive elevation of the ipsilateral side of the pelvis during swing (hip/pelvic hiking)	Inadequate hip or knee flexion or excessive plantar flexion	
	Gait initiation	Hesitation	Parkinson disease, frontal lobe disorders, and normal pressure hydrocephalus
Stance width	Increased	Cerebellar disorders and peripheral neuropathy	
	Path	Weaving	Vestibular disorders
	Scissoring (steps cross over laterally)	CNS disorders	
	Increased variability	CNS disorders (e.g., white matter hyperdensities and lacunar infarcts)	

as task demands increase. Sometimes, the finding of an abnormal body-segment movement or gait characteristic suggests a specific impairment or disease. More often, the abnormality is nonspecific but is amenable to direct intervention in rehabilitation.

Clinical gait assessment tools that include many of these biomechanical elements include the Performance Oriented Mobility Assessment and the Gait Abnormality Rating Scale. A tool for analyzing the elements of bed mobility from the perspective of body segments has been proposed. Mobility and balance assessments can be based on a hierarchy of task difficulty. The Berg balance scale assesses 14 tasks of progressive difficulty from sitting balance to one leg standing and rising onto a step. Some scales have been designed to discriminate mobility capacity among the nonambulatory. The Hierarchical Assessment of Balance and Mobility assesses mobility, transfers, and balance and detects multiple levels within the bed and chair fast. The Physical Disability Index has eight mobility tasks including six items for nonambulatory persons. Mobility task scales usually have a functional rather than a biomedical perspective and are not designed to detect specific impairments. These scales can be used to identify areas for task practice or adaptation in rehabilitation and to assess the effects of treatment.

### Differential Diagnosis Based on a Physiological Perspective

A clinical schema for the comprehensive evaluation of mobility that is derived from Ferrucci, Tinetti, and the author's own work is proposed in Table 115-8. Many impairments are detectable through the usual geriatric clinical history and physical examination. Some sensory systems are amenable to clinical evaluation. Vision can be assessed for acuity by Snellen chart, and fields by confrontation, dark adaptation by history, and depth perception can be assessed with a low-cost portable device resembling a shoe box with two pointers attached to cords. Peripheral sensation can be assessed by proprioception, vibratory threshold, and filaments. Vestibular function is difficult to test clinically, and many people with vestibular disease do not demonstrate vertigo or nystagmus. Tests of visual stabilization during head motion are in development and may become clinically useful. Some central systems can be assessed clinically. Perfusion can be assessed by history of orthostatic symptoms or presyncope and by direct assessment of orthostatic blood pressure change. Reaction time can be assessed by timed finger and foot tapping or grossly by observation of rapid alternating movements. Frontal lobe function can be assessed using the trail making B test or a dual task like walking and saying the days of the week in reverse order. Postural responses can be assessed by a test of the righting reflex. This test can be performed as a sternal nudge or rapid pull on the pelvic rim, with the goal to displace the center of mass sufficiently to require a displacement of the base of support, which generates a need to take a step. A normal response is a single brisk step backward. A grossly abnormal response is the "timber reaction" in which no lower extremity movement occurs. An equivocal response is several small steps. Since older adults can unexpectedly lack righting reflexes, it is essential to be positioned to catch the individual during this test. Absent righting reflexes are often found in Parkinson disease. Absent or decreased righting reflexes can also be found in other poorly defined central nervous system conditions. Poor trunk control, dysmetria, and a wide base of support in standing are seen in cerebellar disorders. Musculoskeletal and neurologic effector factors that can be assessed in the clinic include simple assessments of strength by

manual muscle testing and by maneuvers that require the individual to move their own body mass, like chair rise, standing on the toes (with hands on examination table for stability), and squatting. Focal or asymmetric weakness may be caused by central, spinal cord, or peripheral nerve disorders. Flexibility can be assessed by range of motion. Flexibility in the neck and spine, as well as in the lower extremities, affects mobility. Weight-bearing pain and pain in the chest, back, or legs during motion or exertion can be assessed by history and maneuvers that reproduce the symptoms. Endurance can be assessed, in part, by history and examination of the heart, peripheral circulation, and lungs. A 6-minute walk test in the clinic might be feasible during comprehensive assessment.

Some impairments are hard to detect in the clinic and require further testing. Vestibular testing may be helpful when there is unsteadiness that is not well explained by other impairments or when specific vestibular symptoms are present. Electrodiagnostic testing of nerve conduction velocity or abnormal muscle activity may be indicated when neurological findings are suspicious. Exertional chest pain or dyspnea requires appropriate cardiac and pulmonary testing and a screen for anemia. Leg pain on exertion suggests testing for peripheral vascular disease or lumbar stenosis.

### Psychosocial and Environmental Assessment

Mobility limitations are influenced by psychological, social, and environmental factors (Table 115-9). Depression can have a powerful effect on the desire to be mobile. Fear of falling, lack of confidence, and low self-efficacy can also adversely influence a person's mobility. Screens for these conditions can include a single question or multiple questions (Table 115-3) and should be part of a comprehensive mobility assessment. Apathy and lack of motivation are a common concern in geriatric rehabilitation. Formal and informal social support resources can be critical for the person with mobility limitations. Cultural and financial factors can influence attitudes toward disability and resources for addressing the problem. The safety and accessibility of the living environment can be a barrier or facilitator for persons with mobility problems. A home visit for assessment can offer many opportunities for creative problem solving.

## MANAGEMENT

### Intervening Directly on Mobility

Interventions directed at functional limitations are often rehabilitative in nature and involve exercise, adaptive equipment, and environmental modifications. Mobility limitations can be addressed through mobility task practice and exercise to improve specific impairments in strength, balance, endurance, and/or flexibility. Since deconditioning is almost always present as a direct consequence of reduced mobility and inactivity, and deconditioning has been found to be treatable in many older adults who are sick or frail, general conditioning programs of exercise are frequently indicated. Assistive and orthotic devices can improve stability and reduce weight-bearing pain. The evidence for the effectiveness of rehabilitation and exercise interventions is growing and has been examined in older adults with varying levels of mobility limitations. Chapter 29 on rehabilitation and Chapter 114 on exercise present these interventions in more detail.

**TABLE 115-8**

**Assessment and Treatment of Organ or System Impairments That Cause Mobility Problems**

Functional Domain	Organ System	Impairment	Assessment	Related Causes	Treatment
Sensory	Eye	Acuity	Near and far by Snellen chart	Presbyopia and cataracts	Lenses and surgery
	Eye	Peripheral vision	Confrontation	Glaucoma and stroke	Prisms
	Eye	Depth	Depth testing	Monocular	Lighting, contrast, and avoid multifocal lens while walking
	Eye	Dark adaptation	Self-report	Miotic agents for glaucoma	Change medications and lighting
	Vestibular	Otoliths	Ability to perceive vertical	Benign positional vertigo	Epley maneuver and vestibular rehabilitation
	Vestibular	Semicircular canals	Ability to perceive rotation and acceleration	Meniere's disease	Medications and vestibular rehabilitation
	Peripheral nerve	Neuropathy	Filaments and vibratory sense	Diabetes and peripheral vascular disease	Haptic enhancement (see text) and footwear
Central	Circulation	Decreased brain perfusion	Hypotension and orthostasis	Medications, arrhythmias, postprandial hypotension, and dehydration	Change medications, antiarrhythmics, or pacemaker; increase fluid intake
	Brain	Motor processing	Level of consciousness, digit symbol substitution test, and trail making B test	Medications and CNS disorders (white matter hyperdensities, focal atrophy, and brain infarcts)	Change medication and blood pressure control
	Brain	Postural reflexes	Righting reflexes	Parkinson disease and other CNS disorders	Trial of anti-Parkinson medications
Effector	Muscle	Strength	Manual muscle tests and strength-based motions (chair rise and squat)	Multiple neurological conditions and inactivity	Exercise, bracing, and medication adjustment
	Musculoskeletal	Flexibility	Contractures and range of motion (ROM)	Injury, arthritis, and inactivity	Active and passive ROM and orthotics
	Heart endurance	Cardiomyopathy	Dyspnea at rest or on exertion, fluid retention, and echocardiogram	Systolic or diastolic dysfunction	Standard care for systolic and diastolic dysfunction
	Lung endurance	Hypoxia or reduced air flow	Dyspnea rest or on exertion, hypoxia, and decreased peak flow	COPD, asthma, and other lung	Standard pulmonary care and oxygen
	Circulation endurance	Peripheral vasculature	Leg pain on exertion, decreased pulses, and bruits	Arteriosclerosis and venous insufficiency	Medical and surgical, and exercise
	Hematologic endurance	Anemia	Dyspnea or fatigue on exertion	Multiple causes	Treat based on cause and transfusion for severe
	Muscle endurance	Sarcopenia	Leg fatigue on exertion	Inactivity	Exercise and possibly trophic agents in the future
	Musculoskeletal pain	Bone and joint deficits	Weight-bearing pain	Osteoarthritis, osteoporotic fractures, periarticular conditions, and foot problems	Pain medications, injections, assistive devices, and orthoses
	Neurological pain	Spinal cord, roots, and nerves	Leg and back pain with activity	Spinal stenosis, radiculopathies, peripheral neuropathies, and CNS disorders	Injections, surgery, and medications

TABLE 115-9

## Psychosocial and Environmental Assessment and Management of Mobility

Area	Type	Assessment	Management
Psychological	Depression	Standard screen (see Chapter 70)	Antidepressants and counseling
	Self-efficacy	Interview	Counseling
	Apathy	Interview and observation	Stimulants and social therapies
Social	Emotional and instrumental supports	Interview	Community programs and family engagement
	Culture	Interview	Cultural consultation
	Finances	Interview	Community resources
Environment	Physical barriers	Home visit	Environmental adaptations
	Access	Interview and home visit	Community programs

## Treating Impairments

Some impairments can be linked to diseases and pathological processes that are amenable to treatment, and some impairments can be improved directly regardless of pathological cause (Table 115-8). Visual function for mobility can be modified by optimizing visual acuity with prescription glasses, by use of special prisms in the glasses (lenses that expand the visual field), and by making the best use of environmental lighting. Some vestibular disorders are amenable to rehabilitation through special head and eye exercises. Peripheral sensory disorders are often not correctable, but compensation can be achieved through the use of lighting to improve visual information and use of a cane to enhance haptic perception. Haptic perception is demonstrated by the remarkable decrease in sway with eyes closed, seen in persons with peripheral sensory or vestibular disorders, when they are allowed even minimal, nonsupporting contact with a stable surface such as a table or wall. Haptic sensation implies that another sensory input source can be used by the brain to provide information about body position when information from the feet is lost. When a cane is used to promote haptic sensation, it is providing information to the hand about body position and is not used as a weight-bearing device. Shoe inserts that increase sensory feedback are in development. Interventions for orthostatic hypotension include medication adjustment, compression stockings, and, in some cases, salt loading or medication such as fludrocortisone or midrinone. Treatment of arrhythmias, especially significant tachy- and bradyarrhythmias, when selected judiciously, might reduce dizziness and improve mobility. Delayed movement speed can be reduced if medications that exacerbate the problem are removed. The slowed gait of Parkinson disease can be responsive to medication although the balance disorder is not. Parkinson patients may move faster and thus increase their risk of fall injury when medications are initiated. Cardiac, pulmonary, and anemia-related symptoms that limit endurance may be managed medically. Strength and endurance are amenable to exercise training. Pain may be managed using medications, injections, orthotics, exercise, and sometime surgery.

## Attention to Factors that Modify Behavior and Environment

The modifiable psychosocial factors that influence physical activity may offer opportunities to intervene (Table 115-9). Depression can be managed medically or with psychotherapy. In post acute care settings, methylphenidate has been used short term to treat apathy. Social support and encouragement can be promoted through group

activities. Physical environmental adaptations in the home include ramps and railings, bathroom modifications, proper lighting, and strategic placement of stable furniture items. Further modifications are often indicated in institutional settings.

## Care for the Immobile Person

Interventions to reduce the consequences of immobility include determining the level of care need and living setting, training others to properly position and move the patient, implementing a mobilization plan, use of pressure-reducing devices to prevent pressure ulcer, and, sometimes, using equipment to aid in transfers (see Chapter 58). Persons who are responsible for carrying out transfers of immobile patients, including health aides and family caregivers, need training in proper techniques that reduce injury to the patient and the assistant. Absolute bed rest is almost never indicated and should be discouraged in all settings. Mobilization, including walking, has been shown to be feasible even in the intensive care setting. An exception to routine mobilization might be for humanitarian reasons when an individual is actively dying, where routine mobilization might cause suffering without associated benefit. Mobilization rather than bed rest during hospitalization for acute illness has been one of the most consistent interventions in Acute Care of the Elderly units.

## SUMMARY

Mobility disorders are widespread in older adults. Mobility limitations constrain many functions required for independent living and are powerful indicators of future problems. Mobility can be classified using simple screen. Evaluation starts with a triage function or simple measures like gait speed. Many common contributors to mobility limitations can be managed in the primary-care setting. A comprehensive mobility evaluation is resource intensive and requires a multidisciplinary team. Evaluation and management include a biomechanical approach to function, a biomedical approach to the physiological components of mobility, and a psychosocial and environmental approach to modifying factors.

# Osteoarthritis

Shari M. Ling ■ Yvette L. Ju

## INTRODUCTION

Osteoarthritis (OA) is defined as bony inflammation of a joint or joints. OA is the most common form of arthritis in the United States and Europe. Given the prolonged life expectancy in the United States and the aging of the “baby boomer” cohort, the prevalence of OA is expected to increase further. Although the precise cause of OA is unknown, it is likely that multiple causes and many factors influence disease expression.

## EPIDEMIOLOGY, CAUSES, AND PREDISPOSING FACTORS

Epidemiological and observational studies provide important clues to the mechanisms by which OA develops and progresses and, thus, identify risk factors that might comprise intervention targets for OA prevention and management.

### Age and Gender

Advanced age is the strongest risk factor for the development of OA across all anatomical sites. Prevalence rates for both radiographic OA and, to a lesser extent, symptomatic OA (moderate or severe) increase with age, with a steep rise after the age of 50 years in men and age of 40 years in women. Radiographic OA of the hand is the most prevalent form, followed by knee, then hip. It is not unusual to find incidental radiographic OA in an otherwise asymptomatic older patient. Symptomatic OA of the knee and hip OA are the most prevalent in both sexes, with symptomatic involvement of the hands increasing in women beginning at menopause.

Changes in the hormonal milieu are thought to contribute to OA pathogenesis and are supported by reports of reduced risk of incident hip OA in women receiving hormonal therapy. However, estrogen/progestin replacement has not been proven to reduce the

chance of developing knee pain or disability in women with knee symptoms. Whether estrogen or hormonal therapy is beneficial with regard to OA thus remains controversial and further emphasizes that OA symptom and disease pathogenesis likely develop through different mechanisms.

### Joint Trauma and Nontraumatic Biomechanical Factors

*Joint trauma* of a severity that causes swelling and discomfort lasting several days or longer has been shown to increase risk of knee OA. Prior surgical removal of a meniscus in the knee is also a predisposing factor to OA of the knee. Meniscectomy is associated with a sixfold increase in risk for development of radiographic OA, even if limited rather than total meniscal resection is employed. Obesity, female sex, and preexisting early-stage OA of the knee and concurrent hand OA compound the risks incurred following meniscectomy. Occupation- and sports-related *repetitive injury* and physical trauma contribute to the development of OA of specific joints (e.g., knees in soccer players, elbows of baseball pitchers, and upper limbs of air hammer operators) and account for occurrence at sites not usually affected by OA. Although the prevalence of knee OA is greater in adults who have engaged in occupations that require repetitive bending and strenuous activities, an association with intense exercise or recreational physical activity such as jogging has not been proven. *Joint malalignment* and *varus–valgus laxity* increase the risk of developing OA. Malalignment of the knee appears to explain some of the risk of knee OA progression attributable to obesity. Altered alignment, as in the case of acetabular dysplasia, may also increase risk of hip OA. Although laxity and malalignment may coexist, laxity independently increases risk of OA.

### Obesity

Obesity and excess weight comprise an important risk factor for the development and progression of knee, hip, and even hand OA. It is estimated that persons in the highest quintile of body weight have up to 10 times the risk of knee OA than those in the lowest quintile.

Although mechanical factors are assumed to explain the increased risk of knee and hip OA associated with excess weight and obesity, the association with hand OA with weight raises the possibility of alternative mechanisms.

### Muscle Strength

Weakness of the knee extensor muscles appears to be both a consequence and a risk factor for the development of knee and hand OA. However, muscle strengthening has not been proven to protect individuals from progression of OA. In fact, higher strength has been associated with greater risk of progression in malaligned knees, and also of proximal interphalangeal and carpal–metacarpal joint OA in men and metacarpophalangeal joint OA in men and women.

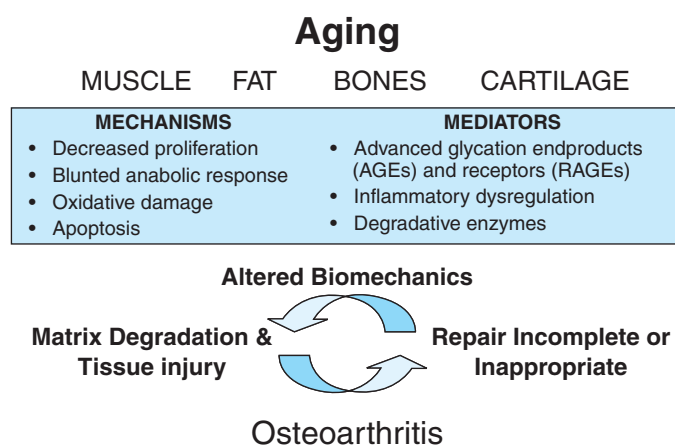

## CLASSIFICATION AND PATHOPHYSIOLOGY

### Classification

The term “primary OA” is used to denote idiopathic OA in contrast to “secondary OA” that results from damage induced by another process (gout, rheumatoid arthritis, and bacterial). Although OA can involve any joint, it is most prevalent in the fingers and thumb base of the hands, knees, hips, and also spine. The classification system developed by the American College of Rheumatology (Table 116-1) integrates patient age, radiographic features, clinical symptoms, and physical abnormalities of the hands, knees, and/or hips. Such classification systems define phenotypes of clinical presentation that may lend clarity to the development of specific treatment modalities in the future. OA that is radiographically apparent but not associated with clinical features specified in the ACR criteria is referred to as “radiographic OA.”

### Pathophysiology

Cartilage degeneration is the hallmark of this disease, with fibrillation and ulceration that begins superficially and eventually extends into deeper layers. In addition, subchondral bone abnormalities and focal synovial inflammation can also be observed. These pathological characteristics are thought to arise owing to disruption of the balance between degradative and repair processes necessary to maintain joint health. Inflammatory cytokines, matrix degrading metallopro-

**FIGURE 116-1.** The process by which aging is theorized to increase risk of OA is depicted. Some of the mechanisms and mediators demonstrated in cellular and system aging are relevant to cartilage and periarticular structures. These changes may predispose the aging individual to altered biomechanics that increase risk of joint injury to which repair is attempted but eventually fails.

teinase enzymes, and chondrocyte apoptosis are likely contributors to this process. Osteophytes develop later and are thought to represent attempted repair. The process by which aging is theorized to increase risk of OA is depicted in Figure 116-1.

## PRESENTATION

### Symptoms

The most common initial symptom of OA is stiffness, which is most noticeable on awakening in the morning and after periods of inactivity. These symptoms are usually temporary and rarely persist for more than 30 minutes. As the disease progresses, patients experience pain with activity, which resolves on resting the joint. With further progression, patients report pain at rest and that awakens them from sleep. Validated questionnaires assessing the severity of painful symptoms referent to specific activities such as walking, stair climbing, and grasping are available and may prove useful in clinical settings, although these are primarily used in research studies of OA. Similarly, measures assessing the intensity and duration of stiffness may also prove useful—particularly in monitoring treatment

**TABLE 116-1**

### Criteria for the Diagnosis of Osteoarthritis of the Hand, Knee, and Hip

HAND	KNEE	HIP
Hand pain, aching, or stiffness and	Knee pain and	Hip pain and
Hard tissue enlargement of two or more joints and	Radiographic osteophytes and	Two or more of the following:
Fewer than three swollen MCP joints and	One or more of the following:	*ESR <10 mm/h
Two or more DIP joints with hard tissue enlargement or	Age ≥50 yr	Radiographic femoral or acetabular osteophytes
Deformity in two or more select joints <sup>†</sup>	Morning stiffness <30 min	Radiographic joint space narrowing
	Crepitus on motion	

\*ESR, erythrocyte sedimentation rate.

<sup>†</sup>Select joints = DIP, PIP, and first CMC.

**FIGURE 116-2.** The features of bony prominence and deformity typical of hand OA are depicted here with Heberden's nodes of the distal and Bouchard's of the proximal interphalangeal joints of the fingers.

response. A history of systemic symptoms such as unintentional weight loss, excessive fatigue, and prolonged morning stiffness that extends beyond an hour suggests an “inflammatory” condition such as polymyalgia rheumatica or rheumatoid arthritis, rather than OA.

### Physical Abnormalities

Physical examination of a joint with early OA may be completely normal. Subtle prominence of the finger joints and effusion of the knee may be present early. Joint tenderness, warmth, and painful motion may be present. Crepitus may be appreciated by palpating the joint during movement. Bony prominence develop later and are exemplified by Heberden's nodes of the distal and Bouchard's of the proximal interphalangeal joints of the fingers (Figure 116-2) (Color Plate 24). These are firm and bony on palpation, in distinction from more inflammatory etiologies that are boggy to palpation. As joint destruction ensues, crepitus and bony prominence become appreciable. Joint laxity or unexpected mobility may be observed on passive joint movement and may suggest incompetence of the supporting ligaments. As the disease progresses, joints may become malaligned and deformed. An example of this is knee deformity that is either

varus (knees pointing outward beyond the femoral–tibial line) or valgus (knees pointing inward). Joint motion becomes limited as the disease progresses. Disease severity may be manifested as OA involvement of multiple joints as well as the spine. In these cases, careful examination of each joint is required to ascertain the source of painful symptoms. For example, “hip pain” may arise from OA of the hip, but also may be pain referred from the knee or spine. Similarly, OA of the neck may manifest as shoulder pain. Accurate localization of the source of painful symptoms is required for effective management.

## EVALUATION

### Diagnostic Imaging

Conventional radiography remains the imaging modality of clinical choice to confirm a diagnosis of OA by the presence of osteophytes, as shown in Figure 116-3. Additional information obtainable from X-ray images includes joint space width and alignment, calcification of cartilage or periarticular structures, and soft-tissue swelling, bony

**FIGURE 116-3.** The radiographic characteristics of osteoarthritis shown in this knee X-ray include osteophytes at the joint margin, asymmetric joint space narrowing, subchondral sclerosis, and cysts. These features can be observed most commonly in the hands (A), knees (B), or hips.

defects (osteomas), and osteopenia and fracture. Scoring schema have been developed and used to assess disease severity as well as confirm disease presence. However, conventional radiographs have limited resolution and are, therefore, not capable of detecting early disease. Additionally, certain views are required to allow measurement of change in specific features (e.g., joint space width and osteophyte size) over time. Although X-rays can be useful in excluding conditions such as fracture and tumor, these can also be misleading because of the high prevalence of incidental radiographic abnormalities in older adults, as discussed further below. Therefore, X-ray abnormalities should be interpreted in the context of clinical history and physical findings or risk, mistakenly attributing symptoms from other illnesses (infection, aneurysm, etc.) to OA.

## Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) offers promise for earlier detection of OA, since focal defects in cartilage can be identified in painful knees that are still radiographically normal. Furthermore, MRI has contributed to our understanding that OA involves a variety of characteristics (e.g., osteophytes, cartilage defects, and bony abnormalities), which often occur together in one or several regions within a joint in a manner that is highly correlated with persistent painful symptoms, and has led the field to appreciate that OA is not a disease that is limited to cartilage. Moreover, changes in cartilage, bone, and synovium often occur together. MRI also allows visualization of structures important to functional stability of the joint (e.g., ligament and meniscus) and should be obtained to evaluate mechanical symptoms of locking or giveway weakness in knees, instability of the hip, and impingement symptoms of the shoulder. However, clinical discretion is required in determining whether visible structural defects require surgical correction. Additionally, MRI may be useful in distinguishing other intensely inflammatory conditions from OA.

## Laboratory Studies

Laboratory studies are generally more helpful to exclude alternative diagnoses such as infectious arthritis, Lyme, or crystalline diseases (gout and CPPD) than to diagnose OA. Several reports of elevated concentrations of C-reactive protein in association with OA support our reconsideration of OA as a mildly inflammatory disease, but it is neither sensitive nor specific enough for diagnostic utility. Additional products of cartilage and bone turnover have been integrated into clinical OA studies but are not applicable to OA management. Collectively, these biologic indicators have contributed to our understanding of the OA process, but, at present, serum, urine, or synovial markers with acceptable test characteristics are not available for diagnostic or prognostic use.

## MANAGEMENT

The objectives of OA management are to lessen painful symptoms and improve function and quality of life. The scope of OA management has appropriately broadened beyond medicinal agents to include physical and rehabilitative and other interventions. Primary-care practitioners can set in motion numerous services (e.g., rheumatology, physiatry, physical or occupational therapy, psychology, nutrition, social work, and orthopedic surgery) in pursuit of these

objectives. Currently used management options are summarized in [Table 116-2](#).

## Patient Education

The effectiveness of OA management is highly dependent on patient compliance. Therefore, patient education should be considered the initial required element in OA management. Educational groups or classes provide an efficient and social vehicle to convey general information pertaining to OA and management strategies. Topics might include warning signs of medication toxicity, exercise, weight management, stress management, sleep hygiene, and general healthy living. Participants in self-management groups report less pain and reliance on nonsteroidal anti-inflammatory agents. Additional benefits of participation in these programs include boosting self-efficacy, increased physical activity, and lessening the frequency of arthritis-related physician visits. However, program participation does not obviate the need for individualized patient education in matters of medication compliance and drug toxicity monitoring.

## Nonmedicinal Interventions

*Weight loss* in obese individuals with OA of the knee can reduce painful symptoms as well as slow disease progression and is, therefore, recommended for all patients who are overweight. In many cases, a structured weight management program with counseling may be required. Although a 10% reduction in weight is considered a reasonable objective, this should be achieved by combined exercise with dietary modification in older adult patients as a result of the additional benefits gained through muscle strengthening.

Type of exercise-isometric, isotonic, etc  
 Frequency number of repetitions and how often  
 Intensity  $\leq 70\%$  one MVC (Maximum Voluntary Contraction)  
 Precautions, e.g., avoid exertion postmeals

**FIGURE 116-4.** Prescribed exercise begins with selecting the form of exercise most appropriate to the patient's current functional and health status and finally to provide the details of intensity, duration, and frequency. Exercise precautions should be reviewed.

### Exercise

Several studies have provided convincing evidence that resistive and aerobic exercise training is an effective means of reducing pain severity and disability in older adults with knee OA. General steps for composing an exercise prescription begin with reviewing absolute and relative contraindications and setting realistic objectives. Additional specifics are depicted in Figure 116-4 and include selecting the form of exercise most appropriate to the patient's current functional and health status, and finally to provide the details of intensity, duration, and frequency. Patients should be advised to watch for signs of excessive joint strain, including pain during activity, pain lasting more than 1 to 2 hours after exercise, swelling, fatigue, and weakness.

*Mobilization* exercises (i.e., stretching and flexibility training) are typically the first steps in restoring function and focus on relieving stiffness and increase joint mobility by increasing length and elasticity in muscles and periarticular tissues. *Isometric* exercises should be introduced early, given benefits of restoring muscle strength and joint stabilization without increasing pain. Straight leg raises, wall sits, and isometric leg presses are some examples of isometric quadriceps-strengthening exercises. Strengthening the quadriceps may realign and stabilize joints. *Isotonic* exercises can be introduced later to strengthen muscles as joints move. Squats, wall slides, and leg presses are some examples of isotonic exercise that strengthen both quadriceps and hamstring muscles concurrently. *Aquatic* exercise provides resistance exercise training while also unloading up to 50% to 60% of body weight. Finally, *aerobic* exercise improves fitness, exercise tolerance, and endurance. Walking and low-impact and aquatic aerobic programs improve overall general fitness and coordination. Patients with weight-bearing OA (knee and hip) should engage in strenuous activities cautiously. Some weight-bearing exercises such as stair climbing and heavy lifting (i.e., loads greater than 10% of body weight) may significantly increase loading on weight-bearing joints, as do speed walking and running.

### Electrical Stimulation

Neuromuscular electrical stimulation delivers low-voltage electrical impulses through surface electrodes placed over motor points of the targeted muscle. Electrical stimulation induces muscle contrac-

tion. Neuromuscular electrical stimulation has been used to increase quadriceps muscle strength and lessen pain in older adults with disabilities with knee OA and may be an acceptable alternative for patients who are unable to participate in exercise owing to severe pain or contraindications.

### Ultrasound

Therapeutic ultrasound is one of the most widely prescribed modalities for pain and loss of function caused by OA. Ultrasound uses high-frequency (0.8–1.0 MHz) sound waves to reduce painful symptoms by pulsed delivery for acute pain and inflammation or by continuous delivery for patients with chronic symptoms that have resulted in joint limitations.

### Cryotherapy and Thermotherapy

Cold and heat are useful adjuncts for the treatment of OA and may decrease both pain and muscle spasms. Cold reduces the inflammation of arthritis, minimizes muscle spasm, and decreases the sensation of pain. Patients should limit use of ice or cold packs to 20 minutes or when the area becomes numb. Cautious use of heat can reduce pain and muscle spasm but should be limited to 20-minute intervals. Contrast therapy, which alternates between hot and cold treatment modalities, provides additional therapeutic benefits compared to either alone.

### Acupuncture

Acupuncture has been included as a potentially useful adjunctive therapy in a comprehensive disease management program for OA. Transcutaneous electrical nerve stimulation delivers acupuncture-like stimulation in random order and is one of the modern changes to classical acupuncture.

### Massage

Rubbing a painful joint is almost a reflex action for some clients. Massage is theorized to reduce pain by enhancing endorphin release. Massage relaxes muscle groups and may be a useful adjunct for patients with anxiety and depression.

### Orthoses

Specific orthoses designed to reduce medial knee pain by unloading the medial compartment of the knee include a valgus unloader brace and a lateral wedge insole. Lateral wedge insoles of 5 and 10 degrees lateral significantly reduced knee varus torque during ambulation by 6% and 8%, respectively. A simpler change to a well-designed running shoe may also lessen pain and damage by decreasing the impact transmitted during ambulation.

### Braces and Splints

Individuals with knee OA may experience knee instability, which can be described as buckling, shifting, or giving way of the knee. Neoprene braces are often requested by patients but unlikely to provide the required structural support, since multiple factors such as lower muscle strength and neuromuscular control and capsuloligamentous laxity likely contribute. However, neoprene braces may alleviate patellofemoral symptoms by improving patellar tracking and provide a greater sense of joint stability by improving joint proprioception.

### Assistive Devices

A cane that is properly fitted to the level of the greater trochanter of the hip and held in the hand opposite to the affected knee or hip can reduce joint loading and symptoms significantly. Patients with advanced hand OA may require task modification or use of meal preparation devices, and hip OA may require additional devices to dress independently.

### Symptom-Directed Medicinal Therapy

Alleviation of painful symptoms constitutes the primary focus of prescribed and over-the-counter medicinal management of OA. In general, treatments should use the least toxic and least expensive medications first. Furthermore, since there is no single best medication for any given patient, selection of specific agents should be based on each patient's symptom severity and weighed against potential adverse events. Finally, it is important to recognize the complexity of treating painful symptoms in older adult patients who are more likely to endure comorbid medical conditions and multiple medications.

### Topical Agents

Topical agents have a role in the treatment of OA. Capsaicin, derived from capsicum, the common pepper plant, is known to be effective in management of OA of the hands when applied two to four times daily. Care should be taken to avoid the inadvertent application of capsaicin in the eyes and other mucous membranes. Topical nonsteroidal anti-inflammatory drugs (NSAIDs) may provide short-term relief of painful symptoms of knee OA. Although generally well tolerated, use of other topical analgesic agents (e.g., nonprescription formulations of menthol- and salicylate-based preparations) has not been proven more effective than placebo.

### Simple Analgesics

Acetaminophen remains the first-line drug of choice for OA management. Acetaminophen should be used at a dose not to exceed 1 g four-times daily (maximum U.S. daily dose of 4 g) and is well tolerated. Despite some evidence of exacerbated renal insufficiency, it is a safer drug than are NSAIDs for patients with renal impairment. Acetaminophen should be used cautiously in patients with impaired liver function and should not be taken with alcohol.

Tramadol is an effective analgesic in management of OA symptoms. A starting dose of 25 mg daily for 3 days can be escalated slowly to a maximum dose thereafter to achieve the desired analgesia. Tramadol also has NSAID-sparing effects. Potential adverse effects include nausea and drowsiness. Seizures and allergic reactions have also been reported at higher doses. Although tramadol is not a controlled substance, it can be abused by patients with opioid dependence.

### Non-steroidal anti-inflammatory Drugs

NSAIDs are the most commonly prescribed agents for treatment of both pain and inflammation in OA and appear to be more effective in relieving moderate-to-severe pain than acetaminophen. Although all NSAIDs inhibit cyclooxygenase enzymes, patient responses to specific agents may vary considerably. Patients vary in their benefit and adverse reactions to various NSAIDs. Difference in half-lives of the NSAIDs may influence patient adherence and dosing. Despite

their efficacy, NSAIDs should be prescribed with caution. Analgesia can often be achieved at low doses. Thus, treatment should begin with the lowest dose and increased incrementally to identify the lowest effective dose for each patient. Additionally, NSAIDs can be used intermittently and in combination with other analgesics.

Patients using NSAIDs should be monitored for gastrointestinal (GI) symptoms of dyspepsia, peptic ulcer disease, gastritis, and GI bleeding; however, GI bleeding may occur in the absence of prior symptoms. In patients at risk of GI events, prophylaxis is highly recommended using one of three strategies. Once-daily proton pump inhibitor therapy decreases dyspepsia and also effectively decreases the development of NSAID-associated ulcers and recurrent NSAID-related ulcer complications. Prophylaxis is also indicated for older adult patients taking low-dose aspirin who are at higher risk of GI toxicity. A second strategy to reduce GI events is cotreatment with misoprostol. Although misoprostol also decreases NSAID-induced ulcers and GI complications, its effectiveness depends on frequent dosing that in itself can cause diarrhea and dyspepsia. A third option for patients at high risk is to add a proton pump inhibitor. Cotreatment with H<sub>2</sub> blockers and sucralfate may reduce GI symptoms but does not reduce the risk of ulcers or serious GI complications.

### Cyclooxygenase-2 Inhibitors

Cyclooxygenase (COX)-2 inhibitors represent the third strategy for reducing NSAID-related GI complications. COX-2 inhibitors (celecoxib, rofecoxib, valdecoxib, etc.) can effectively relieve painful OA symptoms, with less risk of GI symptoms and serious GI adverse events when compared to nonselective NSAIDs. However, the potential benefits of COX-2 use should be weighed against the potential risks. First, data showing an increased risk of acute cardiovascular events in association with the use of selective COX-2 inhibitors have resulted in the removal of two of the three FDA-approved agents from the market (rofecoxib and valdecoxib) and a considerably more cautious approach to the use of the remaining agent (celecoxib). Although cotreatment with aspirin may be considered, concurrent use of low-dose aspirin may compromise the protective advantage of COX-2 selectivity in patients who have already experienced a GI bleed. Therefore, addition of a proton pump inhibitor may be required in patients at high risk. Finally, COX-2 selective agents are as likely as nonselective NSAIDs to reduce kidney function, particularly in older adults with renal compromise. Finally, coagulation parameters should be carefully monitored in patients who add any medication to their anticoagulants because of potential drug interactions. Thus, the risks and benefits of COX-2 selective antagonists must be carefully considered in each patient.

### Nutriceuticals

Numerous nutraceutical products are advertised to reduce painful symptoms and to "promote joint health" with limited well-controlled studies to validate their efficacy. Oral glucosamine and chondroitin sulfate are popular nutritional supplements thought to relieve pain and limit OA progression. Two randomized placebo-controlled trials showed that glucosamine treatment slows rate of joint space narrowing for more than 3 years and chondroitin sulfate treatment for more than 2 years. Interestingly, some studies demonstrating structure modification do not have concomitant symptom improvement, with no consistent improvement in OA symptoms

observed with glucosamine or chondroitin treatment across studies. Fortunately, glucosamine and chondroitin sulfate are relatively well tolerated. Earlier concerns of hyperglycemia, exacerbated diabetes, and possible effects of chondroitin effects on coagulation parameters have not been seen in recent studies. Thus, at present, a 3-month trial is likely safe but should be discontinued if symptoms do not abate. Other products such as *S*-adenosylmethionine or methylsulfonylmethane, shark cartilage, and others remain commercially available and successfully marketed despite the absence of scientific support for their use in the treatment of painful OA.

Diacerein (50 mg twice daily) is an interesting compound that exerts anti-inflammatory effects by inhibiting interleukin-1 and collagenase production, with additional effects on neutrophil chemotaxis macrophage migration and phagocytosis. Diacerein does not alter renal or platelet cyclooxygenase activity and may, therefore, be tolerated by patients with prostaglandin-dependent renal function.

### Narcotic Analgesics

Narcotic analgesics can be effectively prescribed in management of OA pain. Long-acting preparations of oxycodone can be considered for patients with persistent moderate-to-severe pain. For patients with persistent symptoms despite simple analgesics, codeine or propoxyphene can be prescribed. Short-term studies support the use of slow-release formulations of narcotics administered in low doses, such as oxycodone SR 10 mg, for patients with moderate-to-severe OA of the knee in whom pain is inadequately controlled by acetaminophen or NSAIDs alone. Improvements in pain and quality of sleep were comparable for short- versus long-acting narcotic preparations, with comparatively fewer GI side effects. These agents may be particularly useful for chronic management of patients with severe knee or hip OA in patients who are not surgical candidates owing to comorbid cardiac or pulmonary illness.

### Structure-Modifying Medicinal Agents

Although definitive structure and disease-modifying therapies are not yet available for OA, several promising studies have been conducted, which provide hope that such therapy is within reach. Diacerein has been proposed as a slow-acting, symptom-modifying, and perhaps disease-structure-modifying drug for OA. Doxycycline is of interest for its metalloproteinase-inhibiting activity and ability to limit joint space narrowing in obese women, but it does not appear to prevent disease development or improve symptomatic outcomes. Risedronate, a bisphosphonate indicated for treatment of osteoporosis, has recently been shown to reduce markers of cartilage degradation and bone resorption. Other agents of interest as potential OA structure modifiers include antagonists of interleukin-1 and inhibitors of matrix metalloproteinases, inducible nitric oxide synthetase, intracellular signaling pathways such as P38, MEK-1/2, peroxisome-proliferator-activated receptors, and vitamin D. Molecular strategies to inhibit destructive inflammatory cytokines and matrix metalloproteinases and promote to chondrocyte survival and synthesis of cartilage matrix components such as type II collagen and proteoglycans are additional areas of scientific development.

### Intra-articular Therapies

Intra-articular therapies should be considered for patients with peripheral OA with symptoms despite maximal analgesics but may also

be a viable therapeutic alternative for patients in whom NSAID or COX-2 inhibitor use is contraindicated or risky.

### Intra-articular Glucocorticoid Agents

Intra-articular depot corticosteroids may be considered in management of accessible peripheral joints and are proven to achieve short-term relief from painful symptoms. When proper technique is employed, the risks of bleeding and septic arthritis are comparable to phlebotomy. Although recurrent administration is generally well tolerated and has not been observed to result in joint damage, more definitive surgical intervention should be considered.

### Hyaluronic Acid Derivatives

The intra-articular delivery of synthetic and naturally occurring hyaluronan derivatives have gained popularity in management of mild-to-moderate OA of the knee and hip. Several injections are required for the different compounds, and some patients may experience a flare of symptoms after injection. In general, these agents are tolerated as well as corticosteroid injections. Thus far, long-term administration of these agents also appears to be safe.

### Surgical Interventions

Surgical intervention should be considered in patients with OA who have persistent, function-limiting symptoms despite maximal medical management and who are healthy enough to withstand surgery. Several surgical options exist, each with specific indications.

### Arthroscopy with Debridement

Arthroscopy allows direct visualization to assess structural integrity of the joint and is most appropriate for patients with mechanical symptoms (locking and giveway weakness) because of meniscal defects that are either repaired or removed. Arthroscopic lavage for OA of the knee and other joints is controversial but has been used in combination with viscosupplementation as a temporizing measure pending more definitive surgery.

### Osteotomy

Osteotomy follows the principle of transferring load to the unaffected compartment of the knee. High tibial osteotomy is appropriate for OA, involving a single compartment in a varus malaligned knee. High tibial osteotomy achieves effective pain relief and restoration of mobility function in up to 90% of patients at 5 years, and 65% at 10 years. Postoperative alignment is the primary determinant of successful pain relief and may delay the need for joint replacement for up to 10 years. Therefore, young patients with varus malalignment who desire a fully active lifestyle that includes recreational sports are ideal candidates for osteotomy. When appropriately performed, osteotomy should not compromise later arthroplasty if it becomes necessary.

### Arthroplasty

Arthroplasty, prosthetic joint replacement surgery, should be considered for patients who have function-limiting symptoms that have persisted despite receiving maximal medical and nonmedicinal

treatment. Arthroplasty can replace either a single compartment (unicompartment) or the total joint.

**Unicompartment Arthroplasty** It may be considered for patients who are nonobese with discrete pain and disease that is localized to the medial compartment of the knee and who have less than 10% varus malalignment, at least 90 degrees of motion without a flexion contracture, and who do not intend to return to high impact activities. Unicompartmental knee replacement can be achieved through a smaller surgical incision and shorter postoperative and rehabilitative course than total joint arthroplasty. Approximately 95% of unicompartment prostheses survive to 10 years.

**Patellofemoral Arthroplasty** Isolated disease of the patellofemoral joint of the knee occurs in up to 10% of patients with OA of the knee. Several types of patellofemoral arthroplasties are available, but the results have been variable, highlighting the need for careful selection of patients. The most common complications following surgery are patella maltracking, excessive wear of the polyethylene implant, and disease progression in the other compartments of the knee joint.

**Total Joint Arthroplasty** In contrast to patients with discrete symptoms, total joint arthroplasty is more appropriate for patients with diffuse OA of the knee or hip. Total knee replacement achieves rapid and long-term symptom relief in and functional recovery for 85% of patients with severe and diffuse disease of the knee or hip. With advances in design, prosthesis survival has improved to 90% at 15 years. However, arthroplasty revision is occasionally required for persistent and severe symptoms or prosthesis loosening. Flexion contracture and obesity are not contraindications for total joint arthroplasty but may complicate functional recovery.

**Bilateral Knee Arthroplasty** For patients with severe bilateral knee OA, one might entertain bilateral simultaneous arthroplasty—that is replacement of both knees during a single operative session. Existing literature suggests that, in carefully selected patients, bilateral arthroplasty can be performed simultaneously and can achieve good outcomes without increasing perioperative risk.

### Hand Surgery

Several different surgical procedures are available (trapeziectomy, trapeziectomy with ligament reconstruction, trapeziectomy with ligament reconstruction and tendon interposition, and joint replacement) and can lessen pain and improve function in patients with advanced OA of the thumb base. The specific type of procedure recommended will depend on durability and stability requirements of the patient's occupation and recreational activities.

### Restorative Tissue Interventions

Transplantation of autologous chondrocytes has been used successfully to repair discrete defects in articular cartilage. Osteochondral transplantation is also promising. However, because the area of cartilage loss in OA in older adults is usually more extensive and because older chondrocytes are less metabolically active than young chondrocytes, transplantation to repair or replace diffusely degenerating cartilage is currently impractical.

## PREVENTION

Since OA is likely a heterogeneous disease, it is not possible to identify one single factor that, if modified, would reduce risk of all forms of OA. Obesity has been implicated in the development and progression of knee and perhaps also hip and hand OA. Weight loss of this magnitude can alleviate painful symptoms, while also reducing the knee-joint load in overweight and obese older adults with knee OA. For every pound of weight lost, there is a fourfold reduction in the load exerted on the knee per step during daily activities. If this is accumulated for more than thousands of steps per day, the weight lost will be clinically meaningful. Additionally, although severe joint injuries increase risk of OA development, the role of repetitive, relatively minor, trauma in development of OA is not clear. Despite this, interventions to reduce joint injury in recreational sports and adaptations to improve mechanical efficiency for occupations requiring repetitive movements, or bending and lifting are prudent.

## SPECIAL ISSUES

### Pain and Incidental OA

Painful symptoms may be mistakenly attributed to OA as a result of the high prevalence of radiographic abnormalities in older adult patients. Conditions other than OA should be considered in patients who exhibit diffuse pain despite maximal medical and adjunctive therapy. Some of these alternative diagnoses are summarized in [Table 116-3](#). Persistent pain with diffuse tenderness of periarticular regions warrant evaluation for metabolic disturbances that

**TABLE 116-3**

#### Differential Diagnosis of Osteoarthritis

Inflammatory joint disease
Rheumatoid arthritis

Systemic diseases
Diabetes
Malignancy
Autoimmune (lupus and vasculitis)

affect bone, such as vitamin D deficiency or hyperparathyroidism. Fibromyalgia, characterized by pain, fatigue, nonrestorative sleep and soft-tissue tenderness, becomes more prevalent in late life and is also poorly responsive to conventional OA management.

### Conditions Superimposed with OA

Pain caused by OA should be localized to that joint and reproduced on either palpation or movement of that joint. Occasionally, OA is accompanied by periarticular inflammation of the tendons (ten-donitis) or bursae (bursitis), which are both elicited on active, but not passive, range of motion. Evaluation for other etiologies of pain is warranted by a few clinical “red flags.” OA is not accompanied by constitutional symptoms of fever, unintentional weight loss, or severe fatigue. Presence of exquisite tenderness, erythema, and a tense effusion also cannot be explained by OA and warrant prompt evaluation for other causes (e.g., crystalline and infectious), particularly when abrupt in onset.

### Functional Limitations

OA contributes to late-life functional limitations. Recent studies suggest that limitations develop early during the natural history of OA and can span mobility and hand function, including self-care tasks. Furthermore, gait patterns also change with weight-bearing OA to include slower walking speed, shorter stride length, reduced peak vertical ground reaction forces, and longer stance phase. Pain and muscle weakness appear to increase risk of functional limitations and disability and, therefore, comprise key targets of intervention. In addition, being overweight or obese not only increases risk of progressive knee OA but also contributes substantially to mobility limitations. Fortunately, pain relief achieved with weight reduction also improves walking speed in obese adults.

### Falls

Patients with OA of weight-bearing joints (i.e., knee) are at increased risk of injurious falls and fracture. As discussed above, patients with advanced OA of the knee may have proprioceptive deficits. This deficit, usually bilateral, may contribute to the increased risk of falls observed in patients with weight-bearing OA. Recent studies suggest that pain may increase the propensity to trip on an obstacle and that relief of painful symptoms can decrease the propensity to trip and fall over an obstacle. This evidence underscores the importance of treating pain and enhancing muscle training in patients with OA.

### Comorbidities

It is accepted that late-life physical disability is an important consequence of OA and other chronic age-associated diseases. However, beyond the limitations attributable to the cumulative effect of the number of chronic illnesses, specific comorbid disease pairs are of clinical importance and scientific interest. Comorbid OA and heart disease is one such disease pair that presents a significant clinical challenge. Patients with OA may engage in less strenuous activities, thereby having less opportunity to declare classic anginal symptoms. As discussed above, NSAIDs and COX-2 inhibitors that are commonly prescribed in management of OA symptoms must be used cautiously in patients with underlying heart disease. Finally, patients

with significant heart disease would be ill-advised to undergo surgical procedures despite the severe symptoms and disability.

## CONCLUSIONS

OA remains the most prevalent articular disease of older adults. Recommended treatments include safe and adequate pain relief by implementing combined medicinal with rehabilitative and behavioral interventions. Biological markers that will detect early disease and enable interventions capable of modifying or mitigating disease progression are being intensely pursued.

# Osteoporosis

Gustavo Duque ■ Bruce R. Troen

## DEFINITION OF OSTEOPOROSIS

The term *osteoporosis* was first introduced in the nineteenth century based on histological diagnosis (“porous bone”). Osteoporosis is a “disease characterized by low bone mass and microarchitectural deterioration of bone tissue leading to enhanced bone fragility and a consequent increase in fracture incidence.” Osteoporosis can be defined either by the presence of a fragility fracture or by bone mineral density (BMD) measurement. In defining BMD criteria for osteoporosis, the World Health Organization (WHO) used as the standard the BMD of young adult women who are at the age of peak bone mass. For each standard deviation below peak bone mass (or 1 unit decrease in T-score), a woman’s risk of fracture approximately doubles. As seen in Table 117-1, a T-score  $< -2.5$  defines osteoporosis; osteopenia (low bone mass) and normal bone mass are also defined. A BMD measurement allows early diagnosis of osteoporosis and intervention prior to fracture in older adults. In addition, women with osteopenia can be followed carefully for further bone loss. Although the original standards for definitions of osteoporosis were determined in white women, recent data indicate that the standards for men and Hispanic women are probably similar to those of white women. In addition, standards are now being developed for African-American women. However, defining osteoporosis solely by T-score does *not* effectively capture all patients at risk of a fracture. Greater than 50% of all hip fractures occur in those with T-scores that are better than  $-2.5$ . Failure to evaluate and treat such patients adds to the individual and societal cost and consequences of osteoporosis. Therefore, we are still faced with the challenge of improving the identification of the individual patient at risk of fracture and subsequently optimizing both prevention and treatment for the elderly.

Primary or idiopathic osteoporosis has been historically classified as postmenopausal or senile osteoporosis. Postmenopausal osteoporosis, formerly known as type I, occurs in women between 51 and 75 years of age and is related to estrogen deficiency seen with the menopausal transition. In contrast, senile osteoporosis typically

occurs in persons older than 60 years of age. It affects both men and women and has a different pathophysiology, which involves reduced levels of bone turnover owing to a reduction in the numbers of bone-forming cells. Increasing evidence points to a progressive age-related alteration in stem cell physiology that favors adipogenesis and thereby reduces osteoblastogenesis and bone formation. Nevertheless, estrogen probably plays a role in the pathophysiology of senile osteoporosis as well. Secondary osteoporosis is the result of an underlying disease or medications that adversely affect bone. In this chapter, we will focus on the typical characteristics of senile osteoporosis from its pathophysiology to therapeutic approaches.

## EPIDEMIOLOGY

In the United States, women have more than 250 000 and 500 000 hip and spine fractures per year, respectively. Men account for an additional 250 000 fractures per year; 75 000 are hip fractures. By using BMD, osteopenia is estimated to be present in 8 to 13 million men (28–47%) and in 13 to 17 million women (37–50%); osteoporosis is estimated to be present in 1 to 2 million men (3–6%) and in 4 to 6 million women (13–18%). On reaching the age of 90 years, one-third of women and one-sixth of men will suffer a hip fracture. Both women and men have a similar lifetime vertebral fracture risk of 12%.

The consequences of osteoporotic fracture include diminished quality of life, decreased functional independence, and increased morbidity and mortality. Pain and kyphosis, height loss, and other changes in body habitus resulting from vertebral compression fractures diminish quality of life in women and men. These changes lead to declines in functional status such as the inability to bathe, to dress, or to ambulate independently and may result in decrease pulmonary and gastrointestinal function. Approximately 50% of women do not fully recover prior function after hip fracture; older adults have a 20% to 25% mortality in the year following hip fracture. Men are at a

TABLE 117-1

## World Health Organization Criteria for Osteoporosis

WHO CLASSIFICATION	BMD T-SCORE
Normal	$> -1$
Osteopenia	$\leq 1$ but $> -2.5$
Osteoporosis	$\leq -2.5$
Severe osteoporosis	$\leq -2.5$ + fragility fracture

BMD, bone mineral density.

higher risk of dying after a hip fracture than women. Finally, the estimated annual cost of osteoporotic fractures in the United States is more than \$14 billion, which is higher than the money spent treating cardiovascular disease. Therefore, prevention and early diagnosis and treatment of osteoporosis are vital to improving the health of older adults.

## PATHOPHYSIOLOGY

New advances in the understanding of bone physiology have elucidated an active interaction among bone cells, growth factors, and hormones responsible for the maintenance of calcium levels, skeletal structure, and resistance to trauma. Bone is not simply a mineralized structure but a complex system of cell–cell, cell–matrix, and cell–hormone interactions influenced by genetic background, lifestyle, and diet.

Bone is composed of inorganic (calcium phosphate crystals) and organic compounds (90% collagen and 10% noncollagenous proteins). Noncollagenous proteins include albumin, osteopontin, osteocalcin,  $\alpha_2$ -HS-glycoprotein, and growth factors, constituting the so-called bone matrix. The bone matrix is produced by osteoblasts and is the environment in which bone and external factors interact in a well-coordinated manner. There are two types of bone: cortical and trabecular. Cortical bone predominates in the long bones of the extremities, while trabecular bone predominates in the vertebrae and pelvis and makes up 80% of skeletal mass. While both types of bone have an active remodeling process, trabecular bone is metabolically more active than cortical bone and more acutely responsive to alterations in sex-steroid hormone status.

During childhood and adolescence, skeletal growth takes place at growth plates, areas in which cartilage proliferates and gradually undergoes calcification, resulting in new bone formation. However, bone remodeling is a lifelong process that maintains bone in order to harbor bone marrow, support the body, and protect vital organs and to provide a source of minerals. The process of remodeling replaces older, frailer bone with newer, more resistant bone in an organized manner. The end product of remodeling is the maintenance of skeletal homeostasis and the preservation of anatomical integrity. With aging or with menopausal transition, the once-coordinated mechanism of bone remodeling becomes uncoupled, leading to bone loss and increased risk of fracture.

### Bone Cells

The cells involved in bone turnover are osteoclasts, osteoblasts, and osteocytes. Osteoclasts are macrophage-like cells that secrete proteolytic enzymes and hydrogen ions that are required for removal

of the deposited bone matrix. The remodeling cycle begins when osteoclast precursors interact with other marrow cells and are activated, becoming multinucleated osteoclasts, which initiates resorption (Figure 117-1) (Color Plate 25). Bone resorption occurs within the resorption lacuna, a tightly sealed zone beneath the ruffled border of the osteoclast where it has attached to the bone surface. Resorption depends on acidification of this extracellular compartment leading to demineralization, and, subsequently, the organic matrix is degraded by cysteine proteases, chief of which is cathepsin K. Osteoclasts consequently create a functional extracellular lysosome, containing both an acidic environment and typical lysosomal enzymes.

In cortical bone, the resorption period lasts approximately 30 days; the final result is a resorption tunnel that will later be filled in by osteoblasts in a haversian manner. The apposition of these haversian channels takes the shape of a “cut onion,” which gives the cortical bone its typical morphology. In trabecular bone, the erosion period lasts approximately 43 days, resulting in a trench between the trabeculae. The life span of osteoclasts is approximately 2 weeks; once these complete the role as bone-resorbing cells, these undergo apoptosis or programmed cell death.

Bone homeostasis depends the intimate coupling of bone formation and bone resorption. After bone is resorbed by osteoclasts, preosteoblasts differentiate into osteoblasts and migrate to the area of excavated bone and begin to deposit osteoid, which is eventually mineralized into new bone. Osteoblasts are fibroblast-like cells derived from pluripotent mesenchymal cells and localized on periosteal surfaces. Such pluripotent stromal cells can be induced to differentiate along the osteoblastic, adipocytic, fibroblastic, or chondrocytic lineages when required. When bone integrity has to be conserved, mesenchymal stromal cells are committed toward the osteoblastic lineage. Many factors are involved in the process of osteoblastogenesis, including the bone morphogenic protein family—bone morphogenic proteins 2, 4, and 7 are potent inducers of osteoblast differentiation (Table 117-2). A transcription factor called Runx2/Cbfa1 plays a key role in osteoblast differentiation; mice lacking Runx2/Cbfa1 do not form bone. A mature osteoblast is a cuboidal cell with a large nucleus and enlarged Golgi highly enriched in alkaline phosphatase. It produces type I collagen and specialized bone-matrix proteins as osteoid, the basic protein for further bone formation and mineralization. Osteoblasts produce alkaline phosphatase, the specific function of which has yet to be determined. Nevertheless, it is used as a marker of osteoblast differentiation and activity, and indirectly as a marker of subsequent osteoclast resorption. Mice lacking functional alkaline phosphatase suffer from hypophosphatasia characterized by impaired mineralization of cartilage and bone matrix. After osteoblasts complete their bone-forming function, they face one of three fates: (1) they become embedded in the newly formed matrix, becoming osteocytes; (2) they remain on the surface of the newly formed bone and become lining cells; or (3) they undergo apoptosis (see Figure 117-1). The ultimate fate of the osteoblast is determined by hormonal changes, the presence or absence of growth factors, and the aging process in bone.

Osteoclasts and osteoblasts belong to a temporary structure known as basic multicellular unit (see Figure 117-1). The coordinated process of bone resorption and formation by the basic multicellular unit lasts 6 to 9 months and results in newly mineralized bone. Osteoblasts are not only active as bone-forming cells, but these also play an important role in the regulation of osteoclast activity. The interaction between osteoblasts and osteoclasts requires a complex

**FIGURE 117-1.** The cellular components of bone turnover. (A) Bone cell formation: After the expression of specific transcription factors, mesenchymal precursors differentiate into osteoblasts. In contrast, osteoclasts differentiate from mononuclear precursors and will act as bone-resorbing cells in the bone multicellular unit (BMU). After the completion of bone resorption, osteoclasts die by apoptosis and are replaced by active osteoblasts, which are responsible for the formation of new bone. Finally, osteoblasts end as either lining cells or as osteocytes embedded into the osteoid, or die by apoptosis. (B) Basic multicellular unit (BMU—also known as bone metabolic unit): Large multinucleated osteoclasts resorb bone on the left. Osteoblasts cascade into the resorption pit, laying down osteoid (unmineralized bone). The turquoise stain reflects mineralized bone. (From Chan GK, Duque G. Age-related bone loss: old bone, new facts. *Gerontology*. 2002;48:62–71 [Figure 117-1A]; and Dr. Susan M. Ott <http://courses.washington.edu/bonephys> [Figure 117-1B].)

system of factors and is facilitated by integrins and cadherins. Briefly, the major osteoclast/osteoblast interaction depends on the expression by osteoclast precursors and mature osteoclasts of a membrane receptor known as receptor activator of nuclear factor- $\kappa$ B (RANK), which belongs to the family of tumor necrosis factor (TNF) receptors. Osteoclast differentiation, maturation, and survival depend on the activation of RANK by its cognate ligand (RANK ligand—RANKL), which is produced by osteoblasts and osteoblast precursors after exposure to different stimuli such as hormones and cytokines (Figure 117-2) (Color Plate 26). Multiple other factors also act to either enhance or suppress osteoclast formation and activation and subsequent bone resorption (see Table 117-2).

RANKL is mainly a cytoplasmic membrane-bound molecule; to a lesser extent it is secreted. Mature osteoblasts also produce a decoy receptor for RANKL called osteoprotegerin (OPG). OPG binds to RANKL in a competitive manner and prevents the interaction between RANK and RANKL, thus decreasing osteoclastogenesis and osteoclastic bone resorption and increasing osteoclast apoptosis. Recently, a new group of molecules, known as ephrins, has been identified as key players in the regulation of osteoblast/osteoclast in-

teraction. This cellular communication is bidirectional and involves a transmembrane ligand known as ephrinB2, which is expressed by osteoclasts, and its receptor EphB4 expressed by osteoblasts (see Figure 117-2). This signaling seems to limit osteoclast activity while enhancing osteoblast differentiation. Consequently, osteoblastogenesis and osteoclastogenesis, along with corresponding bone formation and resorption, are tightly and ineluctably coupled. The differentiation and activation of both osteoblasts and osteoclasts depend critically on each other.

Osteocytes, the third group of bone cells, are the most abundant cell type in bone. Osteocytes are the focus of intense research; several functions recently described include the synthesis of matrix molecules like osteocalcin and an important role in direct communication with surface osteoblasts through molecules known as connexins. Connexins are believed to play a role in the activation and regulation of bone after physiological and mechanical stimuli. These modulate the response of bone during functional adaptation of the skeleton to mechanical forces and the need for repair of microdamage. More recently, sclerostins have been found to be secreted by osteocytes. Sclerostins inhibit osteoblast differentiation and

Calcitonin	

activation, thereby regulating bone turnover and formation. The final fate of the osteocyte is unknown, but high numbers of apoptotic cells have been found in empty lacunae.

### Genetics

Genetics plays a role in determination of peak bone mass. Racial differences in the incidence of osteoporosis have been reported, including a lower relative risk of fractures and higher peak bone mass in African-American women as compared with white women. No one gene, gene product, or polymorphism has yet been credibly identified to account for the variance seen in BMD in specific geographic areas. Several environmental factors, such as diet, topography, and yearly

sunlight exposure, almost certainly interact with genetic predisposition to explain variance seen in periosteal expansion before puberty and in trabecular number and thickness and periosteal–endosteal remodeling during aging. Several recently described candidate genes for determination of peak bone mass are the vitamin D receptor, the peroxisome proliferator activator gamma, and the low-density lipoprotein receptor-related protein 5. All these polymorphisms have been associated with different levels of peak of bone mass and predisposition to fractures in the adulthood. More generally, there does appear to be a familial predisposition to osteoporotic fracture. Therefore, the risk of fracture is increased if an immediate family member (most typically a mother or sister) has experienced an osteoporotic fracture.

### Mechanical Factors

Approximately 95% of peak adult bone mass is gained by the end of puberty. The level of peak bone mass attained and the subsequent rate of bone loss are the primary factors that determine an individual's bone mass in early and late adulthood. Initial bone formation does not require a mechanical stimulus, but further appositional and endochondral growth is dependent on the mechanical forces generated by the muscles. The magnitude of this loading is directly related to body mass and physical activity. There is some evidence that after mechanical load, microfractures may occur in bone, with subsequent activation of interleukins (ILs) and growth factors and stimulation of bone turnover. Osteocytes appear to be the critical mechanosensors in bone and, therefore, play an important role in this process. The decreased physical activity and immobility that are commonly seen in the elderly result in diminished mechanical forces upon the skeleton, which explains, in part, the age-related loss in mineral density.

### Local Factors

Local factors are important in the regulation of bone turnover and in the interaction between bone matrix and systemic factors and hormones (see Table 117-2 and Figure 117-2) (Color Plate 26). The skeleton responds to mechanical forces by several regulatory

**FIGURE 117-2.** Osteoblast–osteoclast coupling and the regulation of RANK ligand expression. Osteoblast production of M-CSF and RANKL play critical roles in the differentiation and activation of osteoclasts. M-CSF acts to maintain monocytic stem cell survival, and subsequently RANKL acts to commit the cell toward osteoclast differentiation, fusion, polarization, and activation. EphB4 and ephrinB2 interact both to limit osteoclast activity and stimulate osteoblast differentiation. TGF- $\beta$  acts only upon release from the extracellular matrix after osteoclastic resorption, which is mediated in large part by the excretion of CTSK. M-CSF, macrophage colony stimulating factor; RANKL, RANK ligand; TGF- $\beta$ , transforming growth factor- $\beta$ ; BMP-2, bone morphogenetic protein-2; PDGF, platelet-derived growth factor; CTSK, cathepsin K. (Adapted from Duque G, Troen BR. *Understanding the Mechanisms of Senile Osteoporosis: New Facts for a Major Geriatric Syndrome.* *J Am Geriatr Soc.* 2008;56:935–941).

mechanisms including release of cytokines, such as macrophage colony-stimulating factor (M-CSF) and granulocyte colony-stimulating factor, which regulate cell differentiation. Mediators and regulators of cell–cell interaction include insulin-like growth factor (IGF)-1 and IGF-2, parathyroid hormone (PTH)-related peptide, IL-1 and IL-6, and TNF- $\alpha$ . The response to sex-steroid hormones is largely mediated by TNF- $\alpha$ , IL-6, IL-1, and prostaglandins. Although high levels of these factors are necessary for osteoblast–osteoclast regulation and pathogenesis of osteoporosis, their usually stable systemic levels suggest that alterations in local secretion and concentration are critical to bone physiology. These local factors largely determine the activation or inhibition of bone cells, cell recruitment and cell differentiation, and life span.

### Systemic Hormones

A number of systemic hormones affect bone metabolism, including vitamin D, PTH, calcitonin, and sex-steroid hormones (estrogens and androgens) (see [Table 117-2](#)). The major effect of vitamin D is to maintain calcium homeostasis by increasing the efficiency of the small intestine in absorbing dietary calcium. Vitamin D also plays a role in both bone resorption by inducing RANKL expression by osteoblasts, thereby inducing osteoclast differentiation and activation, and bone formation by stimulating osteoblastogenesis and inhibiting apoptosis of mature osteoblasts. Hypovitaminosis D, which is widespread in the elderly, is associated with lower BMD, greater falls, and more osteoporotic fractures.

PTH is secreted by the parathyroid glands through a calcium sensor mechanism. When calcium levels decrease, PTH is released and exerts its function in two major target tissues: kidney and bone. In the kidney, PTH acts on the proximal tubule to reduce  $\text{PO}_4$  resorption and to increase the activity of 1- $\alpha$ -hydroxylase, the enzyme that converts 25(OH) vitamin D to 1,25(OH) $_2$ D $_3$ , the active form of vitamin D. In bone, PTH increases osteoclast-induced bone resorption by inducing RANKL expression and subsequent signaling via RANK. Hypovitaminosis D is often, but not always, accompanied by elevated PTH—secondary hyperparathyroidism. Acute and cyclical exposure to PTH in bone has an antiapoptotic as well as anabolic effect on osteoblasts. This is the basis for using PTH to treat severe osteoporosis (see below). Calcitonin is a hormone secreted by thyroidal C cells in mammals. Its main biologic effect is the inhibition of osteoclastic bone resorption. In vitro and in vivo studies in animals demonstrate that calcitonin causes the osteoclast to shrink and retract from the bone surface, which decreases its bone-resorbing activity and enhances bone formation by osteoblasts.

Sex-steroid hormones play a variety of roles in bone turnover. Although some aspects of its effects remain unclear, estrogen increases the level of OPG, inhibiting osteoclastogenesis. Estrogen also induces osteoclast apoptosis and regulates the action of IL-1, interleukin-1 receptor antagonist (IL-1Ra), IL-6, and TNF- $\alpha$ , and their binding proteins and receptors. Declining estrogen levels lead to increased expression of IL-1, IL-6, and TNF- $\alpha$ , all of which enhance bone resorption. In response to diminished estrogen, osteoblasts produce more RANKL and less OPG, which induces RANKL–RANK interaction and signaling, further stimulating osteoclast differentiation and activation. Since estrogen increases osteoblast differentiation and decreases osteoblast apoptosis, bone formation declines at the time of menopause. Overall, there is a high turnover state with predominant bone resorption, which results in bone loss and susceptibility to fractures. Androgens play an important role in the

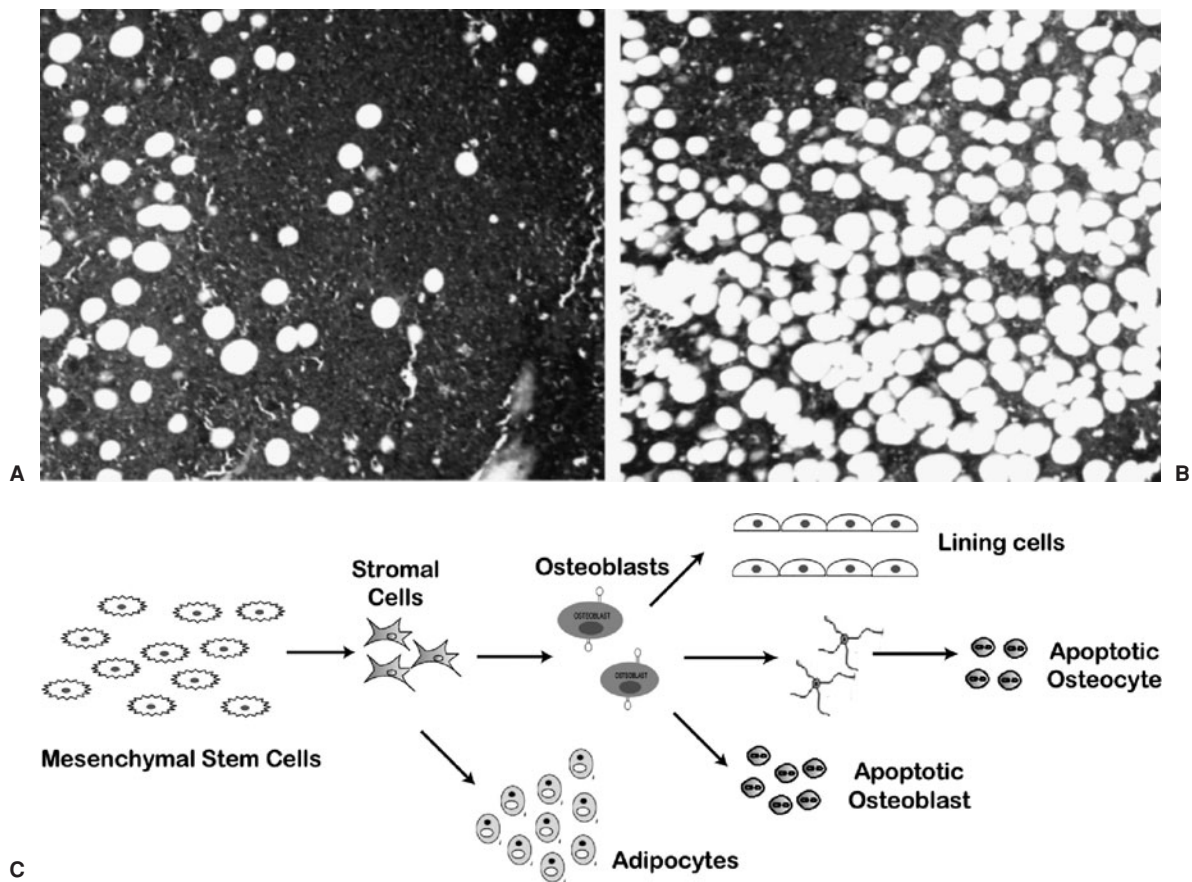

formation of adolescent bone by regulating cytokines in the bone matrix. The effect of progesterone on bone seems to be indirect and limited, through its regulation of calcitonin secretion and thus bone resorption.

Women are at higher risk of osteoporosis because women have lower peak bone mass than men and experience accelerated bone loss during menopause, as described above. Histomorphometric data on the skeletal changes associated with postmenopausal bone loss show an increase in bone turnover in both cancellous and cortical bones. Biochemical markers also support high bone resorption after menopause. These markers return to normal with estrogen replacement. Trabecular bone is affected earlier in menopause than cortical bone because it is more metabolically active. Thus, rapid bone loss is seen primarily in the spine (3% per year) for approximately 5 years after menopause. Subsequently, there is a slower rate of bone loss that is more generalized (approximately 0.5% per year at many sites). A consistent finding in untreated postmenopausal women is a reduction in wall width of bone, indicating reduction in osteoblast activity. Although this could be related to the loss of the antiapoptotic effect of estrogen on osteoblasts, studies are inconclusive.

### Age-Related Bone Loss

Age-related bone loss is a complex phenomenon, with many factors involved in its pathogenesis ([Figures 117-3 and 117-4](#)) ([Color Plates 27 and 28](#)). As an individual ages, distinct changes take place in trabecular bone, cortical bone, and bone marrow. The onset and triggers of age-related bone loss are not well defined, but densitometric studies show a slow and progressive decline in BMD after the third decade of approximately 0.5% per year, even though serum levels of estrogens are still within the normal range. With aging, osteoblastogenesis decreases, resulting in lower numbers of osteoblast precursors and increasing bone marrow adiposity (see [Figure 117-3](#)). The bone marrow of a young individual is virtually devoid of adipocytes. In older adults, however, adipose deposits may occupy up to 90% of the bone marrow cavity.

Although factors that are involved in osteoblast–adipocyte differentiation remain unclear, it is known that adipocytes can transdifferentiate into osteoblasts and osteoblasts can be induced to transdifferentiate into adipocytes (see [Figure 117-4](#)). It has been postulated that pluripotent mesenchymal cells within the bone marrow stroma are, by default, programmed to differentiate into adipocytes, but the presence of specific osteogenic factors in the bone marrow induces osteoblastic differentiation. If this hypothesis is proven true, then it could offer the potential for novel therapeutic approaches to osteoporosis in older adults. In addition, osteoblast apoptosis increases with aging. Histomorphometric data demonstrate that 50% to 70% of the osteoblasts present at the remodeling site cannot be accounted for after enumeration of lining cells and osteocytes. The discrepancy in osteoblast numbers is believed to be a consequence of osteoblast apoptosis. This phenomenon may account for the significant reduction in bone formation that is associated with aging. In men and women, the early changes associated with age-related bone loss are similar, as described above. However, women also experience accelerated bone loss of approximately 3% to 5% per year during menopause. In men, the decline in bone mass is gradual until very late in life, when the risk for fractures increases rapidly. Concomitant with the changes in osteoblast and adipocyte formation, multiple factors enhance osteoclastogenesis and bone resorption (see [Figure 117-4](#)). In particular, the interactions between osteoblast and

**FIGURE 117-3.** Cellular changes in senile osteoporosis. The panel on the right shows the much higher levels of bone marrow fat in the iliac crest of an 85-yr-old subject (A) compared with a 38-yr-old one in the panel on the left (B). There is also a marked reduction in the amount of hematopoietic tissue. (C) Changes in the confluence of mesenchymal stem cells (MSC) accompanied by a reduction in osteoblastogenesis result in the formation of fewer active osteoblasts in the bone multicellular unit. In addition, increasing levels of adipogenic differentiation leads to smaller numbers of differentiated osteoblasts. Finally, increasing osteoblast apoptosis reduces the number of active osteoblasts in the bone multicellular units.

osteoclasts, which are crucial to the dynamic equilibrium that maintains healthy bone, are altered. Consequently, the combination of decreased bone formation and increased bone resorption leads to diminished BMD, poorer bone structure and quality, and, ultimately, enhanced fragility and fractures.

In addition to cellular changes, there are two major changes in calcitropic hormones that have an impact on aging bone. Vitamin D levels decrease with age and reduce calcium absorption. Changes in the aging skin reduce the amount of 7-dehydrocholesterol, the precursor of cholecalciferol (vitamin D<sub>3</sub>), as well as its rate of

**FIGURE 117-4.** Changes in osteoblast–osteoclast interactions with aging. Aging predisposes to more adipogenesis and less osteoblastogenesis. In addition, transdifferentiation from osteoblasts to adipocytes may occur. Reduced physical activity/mechanical loading and decreased levels of bioavailable estradiol and testosterone exert diminished effects on osteoblasts (depicted by the arrows with the hatches), resulting in decreased osteoblast secretion of osteoprotegerin (OPG) and increased expression and secretion of RANKL, IL-1, IL-6, IL-11, and TNF- $\alpha$ . In turn, these compounds directly stimulate greater osteoclast formation and activity. The reduced OPG also permits greater binding of RANKL to RANK, which further facilitates increased osteoclastogenesis and resorption. (Adapted from Troen BR. *Molecular mechanisms underlying osteoclast formation and activation. Exp Gerontol.* 2003;38(6):605–614.)

conversion. Furthermore, declining renal function leads to reduction in the production and activity of  $1\text{-}\alpha\text{-hydroxylase}$ , the enzyme responsible for the activation of vitamin  $\text{D}_3$ . Consequently, a negative calcium balance ensues, which activates the calcium sensor receptor in parathyroid glands. PTH is secreted as a physiologic response, stimulating osteoclast activity, which maintains normal serum calcium levels at the expense of bone mineralization. This theory of secondary hyperparathyroidism was once the classic explanation for age-related bone loss. However, not all individuals with hypovitaminosis D exhibit secondary hyperparathyroidism. Therefore, it is just one of the elements of a syndrome that results in osteoporosis in older adults. However, this mechanism has been recently associated with additional important risk factors for fractures, which are sarcopenia and falls. Vitamin D and PTH appear to modulate neuromuscular function, particularly in the frail elderly. Serum levels of  $25(\text{OH})$  vitamin D lower than  $35\text{ nmol/L}$  increase the risk of falls by 30%, which highly predisposes to fractures. Recent evidence has shown that patients with serum levels between  $35$  and  $80\text{ nmol/L}$ , which were considered normal in the past, are still at risk of falls, suggesting that the therapeutic goal should be to obtain serum levels higher than  $80\text{ nmol/L}$ .

In summary, age-related bone loss results from changes at the cellular level, including decreased osteoblastogenesis, shortened osteoblast life span, and increased adipogenesis, as well as from hormonal changes, including decreased levels and activity of sex-steroid hormones and vitamin D and increased levels and activity of PTH. These mechanisms have been demonstrated both *in vitro* and *in vivo*, mostly in murine models. New histomorphometric data in humans support these findings, although more studies are required to completely explain the pathophysiology and to offer specific therapeutic approaches.

### Osteoporosis in Men

Although the pathophysiology of osteoporosis in men has been a subject of active research in recent years, the relative contribution of hormones and aging, *per se*, remains to be elucidated. It is well established that androgen levels decrease with aging. Testosterone levels decrease by approximately 1.2% per year and the binding protein levels increase with aging, resulting in lower bioavailable testosterone. There is evidence that androgens exert their effect on bone through the action of IGF-1. IGF-1 levels are increased during puberty and are closely related to sex-steroid levels. With aging, lower levels of sex-steroid hormones result in decreased levels of IGF-1, with a reduction in bone formation and bone mass. Dehydroepiandrosterone, another androgen, declines slightly at the sixth decade without major changes thereafter. Contradictory evidence is available about the importance of this decline in dehydroepiandrosterone and of its administration in the treatment of male osteoporosis. Thus, osteoporosis in men appears to result from cellular and hormonal changes, which include lower levels of testosterone, dehydroepiandrosterone, and IGF-1 with subsequent lower osteoblast activity and higher osteoblast apoptosis. However, further study is necessary to delineate the specific roles of these factors in the decline of BMD and high rate of fractures in men after the seventh decade of life. Case reports of low bone mass and increased bone turnover in men with estrogen deficiency—either from an estrogen receptor abnormality or from an absence of aromatase, the enzyme responsible for the conversion of testosterone to estrogen—suggest that estrogen is required for normal bone homeostasis in men. Serum

estrogen levels better predict BMD in men than do serum testosterone levels. In older men in whom both gonadotropin secretion and aromatase conversion are suppressed, estrogen acts as the principal sex-steroid-regulating bone resorption. Blocking the conversion of testosterone to estrogen with the use of an aromatase inhibitor has been shown to increase bone resorption in a short-term study conducted in healthy older men, further supporting a role for estrogen in bone metabolism. Some of the effects of testosterone on bone may be mediated through aromatization of testosterone to estrogen, a possibility that warrants further study. Ongoing studies will provide further information on the role of estrogen in the pathogenesis of osteoporosis in older men.

### PRESENTATION

Osteoporosis is frequently underdiagnosed and undertreated by medical professionals. Osteoporosis is a silent disease, and symptoms may not appear until an incident fracture. Men and women can have osteoporosis prior to a fracture, which is why it is so important to consider clinical risk factors (see below) and possible BMD measurement in those at risk of osteoporosis. Osteoporosis may be detected on plain x-rays (usually a chest x-ray) either by the presence of vertebral fractures or by “osteopenia” in the x-ray report. As many as a third or more of those with “osteopenia” on an x-ray may have T-scores worse than  $-2.5$ , and as many as half will have T-scores in the  $-2.5$  to  $-1.0$  range. Therefore, persons who are diagnosed with “osteopenia” by plain x-ray should have BMD measurement. Osteoporosis may also present as an acute fracture. Most fractures that occur in old age are caused, at least in part, by osteoporosis, and it is important to initiate a therapeutic regimen in these adults. Even after a fracture, the diagnosis is often not considered. Three-quarters of postmenopausal women with a distal radius fracture were either undiagnosed or not treated in one study. As many as 50% of women with a hip fracture leave the hospital without treatment. The overall risk of repeat fracture within the first year is 20%. Fractures that are likely related to osteoporosis and thus should trigger treatment with an approved agent include wrist, vertebral, and hip fractures. Those with such fractures do *not* require BMD testing. Frequently, these fractures are classified as fragility fractures, because there is often little or no trauma associated with the event.

### Secondary Causes of Osteoporosis

The diagnosis of idiopathic or primary osteoporosis is made by bone density measurement prior to fracture or by incident fracture. Secondary osteoporosis is the consequence of diseases or drugs that affect bone either directly (involving changes in bone cells or bone matrix composition) or indirectly (by increasing endogenous or ectopic hormonal production). It is important to exclude diseases that may present as fracture or with low bone mass in the evaluation of women and men with osteoporosis. [Table 117-3](#) lists the major secondary causes of osteoporosis along with laboratory tests used to exclude each disease. These laboratory tests should be considered in persons who present with acute compression fracture or who present with a diagnosis of osteoporosis by BMD measurement. Men are more likely to have a secondary cause of osteoporosis than are women. The most commonly reported secondary causes of osteoporosis in men include hypogonadism and malabsorption syndromes. Secondary osteoporosis can be either prevented or treated if suspected by the

TABLE 117-3

## Recommendations for Evaluation of Secondary Causes of Osteoporosis

DISEASE	EVALUATION
Endocrine abnormalities	
Primary hyperparathyroidism	Ionized calcium, PTH
Page't's disease	Alkaline phosphatase
Osteomalacia	Serum + urine Ca, PO <sub>4</sub> , alkaline phosphatase, and 25(OH)D
Hyperthyroidism	T <sub>4</sub> and thyroid-stimulating hormone
Hypogonadism (men only)	Bioavailable testosterone and prolactin
Cushing's syndrome	Urinary free cortisol
Neoplastic conditions	
Multiple myeloma	Complete blood count and serum and urine protein electrophoresis
Bone metastases	Serum calcium and bone scan
Other conditions	
Alcoholism	Medical history
Malabsorption syndromes	Medical history, anti-gliadin, and antiendomysial antibodies
Medications	
Glucocorticoids	Medical history
Anticonvulsants	25(OH)D and alkaline phosphatase
Heparin (long term)	Medical history
Excess thyroid hormone replacement	Thyroid-stimulating hormone

clinician. Immobilization predisposes to bone mineral loss; thus, a program of early mobilization of hospitalized elderly patients is important. Mild-to-moderate vitamin D deficiency may give rise to osteoporosis rather than to osteomalacia; oral replacement may prevent its occurrence. An additional secondary cause of osteoporosis in men relates to the use of luteinizing hormone-releasing hormone agonists in prostate cancer. Luteinizing hormone-releasing hormone agonists suppress the pituitary gland, decrease testosterone and estrogen to castrate levels, and render men. Several retrospective studies have found increased fracture rates in this population of men. A number of studies demonstrate rates of bone loss that are up to three- to fourfold higher in men treated with luteinizing hormone-releasing hormone agonists, as compared with annual rates of bone loss in normal aging men.

Other medications also may have a detrimental effect on bone. Consideration should be given to dose adjustment, discontinuation of the medications, or preventive treatment. Medications that adversely affect BMD include glucocorticoids, excess thyroid supplementation, anticonvulsants, methotrexate, cyclosporine, and heparin. In older adults, glucocorticoids and thyroid hormone are used quite commonly; accordingly, clinicians should consider the effects these medications may have on the already increased risk of fracture, when prescribing these to older adults.

The prevalence of osteoporosis in adults taking glucocorticoids is approximately 30%. Bone loss typically occurs in the first 6 months of therapy and increases with increasing glucocorticoid dose. Glucocorticoids both suppress bone formation through direct effects on osteoblasts and increase resorption through indirect effects on osteoclasts. Glucocorticoid-induced osteoporosis is preventable if treatment is considered when treatment with corticosteroids is initiated. Replacement of gonadal hormones and treatment with bisphospho-

nates or intermittent PTH has been shown to prevent bone loss in patients taking glucocorticoids. Other measures for prevention of bone loss are calcium and vitamin D supplementation and reduction of glucocorticoid dose to the lowest effective dose for the underlying disease. High doses of high-potency inhaled glucocorticoids may also result in bone loss, and the initiation of preventive measures is important.

## EVALUATION

## Bone Density Measurement

BMD, or bone mass measurement, is the best single predictor of fracture, although previous fracture, maternal history of hip fracture, and age are important additional independent predictors of fracture. BMD of the hip, spine, wrist, or calcaneus may be measured by a variety of techniques. The preferred method of BMD measurement is dual-energy x-ray absorptiometry. BMD of the hip, anteroposterior spine, lateral spine, calcaneus, and wrist can be measured using this technology. Quantitative computerized tomography is also used to measure BMD of the spine. Specific software can adapt computerized tomography scanners for BMD measurement. The advantages of dual-energy x-ray absorptiometry over quantitative computerized tomography include lower cost, lower radiation exposure, and better reproducibility over time. Peripheral dual-energy x-ray absorptiometry (measures wrist BMD) or ultrasonography of the calcaneus may be useful for general osteoporosis screening, and these have the advantage of reduced cost and portability. Peripheral bone densitometry (performed at the heel, finger, or forearm) is highly predictive of hip, spine, wrist, rib, and forearm fractures for the subsequent 12 months. Assessment of BMD should be considered for (1) postmenopausal women younger than 65 years with one or more additional risk factors (other than menopause); (2) all women older than 65 years, regardless of additional risk factors; and (3) women considering therapy for osteoporosis, if BMD testing would facilitate the decision. A study of more than 200 000 postmenopausal women from more than 4000 primary-care practices in 34 states reported that approximately 50% of this population had low BMD that was previously undetected, including 7% of women with osteoporosis. An additional study found that screening postmenopausal women with BMD reduced the incidence of hip fracture by 36%. These studies suggest that efforts should be made to increase BMD measurements in postmenopausal women. However, further investigation is required to determine if BMD screening is truly cost effective and to assess the usefulness of various clinical decision rules in medical practice. Postmenopausal women who present with a fracture do *not* require BMD to confirm a diagnosis of osteoporosis or to determine severity. In addition, postmenopausal women with a significant kyphosis and clinical risk factors also do *not* require BMD testing. Instead, both of these subsets of patients deserve treatment for osteoporosis. It is important to recognize that age is a much more important factor than BMD in determining fracture risk. The 10-year probability of a fracture in an 80-year-old is more than twice as great as the probability of fracture in a 50-year-old with the same BMD T-score (Figure 117-5).

BMD may also be used to establish the diagnosis and severity of osteoporosis in men and should be considered in men with

Age (years)	T-score 0	T-score -0.5	T-score -1.0	T-score -1.5	T-score -2.0	T-score -2.5	T-score -3.0
50	3.8	4.7	5.9	7.4	9.2	11.3	14.1
55	4.1	5.3	6.7	8.5	10.7	13.4	16.8
60	5.1	6.5	8.2	10.4	13.0	16.2	20.2
65	6.3	8.0	10.0	12.6	15.6	19.3	23.9
70	7.1	9.0	11.5	14.6	18.3	22.8	28.4
75	7.0	9.1	11.8	15.2	19.4	24.5	30.8
80	7.7	9.9	12.7	16.2	20.5	25.6	31.8

**FIGURE 117-5.** Ten-year probability of fracture in women by age and T-score. (Data from Kanis et al. *Osteoporos Int.* 2001;12:989–995.)

low-trauma fracture, radiographic changes consistent with low bone mass, or diseases known to place an individual at risk of osteoporosis. Data relating BMD to fracture risk were originally derived from studies completed in women, but recent data suggest that similar associations may be valid in men as well. Assessment of BMD should also be strongly considered in both perimenopausal women and elderly men who are about to undergo long-term treatment with corticosteroids. Bone densitometry less frequently can be used to assess response to therapy. However, usually 2 years between tests are necessary to obtain accurate and useful information. Biochemical markers of bone turnover yield much quicker information about compliance and success of therapy (see below).

### Clinical Risk Factors

While recent approaches to the patient with osteoporosis have based treatment on T-scores, assessment of clinical risk factors can improve identification of individual patients who are more likely to suffer from vertebral and nonvertebral fractures. This is particularly important, since the majority of fractures occur in postmenopausal women with T-scores that are better than  $-2.5$ . The age of the patient is the single most important contributor to fracture risk. Additional important factors include a previous fracture history as an adult, history of fracture risk in a first-degree relative, body weight less than 127 lb, current history of smoking, and corticosteroid use for more than 3 months (Table 117-4). Impaired vision, early estrogen deficiency, dementia, frailty, recent falls, low calcium and vitamin D intake, low physical activity, and alcohol consumption of more than two drinks per day are additional clinical risk factors. Prior recent fracture is a very strong predictor of future fracture. The increased risk is similar in both men and women and is the same as the risk of a first fracture in a woman who is 10 years older. Half of patients will re-fracture within 10 years, and half of those will occur within 2 years of the first fracture. Therefore, most elderly patients with a prior fracture are candidates for treatment. If additional clinical risk factors are present in such patients, BMD testing is not needed before initiating therapy. Conversely, in those patients without a history of fracture, clinical risk factors are useful in identifying women who should have BMD testing (Figure 117-6).

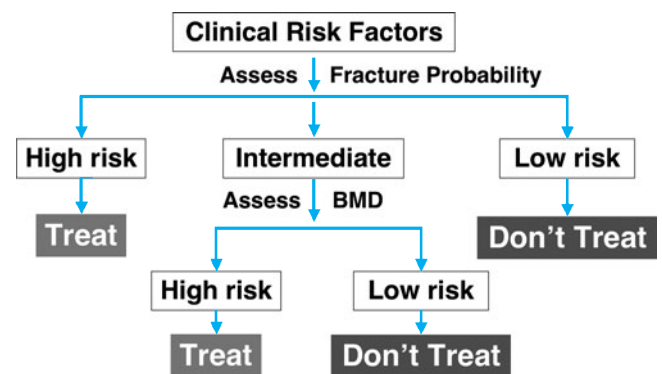

Since many osteoporotic fractures result from falls, it is essential to assess patients for fall risk and to institute preventive measures

**TABLE 117-4**

### Risk Factors for Osteoporotic Fracture

POTENTIALLY MODIFIABLE	NONMODIFIABLE
Current cigarette smoking	Personal history of fracture
Low body weight (<127 lb)	History of fracture in first degree relative
Estrogen deficiency	Advanced age
Early menopause (<45 yr of age)	
Prolonged premenopausal amenorrhea (>1 yr)	Female sex
	White or Asian race
Low calcium intake (lifelong)	Dementia
Alcoholism	
Taking sedative medication	History of corticosteroid medication
Impaired eyesight	Taking seizure medication
Recurrent falls	
Inadequate physical activity	Poor health/frailty
Arms usually required to stand	
Poor health/frailty	

where appropriate. The causes of falls are often multifactorial and include medications, poor vision, impaired cognition, maladaptive devices, alcohol, orthostatic hypotension, impaired balance and gait, environmental hazards, and lower extremity weakness. Recent studies suggest that specific performance measures can help to identify those at greater risk of falling. Individuals who are unable to maintain a semitandem stand for 10 seconds with their eyes open are at increased risk. A normal gait velocity of less than 0.7 m/s also predicts a greater propensity to fall. Additional office-based screening tests that identify potential fallers include the inability to complete

**FIGURE 117-6.** Approach to the osteoporosis patient. Clinical factors such as described in the text and in Table 117-4 help to assess contributions to fracture risk. The absence of these factors in younger women places them at low risk, and they do not require treatment. The presence of several factors in patients  $\geq 70$  yrs, particularly prior history of fracture and a fall history, suggests that treatment should be initiated without the need for densitometry. The greatest challenge lies in those patients who may have one or two clinical factors such as postmenopausal with poor calcium intake and low physical activity. Assessment of BMD can help stratify fracture risk and guide the decision to treat. The combination of clinical factors plus the BMD can be used in fracture risk calculators (for example, see <http://courses.washington.edu/bonephys/FxRiskCalculator.html>) to determine the cost effectiveness of treatment. (From Kanis J. *Annual meeting of the ASBMR, Philadelphia, PA; 2006.*)

the timed up and go test in 14 seconds, the inability to maintain a one leg stand for at least 5 seconds, and a score of less than 19 on the performance-oriented mobility assessment.

### Biochemical Markers of Bone Turnover

Serum and urine biochemical markers that reflect collagen breakdown (or bone resorption) and bone formation are useful to monitor treatment of osteoporosis. Higher levels of resorption markers have been associated with increased hip fracture risk, decreased bone density, and increased bone loss in older adults in some studies. However, biochemical markers in many patients with osteoporosis will lie within the normal range. In addition, there is often substantial overlap of marker values in women with high and low bone density or rate of bone loss. Therefore, at this time, markers are not recommended for screening or diagnosis of osteoporosis. In addition, few studies have compared the response of a particular marker (or combination of markers) and bone density to therapy in order to determine the magnitude of decrease of a biochemical marker necessary to prevent bone loss or, more importantly, fracture. Markers are most useful in assessing the response of an individual patient to treatment. Markers of bone resorption and formation decrease in response to antiresorptive treatment and increase in response to PTH, a treatment with anabolic properties. The advantage of the serum versus urinary markers is that the inpatient variability tends to be lower with serum markers, thus reducing error. It is important to assess a marker before initiating treatment. Many of the osteoclast-specific markers can then be rechecked as early as 6 weeks after beginning therapy. Bone markers yield quicker information, cost less, and incur no radiation when compared to repeating bone densitometry to assess response to therapy. The total alkaline phosphatase that is commonly obtained in routine serum chemistries, while not specific, is also useful to determine response to antiresorptives. However, it should be rechecked 12 weeks after beginning therapy. Successful antiresorptive therapy, which also means compliance, will result in a reduction of serum levels of markers of both resorption and formation, since these processes are tightly coupled. However, changes in bone formation markers, such as alkaline phosphatase, will lag several months behind changes in bone resorption markers.

## MANAGEMENT

Osteoporosis develops in older adults when the normal processes of bone formation and resorption become uncoupled or unbalanced, resulting in bone loss. Osteoporosis prevention and treatment programs, then, should focus on strategies that minimize bone resorption and maximize bone formation, as well as strategies that reduce falls. A number of nonpharmacological and pharmacological options are available to health-care providers (see [Tables 117-5 and 117-6](#)). Modification of risk factors (see [Table 117-4](#)) is an important first step in preventing osteoporotic fractures in older adults.

### Nonpharmacological

#### Exercise

Exercise is an important component of osteoporosis treatment and prevention programs. Data in older men and women suggest a posi-

**TABLE 117-5**

### Treatment of Osteoporosis in Older Adults

Exercise	Walking and weight-bearing three times a week
Physical therapy	Postural exercises, gait and/or balance training, and muscle strengthening
Calcium (carbonate or citrate)	1200–1500 mg qd
Vitamin D (cholecalciferol)	Minimum 800 IU qd, may need 2000–5000 IU qd
Bisphosphonate	
• Alendronate	70 mg po once a week
• Risedronate	35 mg po once a week
• Ibandronate	150 mg po once a month, 3 mg IV push once every 3 months
• Zoledronate	5 mg IV infusion (15 min) once a year
Teraparotide	20 $\mu$ g SC qd
Strontium ranelate	2 g po QHS

tive association between current exercise and hip BMD. Among regular exercisers, those who reported strenuous or moderate exercise had higher BMD at the hip than did those who reported mild or less-than-mild exercise. Similar associations were seen for lifelong regular exercisers and hip BMD. In a randomized study of women at least 10 years past menopause, the group receiving calcium supplementation plus exercise had less bone loss at the hip than did those assigned to calcium alone. Furthermore, high-intensity strength training effectively maintains femoral neck BMD as well as improves muscle mass, strength, and balance in postmenopausal women compared to nonexercising controls, suggesting that resistance training would be useful to help maintain BMD and to reduce the risk of falls in older adults.

Marked decrease in physical activity or immobilization results in a decline in bone mass; accordingly, it is important to encourage older adults to be as active as possible. Weight-bearing exercise, such as walking, can be recommended for older adults who should be encouraged to start slowly and gradually increase both the number of days and the time walked each day. Physical therapy is an important part of osteoporosis treatment programs, especially after acute vertebral compression fracture. The physical therapist can provide postural exercises, alternative modalities for pain reduction, and can suggest changes in body mechanics that may help prevent future falls and fracture. Gait training or balance training along with muscle strengthening can help to prevent falls, even for relatively frail elders. A meta-analysis of randomized clinical trial interventions to reduce falls concluded that all types of exercises achieved similar benefits in balance, endurance, flexibility, and strength. The key message is to prescribe a program for those patients who are mobile and functional enough, in addition to cognitively capable, to participate.

#### Nutrition

Calcium and vitamin D are required for bone health at all ages. Elemental calcium, 1200 to 1500 mg/day, for postmenopausal women and men older than 65 years is needed to maintain a positive calcium balance. The amount of vitamin D required is at least 800 IU/d, although recent evidence suggests that as much as 2000 IU of cholecalciferol per day and more are required to obtain appropriate

TABLE 117-6

## Pharmacological Effect of Osteoporosis Medications on Bone Cellularity

COMPOUND	OSTEOBLAST	ADIPOCYTE	OSTEOCLAST
Bisphosphonates	↑ differentiation ↑ activity ↓ apoptosis		↓ differentiation ↓ activity ↑ apoptosis ↓ activity
Calcitonin			↑ apoptosis
PTH	↑ activity ↑ survival ↑ differentiation	↓ differentiation	↑ activity
SERMs			↓ differentiation ↓ activity

Vitamin D	↑ differentiation ↓ apoptosis	↑ transdifferentiation to osteoblasts	

PTH, parathyroid hormone; SERMs, selective estrogen receptor modulators; ↑, increase; ↓, decrease.

Duque G, Troen BR. Understanding the Mechanisms of Senile Osteoporosis: New Facts for a Major Geriatric Syndrome. *J Am Geriatr Soc.* 2008;56:935–941.

serum levels (25(OH) vitamin D  $\geq 80$  nmol/L) effective for fall and fracture prevention. Calcium plus vitamin D can increase or maintain bone density in pre- and postmenopausal women and prevent hip and other nonvertebral fractures in older adults. Serum levels of 25(OH) vitamin D up to 120 nmol/L are associated with greater BMD. Furthermore, women with acute hip fracture have lower 25(OH) vitamin D levels and higher PTH levels than do women admitted for elective hip replacement with or without osteoporosis by BMD, supporting a role for vitamin D deficiency and secondary hyperparathyroidism in hip fracture. In a recent meta-analysis, 800 IU/d of vitamin D reduced fracture risk and fall risk, whereas 400 IU/d did not. Thus, adequate calcium and vitamin D should be recommended to all older adults, regardless of BMD, in order to maximize bone health. Furthermore, supplementation with vitamin D enhances the BMD response to bisphosphonates.

Two recent prospective studies examined the effect of additional nutritional factors on bone loss and fracture risk in older adults. The Framingham Osteoporosis study found that higher baseline magnesium, potassium, and fruit and vegetable intakes were associated with higher baseline BMD. In men, increased potassium and magnesium intakes were associated with lower bone loss at the femoral neck. Additionally, this study showed a correlation of hip fractures with higher serum levels of homocysteine. Although homocysteine levels are associated with vitamin B-12, serum levels of this vitamin have not been associated with lower BMD, suggesting that the role homocysteine plays in bone biology remains to be elucidated. However, other studies have not found a clear association of homocysteine levels and fracture. Lower baseline protein intake or percent of total energy from animal protein, however, has been associated with greater bone loss at the femoral neck and lumbar spine. In another prospective cohort study, the Study of Osteoporotic Fractures, BMD was not associated with the ratio of animal to vegetable protein intake, but a higher ratio of animal/vegetable protein intake was associated with greater femoral neck bone loss and increased risk of hip fracture. These studies suggest that nutritional factors other than calcium and vitamin D are important for bone health

in older adults. Prospective randomized studies are indicated to further elucidate the role of nutrition in prevention and treatment of osteoporosis in older adults.

## Pharmacological

### Estrogen Replacement Therapy

Multiple studies demonstrate that postmenopausal estrogen use will prevent bone loss at the hip and spine when initiated within 10 years of menopause, and other studies suggest that older women with low initial bone mass gain more bone than younger women. However, there have been few prospective studies of ERT (estrogen replacement therapy) and fracture prevention. One was a small study that demonstrated a reduction in vertebral fractures in postmenopausal women with transdermal estradiol, compared to placebo. The Women's Health Initiative study demonstrated a 24% reduction in all fractures and a 33% reduction in hip fractures in women taking estrogen plus progestin. However, the Women's Health Initiative study also concluded that the overall risks of estrogen plus progestin outweighed the benefits, including those associated with reduction of fractures.

Few studies have evaluated the use of estrogen in women in older than 70 years. Observational data, however, from the Study of Osteoporotic Fractures support a protective effect of current estrogen use against hip fracture, even in the oldest women. Furthermore, small short-term studies suggest that older women are responsive to estrogen treatment, and a recent study demonstrated that ERT increased BMD of the spine and hip in frail older women with just 9 months of treatment. Other studies suggest that low-dose estrogen, in combination with calcium and vitamin D, has an additive effect on bone turnover in women older than 70 years of age. Lower doses of estrogen are also effective in reducing bone resorption and bone loss in older women; the lower doses also result in fewer side effects than the usual replacement doses typically used by clinicians. In a randomized placebo-controlled study, 0.25 mg/day was as

effective as 0.5 and 1.0 mg/day of  $17\beta$ -estradiol in reducing biochemical markers of bone turnover in 75-year-old women, compared to placebo. In this study, the side-effect profile of 0.25 mg/day was similar to placebo and significantly different from the two higher doses. In a longer-term study, 0.3 mg/day conjugated equine estrogen plus 2.5 mg/day medroxyprogesterone acetate increased bone density of the hip and spine in older women who were vitamin D replete. While a recent report from the Women's Health Initiative study demonstrates cardiovascular benefit in women aged 50 to 59 years who took estrogen, at this time, better alternatives to treatment of osteoporosis in older patients exist. Therefore, in elderly patients, particularly those at least 5 to 10 years postmenopausal, estrogen is not recommended.

### Bisphosphonates

Bisphosphonates have gained wide acceptance as the primary antiresorptive treatment for osteoporosis. In postmenopausal women, both alendronate and risedronate reduce vertebral, nonvertebral, and hip fracture risk. Ibandronate has been shown to reduce vertebral fracture incidence. Although bisphosphonates have demonstrated their effectiveness in fracture prevention and gain in bone mass, their effectiveness in the very old (75 years and older) remains unclear because of the limited number of subjects included in the major trials. One of the major advantages of bisphosphonates is the dosing, since these can be given at different intervals from weekly to annually, depending on the medication used. Bisphosphonates act on the osteoclast, inhibiting differentiation and activity and inducing apoptosis. Additionally, there is recent evidence showing that bisphosphonates can enhance bone formation through the inhibition of bone marrow adipogenesis and induction of osteoblastogenesis. The only study using alendronate in older adults (>75 years) is a subpopulation of the Fracture Intervention trials. Alendronate reduced the risk for vertebral fracture, which was not affected by the subject's age. In addition, the absolute risk reductions for hip fractures in women aged 75 to 85 years with low BMD increased with age, supporting an increase in the cost effectiveness of bisphosphonate treatment in older patients. Currently, the recommended dose of alendronate is 70 mg weekly, together with calcium and vitamin D. Patients with low levels of 25(OH) vitamin D exhibit poorer response to bisphosphonate therapy. Conversely, supplementation with vitamin D enhances the BMD response to alendronate.

In the Hip Intervention Programme trial of risedronate, women aged 70 to 79 years with osteoporosis and women aged 80 years and older with at least one nonskeletal risk factor for hip fracture or a low BMD were assessed. This study did not show a reduction in nonvertebral fractures in women older than 80 years; however, it is possible that a proportion of them were not osteoporotic, as a result of the subject selection process. Indeed, even pooled data analysis from the Hip Intervention Programme, Vertebral Efficacy with Risedronate Therapy—Multinational (VERT-MN), and VERT North America (VERT NA) trials in patients older than 80 years with documented osteoporosis did not reveal a reduction in nonvertebral fracture risk (such as wrist, rib, and pelvis).

The efficacy of risedronate in women older than 80 years in reducing vertebral fracture risk was demonstrated using a post hoc pooling of data from three randomized, double-blind, controlled, 3-year fracture end point trials (Hip Intervention Programme, VERT-MN, and VERT NA). In individuals treated with risedronate ( $n = 704$ ; 2.5 or 5 mg/day), the risk of new vertebral fractures was 81%

lower than for those treated with placebo ( $n = 688$ ,  $p < 0.001$ ) after 1 year. Additionally, the magnitude of the risk reduction associated with risedronate was larger in the first year of treatment of patients 80 years and older, but the efficacy was still apparent after 3 years of treatment. The recommended dose of risedronate is 35 mg weekly in combination with calcium and vitamin D.

The MOBILE (Monthly Oral iBandronate In LadiEs) study has shown efficacy for monthly ibandronate administration up on BMD, similar to that observed for the weekly administration of either alendronate or risedronate. In addition, it has also been approved for intravenous administration every 3 months to treat postmenopausal osteoporosis. However, its effectiveness in very old populations has not been studied. Recently, intravenous zoledronate, at a dose of 5 mg/IV yearly, has been assessed for its efficacy on fracture prevention in a population of 3889 patients (mean age 73 years) who were treated for 3 years. In this randomized control trial, intravenous zoledronate markedly lowered the risk of hip fracture by 41% and reduced nonvertebral fractures, clinical fractures, and clinical vertebral fractures by 25%, 33%, and 77%, respectively. The FDA has recently approved zoledronate for the treatment of osteoporosis. The zoledronate-treated subjects exhibited a small but statistically significant greater incidence of atrial fibrillation, which generally resolved within a month. A more recent study has demonstrated that treatment of hip fracture patients with zoledronate reduced subsequent vertebral and non-hip-non-vertebral fractures and also reduced overall mortality. In addition, no difference in the incidence of atrial fibrillation in the zoledronate-treated patients was found. Although these results suggest that zoledronate could become the treatment of choice for osteoporosis, with the advantage that compliance would be assured, the possibility of side effects suggests that more studies are required in the frail elderly population.

Bisphosphonates are generally safe, but administration can cause a rash or transient hypercalcemia. In addition, oral bisphosphonates can cause esophageal irritation and ulceration. Hence, patients need to take oral bisphosphonates with 8 oz of water and remain upright for at least 30 minutes. Intravenous bisphosphonates can acutely cause fever, myalgia, transient leukopenia, acute-phase reaction, arthralgia, headache, bone pain, and atrial fibrillation. However, the flu-like symptoms can be successfully ameliorated with acetaminophen. In addition, the symptoms are less prevalent with subsequent administration.

Longer-term administration has been associated with osteonecrosis of the jaw. It is important to stress that the great majority of cases of osteonecrosis of the jaw occur in patients with underlying neoplastic disease who have received high doses of intravenous pamidronate or zoledronate. The risk of osteonecrosis of the jaw in patients with postmenopausal osteoporosis taking oral bisphosphonates is exceedingly low. In fact, it has been estimated that the risk of osteonecrosis of the jaw is only 0.7/100 000 people per year, which is comparable to the risk of dying from lightning in New Mexico and much less than dying by anaphylaxis from a shot of penicillin (32/100 000 people per year).

### Calcitonin

Calcitonin is a peptide hormone that is used to treat osteoporosis. It is available as a subcutaneous injection and a nasal spray. The advantages of a nasal spray over injectable calcitonin are fewer reported side effects and greater patient acceptance. Calcitonin has been shown to increase bone density in the spine and to reduce vertebral fractures.

In epidemiologic studies, calcitonin reduces hip fractures, although in clinical trials hip bone density does not increase. A recent 5-year study demonstrated a decrease in vertebral fracture in women on nasal spray calcitonin (200 IU/d), as compared to those women on placebo; in this study, 400 and 100 IU did not have any significant effect on vertebral fracture rate. Bone density at any site and markers of bone turnover did not change, compared to placebo. Nasal spray calcitonin does not appear to be as effective in preventing fractures as other approved agents; therefore, its use should be limited to those women who are unable to tolerate other treatments. The only current indication for the use of calcitonin is for analgesic treatment in acute compression fractures, in Paget's disease of bone and in bone pain because of metastatic disease.

### Selective Estrogen Receptor Agonists

The selective estrogen receptor modulators are agents that act as estrogen agonists in bone and heart but act as estrogen antagonists in breast and uterine tissue. These medications have the potential to prevent osteoporosis or heart disease without the increased risk of breast or uterine cancer. Tamoxifen, an agent used in breast cancer treatment, has been shown to have beneficial effects on bone in several studies but has stimulatory effects on the uterus; it is not approved for treatment or prevention of osteoporosis. Raloxifene, a nonsteroidal benzothiophene, is a newer selective estrogen receptor modulator that has been approved for prevention and treatment of osteoporosis in postmenopausal women. In one study of postmenopausal osteoporotic women, raloxifene resulted in decreased bone turnover and increased BMD of the hip, spine, and total body bone density, as compared to placebo. Furthermore, raloxifene did not increase endometrial thickness for more than 2 years and had positive effects on the lipid profile. A later study examined the effect of 60 or 120 mg/day raloxifene on fractures. Raloxifene decreased the risk of new vertebral fractures (relative risk [RR] 0.5 [0.4–0.8] to 0.7 [0.6–0.9]). There was no difference in nonvertebral fracture incidence in the raloxifene-treated groups, as compared to placebo. BMD of the lumbar spine and femoral neck increased in both raloxifene-treated groups compared to placebo. Interestingly, the BMD increases with raloxifene were modest in this study, yet the reduction in vertebral fracture risk was clinically significant, suggesting that antiresorptive agents have effects on bone that are not reflected in BMD measurement. The major serious adverse effect of raloxifene was an increase in venous thromboembolic events, including deep vein thrombophlebitis and pulmonary embolism events (RR 3.1 [1.5–6.2]). However, raloxifene-treated women in this study had a reduced risk of breast cancer incidence (RR 0.3 [0.2–0.6]). In a 6-month study, raloxifene had effects on bone histomorphometry and bone turnover that were similar in direction to conjugated equine estrogen but were lower in magnitude.

### Parathyroid Hormone

PTH, when administered daily subcutaneously, markedly increases bone mass and BMD. Multiple studies demonstrate significant reductions in vertebral and nonvertebral fracture risk. Administration of PTH increases osteocalcin, a marker of bone formation, more rapidly than deoxypyridinoline cross-links, a marker of bone resorption, suggesting early uncoupling of the bone remodeling cycle and providing a potential mechanism for the anabolic effect on bone. The PTH analog teraparotide effectively increases spinal BMD in

osteoporotic men and women and reduces both vertebral and nonvertebral fractures in postmenopausal women. PTH also enhances BMD in glucocorticoid-dependent osteoporosis. The recommended dose is 20  $\mu\text{g}$  SQ/d. Indications for PTH include a T-score worse than  $-3.5$  or prevalent fractures in the setting of a T-score worse than  $-2.5$ . In addition, patients who continue to fracture or lose BMD after 2 years of bisphosphonate treatment are also candidates for PTH. The side effects that occurred more frequently in the PTH-treated groups were headache, nausea, dizziness, and hypercalcemia. The major limitations to the use of PTH in the elderly are its significant cost and the mode of administration, since subcutaneous dosages require an appropriate cognitive status, a high degree of motivation, and a significant level of functional independence. At present, studies suggest that PTH should *not* be combined with bisphosphonate therapy, since concurrent bisphosphonate treatment appears to blunt the BMD response to PTH. PTH therapy should continue no longer than 2 years. It is very important, however, to treat with an antiresorptive after discontinuation of PTH, in order to maintain gains in BMD.

### Other Agents

**Strontium Ranelate** This agent appears to act as both an anabolic and an antiresorptive medication for osteoporosis. Treatment with strontium ranelate reduces vertebral fractures by 40% in postmenopausal women with osteoporosis. The Treatment of Peripheral Osteoporosis study in postmenopausal women showed a reduction in the relative risk for all nonvertebral fractures of 16% and a decline of 19% for all major fragility fractures (hip, wrist, pelvis, sacrum, ribs, sternum, clavicle, and humerus) after 3 years of treatment at a dose of 2 g/d. In a subgroup analysis of high-risk women (age  $>74$  years, femoral neck BMD T-score less than  $-3.0$ ), the strontium reduced hip fractures by 36%. The fact that this agent is given as a soluble powder favors its acceptance and tolerance except for mild gastrointestinal adverse effects (nausea and diarrhea), which usually resolved by 3 months of treatment.

**Denosumab** Denosumab is a fully humanized monoclonal antibody directed against RANKL. It binds with high affinity and, therefore, blocks RANKL-stimulated osteoclast formation and activation. Although denosumab is still undergoing experimental trials, a phase 2 dose-ranging study in postmenopausal women with low BMD demonstrated that subcutaneous administration once every 6 months produced increases in lumbar spine and hip BMD at 12 months comparable to that seen with alendronate, both of which were significantly better than placebo. Adverse events were not significantly different from placebo- or alendronate-treated patients. More recently, a phase 3 trial (FREEDOM study) demonstrated that denosumab administered to postmenopausal woman once every six months for three years reduced vertebral, non-vertebral, and hip fractures by 68%, 20%, and 40%, respectively. These benefits were accompanied by increases in bone mineral density at both lumbar spine and total hip of 9.2% and 6.0%, respectively. There were no significant differences in adverse events between placebo and denosumab treatment.

### Osteoporosis in Nursing Homes

There is increasing concern about the underdiagnosis and under-treatment of patients with osteoporosis in special settings, such

as long-term care institutions. Institutionalized patients, whether mobile or immobile, are at high risk of osteoporosis. All institutionalized patients should be treated with a combination of vitamin D (minimal dose of 800 IU/d) plus calcium (1500 mg/day). Because the frail elderly may be markedly insufficient for vitamin D or exhibit an unpredictable response to supplementation, the serum level of 25(OH) vitamin D should be obtained before beginning supplementation. Preliminary reports suggest that between 1500 and 5000 IU/d may be needed. If the 25(OH) vitamin D level is  $\leq 50$  nmol/L, patients should be started on 2000 IU/d of cholecalciferol. For those who are frankly deficient (25(OH) vitamin D less than 20 nmol/L), 50 000 units of ergocalciferol weekly for 4 weeks should be administered, followed by 2000 IU of cholecalciferol per day. The serum level of 25(OH) vitamin D should again be assessed 8 to 12 weeks later. Additionally, the presence of risk factors and/or previous fractures strongly supports the use of pharmacological treatment with either antiresorptives or anabolics. The clinician should consider the patient level of functionality, quality of life, and life expectancy before starting pharmacological treatment for osteoporosis in a long-term care setting. However, since hip fractures lead to a decline in the quality of life and life expectancy, and fracture risk reduction can be achieved as quickly as 6 months of treatment, pharmacological approaches are justified in institutionalized patients who are at risk.

# Hip Fractures

*Ram R. Miller ■ Colleen Christmas ■ Jay Magaziner*

## INTRODUCTION

Hip fracture is a major public health problem with significant consequences for the older patients, their families, and the health-care system. In 2003, there were 310,000 hospital admissions for hip fracture in the United States alone. Recent worldwide estimates are in the order of 1.6 million hip fractures annually. By the middle of this century, the number is expected to more than double. As seen in [Figure 118-1](#), hip fracture incidence increases exponentially in both men and women with advancing age. The average age of a patient with hip fracture is 82 years. Although hip fractures are thought to be a condition faced primarily by older white women, approximately 20% of hip fractures occur in men, and, in the United States, 8% occur in nonwhites. Prominent risk factors for hip fracture are osteoporosis and propensity to fall. Underlying these essential conditions for having a hip fracture are the reduced bone strength and quality that are characteristic of osteoporosis and the multiplicity of medical, psychosocial, and environmental factors that lead to falls.

The direct medical and indirect nonreimbursed costs (e.g., unpaid caregiving services and lost wages of patients and caregivers) of hip fracture have been estimated at more than \$15 billion annually in the United States. Of those who have a hip fracture, approximately 18% of women and 36% of men are expected to die within the first year of their fracture, with the most dramatic increases in mortality seen within the first few months of a fracture among those who are in the poorest health. Comparison of survival in women with hip fracture to similarly impaired women without fractures indicates that the fracture itself is responsible for nine extra deaths per 100 patients during the first 4 years following the fracture. There also is suggestion from epidemiological data on women that even in those with the fewest medical comorbidities and best functioning at the time of fracture, the mortality attributable to hip fracture continues to increase well beyond the first year post fracture. Causes of death in women and men are similar and approximately four times

greater than their nonfracture counterparts for heart disease, three times greater for cerebrovascular disease, and three times greater for chronic obstructive pulmonary disease. Interestingly, one recent study showed that men are far more likely than their nonfracture counterparts to die from infectious causes such as septicemia and pneumonia, in the first 2 years following hip fracture.

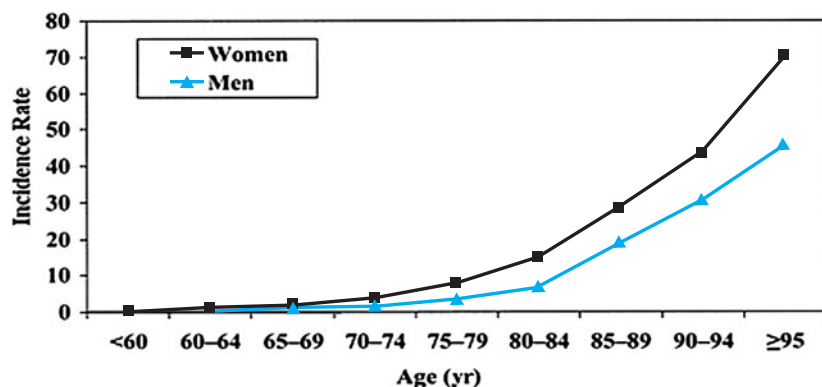

The intent of this chapter is to provide information about the medical and psychosocial status of the older patient who presents with a hip fracture and to discuss strategies for care and the role of the geriatrician in providing that care during the hospital stay and for the subsequent year or more of follow-up care.

## WHAT TO EXPECT WHEN SEEING PATIENTS IN HOSPITAL

The cumulative effect of environmental exposures, lifestyle, and genetic influences results in a remarkably heterogeneous geriatric population. Aging impacts most organ systems, although the degree to which organs are impaired from aging varies from individual to individual. In addition, several chronic medical conditions may also exist in a given individual. Medical care of the patient with hip fracture must, therefore, be adapted to the individual patient's needs. This requirement for a tailored approach to care is both the challenge and the pleasure of geriatric medicine.

The changes that occur with aging physiology result in decreased resilience to stress, or the so-called "homeostenosis" in most organs. For example, older individuals have stiffening of their rib cages and decreased mucociliary clearance of their lungs, resulting in an increased propensity toward postoperative atelectasis and pneumonia and poorer tolerance of these complications when these do occur. By mechanisms that are yet to be understood, older individuals can more easily become delirious during the pre- and postoperative period. This complication not only increases the patient's risk of dying

**FIGURE 118-1.** Age-specific incidence rates of hip fracture (per 1000 person-years): the Framingham study. (Samelson et al. *Am J Public Health*. 2002;92(5):858–862.)

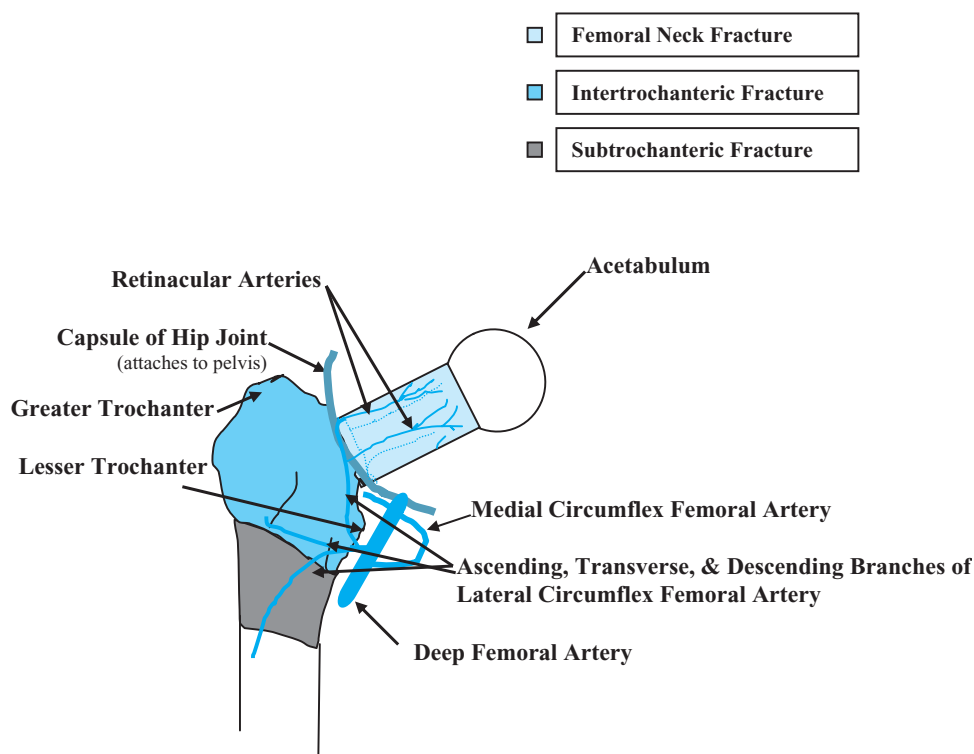

in the coming year, but also can impact an individual's ability to participate in rehabilitation and significantly limit the patient's ability to recover after a fracture. Because of this decreased physiological reserve, older individuals are at particular risk of a wider range of iatrogenic complications and do not recover as well when complications and adverse events do occur. Thus, all interventions must be monitored very closely to quickly determine their impact on the patient.

### Medical Presentation and Fracture Characteristics

Classically, a patient with hip fracture presents with a painful, shortened, and externally rotated lower extremity after a fall and landing on the affected hip. Usually, but not always, patients are unable to bear weight on the extremity. There are many exceptions to this description, however. While a small percentage of hip fractures occur without trauma preceding the fracture event, nearly a third do not recall or cannot give a clear history of the precipitating fall. In nondisplaced femoral neck fractures, the extremity may be neither shortened nor externally rotated, and patients with stable impacted

fractures or nondisplaced “hairline” fractures may be able to bear weight and ambulate. Occasionally, patients like this are sent home without fracture management but soon return for care, owing to continued pain and discomfort when ambulating. Thus, a better guiding principle is that all elderly patients with hip pain after trauma should be considered to have a hip fracture until proven otherwise. Similarly, patients having pain with gentle rolling of the lower extremity must be ruled out for hip fracture, irrespective of recollection of trauma.

Approximately half of all hip fractures occur in the area of the femoral neck (or “intracapsular fractures”), and the other half occur in the area between the greater and lesser trochanters (“intertrochanteric fractures” or “extracapsular fractures”). Far less common are fractures that occur within 5 cm below the lesser trochanter; these are called “subtrochanteric fractures.” Patients with intertrochanteric fractures tend to be older than those with femoral neck fractures and are more likely to have multiple medical comorbidities pre-fracture. A schematic of the hip anatomy is shown in [Figure 118-2](#), which also indicates the anatomy of the vascular supply

**FIGURE 118-2.** A schematic diagram of the anatomy of the hip.

to the hip region. This schematic is useful to understand the various surgical approaches to hip fracture care and the potential for blood loss at each site. As demonstrated in the schematic, the regions of the femoral neck and the femoral head derive their main blood supply from fine retinacular arteries that stem from the medial circumflex femoral artery. These delicate vessels are closely apposed to the femoral neck in this region. Therefore, a fracture in this region of the hip, particularly if any displacement occurs, is more likely to disrupt the vascular supply to the femoral neck and head, which can result in longer-term nonunion and osteonecrosis. Thus, fractures in the femoral neck region, particularly displaced fractures, are usually replaced rather than internally fixed. In contrast, the blood supply to the intertrochanteric area is plentiful and redundant, such that nonunion and osteonecrosis are less common in this region, and often fractures in this area heal well if internally reduced with screws, nails, or pins.

### Cognitive Status

Dementia is a prominent risk factor for falls and fractures, so, not surprisingly, a significant number of patients with hip fracture have underlying cognitive impairment. Delirium is also a very common occurrence both at time of presentation to the emergency department and especially postoperatively, where up to 60% may develop confusion after hip fracture repair, with underlying dementia again being a powerful risk factor for the development of delirium. The presence of delirium and cognitive impairment very significantly portends a worse functional recovery for patients with hip fracture. Identification of underlying dementia and especially identification of risk factors for delirium are important both prognostically and so that some of the modifiable risk factors may be eliminated in hopes of reducing the occurrence of delirium. Given the high risk of delirium in this patient population, it is particularly important to prepare the patient and family emotionally for this potential complication, especially in those with identified risk factors for delirium, as the manifestations of delirium can be quite frightening to unprepared family members.

Risk factors for delirium in hospitalized patients have been well described by many sources. Some of the most consistently reported risk factors include advanced age, sensory impairment, male sex, presence of comorbid psychiatric disease, the use of psychoactive drugs, infection, polypharmacy, use of restraints, sleep deprivation, and undertreatment of pain. Allowing people to sleep at night and remain active during the day, minimizing sensory impairment, promptly removing unneeded tethers such as Foley catheters and IVs, providing daily orientation, and careful attention to pain and medications may be useful in reducing the incidence of delirium in patients with hip fracture, as has been demonstrated in geriatric general medical in-patients. Undertreatment of pain, particularly in cognitively intact individuals with fracture, appears to be a more powerful predictor of the development of delirium than use of narcotics. In one study, proactive geriatric consultation with recommendations on oxygen delivery, fluid balance, analgesia, elimination of unnecessary medications, regulation of bowel and bladder function, nutritional intake, mobilization, prevention of postoperative complications, assessment of environmental stimuli, and treatment of agitated delirium reduced the incidence of delirium overall by a third and the incidence of severe delirium by half.

### The Geriatrician's Role in Caring for Patients with Hip Fracture on Entry into Acute Care and Recommendations Regarding Surgical Intervention

The geriatrician can serve a central role in caring for patients on entry into the acute hospital not only by evaluating the medical pre- and perioperative issues, and ensuring maximal medical stabilization prior to surgery, but also by providing vigilance and early detection of postoperative medical complications, by facilitating a smooth transition to rehabilitation or subacute care and by preparing the patient for long range preventive strategies to reduce future fractures.

Several studies demonstrate that services that use a multidisciplinary approach to acute care of the patients with hip fracture reduce medical complications and may shorten hospitalization, and the more involved the geriatrician is in providing or overseeing patient care, the greater the clinical benefits of the service. For example, a coattending model, in which both the geriatrics and the surgical services are responsible for the patient's care, is more effective than daily consultation, and daily consultation is more effective than twice-a-week consultation in most studies.

The geriatrician can first help by providing a "big picture" view of whether or not the patient will benefit from pursuing surgery to repair the hip or not. Although for most patients with hip fracture, surgical approaches will typically offer more benefits than nonsurgical approaches, surgical repair is usually presented as the only option, despite the fact that nonsurgical approaches may be equally or more appropriate for some selected patients. The clearest benefit of surgery over the usual nonsurgical approach of bed rest, pain management, bowel regimen, and prophylaxis against pressure ulcers and deep venous thrombosis is that surgery results in better anatomic alignment and better likelihood of ambulation. There is currently no evidence that surgery provides better pain control over bed rest. Thus, in patients who are unable to ambulate prior to the fracture and who are not likely to ambulate later, or for those in whom surgical risks are very high or life expectancy is very short, nonsurgical approaches may be considered. Geriatricians, like other providers, need to be careful not to prematurely judge the patient's likelihood of dying, since it may be difficult to base a prognosis on the presentation at the time of fracture and the determination of what might be most appropriate for a patient requires an understanding of that patient's prior status, goals, and priorities as well as the patient's medical conditions and psychosocial milieu to determine how the patient can best achieve those goals.

The majority of patients with a hip fracture will undergo surgical repair. The types of surgical approach and anesthesia employed are largely the purview of the surgeon and the anesthesiologist and often depend on local trends and the training of these physicians. Although, historically, regional anesthesia has been advocated over general anesthesia in frail elderly patients, observational studies suggest that there is little difference in short- and long-term outcomes with these two approaches.

In preparing a patient for hip fracture surgery, as with any surgery, one would determine the risks of cardiovascular, pulmonary, and other complications and strive to reduce those risks. (Refer to Chapter 35 for more details on the use of preoperative testing for risk stratification, preoperative pulmonary treatments, and the use of beta-blockers and other medications to reduce the risk of perioperative adverse cardiac events in high risk patients.) The geriatrician also is in a good position to step the patient and family through the many

hospital and postacute care procedures and transitions that they can expect to encounter, thereby reducing uncertainty and alleviating anxiety at this unanticipated and challenging time.

Finally, while soliciting the preoperative history, the geriatrician is in a good position to use this opportunity to determine the patient's risk for subsequent falls and fractures. A thorough falls history should be obtained, including a complete description of the fall that led to the fracture as well as any previous falls, with particular attention to remediable risk factors to be altered prior to discharge back to home (see Chapter 54). Similarly, the geriatrician may begin to prepare the patient, family, and other providers about the need to evaluate for and treat osteoporosis to reduce the risk of subsequent fractures after discharge back to home (see Chapter 117).

## POSTOPERATIVE CARE IN HOSPITAL

### The Geriatrician's Role in Postoperative Care

Usually a patient will remain in the acute hospital for 2 to 5 days after surgery for hip fracture, although this may be longer in some health-care settings. Depending on the surgical approach used and the adequacy of the anatomic repair, most patients will resume a normal diet, have bladder catheters removed, and begin getting out of bed with physical therapy on postoperative day number 1. Early mobilization has been shown to be safe and is effective in minimizing deconditioning, reducing the risk of delirium, constipation, pneumonia, thromboembolism, and pressure ulcer formation. Adequate treatment of postoperative pain is useful in maximizing participation in physical therapy and increasing mobility.

The geriatrician must monitor the patient very closely for development of postoperative complications and is in a key position to detect subtle delirium that could be a harbinger of an ominous underlying complication, such as pulmonary embolus or pneumonia. Postoperative pulmonary complications are among the most lethal complications in this population, so the geriatrician should be particularly wary of these and enforce the use of deep breathing exercises with or without an incentive spirometer, early mobility, and use of physical and/or pharmacological approaches to reduce

the risk of deep venous thrombosis. Other important postoperative medical considerations the geriatrician may be particularly adept at managing are reducing polypharmacy, maximizing sensory input, explaining the treatments and progression of care to patients and family, and communicating across the transitions to reduce errors during this vulnerable time.

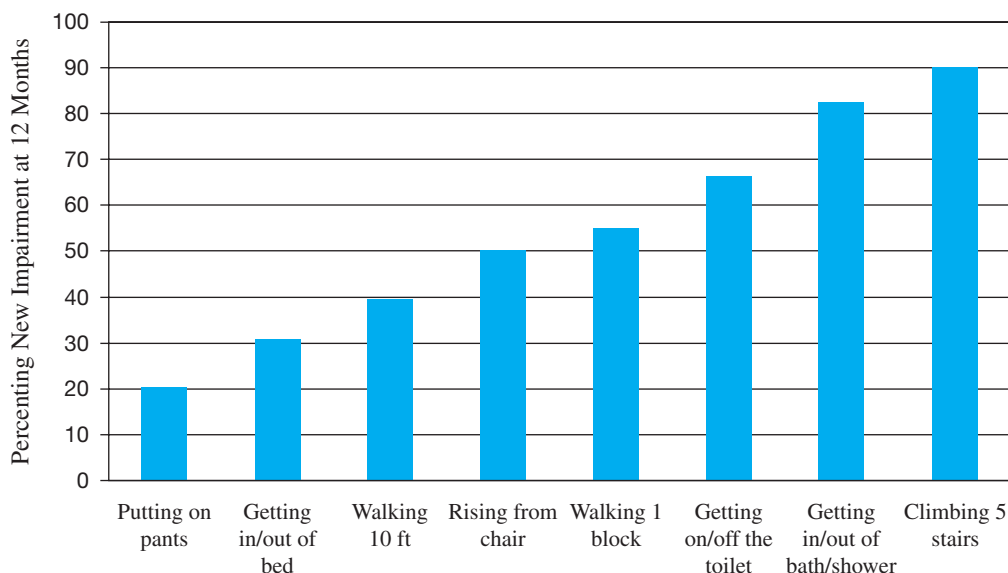

## POSTFRACTURE CHANGES IN PHYSICAL AND PSYCHOSOCIAL FUNCTION AND IMPLICATIONS FOR CARE

### Physical Function

Hip fractures have significant effects on functioning and body composition. Figure 118-3 shows the proportion of patients with hip fracture who were able to perform routine tasks involving lower extremities prior to their fracture and who are not able to perform them a year later. Twenty percent of those who could put their own pants on without assistance prior to their fracture will require assistance to do so a year later. More striking is the proportion of patients who will need assistance of another person or equipment to walk across a small room (40%), use the toilet (66%), or climb five stairs (90%). Instrumental tasks also are affected, with 62%, 53%, and 42% who could do their own housecleaning, get places out of walking distance independently, and shop without assistance, respectively, prior to their fracture, requiring assistance to perform these tasks a year later. Other functional consequences of hip fracture include increases in cognitive impairment and depressive symptoms, as well as increases in problems with gait and balance.

### Psychological Status

The diagnosis of hip fracture conveys to patients and families a significant degree of psychological stress. Most lay persons are quite aware of the poor recovery of function for many individuals, the high rate of nursing home use and even long-term placement, and, for those who do return to the home, the high rates of dependency on others for care, at least transiently. Many patients and families

**FIGURE 118-3.** Lower extremity activities of daily living—percentage of those unimpaired pre-fracture with impairment at 12 months post fracture. (Magaziner et al. *J Gerontol Med Sci.* 2000;55A(9):M498–M507.)

**FIGURE 118-4.** Expected and observed change in total hip bone mineral density (A) and femoral neck bone mineral density (B) during the 12 months following fracture. Legend for both panels: ● with solid line, hip fracture (observed mean and standard error); broken line, Study of Osteoporotic Fractures (SOF; expected mean based on interpolated data obtained for a 42.3-month period). (Magaziner et al. *Osteoporos Int.* 2006;17:971–977.)

believe that having a hip fracture signifies the “beginning of the end.” It is likely that these facts, in addition to other physiological changes that happen with hip fracture or hip fracture repair, contribute to the high rates of postoperative depression that have been described. Patients may endorse depressive symptoms during their hospital stay and for up to 6 months after fracture; those who report symptoms of depression even transiently tend to recover less well than those who do not endorse depressive symptoms at all.

### Physiologic Changes Post Hip Fracture

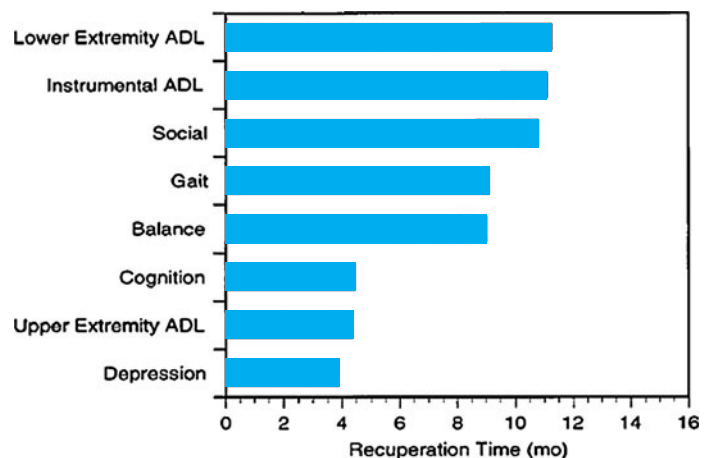

Changes in body composition also are notable after a hip fracture. The average woman who fractures a hip can expect to lose 3% to 6% of her muscle mass within 2 months of the hip fracture and to have an increase in fat mass of 3% to 4% during the postfracture year, under circumstances of usual care. Losses of bone mineral density also are profound in this already osteoporotic group of older women. In fact, older women lose nearly 3% of their total hip bone mineral density and more than 4.5% of their bone mineral density in the contralateral femoral neck during the year following a hip fracture. This is 12.5 times more than the loss of 0.5% that would have been expected in a group of women of the same age, comorbid disease status, and starting level of bone mineral density (Figure 118-4).

### FUNCTIONAL RECOVERY POST HIP FRACTURE

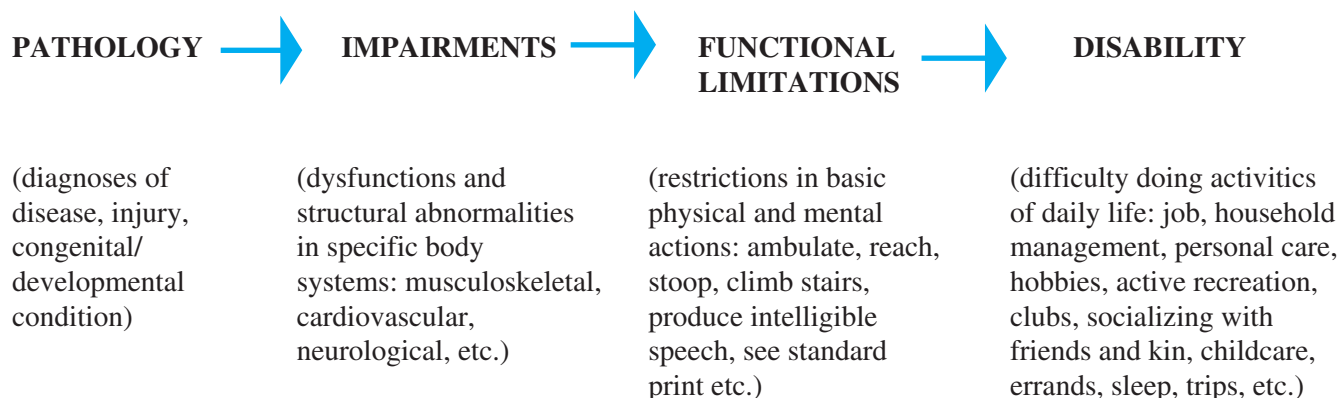

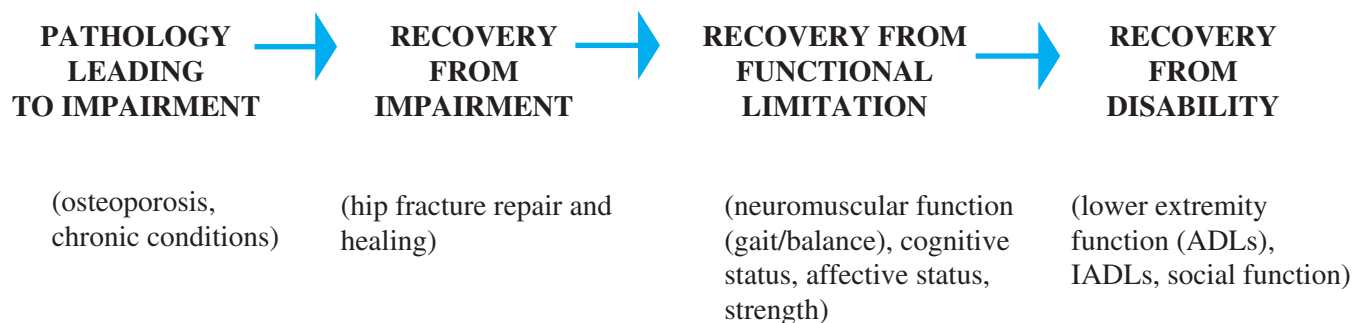

Recovery in function following a hip fracture can be anticipated in many patients, despite the large numbers who fail to achieve pre-fracture levels, and this recovery appears to follow a sequence that may be instructive in deciding on the most appropriate intervention to recommend and/or provide during the postfracture year. After examining the patterns of recovery in several functional domains that are affected by hip fracture, it was noted that depression, upper

extremity activities of daily living, and cognitive function reach their peak recovery by approximately 4 months post fracture, while tasks associated with physical impairments such as balance and gait reach their natural plateau at approximately 9 months post fracture. Interestingly, the more complex tasks that are indicative of disability, such as performing lower extremity and instrumental tasks, recover by approximately a year if these are going to recover (Figure 118-5). This pattern of recovery seems to parallel the pattern by which disability develops according to the disablement process model proposed by Verbrugge and Jette (Figure 118-6).

When considering this pattern and the fact that different tasks recover at different postfracture times, it would seem worthwhile to consider delivery of targeted interventions in a way that addresses the specific deficits observed and takes full advantage of what we know

**FIGURE 118-5.** Time to recuperation following hip fracture in eight areas of function. (Magaziner et al. *J Gerontol Med Sci.* 2000;55A(9):M498–M507.)

**(A) THE DISABLEMENT PROCESS****(B) THE RECOVERY PROCESS FOLLOWING HIP FRACTURE**

**FIGURE 118-6.** The disablement (A) and recovery (B) processes following hip fracture. [Verbrugge, Jette. *Soc Sci Med.* 1994;38:1–14 [Figure 118-6A]; Magaziner et al. *J Gerontol Med Sci.* 2000;55A(9):M498–M507. [Figure 118-6B]]

about the recovery sequence. A sequence that might be appropriate is shown in Figure 118-7. It is also worthwhile to consider the risk factors for mortality and failure to recover with the ultimate goal of reducing risk as a way of improving outcomes. Among the known risk factors for mortality are male sex, older age, and having multiple comorbid conditions. Those factors known to be associated with poorer recovery include older age, male sex, delirium, dementia, depressive symptoms, lack of telephone contact with family after the fracture, and vitamin D deficiency at the time of fracture.

## POSTFRACTURE REHABILITATION

### Discharge Planning

Prior to discharge from the in-patient setting, a multidisciplinary assessment involving the geriatrician, the orthopedic surgeon, nursing, social work, physical therapy, and occupational therapy must be performed. The goal of this assessment is to decide on discharge plans

and rehabilitation needs and goals. The following considerations should be taken into account: the patient's current level of function, the patient's postoperative medical and skilled nursing needs, the home environment, family and resources available, self-care skills, and requirements for activities of daily living. The geriatrician plays a key role in the coordination of the patient's care and communication with patients and families as patients transition through the health-care system, with regard to their medical needs, functional status, and living requirements. One critical role for the geriatrician is to ensure continuity of care. Recent studies have shown that, with each transition to a different site of care, there is the potential for an adverse effect on the care of patients with hip fracture, and physicians must, therefore, be vigilant to ensure adequate communication and good continuity of care to minimize this risk.

While the medical diagnoses and baseline functional status are important considerations of the ability of a patient to maximally recover function, return to a high quality of life may be even more dependent on the patient's support network and environment than the patient's medical illnesses. These factors will often dictate how long a patient needs to stay in in-patient rehabilitation before it is

Recovery Process	Possible Treatments
<u>Treat Pathology</u>	
Osteoporosis Chronic conditions	Bone strengthening medications Stabilize exacerbations, control complications
<u>Treat Impairment</u>	
Hip fracture	Surgical management to repair bone
<u>Reduce Functional Limitations</u>	
Neuromuscular training Cognitive Affective	Gait training, balance training, strength Medical stabilization, orientation therapy Medication, psychological therapy
<u>Minimize Disability</u>	
ADLs IADLs Social activity	Physical therapy Occupational therapy Social engagement therapies

**FIGURE 118-7.** Hip fracture treatments suggested by recovery sequence.

safe to discharge that patient back to home. For example, if a patient had been previously living independently in a three-story home where the bathroom and bedroom are on the second floor and the kitchen on the first, one could surmise that that individual would need one of three things to occur before the individual could be discharged home: (1) the patient would need to be able to negotiate a full flight of stairs independently and safely, (2) the patient would need to rearrange the home to live on the ground floor (e.g., move a hospital bed into the dining area and use a commode chair that someone emptied regularly) and be able to transfer and ambulate short distances on a level surface independently, or (3) the patient would need a responsible caregiver to assist with daily tasks. Obviously, to achieve option 1 would require more work for the patient and likely more time in the rehabilitation facility than option 3, and the more time a caregiver were available to assist the patient, the lower the target functional achievement needed for a safe discharge to home. Not all patients have access to assistance in their homes, but some families or friends are able to make significant adjustments to be able to provide this support, usually un-reimbursed, which can be a major stressor when the caregiver has taken a prolonged period away from work to do so. The geriatrician or internist may help the potential caregivers anticipate and prepare for the patients' upcoming needs by assessing the home environment and discussing these issues early in the course of the hip fracture treatment.

### Rehabilitation Services

The majority of patients with hip fracture will undergo a period of rehabilitation therapy after the fracture. Rehabilitation services are provided to the patient with hip fracture only if both of the following requirements are fulfilled: (1) the patient has a functional loss and (2) the individual is able to participate in rehabilitation efforts. Based on these principles, individuals with severe cognitive impairment, or those with unresolved delirium and who may be unable to participate in standard rehabilitation and will require special attention, those with severe pre-fracture disability (e.g., bed-bound pre-fracture), and those with terminal illness may not qualify for rehabilitation services.

This rehabilitation typically takes place in one or more of the following settings: an inpatient rehabilitation setting, which can be

either acute or subacute, or on an outpatient basis, either at home or in a clinic. In the United States, rehabilitation is typically limited by Medicare reimbursement and rarely goes beyond 30 days. In one study, approximately half of all patients were discharged to a skilled nursing facility for rehabilitation, 20% received rehabilitation in an acute rehabilitation facility, 15% were discharged to home, and 14% were discharged directly to long-term care.

Inpatient acute rehabilitation units are usually located in specialized units of an acute care hospital, in dedicated rehabilitation hospitals, or in skilled nursing facilities with specialized acute rehabilitation units. Patients with complex medical or rehabilitation needs and with good endurance may receive their rehabilitation in the acute setting. The requirements for acute rehabilitation are that the individual must be able to participate in therapy for at least 3 h/d and that they require at least two therapies (example physical therapy and occupational therapy).

Patients with less complex medical or rehabilitation needs, who may not be able to participate in 3 h/d of rehabilitation but who otherwise have a functional decline that would benefit from rehabilitation and are unable to be discharged to home, typically receive rehabilitation in the subacute setting. Subacute inpatient rehabilitation is usually delivered in skilled nursing facilities. These patients typically receive interventions from a licensed professional 5 days a week, however, on a less intense basis than in the acute rehabilitation setting.

Patients with more mild impairments or with good support at home may receive their rehabilitation on an outpatient basis, either at home or at an outpatient facility. In order to qualify for home rehabilitation, patients must have a functional decline that would benefit from rehabilitation, have good home supports that enable them to be discharged to home, and be homebound and therefore unable to attend rehabilitation at an outpatient clinic. Since rehabilitation will be delivered by home-care professionals in the patient's home, heavy equipment must not be required.

For individuals with less complex rehabilitation needs, services may be delivered in an outpatient clinic. Outpatient rehabilitation may follow rehabilitation in the acute, subacute, and home-care settings and may continue until the individuals attain their rehabilitation goals.

## The Role of the Geriatrician in the Rehabilitation Setting

The geriatrician may also play a key role in the medical management in these rehabilitation settings, especially for the majority of patients with hip fracture who undergo rehabilitation in skilled nursing facilities. Regardless of the setting of rehabilitation, medical care depends on the following principles: continued postoperative hip fracture care, treatment of chronic medical conditions, prevention of complications from the functional decline and immobility following hip fracture, and prevention of future falls and fractures.

Despite ongoing therapy by rehabilitation professionals, increased risk for complications related to immobility, such as DVT, pressure ulcers, and constipation, persist into the rehabilitation setting. Thus, continued vigilance to their prevention and detection must be exercised. Based on current recommendations, DVT prophylaxis should be continued for 28 to 35 days after hip fracture surgery. Pressure ulcers are common after hip fracture surgery, with reports of an incidence rate of stage II or greater ulcers within 21 days of fracture of approximately 35%. Given the decreased mobility and frequency of use of narcotic analgesics for postoperative pain, constipation is a common occurrence and efforts should be made to prevent this with an adequate bowel regimen.

Many patients with hip fracture in the acute and subacute rehabilitation settings receive their medical care from a physician who was not their primary-care provider pre-fracture and who is not familiar with the patients' history or support system. Care for these patients represents a challenge for the attending physician, as these patients are typically older and with significant and complicated comorbid disease. More than 75% of patients with hip fracture have at least four comorbid medical conditions prior to their fracture. In addition to supervising the care of the hip fracture and any sequelae, the attending physician in inpatient rehabilitation setting must ensure that these chronic medical conditions continue to be addressed while the patient is being cared for in these settings.

### What to Tell the Patient and Family to Expect in Terms of Function

Because hip fracture may result in persistent functional limitations and disability, patients with hip fracture may anticipate significant changes in their lifestyle. The geriatrician needs to provide support and encouragement during the initial recovery period following hip fracture surgery when pain and disability are greatest. Patients and their families can be reassured that patients are likely to experience significant improvements in their lower extremity function during the first few months postfracture, while at the same time cautioned that lower extremity limitations can be prolonged. Up to 50% of elders who had previously been independent may be dependent on mobility aids, such as a cane or a walker, for ambulation at 1 year post fracture. These limitations and fear of recurrent falls may result in limitation in their activities.

These declines in function may result in loss of independence in the older patient, and, as a result, the older patient with hip fracture may be facing the prospect of moving from their independent residence to a higher level of care for the first time. Individuals who have an injury, such as a hip fracture, as a result of a fall are 10 times more likely to be admitted to a skilled nursing facility. This may be one

of the most frightening aspects of the postfracture recovery facing the patient with hip fracture, and helping them to understand that this is an expected reaction to having a hip fracture may help them to overcome this fear and resume their activities more quickly.

Older patients and those with other health problems may need to be told that their recovery may be slower than for others. Compared to younger patients, those who are older than 85 years have been found to require longer rehabilitation stays, have worse recovery of lower extremity function, are more likely to be discharged to long-term care, and are more likely to have persistent pain, which may be accompanied by Activities of Daily Living (ADL) limitations and reduced quality of life. Depression and cognitive limitations should also be discussed with patients and families. It is important for them to understand that depressive symptoms and cognitive limitations are common after a hip fracture. They should also be informed that these changes are not always persistent, as depressive symptoms and cognitive limitations will frequently resolve with limited intervention for the next 2 months, and that treatment for mild depression is often useful to avoid any lingering anxiety or depression that accompanies the hip fracture.

### THE GERIATRICIAN'S ROLE IN CARING FOR PATIENTS WITH HIP FRACTURE FOLLOWING REHABILITATION

After the patient has returned home, the focus in follow-up care is on monitoring to be sure that the patient is making expected gains in recovery, on evaluation for contributing causes if expected gains are not achieved, and on preventing subsequent falls and injury. Most people will have recovered most of the function they will recover in the first 6 months after fracture, but the occurrence of complications may alter that course and many will continue to realize gains with longer amounts of time. A home safety evaluation is often high yield, done either by direct observation or by providing the patient or an involved care member a check list, as is determination of gait and balance with consideration for the use of an appropriate assistive device.

Problems with gait and balance remain a problem for older adults after hip fracture, and these individuals remain at high risk of recurrent falls. Community-based multidisciplinary fall risk assessment (example: home environment assessment, medication review, vision testing, postural blood pressure measurement, gait and balance testing, and targeted neurological, musculoskeletal, and cardiac examinations) followed by interventions directed at these risks has been shown to reduce fall risk and to be cost effective in older adults at risk of recurrent falls. Gait and balance training interventions in the clinical setting have also been shown to reduce recurrent falls rates.

Despite the fact that almost all older adults who have a hip fracture have preexisting osteoporosis, only a minority receives treatment for osteoporosis prior to the fracture and only this same minority typically receives these treatments after the fracture. The occurrence of a minimal trauma fracture, such as hip fracture, should provide an opportunity to address bone health in an older adult. A hip fracture is associated with an increased risk of subsequent fracture, including a second hip fracture. Although there is only one published randomized study on the secondary prevention of fractures in elders post

**TABLE 118-1****Focus of the Geriatrician at Various Stages of Care for Patients with Hip Fracture**

SETTING OF CARE	WHAT THE GERIATRICIAN IS FOCUSED ON
Acute hospital—preoperative	<ol style="list-style-type: none"> <li>1. Do surgery or nonoperative approaches best meet this patient's goals?</li> <li>2. What are the preoperative cardiac, pulmonary, cognitive, and other risks for this patient and what can be done to reduce these?</li> <li>3. What must be done to prevent postoperative complications, especially pressure ulcers, delirium, anemia, and pneumonia?</li> <li>4. Why did this person fall and how can this information be used to ensure that medical status is optimized for surgery or nonoperative management?</li> </ol>
Acute hospital—postoperative	<ol style="list-style-type: none"> <li>1. What can be done to prevent postoperative complications, such as pressure ulcers, delirium, anemia, and pneumonia?</li> <li>2. Is pain adequately treated?</li> <li>3. Is there delirium and how can it be addressed?</li> <li>4. What is the next appropriate level of care and when is the patient ready to go there?</li> <li>5. Who will next provide medical care and how can continuity of care be ensured?</li> </ol>
Subacute setting—rehab	<ol style="list-style-type: none"> <li>1. Is pain adequately treated?</li> <li>2. Are there any complications requiring treatment, such as constipation, delirium, pneumonia, venous thrombosis, deconditioning, and pressure ulcers?</li> <li>3. Are there signs of active depression limiting participation in rehabilitation and what can be done to address this during rehabilitation and after discharge?</li> <li>4. Why did this person fall and what can be done to reduce the chances of future fractures?</li> <li>5. Is this person on appropriate osteoporosis therapy?</li> <li>6. What does this person need to do to be able to go home safely?</li> <li>7. Who will next provide medical care and how can continuity of care be ensured?</li> </ol>
Outpatient setting—primary care	<ol style="list-style-type: none"> <li>1. Is this person receiving appropriate interventions to prevent falls and fractures and increase activity level and reengagement into community life?</li> <li>2. Is this person safe in the current living arrangement?</li> <li>3. Is recovery occurring in the expected sequence and in the expected time frame?</li> <li>4. Is pain resolved?</li> </ol>

hip fracture that demonstrated a benefit of a bisphosphonate therapy (i.e., zoledronic acid), interventions such as vitamin D and calcium supplementation, weight-bearing exercise, and pharmacological treatment with other antiresorptive agents such as bisphosphonates or the anabolic agent teriparatide, are also believed to be of benefit and should be considered.

Although hip protectors have recently received significant attention for their potential to reduce hip fractures, many older adults and their care providers may prefer their use to taking additional

medication. The evidence for the efficacy of hip protectors in prevention of hip fracture is conflicting. Meta-analyses suggest that these offer little or no benefit for patients in randomized studies. As a result, these devices should not be considered as alternatives to the other fall reduction and bone-strengthening interventions listed above.

## CONCLUSIONS

Care for the older patients with hip fracture represents one of the greatest challenges for the geriatrician because of the multiplicity of medical and psychosocial factors involved in their postfracture care. A summary of some of the key issues a geriatrician should focus on at various stages of hip fracture care appears in [Table 118-1](#). Answering these questions requires vigilant attention preoperatively, postoperatively, in the rehabilitation setting, and after rehabilitation efforts have terminated. Although a hip fracture event has significant consequences for patients and their families, through this attention and communication with patients, families, and the other clinicians involved in the care of the patients as they transition through the various sites of care, it is the goal of the geriatrician to minimize long-term adverse effects and to ensure that the overall well-being of the patient is maximized.

## ACKNOWLEDGMENTS

The overview of hip fractures presented in this chapter is derived, in part, from research supported by the National Institute on Aging Grant R37 AG09901 (Baltimore Hip Studies Project) and National Institute on Aging Grant P60 AG12583 (Claude D. Pepper Older Americans Independence Center Junior Faculty Award to Dr. Ram R. Miller). The authors also wish to express their appreciation for the research assistance provided by Christopher D'Adamo, Doctoral Candidate, Epidemiology, University of Maryland, Baltimore.

# Myopathy, Polymyalgia Rheumatica, and Temporal Arteritis

Yuri R. Nakasato ■ Bruce A. Carnes

## SKELETAL MUSCLE, AGING, AND DISEASE

Skeletal muscle is a large and important organ system in the human body. Disorders and diseases of muscle are common in late life and have a major impact on function and quality of life. Many diseases affect muscle and are considered forms of myopathy. Myopathies are generally considered to be inflammatory or noninflammatory and will be addressed below. Loss of skeletal muscle mass owing to any disease or condition is called sarcopenia. Sarcopenia derives from the Greek and translates as “poverty of flesh.” As a medical term, sarcopenia is nonspecific and can be caused by aging, disuse, wasting illness, or starvation or can be a secondary consequence of ischemia or neuropathy. [Table 119-1](#) describes the characteristics of each of these forms of sarcopenia and highlights implications for care of the older adult. Sarcopenia can also develop in the course of some myopathies. Sarcopenia caused by aging itself is difficult to characterize since aging is often accompanied by the other contributors to loss of muscle described in [Table 119-1](#).

Sarcopenia is now definable based on formal assessment of body composition using dual-energy x-ray absorptiometry. Similar to the use of relative bone mass to make the diagnosis of osteoporosis, dual-energy x-ray absorptiometry can yield estimates of lean body mass, which can be reported as absolute values or as scores relative to normal gender-specific values and skeletal size. In order to adjust for differences in skeletal size, the “relative skeletal muscle index” (RSMI) is defined as the predicted or measured (dual-energy x-ray absorptiometry) muscle mass (kg) divided by stature in square meters ( $RSMI = \text{kg}/\text{m}^2$ ). On this scale, sarcopenia is defined by index values less than 2 standard deviations below the gender-specific mean for RSMI in a healthy, younger population. Thus, cutoff values for sarcopenia would be less than  $7.26 \text{ kg}/\text{m}^2$  for males and  $5.45 \text{ kg}/\text{m}^2$  for females. Since aging tends to alter body composition, with reduced muscle and bone and increased extracellular fluid volumes, the prevalence of sarcopenia increases with age. Sarcopenia

defined as RSMI less than 2 standard deviations below normal occurs in approximately 15% of people aged 60 to 69 years and approximately 40% of people older than 80 years.

## MYOPATHIES

### Idiopathic Inflammatory Myopathies (IIM)

Several of the most important diseases that primarily affect muscle are inflammatory in nature, are together termed idiopathic inflammatory myopathies, and carry labels using the term “myositis.” The most common forms include polymyositis (PM), dermatomyositis (DM), and inclusion body myositis (IBM). Each will be described in the sections below. Since all three are often treated with glucocorticoids, a separate section discusses steroid treatment.

### Polymyositis

PM is an IIM that affects all ages, with approximately one-third of cases in persons older than 65 years. Females are affected more than males. While the exact pathophysiology is not known, muscle biopsy shows inflammation that is mediated by T cells, mostly CD8+ T cells and macrophages causing perimysial and perivascular infiltrations. The inflammatory cells surround and invade non-necrotic muscle fibers, leading to necrosis at various stages alternating with regeneration and replacement by fibrous connective tissue and fat.

PM usually presents in an insidious fashion, and the course may be subacute or chronic with either no or mild pain. Common systemic features include fatigue, weight loss, arthralgias, and fever. Skin sensation and reflexes are typically normal. Symmetrical proximal weakness manifests in the neck flexors and extensors, as well as the shoulders and hips; dysphagia may occur in 25% of cases.

**TABLE 119-1**

**Conditions That Contribute to Sarcopenia**

	<b>INTRINSIC MUSCLE AGING</b>	<b>DECONDITIONING/ DISUSE</b>	<b>WASTING OWING TO CANCER, HIV, INFLAMMATORY CONDITIONS, OR CHRONIC DISEASES</b>	<b>STARVATION (PROTEIN MALNUTRITION) OR INCREASED METABOLIC DEMANDS</b>	<b>ISOLATED MUSCLE LOSS OWING TO LOCALIZED NERVOUS SYSTEM DISEASE OR CARDIOVASCULAR DISEASE</b>
Myopathy	Not a myopathy, considered normal	Yes, considered abnormal	Yes, considered abnormal	Yes, considered abnormal	Yes, considered abnormal
Etiology	Normal intrinsic aging process	Loss of stimulation to muscle protein synthesis and maintenance of neuromuscular junctions. Similar to effects of low-gravity environment.	Increased inflammatory markers	Lack of sufficient protein reserves to counteract for muscle catabolism. Fasting results in decreased synthesis and increased breakdown of both myofibrillar and soluble muscle proteins and creates alternative sources of energy.	Peripheral vascular disease with consequent ischemia of an extremity, severance of a specific peripheral nerve with paralysis, cardiovascular accidents with paresias or paralysis, and loss of neuromuscular junctions because of similar conditions.
Creatinine kinase (CK)	Normal	Normal	Normal	Normal	Normal, unless there is an infarct of the region.
Potential implications for aging	Isolated effects of aging are hard to define, since most older adults also have other conditions that contribute to sarcopenia. The muscular system is integrated with other organ systems and is affected by disorders in other systems.	Levels of activity tend to decrease with aging. Many diseases reduce activity and cause secondary deconditioning.	Many wasting diseases increase in prevalence with age.	Calorie and protein intake can decrease with age and many conditions. Gastrointestinal absorption of nutrients may also decrease owing to several conditions that occur in older adults.	Cardiovascular and neurological conditions are common in older adults.
Usual presentation	Very chronic across decades of later life	Acute, subacute, or chronic	Acute, subacute, or chronic	Rarely acute. Usually subacute and chronic	Acute or subacute onset, eventually chronic
Caloric ingestion	Normal	Normal	Normal	Abnormal	Normal
Usual age of presentation	Starts around fourth decade of life	Any age	Any age	Any age	Any age
Approximate rate of loss	~1% per year	~1% per day	~1% per day	~1% per day	~1% per day
Usual outcome	Irreversible	Reversible	Potentially reversible	Reversible	Irreversible, partially reversible, or potentially reversible in rare cases
Histology	Muscle atrophy with no evidence of necrosis: loss of muscle cells, decrease in the size of existing muscle cells. Affecting type 2B cells more at the beginning, then affecting all types.	Muscle atrophy with no evidence of necrosis: decrease in size of muscle cells (fiber).	Muscle atrophy with no evidence of necrosis: decrease in the size of existing muscle cells. There could be loss of muscle cells.	Muscle atrophy with no evidence of necrosis: decrease in the size of existing muscle cells.	Muscle atrophy unless there is an infarction where muscle necrosis ensues.
Treatment	No cure. However, exercise can hypertrophy existing muscle cells and improve muscle function to compensate for the decrease in muscle cells and minimize the clinical impact of the muscle loss over time.	Aerobic and anaerobic exercise. Encourage physical therapy and occupational therapy.	Correction of the underlying cause and aerobic and anaerobic exercises	Nutritional correction and aerobic and anaerobic exercises	Rehabilitation exercise for recovery of remaining upper motor neurons for plasticity as in the case of stroke. Stent placement or angioplasty or surgery in the case of peripheral vascular disease. Aerobic and anaerobic exercise.

Creatinine kinase (CK) is elevated in 90% of cases, but myoglobinuria is usually not present. Anti-Jo-1 or anti-Mi2 antibodies may be present. Patients usually present with anemia and positive inflammatory markers. PM may be associated with inflammation in other organ systems such as pulmonary interstitial fibrosis or myocarditis and is sometimes a component of other connective tissue disorders. The electromyogram is abnormal in 90% of cases and shows motor unit action potentials (MUAPs) that are of short duration, of small amplitude, or polyphasic with early recruitment. Fibrillations and positive waves indicate active inflammation.

PM is treated mainly with steroids and cytotoxic agents. More detail about treatment is presented in the section below. With or without treatment, the disease may progress to dysphagia and respiratory failure. Prognosis for recovery is poorer in older adults, in part because of the effect of age on susceptibility to the complications of immunosuppressive drugs.

### Dermatomyositis

DM is an IIM that affects all ages, with approximately one-quarter of cases developing in older adults. It has a female preponderance. While the pathophysiology is not fully understood, muscle biopsy shows endomysial inflammation with a more humoral component (CD4+ T cells and B cells). Perifascicular atrophy (atrophic fibers at the edges of the fascicles) may be caused by hypoperfusion, since capillary density is significantly reduced. Vessels are positive for complement membrane attack complex.

Presentation is insidious and the course is subacute with systemic features such as fatigue, weight loss, arthralgias, and fever. Pain is absent or mild. Sensation and reflexes are preserved. Photosensitivity rashes are common. Typical skin changes include heliotrope rash, Gottron's papules, V sign, Shawl's sign, and mechanic's hands. Heliotrope rash is a violet or purplish discoloration seen around the eyes and on the extremities. Gottron's papules are erythematous, raised areas at the bony prominences in the hands, elbows, and knees. V sign is a macular erythema on the chest in a V shape. Shawl sign is a macular erythema over the posterior thorax. Mechanic's hands are rough, cracked regions of skin on the palms and radial aspects of the fingers. Dysphagia occurs in approximately 25% of DM cases. Symmetrical proximal weakness appears in the neck flexors and extensors, as well as shoulders and hips. CK is elevated in 90% of cases, and myoglobinuria is usually not present. Jo-1 antibodies are associated with pulmonary interstitial fibrosis, and anti-Mi2 antibodies are associated with classic DM. Patients usually present with anemia and positive inflammatory markers. DM is sometimes associated with myocarditis and other connective tissue disorders. Electromyograms for DM and PM are indistinguishable.

Treatment involves steroids and cytotoxic agents. The disease sometimes progresses to dysphagia and respiratory failure. Prognosis, even with treatment, is worse for older than younger adults. Routine cancer screening is required, since 25% of cases with DM develop some type of associated cancer (mostly colon).

### Inclusion Body Myositis

IBM is an IIM with a male preponderance and is the most common IIM in older adults. While the pathophysiology is not known, muscle biopsy shows endomysial infiltrates with CD8+ T cells, macrophages invading non-necrotic muscle fibers, as well as rimmed vacuoles and amyloid deposits in the muscle fibers.

The onset of IBM is more insidious than PM and DM, and its course is either subacute or chronic. Pain is absent or mild. Reflexes are either diminished or absent as a result of associated peripheral neuropathy. As opposed to the proximal muscle weakness that predominates in PM and DM, in IBM the proximal and distal muscles are equally involved. IBM might typically present with weakness of bilateral wrists, finger flexors, quadriceps, and foot dorsiflexors. IBM can present with atrophy of the quadriceps muscles. CK elevation in IBM is less than that for PM and DM. Skin involvement and myoglobinuria are usually not present.

The electromyogram shows a chronic myopathy with an active component (fibrillation). Fibrillations and positive waves indicate active inflammation. Nerve conduction studies reveal mild neurogenic features.

IBM is typically unresponsive to steroids. Up to one-third of cases will stabilize or improve with or without treatment. IBM medications, when used, are similar to those for PM and DM.

### Treatment of Idiopathic Inflammatory Myopathies

Glucocorticoids are the first-line treatment for inflammatory myopathies. Initial dosage can be reduced for older compared to young adults, because overall muscle mass is expected to be lower with age. While prednisone dosing in young adults is calculated at 1.5 mg/kg (up to 100 mg/day), the dose in older adults is calculated at 1.0 mg/kg (up to 60 mg/day). The initial dose should be maintained until there is evidence of clinical response, especially a clinically detectable improvement in muscle strength. If there is no clinical response in 3 or 4 months, the patient should be considered steroid unresponsive and another immunosuppressive agent should be considered. Tapering begins with clinical response. Dosing can switch immediately to an alternate-day pattern (e.g., 60 mg every other day) or can be gradually converted to an alternate-day pattern (e.g., reduce the alternate or "off-day" dose by 10 mg per week). Continue the alternate-day regimen until either the patient's strength is normalized or improvement reaches a plateau (usually 4–6 months). Next, reduce the dosage by 5 mg every 2 to 3 weeks until the lowest dose capable of controlling symptoms and maintaining muscle strength is achieved. A maintenance dose of 10 to 25 mg every other day may be needed to achieve stability. This approach to tapering steroids can also apply to other inflammatory conditions such as polymyalgia rheumatica (PMR) and temporal arteritis.

Glucocorticoids are the only agents approved by the U.S. Food and Drug Administration (FDA) for treatment of inflammatory myopathies. The efficacy of other immunosuppressive agents in inflammatory myositis is unproven, and a recent systematic review found insufficient high-quality randomized controlled trials to make evidence-based conclusions. However, second-line use of other immunosuppressive agents might be considered in several circumstances. First, second-line agents might be helpful when a steroid-sparing effect is needed to avoid complications associated with steroid therapy. Second, such agents might be used when a relapse occurs repeatedly after attempts to taper steroids. Third, second-line agents might be attempted when first-line therapy with steroid has failed to show a clinical response after at least 3 months. Fourth, second-line agents might be added to steroids when the disease is progressing rapidly, with life-threatening manifestations such as severe weakness and/or respiratory failure. [Table 119-2](#) summarizes the available agents. Some of these agents are very expensive,

**TABLE 119-2****Disease-modifying Antirheumatic Drugs (DMARDs) That Can Be Considered as Second-Line Agents for Treatment of Idiopathic Inflammatory Myopathy\***

Drug	Usual Dose	Main Side Effects
Methotrexate	7.5–20 mg oral or injection dose weekly	Diarrhea, mucosal ulcers, bone marrow toxicity, liver toxicity, and interstitial pneumonitis. Avoid methotrexate if patient has Jo-1 antibodies. Increased risk of opportunistic infections.
Azathioprine	50–150 mg oral dose daily	Bone marrow toxicity and liver toxicity. Increased risk of opportunistic infections.
Mycophenolate mofetil	2–3 g oral dose daily	Diarrhea and bone marrow toxicity. Increased risk of opportunistic infections.
Cyclophosphamide	50–150 mg oral dose daily	Nausea, vomiting, alopecia, bone marrow toxicity, and hemorrhagic cystitis. Increased risk of opportunistic infections.
Intravenous immunoglobulin (IVIg)	2 g/kg monthly (×3 months)	Patient deficient in serum IgA may be predisposed to anaphylactic reactions.
Cyclosporine A	100–400 mg oral dose daily	Bone marrow toxicity, hypertension, renal toxicity, liver toxicity, and increased risk of opportunistic infections.

\*No DMARDs are FDA approved for treatment of inflammatory myopathy but are used as second-line agents under specific conditions. See text for further discussion.

and cost versus likelihood of benefit and harm should be carefully considered. It is good practice to involve the patient, and the family if the patient desires, in discussions about treatment options.

Complications of steroid use are a serious problem whenever they are prescribed and are a special problem in older people who are even more vulnerable to serious adverse events due to these agents. [Table 119-3](#) lists the main complications of steroid use. Every effort should be made to minimize steroid exposure, to anticipate and prevent complications, and to educate the patient and family about what to expect.

## OTHER MYOPATHIES

### Steroid-Induced Myopathy

Steroid-induced myopathy is associated with either intrinsic or extrinsic excess of glucocorticoids. It can occur at any age and is more

prevalent in women. Intrinsic corticosteroid excess may be secondary to diseases such as adrenal hyperplasia, neoplasia, and adrenocorticotropic hormone overproduction by pituitary or other neuroendocrine tumors. Extrinsic steroid use for less than 4 weeks is unlikely to cause myopathy.

The histopathological appearance of involved skeletal muscle is similar, whatever the source of the excess steroids. Excess glucocorticoids alter muscle lipid, carbohydrate, and protein metabolism. While muscle biopsy may show no inflammation, there is often evidence of type 2 muscle fiber atrophy with increased muscle glycogen. The prominent subsarcolemmal lipid deposits found in some biopsies indicate altered muscle lipid metabolism. Electron microscopy reveals mitochondrial aggregation, swelling, vacuolization, and myofibrillar degeneration.

The onset of steroid-induced myopathy is usually insidious and the course is either subacute or chronic, depending on the magnitude or duration of elevated steroid levels. Proximal weakness tends to involve legs more than arms, the strength of the neck flexors is unaffected, and the cranial nerve-innervated muscles and sphincters

**TABLE 119-3****Adverse Effects of Glucocorticosteroids**

SYSTEM	CONSEQUENCE	PREVENTION
Cardiovascular	Hypertension and hyperlipidemia	Manage cardiovascular risk factors; adjust cardiovascular medications upward or downward.
Muscle	Steroid-induced myopathy	Exercise (aerobic or anaerobic) to minimize impact of muscle atrophy.
Bone	Glucocorticoid-induced osteoporosis usually occurs during the first 6 months of therapy. Chronic use leads to increased risk of fracture and aseptic necrosis of femoral and humeral heads.	Get a baseline bone mineral density and start calcium 1500 mg a day plus vitamin D 800 IU. If therapy is prolonged, a bisphosphonate should be added.
Gastrointestinal	Peptic ulcer disease and upper gastrointestinal bleeding	Consider histamine-2 blockers or proton pump inhibitors.
Endocrine	Cushingoid habitus, glucose intolerance, and exacerbation of diabetes mellitus	Adjust diabetes medications during induction and tapering phase
Ophthalmic	Cataracts and glaucoma	Follow up with ophthalmology.
Immune	Immunosuppression and subsequent infections	Atypical presentation of infections occurs in the elderly. Acute abdomen may present differently. If possible, obtain a tuberculosis test (PPD) and give pneumococcal vaccination before starting treatment. Sepsis is more common.
Neurological	Psychosis with delirium	Taper the dose of steroids as soon as possible.
Skin	Thinning with capillary fragility; striae.	Minimize nonsteroidal anti-inflammatory drugs and aspirin if possible. Taper steroids as soon as possible.

are spared. The clinical examination is likely to reveal other signs of excess steroids, such as classic Cushingoid facies, central obesity, thin skin, and capillary fragility. CK is usually normal. The electromyogram typically shows no fibrillations. MUAPs are of low amplitude and short duration. Sharp waves or fibrillation potentials may also be present.

Treatment of steroid-induced myopathy is focused on reducing exposure to steroids, either by managing the underlying source of excess intrinsic steroids or by exploring options for tapering extrinsic steroids. Exercise may be helpful in preventing or ameliorating steroid-induced myopathy. Inactivity appears to increase glucocorticoid receptors in muscle while activity reduces these receptors and thus can help prevent atrophy. Since fluorinated steroids (triamcinolone, betamethasone, and dexamethasone) are more likely to cause muscle weakness, nonfluorinated steroids are preferred when chronic steroid treatment is planned. Consider the use of a steroid-sparing agent whenever long-term steroids are required to control inflammation. The course of recovery from steroid-induced myopathy after the source of excess steroids has been withdrawn is weeks to months.

### Hypothyroidism-Related Myopathy

Hypothyroidism-related myopathy occurs when serum levels of thyroid hormone are low. Hypothyroidism reduces the basal metabolic rate and the number of adrenergic receptors on muscle cells, resulting in diminished glycogenolysis that, in turn, may contribute to muscle cramps and fatigability. Both protein synthesis and degradation are reduced with net protein catabolism. Hypothyroidism is more prevalent in older women than in men. The histopathological findings on muscle biopsy are nonspecific and include fiber size variation, type 2 fiber atrophy, internalization of nuclei, sporadic necrosis and regeneration, disrupted mitochondria, myofibrillar disorganization, and glycogen accumulation.

The onset is insidious and the course is chronic. Symptoms include nonspecific muscle soreness, weakness or stiffness, or cramping without actual weakness. Proximal muscle wasting and weakness are associated with weight gain. Myoedema (local contracture produced by tapping or pinching the muscle) and muscle enlargement may occur. Sensation is typically normal, but ankle reflexes are slow in the relaxation phase of the muscle and pseudomyotonia (a delay in relaxation with handgrip) can occur. Other clinical signs of hypothyroidism may be present (see Chapter 108 on thyroid disease). CK is elevated, but myoglobinuria usually is not present unless there is also rhabdomyolysis.

The electromyogram can be normal or may show low-amplitude polyphasic MUAPs, increased insertional activity, and occasional positive waves. Fibrillations or fasciculations indicating coincidental neuropathy may occur. Myoedema is electrically silent.

Treatment involves restoration of euthyroidism. Recovery takes weeks to months, and weakness may improve more slowly than the chemical and electromyographic abnormalities. Although most patients have recovered normal strength by 6 months, one-quarter of cases still have neuromuscular symptoms and 10% have weakness on physical examination 1 year after treatment.

### Hyperthyroidism-Related Myopathy

Hyperthyroidism-related myopathy is associated with increased serum levels of thyroid hormone. It develops insidiously and progresses slowly. The mean age of onset is in the late forties. Hyperthyroidism in late life is more common in women than in men.

The muscle complications of hyperthyroidism are related to excess thyroid hormone effects, such as increased basal metabolic rate and heat production with increased consumption of mitochondrial oxygen, pyruvate, and malate, together resulting in skeletal muscle catabolism. Muscle biopsy is usually normal or may show mild abnormalities, including varying degrees of fatty infiltration, fiber atrophy, and nerve terminal damage. The clinical presentation includes myalgia, fatigue, and exercise intolerance. Although severe muscle wasting can occur, the muscle weakness is out of proportion to the amount of muscle wasting in up to half of cases. Distal muscle weakness develops later in the disease progression and is less severe than proximal weakness. Sphincters are spared and tendon reflexes are usually normal with 25% having shortened relaxation times. CK is usually normal but may be elevated in thyroid storms. Myoglobinuria is usually not present even during thyroid storm unless rhabdomyolysis is present.

The electromyogram is characterized by short-duration MUAPs and increased polyphasic potentials in proximal muscles. The EMG may be abnormal in up to one-third of cases with apparently normal muscle strength. The EMG is abnormal in distal muscles in only approximately 20% of cases. Spontaneous electrical activity is rare, and nerve conduction velocity is normal.

This myopathy is reversible if patients are returned to the euthyroid state. Adrenergic blocking agents may improve muscle strength acutely as may glucocorticoids that block the peripheral conversion of T3 to T4. See Chapter 111 for further discussion of hyperthyroid disease.

### Statin-Induced Myopathy

Statin-induced myopathy is associated with use of statin-based cholesterol-lowering agents. It can present in a variety of fashions including myalgias, isolated CK elevation, weakness, or rhabdomyolysis. The risk of developing statin-induced myopathy is increased with higher dose of the statin, low body size, renal insufficiency, hepatic disease, hypothyroidism, age, diabetes, and drugs that use P-450 (CYP) 3A4 pathway (e.g., niacin, erythromycin, diltiazem, and cyclosporine). Muscle biopsy shows scattered muscle fiber necrosis with phagocytosis and small regenerating fibers. Electron microscopy demonstrates the subsarcolemmal accumulation of autophagic lysosomes. CK is often elevated, and myoglobinuria could present in cases of rhabdomyolysis.

The electromyogram is usually normal except when a generalized necrotizing myopathy has developed. In that case, there is increased insertional and spontaneous activity and small-amplitude, short-duration, polyphasic, or “myopathic” MUAPs. Fibrillation potentials or positive sharp waves can also occur.

Statin-induced myopathy is reversible with discontinuation of the offending agent. Since the severity of the condition varies widely, there may be situations where a mildly elevated CK without clinical consequences could be monitored and the drug continued, especially if there is a compelling need for the use of the statin. This option should be clearly discussed with the patient, who should be involved in the weighing of risks. See Chapter 75 for further discussion of statin use.

### Other Myopathies

*Mixed Connective Tissue Disorder (MCTD)* has elements of systemic lupus erythematosus, scleroderma, and myositis and can present as a myopathy. Muscle biopsy in patients with MCTD is similar to

those with DM/PM. Myalgias are common in MCTD, and half of MCTD cases have an inflammatory myositis. There is generalized weakness but little, if any, wasting. Patients may have normal or proximal weakness. The pelvic girdle is affected more than the shoulder girdle. Focal myositis may also occur. More severe cases can present with dysphagia and diaphragmatic dysfunction. CK is elevated and myoglobinuria is uncommon. Autoantibodies to ribonucleoprotein (anti-U1-snRNP) are a feature of MCTD but are not specific. The electromyogram is similar to DM/PM and has inflammatory features when myositis is present. Glucocorticoids are the main treatment and are prescribed as in PM and DM. See Chapter 120 for further discussion of autoimmune disease, including MCTD.

*Osteomalacia* is a metabolic bone disease characterized by undermineralized matrix because of lack of vitamin D. The disease can be associated with a myopathy. The risk of vitamin D deficiency is increased among older adults (see Chapters 116 and 117 on osteomalacia and on deficiency of vitamin D). This myopathy can present with proximal weakness, waddling gait, nonspecific bone pain, and tenderness with or without fractures. CK is typically normal. The electromyogram shows a myopathic process, and MUAPs are of low amplitude and short duration. Muscle biopsy shows minimal inflammatory infiltrates. This myopathy is reversible with administration of vitamin D.

*Mitochondrial myopathies* are associated with mitochondrial dysfunction. The clinical presentation of mitochondrial myopathy can be slow and progressive. Muscle biopsy shows ragged red fibers (Gomori trichrome stain). Patients usually present with droopy eyelids and double vision owing to ophthalmoplegia. CK is mildly elevated, and there is usually no myoglobinuria. The electromyogram is normal. There is no specific treatment other than physical therapy and vitamin supplementation to assure adequate nutrition.

*Amyloid myopathy* is associated with amyloidosis. The muscle biopsy shows extracellular amyloid deposits around the muscle fibers and blood vessel walls within the muscle. Sometimes there are inflammatory changes. Although rare, amyloid myopathy can occur in older people who have multiple myeloma. CK is usually elevated with no myoglobinuria. The electromyogram may reflect the inflammatory changes, but it is not specific. Treatment is aimed at the underlying cause (i.e., treatment of multiple myeloma, tuberculosis, etc.). See Chapter · · · for a more detailed discussion of multiple myeloma.

*Alcohol-induced myopathy* is related to chronic alcohol use. Since alcohol overuse is an important and often overlooked problem for older adults, alcohol-induced myopathy should be considered in older people presenting with a myopathic picture. The clinical presentation can be chronic, subacute, or acute and can be accompanied by weakness and myalgias. Muscle biopsy shows inflammation and necrosis in the acute and subacute form. Atrophy of type 2 fibers can be seen in the chronic presentation. CK is elevated, and myoglobinuria may be present with rhabdomyolysis. The electromyogram may show inflammatory changes in the acute or subacute presentation but may have noninflammatory myopathic changes in the chronic presentation. The myopathy can improve with alcohol abstinence. See Chapter 51 on alcohol and aging.

*Late-onset muscular dystrophies* are degenerative myopathies characterized by loss of muscle fibers, variation in fiber size, muscle fiber necrosis, and other nonspecific changes. Although these myopathies usually affect the young, these can develop de novo or worsen later in life. The dystrophies are characterized by the muscle groups that are affected and form three main patterns: (1) facioscapulohumeral

dystrophy, (2) oculopharyngeal dystrophy, and (3) limb girdle dystrophy. CK is usually elevated or normal with no evidence of myoglobinuria. The electromyogram shows a nonspecific myopathic pattern. There is no treatment or cure. Management is conservative with major goals to prevent aspiration and avoid deconditioning.

## POLYMYALGIA RHEUMATICA

Polymyalgia rheumatica is a clinical syndrome characterized by aching and stiffness in the proximal portion of the extremities and torso. The annual incidence of PMR in the United States oscillates around 58.7/100 000 and its prevalence around 300/100 000. The incidence is higher in females, and it is most commonly found among persons of Northern European origin. PMR primarily affects the elderly and is rare in patients younger than 50 years old.

The etiology of PMR is unknown, but the systemic inflammation involved resembles that found in giant cell arteritis (GCA). In fact, 6% to 33% of patients with PMR will develop GCA. In addition to the vasculitis typical of the condition, synovitis (inflammation of the synovial lining of joints) can also be present. This form of synovitis is called “benign synovitis” because it does not progress to joint erosions.

The onset of PMR is often insidious, and its course is subacute or chronic. Fever, anorexia, weight loss, malaise, night sweats, and depression are common manifestations of the systemic inflammation associated with PMR. There is stiffness and pain around the muscles of the neck, shoulders, and pelvic girdle but no weakness. Glenohumeral joint synovitis and long-head biceps tenosynovitis can coexist in approximately 60% to 80% of patients. However, the passive range of motion of large joints is maintained. Laboratory findings usually include elevated erythrocyte sedimentation rate (ESR), elevated C-reactive protein, thrombocytosis, and normocytic normochromic anemia.

The diagnosis of PMR is made on clinical grounds. The differential diagnosis includes elderly-onset rheumatoid arthritis, seronegative rheumatoid arthritis, shoulder bursitis, trochanteric bursitis, and fibromyalgia, among others. Magnetic resonance imaging and ultrasound studies both show similar inflammatory shoulder lesions (synovitis). Bilateral subacromial/subdeltoid bursitis represents the imaging hallmark in PMR even in patients with normal erythrocyte sedimentation rate.

Corticosteroids are the main therapy. Initial treatment is usually prednisone up to 20 mg/day for 7 days. If there is no response, the dose can be increased to 30 mg/day for another week. Seek an alternative etiology if no response is observed. If the patient responds to the initial dose, then monitor for signs of GCA and start tapering the dose after muscle pain and stiffness have improved. A response to small doses of glucocorticoids is considered typical of PMR and can be used to affirm diagnosis, although symptoms, as a result of other conditions, may also respond transiently to steroids. Prednisone tapering must be pursued slowly in order to prevent recurrence of symptoms and can take up to 1 to 2 years.

## TEMPORAL ARTERITIS (CLASSIC CRANIAL GCA)

GCA is a systemic vasculitis that mainly affects large vessels. It is a panarteritis. Temporal arteritis, also called cranial GCA, is a type of GCA that involves carotid artery branches, both external

(mostly superficial temporal arteries and occipital arteries) and internal branches (ophthalmic arteries and posterior ciliary arteries).

There are several major subtypes of GCA and not all of them involve the cranial arteries. A form of large-vessel GCA, often called Takayasu's arteritis, produces a distinct spectrum of clinical manifestations and often occurs without involvement of the cranial arteries. It is characterized by upper extremity vascular insufficiency and it mainly affects young females. Large-artery GCA could also present as an aortic arch syndrome, with the arteritis spreading from medium-sized vessels to the subclavian and axillary vessels. The type of GCA that is most common in older adults is the cranial form.

The annual incidence of cranial GCA is around 7–27/100 000 and the prevalence around 200/100 000 in the United States. As was the case with PMR, it primarily affects females of Northern European origin who are older than 50 years of age.

The etiology of GCA is unknown. A plausible theory is that an antigen in the arterial wall activates T cells and macrophages that produce granulomatous reactions. This T-cell triggering occurs in the adventitia (where the vasa vasorum provides a port of entrance for inflammatory cells). The T cells secrete interferon- $\gamma$ , a cytokine that regulates effector functions of macrophages recruited to the lesions. The recruited macrophages then differentiate into distinct subsets of tissue-injurious effector cells and produce a matrix of metalloproteinases and reactive oxygen intermediates. Macrophages and multinucleated giant cells also provide growth factors and angiogenic factors that support the response-to-injury program of the artery, which leads to the formation of lumen-occlusive intimal hyperplasia.

GCA can present either abruptly or insidiously. Its course can be subacute or chronic. While the sedimentation rate and C-reactive protein are usually elevated, these can be normal at initial presentation in a minority of patients. Thrombocytosis and normocytic normochromic anemia are common. Systemic manifestations include fever, anorexia, weight loss, malaise, night sweats, depression, and PMR. PMR occurs in approximately 41% of patients and may develop before, during, or after the diagnosis of GCA. Peripheral musculoskeletal manifestations occur in approximately one-quarter of patients and include peripheral arthritis of knees, wrists, and metacarpophalangeal joints. This arthritis pattern may satisfy the American College of Rheumatology criteria for rheumatoid arthritis. Other associated manifestations include distal extremity swelling with pitting edema, distal extremity swelling without edema, distal tenosynovitis, and carpal tunnel syndrome.

Headache with no particular anatomical pattern, accompanied by severe and sometimes throbbing pain, is a common manifestation of GCA. The pain often manifests as scalp tenderness or may localize to the temporal area and be elicited by touching, grooming, or wearing glasses. One or both temporal arteries can be swollen, thickened, tender, or nodular and have decreased pulses. Jaw claudication can be elicited by prolonged talking or chewing. As a type of claudication, pain comes on with activity and is relieved by rest. This symptom is attributed to reduced blood flow to the masseter and temporalis muscles. Jaw pain that stops when talking or chewing stops is a strong indicator of GCA with high specificity. Ocular symptoms are less common and are related to stenosis of the ophthalmic artery. Symptoms include transient or persistent partial or complete visual loss, or transient or persistent oculomotor deficits like diplopia. Unilateral or bilateral blindness is the most feared complication of GCA and may be permanent. It is attributed to occlusion of the posterior ciliary branches of the ophthalmic artery causing an-

terior ischemic optic neuropathy. Visual loss can also be secondary to central retinal artery occlusion, retrobulbar optic neuritis, or cortical blindness because of vertebral–basilar stroke. Other manifestations include odynophagia (painful swallowing), nonproductive cough, limb claudication elicited by the use of arms and paresthesias. More rare manifestations include ischemia of the tongue, face, or neck and facial swelling.

Imaging by angiogram may show beading and constrictions consistent with vasculitis. Biopsy of involved arteries shows discontinuous vascular inflammation, so arterial specimens should be at least 2 to 3 cm in length. In order to make the most of the opportunity to make the diagnosis by biopsy, frozen sections from the first temporal artery should be inspected, and if inflammatory infiltrates are absent, then the contralateral side should be biopsied.

The proper sequence for biopsy and steroid treatment is controversial. Immediate treatment with steroids may reduce pathologic findings of inflammation and produce false-negative biopsy results but may be indicated in the face of a high risk of vision loss if treatment is delayed. A temporal biopsy positive for GCA shows panarteritis, with lymphocytes and macrophages concentrated in the media at the media–intima junction. Multinucleated giant cells occur in approximately 50% of cases and tend to be grouped along the fragmented internal elastica lamina. Inflammatory infiltrates can sometimes be limited to the adventitia, indicating that panarteritis is not full-blown.

GCA increases the risk of cranial ischemic complications (CICs), which present as types of stroke. Stroke can develop even before GCA is diagnosed, or within the first month after starting prednisone therapy. Risk of CICs is increased when there is also thrombocytosis, a paucity of constitutional symptoms, jaw claudication, previous episodes of transient visual loss, and CICs at presentation. Some patients with GCA are particularly predisposed to ischemic complications; this predisposition is associated with a poor inflammatory response. GCA-induced strokes can involve a range of vascular territories including vertebral–basilar, temporal–occipital, cerebellar–occipital, temporal–occipital, and brain stem. Clinical consequences are protean and follow the pattern of the ischemic brain lesion. According to some authorities, posterior circulation strokes may be more common in GCA than in atherosclerosis.

Visual loss can occur in up to one-fifth of patients with GCA and may not be preceded by any systemic symptoms. It is sudden and painless; one or both eyes may be affected. Warning symptoms include amaurosis fugax, posture-related visual blurring, and diplopia. Funduscopic examination may reveal a pale edematous disc, or splinter hemorrhages at the disc margin or cotton wool spots in the peripapillary region. The risk of permanent visual loss is increased in patients with transient visual loss and/or jaw claudication and decreased in those with elevated liver enzyme levels and/or constitutional syndrome suggestive of systemic inflammation. Treatment markedly reduces the risk of vision loss to approximately 1% overall, but treatment is somewhat less effective if visual loss is present at diagnosis, in which case the subsequent risk of vision loss is halved to approximately 13%.

GCA is treated with oral glucocorticoids as described in the section above, which summarizes steroid treatment. Steroids provide dramatic relief of clinical symptoms and help prevent ischemic events. The central goal of GCA treatment is to prevent blindness and strokes. Low-dose aspirin may also help prevent CIC complications of GCA. Patients on low-dose aspirin are less likely to experience ischemic complications, especially if they are also receiving

prednisone. Steroids are not always effective. CIC affecting the eye, face, and central nervous system can develop in 25% to 33% of patients even after receiving corticosteroids. If visual loss has occurred, partial therapeutic success is more likely if treatment is started within the first day of visual loss.

Steroid induction means starting with large parenteral loading doses of glucocorticoids. The goal of induction is to gain rapid control of symptoms, reduce the cumulative maintenance dose, and, perhaps, reduce glucocorticoid-related side effects. A typical induction would involve intravenous methylprednisolone at 15 mg/kg of ideal body weight/d (approximately 1000 mg/day for an average 70-kg patient) for 3 days. Patients simultaneously receive oral prednisone 40 mg/day. Induction doses sometimes vary in amount and duration of treatment. Further tapering is performed as described in the section on steroid use. In the absence of visual or cranial symptoms, prednisone can be initiated at 40 to 60 mg daily and tapered as described above. Since it can be difficult to completely wean patients with GCA and PMR from all steroids, slow tapering of low-dose steroids for months can be necessary. Typically when the daily dose is below 10 mg, dose is reduced by 1 mg/day every 2 weeks.

Relapse is defined as return of signs and symptoms and/or an increase in either erythrocyte sedimentation rate or C-reactive protein level while still on prednisone treatment. The prednisone dose should be increased, for example, by 10 mg daily if the patient is taking  $\geq 25$  mg/day. Once administered, maintain the new dosage for at least 2 weeks before tapering again according to a scheduled protocol. Recurrence is defined as a return of signs and/or symptoms and/or changes in laboratory parameters after all steroid therapies have been stopped for at least 1 month and may require reexposure to prednisone in varying doses.

Since it is often difficult to stop steroids in GCA and PMR, their use often becomes chronic, can last for years, and increases the probability of steroid complications. Steroid complications and their prevention are described in [Table 119-3](#). Thus, there is a great need for steroid-sparing agents. While potentially helpful, clinical trials have not shown that use of methotrexate helps reduce steroid side effects. Given this lack of evidence, the use of methotrexate in GCA and PMR remains controversial. Other potentially steroid-sparing

agents, including statins and tumor necrosis alpha inhibitors, are currently under study.

# Rheumatoid Arthritis and Other Autoimmune Diseases

*Raymond Yung*

Our understanding of the pathogenesis and approach to treatment of autoimmune diseases continue to evolve. However, key questions concerning the epidemiology, pathogenesis and optimal treatment of these diseases in the elderly population remain unanswered. Despite the many exciting new therapeutic advances, immunosuppression in elderly patients with autoimmune diseases continues to pose a dilemma. Changing population demographics and the advent of biologics, coupled with the lack of the availability of a rheumatologist in many smaller communities, will significantly impact the geriatrician's role in the care of older adults with autoimmune diseases in the coming years. This chapter summarizes key recent advances, with specific references to the geriatric population.

## RHEUMATOID ARTHRITIS

### Definition

Rheumatoid arthritis (RA) is a chronic systemic inflammatory disease that preferentially affects diarthrodial joints. The current and most widely used classification criteria for RA were developed in 1987 by the American College of Rheumatology (ACR), based on the study of predominantly middle-aged patients attending hospital outpatient clinics (Table 120-1). While the criteria set is useful for diagnosing established and active disease in younger patients, its usefulness in detecting early disease and elderly-onset (>60 years old) rheumatoid arthritis (EORA) has not been established. This is important because the disease presentation in EORA may be distinct from that of young-onset RA (YORA).

One important advance that may lead to the eventual modification of the ACR classification criteria for RA is the discovery that the majority (70–90%, depending on the assay) of patients with RA has in their blood circulating anticyclic citrullinated peptide (anti-CCP) antibodies. Citrullination is a posttranslational modifi-

cation of protein-bound arginine into the nonstandard amino acid citrulline, and many citrullinated proteins have been found to be expressed in inflamed joints. Anti-CCP antibodies are as sensitive as, and more specific than, IgM rheumatoid factor (RF) in early and fully established disease. Furthermore, the presence of these antibodies is a marker for erosive disease and may predict the eventual development of RA in patients presenting with undifferentiated arthritis. These antibodies may also be detected in healthy individuals years before the onset of clinical RA. Unlike classical RF, the incidence of anti-CCP antibodies does not appear to increase with normal aging, making it a particularly useful marker for this disease in the elderly population.

In addition to classification criteria for the diagnosis of RA, the ACR has established criteria for functional status and for determining clinical remission in RA. The usefulness of these classification systems in older patients who often suffer functional disability from concomitant osteoarthritis, soft-tissue rheumatism, and cardiovascular or neurological diseases is unclear.

### Epidemiology

Although the overall incidence of RA may be declining, the disease still affects approximately 1% of the population in the United States and in many western developed countries. Lower prevalence rates of 0.2% to 0.3% have been observed in China, Japan, some regions in Greece, and Africa. Southern Europeans may have a milder disease, with less extra-articular complications and less evidence of radiographic damage. Conversely, a much higher prevalence rate (up to 7%) and a more aggressive clinical course have been reported in several American-Indian and Alaska native populations. Gender and age are important factors in RA. Overall, women are affected by the disease two to three times more than men. However, this gender parity disappears in old age. The prevalence of RA increases with age and is commonest in the most elderly group studied (often 65 years and older or 70 years and older). Approximately 5% of

TABLE 120-1

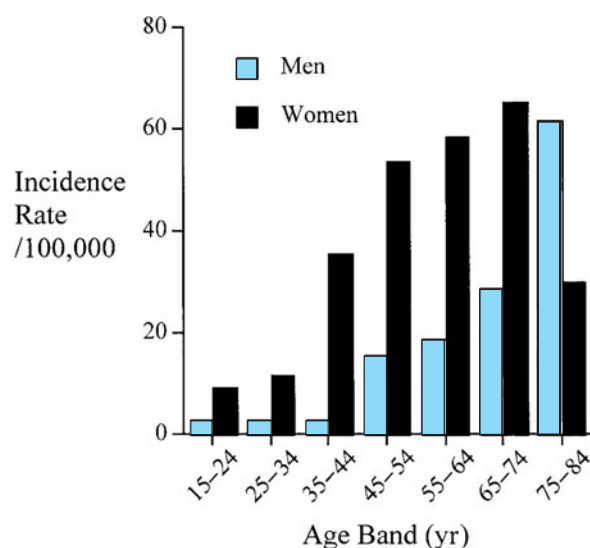

Classification Criteria for Rheumatoid Arthritis\* (R<sub>3</sub>A<sub>4</sub>)

Rheumatoid factor	Using a method with positive results in <5% of normal controls
Rheumatoid nodules	Subcutaneous nodules over bony prominences, extensor surfaces, or in juxta-articular regions
Radiographic changes	Typical changes of RA on hand and wrist radiographs, including erosions or unequivocal bony decalcification localized in or adjacent to the involved joints
Arthritis of the hand joints	Swelling of wrist, metacarpal phalangeal (MCP), or proximal phalangeal (PIP) joints for at least 6 weeks
Arthritis in three or more joints	Soft-tissue swelling or fluid present simultaneously for at least 6 weeks. Possible areas include PIP, MCP, wrist, elbow, knee, ankle, and metatarsal phalangeal joints
Arthritis that is symmetrical	Simultaneous involvement of the same joint areas on both sides of the body for at least 6 weeks
AM (morning) stiffness	Morning stiffness in and around the joints, lasting at least 1 h before maximal improvement at anytime in the disease course

\*Requires at least four criteria for the classification of rheumatoid arthritis.

women older than the age of 55 years are affected by the disease. The incidence of RA also increases with age, with the peak incidence occurring in the sixth to eighth decades (Figure 120-1). The reason for the age-associated increase in disease susceptibility is currently unknown.

## Pathophysiology

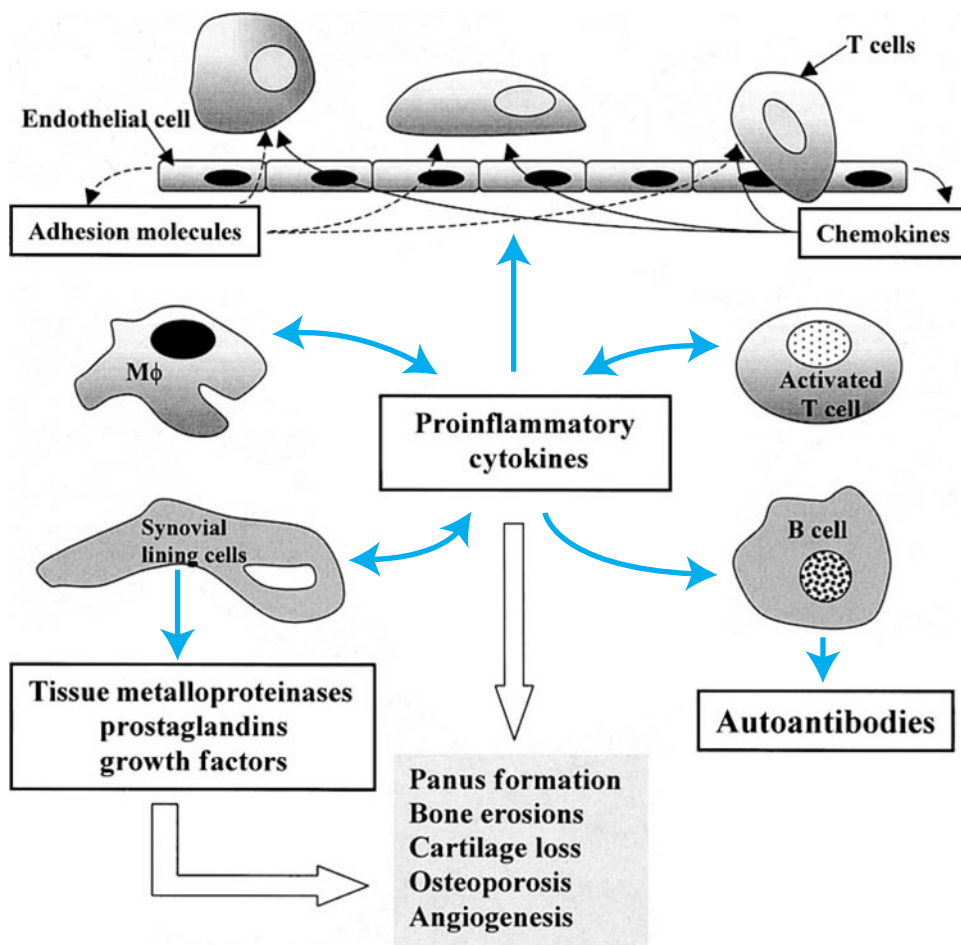

RA begins as a disease of the synovium. Earlier on in the disease the normally one- or two-cell-layer-thick synovium becomes markedly hyperplastic and edematous, accompanied by prominent new blood vessel proliferation. Left unchecked, this is followed by the activation and recruitment of T cells into the RA joint, which set into motion a complex cascade of inflammatory responses (Figure 120-2). This results in further accumulation of inflammatory cells, panus formation, localized osteoporosis, bony erosions, and destruction of peri-articular structures, which are characteristic of this disease. Rheumatoid synovitis is accompanied by the accumulation of inflammatory joint fluid with white cell count typically in the range of 2000 to 20 000 cells per milliliter. Soluble proteins that have been implicated in the inflammatory process include a number of proinflammatory cytokines (interleukin [IL]-1, IL-6, IL-13, IL-15, and tumor necrosis factor [TNF]), metalloproteinases (stromelysin, collagenases, and gelatinases), transforming growth factor- $\beta$ , granulocyte colony-stimulating factor, and activated complement components.

There appears to be a genetic susceptibility component to RA. The concordance rate for monozygotic twins is between 12% and 15%, approximately three times that of dizygotic pairs and much higher than the 1% background prevalence rate of the general population. The fact that most monozygotic twins are discordant for RA also highlights the importance of environmental factors. The association between RA and human leukocyte antigen (HLA) has been refined to alleles coding for a “shared” epitope (the sequences QRRAA or QKRAA) on the HLA-DRB1 genes. The presence of the DRB1\*04 (DR4) allele (especially if both alleles are present) is a marker for increased susceptibility and severe disease. Population differences in the prevalence of the “shared epitope” may help to explain in part the geographic variation in the prevalence of RA.

An infectious etiology for RA has been postulated for more than half a century. The onset of RA can be heralded by polyarthralgias, fever, and malaise that are indistinguishable from an acute infection. The joints are known targets for diverse microorganisms from gonococci to *Borrelia burgdorferi* and *Mycobacterium tuberculosis*. Acute and chronic “reactive” arthritis can follow specific gastrointestinal (GI) or genital urinary infection. A transient RA-like illness can be seen in viral infections including parvovirus B19, Epstein–Barr virus, and human T-lymphotropic virus type 1.

Tantalizing evidence of a potential pathogenic role for microorganisms in RA includes the following: (1) Retroviral-like particles have been observed in RA synovial fluid. (2) Viral or bacterial superantigen can reawaken a latent or subclinical disease in animal models of inflammatory arthritis. (3) Heat shock proteins (viral and cellular) can act as autoantigens. Interestingly, both the dnaJ class of bacterial heat shock protein and the gp110 capsid protein of Epstein–Barr virus have the QKRAA “shared epitope” amino acid sequence.

Despite these observations, a direct role for infection in the pathogenesis in RA has not been proven. It is possible that transient exposure of the joints to microorganism protein with homology to normal antigen could attract lymphocytes to the synovium. This, in turn, may set up an autoimmune response through a molecular mimicry mechanism without requiring the presence of the inciting organism (the “hit and run” theory). Some investigators have shown that RA synovial cells may have defective apoptosis and a transformed phenotype. This opens up the possibility that environmental agents, including viruses, may transform synovial or lymphoid cells to cause

**FIGURE 120-2.** The inflammatory cascade in rheumatoid arthritis.

inflammation and tissue destruction without requiring the presence of the inciting agent.

Gender differences in reproductive hormones may explain the high female prevalence in RA. However, since the peak incidence of RA in women is in their fifties, high levels of female sex hormones may play a modifying, but not necessary, role in the pathogenesis of this disease.

The linkage of RA to specific major histocompatibility complex alleles, the abundance of specific T-cell subsets in synovial tissue and fluid, and other evidence from animal models of inflammatory arthritis all point to a central role of T lymphocytes in the immunopathogenesis of this disease. RA is considered to be a Th (T helper) 1-mediated disease based on the cytokine and more recently the chemokine receptor profile of T cells in synovial joints. Although it is tempting to postulate that RA-associated DRB1 epitope triggers disease by presenting an arthrogenic peptide to T cells, extensive search of unique peptides that are displayed selectively by RA-associated HLA molecules has so far been unsuccessful. Costimulatory molecules, including CD28 and CD60, may play a role in activating T cells in RA joints. However, their precise role in human disease is unclear. Signal transduction through the T-cell receptor is defective in RA, suggesting that non-T-cell-receptor-activating pathways may be important in T-cell activation in this disease.

#### Aging Effects

The reason for the age-associated increase in RA susceptibility is unclear. The traditional view that aging is associated with a “decline”

in immune response does not explain the high incidence and severe onset of this autoimmune disease that is commonly seen in older adults. Decline in sex hormone production in postmenopausal years also cannot account for the high incidence of RA in elderly females. Unlike their younger counterparts, EORA occurs with equal frequency in males and females. Again, the rising incidence of RA in postmenopausal women suggests that while reproductive hormones may influence the disease manifestation, they are unlikely to play a major pathogenic role in the elderly population.

Animal studies suggest that aging is accompanied by a shift from a Th1 to a predominantly Th2 cytokine profile. However, such changes cannot explain the high incidence of RA, a predominantly Th1-mediated disease, in the elderly population either. Studies on the effect of age on the adenovirus vectors model of inflammatory arthritis have yielded conflicting results, with some strains showing more chronic and destructive arthritis in older female animals. The enhanced production of proinflammatory cytokines, including TNF- $\alpha$  and IL-1, in aging, may contribute to the clinical features of EORA. The recruitment and retention of T cells in the RA synovial joint are complex processes determined by the interaction of leukocyte adhesion molecules and chemokine receptors interacting with their respective ligands expressed by synovial and vascular endothelial cells. T cells from aged animals may express high levels of selective chemokine receptors that are important in the recruitment of T cells to RA joints. These lines of research may eventually provide the explanation for the increased susceptibility and severity of RA in elderly people.

## Presentation

Whether EORA is a different disease from YORA is controversial. The clinical studies that address the issue were mostly descriptive or cross-sectional studies done in the 1950s and 1960s that have significant methodologic problems. The older definition of RA used in these studies also allowed terms such as “classical,” “definite,” and “probable” RA, which are no longer used today. As mentioned before, the most widely accepted classification of RA currently in use has not been validated in the elderly population.

**Table 120-2** summarizes the features of EORA. In general, patients with EORA have a more equal gender distribution. The large joints, including the shoulder joint, are more often involved at presentation in EORA. Whether this is a result of concomitant rotator cuff disease that is prevalent in this age group is unclear. Symptoms in the proximal girdles have led to the belief that EORA may present with a polymyalgia rheumatica-like illness. Erythrocyte sedimentation rate (ESR) normally increases with age, especially in females. Elevated ESR is also more common in EORA. The prevalence of RF similarly increases after the age of 60 years, reaching 30% by the age of 90 years. Earlier reports suggest a lower frequency of RF in EORA than YORA. However, this has not been confirmed in more recent studies. As in younger patients, patients with EORA who are seropositive for RF have more severe clinical disease, more bony erosions on x-ray, worse functional outcome, and increased mortality. Whether patients with EORA who are seropositive have worse prognosis than do their younger counterparts is unclear. It is possible that the poor prognosis of EORA reported in some studies reflects the greater number of comorbid conditions that are present in older patients.

“Benign polyarthritis of the elderly” person occurs in up to a third of patients with EORA. They have a more explosive disease onset associated with systemic features such as fever and night sweats. The clinical features have led some to describe the disease as “infectious like.” The disease is called benign because its general prognosis is good, with most people going into remission within 1 year with or without treatment. Within this group can be included a peculiar syndrome unique to the elderly population called the RS<sub>3</sub>PE (remitting, seronegative, and symmetric synovitis with pitting edema) syndrome. This typically affects elderly men (2–3:1, male:female ratio) and is characterized by acute onset of symmetric polyarthritis/tenosynovitis with pitting edema involving both upper and lower extremities. As the name implies, these patients generally have nega-

tive RF and antinuclear antibody (ANA). They often have high ESR and respond to low-dose prednisone. The association with HLA-B7 has been reported inconsistently. RS<sub>3</sub>PE may occasionally be associated with other rheumatic diseases, including polymyalgia rheumatica, spondyloarthropathies, psoriatic arthritis, RA, and sarcoid, and, rarely, malignancies.

## Evaluation

The assessment of RA in older adults is different from that of the younger age group. The nonspecific symptoms and signs of RA are prevalent in the geriatric population. Rheumatic diseases that can mimic EORA, such as polymyalgia rheumatica, osteoarthritis, and crystal-induced arthritis, are prevalent in the elderly population. Anti-CCP antibody measurement may be useful in distinguishing EORA from polymyalgia rheumatica. In one small study, 65% of patients with EORA were anti-CCP antibody positive, but none of the patients with PMR or the aged healthy subjects had the antibodies. Arthritis associated with malignancy can be misdiagnosed as RA before the correct diagnosis is made months or years later. Other differential diagnoses of RA in the elderly population include inflammatory (erosive) osteoarthritis, late-onset spondyloarthropathy, endocrinopathy (e.g., hypothyroidism, hyperparathyroidism, and diabetic cheiroarthropathy), amyloidosis, and the edematous phase of scleroderma. Conditions such as sarcoidosis, adult Still’s disease, hemochromatosis, and glycogen storage diseases can mimic RA but are unlikely to present for the first time so late in life.

In addition to the above considerations, the initial evaluation of an elderly patient with RA should include a careful assessment of the patient’s living condition, social support, and cognitive and functional status. Many elderly patients have the misconception that there is no effective treatment for arthritis, and they should accept their physical suffering as part of normal aging. Older adults are often embarrassed about their arthritis pain. They may minimize their symptoms by using terms such as “aching” and “stiff” instead of pain. Unfortunately, many clinicians also do not take their symptoms seriously, resulting in the patients frequently feeling that their care resembles “a lick and a promise.” Because pain is, by far, the commonest presenting symptom of RA, pain assessment should be an integral part of the patient’s evaluation at presentation and in subsequent office visits. This can be difficult in the elderly patient who has significant cognitive or verbal impairment. Information from caregivers, nonverbal pain behavior, physical evidence of active joint inflammation, and decline in functions are important clues that more aggressive therapy may be necessary.

The ACR classification system for assessing the functional status of patients with RA is shown in **Table 120-3**. However, use of this classification for an elderly patient may be difficult because of functional disability from other coexisting diseases. This quick assessment tool is useful for describing the global functional status and allows patients to be grouped for studies. Patients with RA with the worst (class IV) functional status were reported to have extremely poor prognosis, with survival similar to patients with multi-vessel coronary artery disease and stage IV Hodgkin’s lymphoma. Many clinicians now feel that the prognosis for RA has improved with the advent of better therapeutic regimens for RA in the past two decades. Whether this translates into prolonged survival remains to be determined. Concomitant medical conditions affecting the patient’s hearing, eyesight, continence, and balance need to be

**TABLE 120-2**

### Clinical Features of Elderly Onset Rheumatoid Arthritis

Age of onset >60 yr
Male:female ~1:1
Acute presentation
Oligoarticular (two to six joints) disease
Involvement of large and proximal joints
Systemic complaints, e.g., weight loss
Absence of rheumatoid nodules
Sicca symptoms common
Laboratory: high erythrocyte sedimentation rate; often negative rheumatoid factor

**TABLE 120-3****American College of Rheumatology 1991 Revised Criteria for the Classification of Global Functional Status in Rheumatoid Arthritis**

Class I	Completely able to perform usual activities of daily living (self-care, vocational, and avocational)
Class II	Able to perform usual self-care and vocational activities but limited in avocational activities
Class III	Able to perform usual self-care activities but limited in vocational and avocational activities
Class IV	Limited in ability to perform usual self-care, vocational, and avocational activities

Adapted with permission from Hochberg MC, Cahne RW, Dwosh I, Lindsey S, Pincus T, Wolfe F. The American College of Rheumatology 1991 revised criteria for the classification of global functional status in rheumatoid arthritis. *Arthritis Rheum.* 1992;25:498–502.

addressed to optimize functional ability and to prevent falls. Current and past medical histories are important elements of the initial evaluation. This information is important in determining the selection of specific treatment (see “Management” section). In contrast, family history is not as helpful in assessing elderly patients with RA.

In addition to excluding diseases mentioned above, a new patient suspected of having RA should be tested for the presence of anemia, cytopenia, liver or renal dysfunction, RF, and elevated ESR. The presence of extremely high RF should prompt the clinician to consider the possible diagnosis of cryoglobulinemia. Some patients have negative RF but positive ANA. These patients tend to have more severe disease, similar to the patients with positive RF. A workup for secondary Sjögren’s syndrome should be done in patients with concurrent sicca symptoms (dry eye and dry mouth). In general, ESR is a better indicator of disease activity than changes in the titer of RF. For some patients C-reactive protein level may more closely parallel their clinical course than ESR.

Radiographic joint examination is an integral part of the evaluation of patients with RA. Elderly patients with RA for more than 10 years are at particular risk of cervical spine disease and atlantoaxial

joint instability. This is an important consideration before a patient is submitted to a surgical procedure, as overextension of the cervical spine during intubation may compromise the brainstem or spinal cord. Early x-ray changes include soft-tissue swelling and regional osteoporosis around the joint. Typical erosions in hands and feet involve the juxta-articular “bare areas” of bone not covered with cartilage (Figure 120-3). Isolated erosions in the first and second metacarpophalangeal joints may prompt the clinician to search for occult calcium pyrophosphate depositive disease, hyperparathyroidism, or hemochromatosis. Erosions are less common in the knee and hip joints. At these sites, RA typically causes cartilage loss and joint-space narrowing. Joint-space narrowing occurring predominantly in the lateral compartment of the knee and diffusely in the hip without bony proliferation is helpful features for distinguishing RA from osteoarthritis. To assess for joint-space narrowing of the knees, clinicians should request semiflexed weight-bearing films.

Because of the limitation of clinical examination in detecting subtle signs of inflammation, ultrasound and magnetic resonance imaging have been used for detecting synovitis. It is clear that these modalities are extremely sensitive for detecting active inflammation. One study found that the majority of patients with treated disease and considered by their physicians to be in remission continued to have magnetic resonance imaging evidence of active synovitis. The unanswered question is whether more aggressive treatments of patient with clinically inactive disease but imaging evidence of ongoing synovitis affect patient outcomes such as long-term disability. Elderly patients with RA have additional facets that need to be taken into consideration, such as a more limited lifespan and greater infection risk with immunosuppression. At this point, the utility of these sensitive imaging modalities in clinical practice is undefined.

There is no evidence that patients with EORA are more likely to develop extra-articular disease, as compared to those with YORA. However, the elderly population may be disproportionately affected because extra-articular manifestations are more common in chronic RA. High titer of RF is a risk factor for extra-articular RA, especially in male patients. Rheumatoid nodules are the most characteristic extra-articular manifestation of RA and are present in up to 40% of seropositive white patients. These are most commonly found in

**FIGURE 120-3.** Radiographic changes of rheumatoid arthritis. (A) x-ray of the cervical spine in the flexed position showing severe atlantoaxial joint subluxation in a patient with chronic rheumatoid arthritis, with arrows highlighting the abnormal distance between the posterior surface of the anterior arch of the atlas and the anterior surface of the odontoid process. Arrowhead points to the erosion on the surface of C5. (B) Early erosive changes in the metacarpal phalangeal joints affecting the “bare area” of the bone not protected by cartilage. (C) Bilateral hand x-ray with advanced rheumatoid arthritis. Some of the features include juxta-articular osteoporosis, collapse of the carpal bones, radial deviation of the radiocarpal joint of the wrist (arrows), and erosion and destruction of metacarpal phalangeal joints (arrowheads). Note also the symmetric nature of the disease. (Courtesy of Curtis Hayes, MD, University of Michigan.)

areas of pressure such as the elbows, heels, and sacrum. Their presence does not correlate with disease activity and may increase in number during methotrexate therapy when synovitis is improving. Rheumatoid vasculitis affects vessels of all sizes. This complication may present as cutaneous vasculitis, mononeuritis multiplex, nail fold infarcts, or deep “punched-out” ulcers at atypical sites that fail to respond to conventional therapy. Pleuritis and pericarditis are found in 20% to 30% of patients with RA and do not usually cause any symptom. Other respiratory complications of RA include pulmonary granuloma (often in the upper lobes), Caplan’s syndrome, fibrosing alveolitis, and bronchiolitis obliterans. Felty’s syndrome (RA with splenomegaly and neutropenia) typically occurs in white patients with long-standing, chronic erosive RA. These patients are at increased risk of developing lymphoproliferative malignancies. Thrombocytopenia may occur, in part, because of splenic sequestration. Mild-to-moderate normochromic, normocytic anemia is extremely common in patients with chronic RA. Iatrogenic causes (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs] and methotrexate) of anemia need to be excluded in all patients with RA who have anemia.

## Management

### Nonpharmacological Therapies

Successful management of RA involves patient participation in his/her care. In addition, family, social, and psychological supports are particularly critical in maintaining the older RA patients’ independence. Older patients diagnosed with the disease may be particularly fearful of what it means to their independence or may become depressed. Establishing a good rapport, gaining the trust of the patient and the family, providing information about the nature of the disease, and setting realistic goals are all important elements of the initial management of RA. Many patients and their relatives also find it helpful to seek out support groups in their local area. Increasingly, elderly patients and their families are turning to the Internet, health magazines, and other nontraditional sources for information about treatment options, including over-the-counter complementary therapies. It is important that health-care professionals be aware of the pros and cons of these options. In this regard, resources such as The Arthritis Foundation’s Guide to Alternative Therapies can be helpful. Unfortunately, the unexpected side effects of over-the-counter medications are increasingly being recognized. The latest information is often not available in traditional textbooks. Directing the patients to reputable websites such as that offered by the National Institute on Aging can be useful for more up-to-date information.

Nonpharmacologic therapies are crucial components of the total care of the patient with RA, which should be emphasized throughout the treatment course. In addition to their inherent usefulness, participation in these treatment modalities often provides the patients and their families with a sense of control over their chronic illness. The team approach that typifies geriatric medicine is eminently suitable for treating elderly patients with chronic arthritis. Physical and occupational therapy should be offered to every patient with RA, including those with mild and early disease. Education about rest/activity, use of cold/heat, massage, adaptive devices (to improve function and to prevent/correct joint deformity) are important. Performing exercises to strengthen muscles and ligaments for joint protection, gait training, and fall prevention can make a big

difference in the life of patients with RA. Community-based exercise programs such as PACE (Patients with Arthritis Can Exercise, the Arthritis Foundation) are a good resource for those who are able to participate. Psychological counseling and support groups are often helpful, especially to those who are socially isolated because of their arthritis. Depression is increasingly recognized as a common problem in the elderly and in those with chronic illness. Adequate treatment will help break the vicious cycle of pain, depression, and disability. Although nonpharmacologic therapies have not been shown to affect the course of RA, these can improve the patient’s quality of life and help to reduce the requirement for pain medications that have significant potential for side effects in this vulnerable population.

### Pharmacological Therapies

Recent years have seen an exciting explosion of new drugs available for the treatment of RA. Pharmaceutical companies have increasingly included the geriatric population in pre- and postmarketing clinical trials. Although this provides some reassurance to clinicians, knowing that these agents may be efficacious in the elderly population, it is important to remember that subjects participating in these studies rarely mirror the patients geriatricians see in their clinic who have multiple comorbidities and who already suffer from polypharmacy. The costs of these new agents may be out of reach for patients who do not have prescription coverage. Because of the complexity of modern treatment regimens, coupled with the need to monitor many potentially serious side effects, drug therapy for RA should ideally be instituted in consultation with a rheumatologist. Involvement of physicians experienced in the use of immunosuppressive therapies (e.g., hematologists and oncologists, or a gastroenterologist in the case of infliximab) will be helpful in patients living in isolated communities where there may not be a local rheumatologist.

The gradualism of the “pyramid approach” to RA treatment in the 1980s has been replaced with the widespread belief that rheumatoid inflammation should be suppressed as completely and as soon as possible once the diagnosis is confirmed. This change in philosophy is, in part, a result of the recognition that joint damage occurs much sooner than was previously believed. Results of well-designed clinical trials in the past decade have persuaded many that this new standard is attainable with more aggressive drug regimens. In the ACR updated *2002 Guidelines for the Management of Rheumatoid Arthritis*, it is suggested that the majority of patients with newly diagnosed RA should be started on disease-modifying antirheumatic drug (DMARD) therapy within 3 months of diagnosis.

Although NSAIDs are useful adjunct therapies for RA, many geriatricians are reluctant to prescribe this class of medication because of concern that elderly persons are vulnerable to the potential serious toxicity that can occur in almost every major organ system in the body. Meta-analysis of epidemiologic studies published in the 1990s found that NSAID use is associated with a 5- and 3.5-fold increased risk of serious upper GI tract disease in women and men, respectively. Age alone is a risk factor for upper GI bleeding (relative risk of 4.5 in 70–80 years age group, and 9.2 in those older than age 80 years). Because of the high background rate of upper GI events in the elderly population, the relative risk for GI bleeding only increases modestly in elderly patients on NSAID. Not surprisingly, elderly patients with history of GI bleeding are at the greatest risk of serious GI complications when they are placed on an NSAID. The concurrent use of glucocorticoids further increases the risk of GI bleeding.

The use of selective cyclooxygenase-2 (COX-2) inhibitors has decreased substantially in recent years when it was discovered that some of these agents are associated with an increased incidence of cardiac events in large population studies. In addition, COX-2 inhibitors shares similar renal toxicity, including hypertension, peripheral edema, and rising serum creatinine as traditional NSAIDs. Chronic use of these agents should, therefore, be avoided when possible. NSAID-induced renal complications are more likely to occur in patients who are on concurrent diuretics or angiotensin-converting enzyme inhibitors. One study showed that prolonged dosing of ibuprofen blocked the platelet inhibition effects of aspirin. Although other NSAIDs tested so far do not appear to have the same problem, this raises the concern that the aspirin/ibuprofen combination may not be ideal for patients having RA with cardiovascular risk factors. Concurrent use of low-dose ( $\leq 325$  mg/day) aspirin increases the already high risk for GI events in elderly patients taking traditional NSAIDs and may negate most of the GI-sparing effect of COX-2 inhibitors. At present, it appears that most at-risk elderly patients with RA requiring a traditional NSAID or a COX-2 selective agent plus aspirin should receive GI cytoprotection.

Low-dose glucocorticoid is effective for short-term symptom control in patients with active RA. There are also intriguing data showing that prednisone in early disease may be “disease modifying.” Unfortunately, elderly patients commonly develop significant side effects but become functionally dependent on the drug. The lowest dose, and, if possible, alternate-day dosing should be prescribed. Assessment, prophylaxis, and treatment of osteoporosis, cardiovascular risk factors, diabetes, and GI complications are important. Judicious use of intra-articular steroid injections may provide local (and systemic) symptom relief and may be safer than oral glucocorticoids in elderly patients with poorly controlled diabetes, severe osteoporosis, and congestive heart failure.

Antimalarials including hydroxychloroquine and chloroquine are useful in mild cases of RA and are most often prescribed as part of a combination regimen. Hydroxychloroquine is often preferred over chloroquine because it has a lower incidence of ocular complications. Approximately 50% of hydroxychloroquine is protein bound in the plasma, a property that is important in elderly patients with low serum albumen and who are taking other highly protein-bound drugs. The mechanism of drug action is uncertain but is postulated to include changes in intracellular pH, which, in turn, affect antigen presentation by immune cells. An added benefit in patients with RA who are at increased risk of coronary heart disease is the drug's favorable effect on serum cholesterol level. There are also intriguing new data suggesting that patients with RA on hydroxychloroquine have up to 77% less risk of developing diabetes. The major side effect of hydroxychloroquine and chloroquine is retinal (macular) toxicity with the classical “bull's-eye” lesion. The patients most susceptible to this complication are those older than 70 years who are on  $>6.5$  mg/kg daily dose or who have a cumulative dose of  $>800$  g of the drug. Elderly patients with macular degeneration or inoperable dense cataract are not candidates for this drug.

Sulfasalazine is only occasionally used as monotherapy in the United States, although there are data showing that the drug may slow the progression of radiographic damage in RA. Its mechanism of immunosuppression is unclear but may include reducing immunoglobulin (Ig) levels, suppressed T- and B-cell proliferative response, and cytokine inhibition. Cytopenias (particularly leukopenia), GI symptoms (nausea and vomiting, and dyspepsia), and skin

rashes are the commonest side effects. In addition to monitoring for hematologic toxicity, some experts recommend that liver enzyme levels should be tested regularly as well.

Methotrexate, an analog of folic acid, is the most commonly prescribed DMARD for RA in the United States. More than 50% of patients on methotrexate continue the drug beyond 3 years, longer than any other DMARD. The drug and its metabolites are potent inhibitors of dihydrofolic acid reductase and other distal enzymes in the folic acid metabolic pathway. The immunosuppressive effects may be partly a result of folate-dependent inhibition of lymphocyte proliferation. Methotrexate has also been reported to reduce the production of leukotriene B<sub>4</sub> and to directly alter phospholipase A<sub>2</sub> activity. Common side effects include cytopenias (particularly anemia), liver toxicity (fibrosis and cirrhosis), hypersensitivity pneumonitis, infections, mucosal ulceration, and alopecia. The elderly population is particularly susceptible to these side effects because methotrexate is excreted primarily by the kidneys and renal impairment is common in this group. Great caution and dose adjustment are, therefore, needed when using the drug to treat elderly patients with RA and those with a history of hepatitis. In addition, folic acid (1–3 mg/day) or folinic acid (leucovorin, 2.5–5 mg given 24 hours after methotrexate) supplementation reduces the incidence of many of methotrexate side effects and should be used routinely.

A number of other DMARDs are occasionally used as monotherapy for RA. Clinicians are often reluctant to use them because of their limited efficacy, high dropout rate, and potential serious side effects, especially in the elderly population. These include cyclosporin, azathioprine, gold, and penicillamine. Staphylococcal protein A immunoabsorption column may be useful in a small subset of patients with RA who have refractory disease. However, difficulty in administering treatment and high cost has prevented the treatment from being used widely.

Most combination therapies involve adding one or more DMARD to methotrexate. The triple therapy of methotrexate, hydroxychloroquine, and sulfasalazine is more efficacious than methotrexate alone. Similarly, patients treated with methotrexate and leflunomide experienced better outcomes than methotrexate alone. Interestingly, although methotrexate plus hydroxychloroquine is the commonest combination used in this country, its efficacy, as compared to methotrexate, has not been examined systematically. The main advantage of using combination therapy over the anticytokine treatments is cost. The argument that biologics may be cost effective because these reduce work disability may not apply to elderly, retired patients. However, whether the elderly tolerate combination therapies as well as monotherapy is uncertain. As high as 60% of patients receiving both methotrexate and leflunomide develop elevated liver enzyme levels. Combining methotrexate with a nephrotoxic drug such as cyclosporin has been used successfully in the treatment of RA but is potentially hazardous in the elderly patient who may already have underlying renal insufficiency and hypertension.

### Biological Response Modifiers

The number of biological response modifiers available to clinicians has expanded considerably in the past few years, with many more in the late stages of clinical development. The success of these agents, which target soluble inflammatory proteins, T cells, and B cells, suggests that targeting the downstream mediators may be sufficient

to modulate the disease. A critical issue is to determine which patient will best benefit from which class of biologic agent. While it is unlikely that primary-care providers will prescribe biologics for their patients with RA, understanding their use and potential side effects will be helpful in the day-to-day care of these patients. This portion of the chapter includes a general description of the currently available drugs and will emphasize the safety issues associated with these drugs, as these issues have great relevance to geriatrics health-care providers.

An important advantage of these agents is rapid onset of action, with many patients experiencing improvement within a few weeks of treatment. These agents appear to be effective in patients with both seropositive and seronegative rheumatoid. The decision as to which biological modifier to use will depend on individual patient characteristics such as comorbidity, patient preferences such as administration schedule, physician experience, and insurance coverage owing to the high cost of these drugs.

*Leflunomide* is an inhibitor of pyrimidine synthesis and has been available for the treatment of RA in the United States since 1998. The oral medication is rapidly metabolized to an active metabolite that is partially excreted in the bile and reabsorbed by the enterohepatic circulation. The plasma half-life of leflunomide is approximately 14 days. However, the excretion can be accelerated by oral cholestyramine. In clinical studies, leflunomide has been shown to be equal to methotrexate in efficacy. It is also the first drug to receive an FDA-approved label indication to retard structural damage in RA as evidenced by x-ray erosions and joint-space narrowing. The commonest side effects include diarrhea (20%), reversible alopecia (10%), and elevated liver function enzymes.

There are currently three TNF antagonists in clinical use. *Etanercept* is a recombinant soluble p75 TNF receptor fused to the Fc portion of human Ig G<sub>1</sub>. The drug is usually given by subcutaneous injection once or twice a week, with or without concomitant methotrexate. *Infliximab* is a chimeric (mouse–human) anti-TNF monoclonal antibody that is given to patients intravenously every 4 to 8 weeks, usually in combination with methotrexate. *Adalimumab*, a fully human anti-TNF antibody, is given subcutaneously every 2 weeks, usually with methotrexate. Accumulating evidence suggests that patients who have “failed” one anti-TNF agent may still benefit from a trial of a different anti-TNF drug.

*Anakinra* is a recombinant human form of IL-1 receptor antagonist (IL-1ra) that blocks the binding of IL-1 $\alpha$  and  $\beta$  to the IL-1 receptor. The drug is administered daily by subcutaneous injection with or without methotrexate. Anakinra has not been as popular as the anti-TNF agents among rheumatologists in part because of the high incidence of local skin injection site reactions and the requirement of daily injection. Furthermore, many have found the drug to be less efficacious as the anti-TNF agents, although there is no randomized comparison trial to date. Because the plasma clearance of the drug is reduced by 16%, 50%, and 70% to 75% in patients with mild (creatinine clearance 50–80 mL/min), moderate (creatinine clearance 30–49 mL/min), and severe (creatinine clearance <30 mL/min) renal insufficiencies, respectively, it is usually necessary to adjust the dose when used in older adults because of the frequency of reduced renal function in this population.

*Rituximab* is a chimeric anti-CD20 antibody, originally used for the treatment of a subset of patients with non-Hodgkin’s lymphoma. The drug works by depleting B cells with CD20 on their surface. The drug is approved in the United States for the treatment of patients with RA with an inadequate response to anti-TNF agents. Since rit-

uximab has nonhuman protein sequences, it should be used in conjunction with another immunosuppressive agent such as methotrexate. Patients are usually given one course of two infusions 2 weeks apart. It is possible to repeat the treatment 6 months later.

*Abetacept* is a recombinant fusion protein combining the extracellular domain of human CTLA-4 and an Fc domain of human IgG1 that has been modified to avoid complement fixation. The drug competitively binds to the costimulatory molecules CD80/CD86 to prevent these molecules from engaging CD28 on T cells and thereby prevents full T-cell activation. This, in turn, suppresses T-cell proliferation and inhibits the production of TNF- $\alpha$ , interferon (IFN)- $\gamma$ , and IL-2. Abetacept is dosed according to the patient’s body weight. Since most of the published data have examined the efficacy of a combination regimen using concomitant methotrexate, most patients should be on both drugs rather than abetacept monotherapy.

### Safety and Other Issues with Biologics

While there is little doubt about the potential efficacy of the biologics in RA, there remains significant concern about their side effects, especially in vulnerable populations such as elderly patients with RA having multiple comorbidities. In addition, the significant cost associated with these drugs is prohibitive to many elderly patients without prescription drug coverage. One useful acronym for the safe use of biologics is SAFETY, outlined in [Table 120-4](#). TNF is involved in host defense against foreign pathogens and in tumor surveillance. The most important risk associated with anticytokine therapy for elderly patients with RA is the increased incidence of fungal infections, tuberculosis, and atypical mycobacterial infections. As tuberculosis is usually caused by reactivation of latent infection, tuberculosis skin testing and a chest x-ray should be done prior to starting these agents. Whether yearly skin test and chest x-ray to detect new exposure are necessary in countries with a low incidence of tuberculosis is unclear. Yearly screening is recommended for selected patients who are at risk, such as those who travel regularly to TB endemic areas and nursing home residents.

**TABLE 120-4**

#### SAFETY of Novel Immunomodulatory Therapies: Optimizing Treatment

*Stratify:* Identify the patient’s risk of adverse effects based on various factors, such as comorbidities (e.g., chronic obstructive pulmonary disease and diabetes mellitus), age, concomitant medication use, and a history of similar events (e.g., opportunistic infection).

*Assess:* Evaluate the patient for important risks (e.g., exposure to tuberculosis or hepatitis B or C virus infection, vaccination status, and status of comorbid conditions).

*Fend off:* Optimize the patient’s health before treatment (e.g., wherever possible, vaccinate against infections and treat and/or control the patient’s comorbidities).

*Evaluate:* Quickly evaluate adverse events, remembering that both typical and atypical presentations may be seen.

*Treat:* Aggressively manage adverse events to help minimize their severity.

*Yearly:* Reevaluate the patient on a regular basis.

*Adapted with permission from Hennigan S, Kavanaugh A. Optimizing the use of TNF- $\alpha$  inhibitors. J Musculoskel Med. 2007;24:293–298.*

Rituximab dramatically lowers the peripheral blood B-cell count for months after the infusion, and these patients also have lower IgG and IgM levels. The use of rituximab has been associated with the reactivation of JC polyoma virus infection, resulting in the disease progressive multifocal leukoencephalopathy. This complication, although very rare, highlights the potential for the development of all B-cell-dependent viral diseases in patients receiving the drug. Interestingly, progressive multifocal leukoencephalopathy has also been reported in patients with multiple sclerosis receiving natalizumab, a chimeric anti- $\alpha 4$  integrin antibody.

Rare cases of demyelinating disorders, aplastic anemia, lupus-like illnesses, and depression have also been associated with anti-TNF therapies. The long-term consequences of anticytokine suppression are unknown. One meta-analysis reported a fourfold higher rate of malignancies in patients treated with TNF inhibitors.

In addition to the concern about infection risk, abatacept can be potentially problematic in older adults with multiple comorbidities. Patients with chronic obstructive pulmonary disease have a higher incidence of adverse drug reaction and respiratory complaints such as chronic obstructive pulmonary disease exacerbation, cough, and dyspnea. Diabetic patients should be alerted to the fact that the abatacept formulation contains maltose and can give falsely elevated glucose readings in some glucose monitors on the day of the infusion.

Are biologics “cost effective” in the treatment of older adults with rheumatic diseases? Cost effectiveness for young patients with RA has been shown based on remaining in the work force, but there are no such data for the geriatrics cohort of retirees, and it is hard to define the economic value of improved functional status or quality of life. However, given the potential serious side effects that may more likely affect frail older adults, the author’s approach is to start with traditional DMARDs such as methotrexate and hydroxychloroquine for such patients and move on to biologics only after these have failed or if the patients experience unacceptable side effects from the DMARDs.

As in other populations, cardiovascular disease is the single largest cause of death in patients with autoimmune inflammatory disorders. However, after accounting for the known traditional risk factors for heart diseases, patients with RA and lupus are at greater risk of developing coronary artery disease and stroke than those without these conditions. The reason for the increased incidence of cardiovascular disease in patients with these disorders of autoimmunity is not clear. Furthermore, a patient with rheumatoid arthritis who has a myocardial infarction has a similar prognosis as that of a diabetic patient with a similar event. Some findings suggest that conventional therapies, such as the use of lipid-lowering agents, may not reverse the cardiovascular risk associated with these inflammatory conditions. While not proven, it is hoped that use of more aggressive immunosuppressive regimens will help reduce the cardiovascular morbidity and mortality in these patients. However, the use of anti-TNF agents has been linked to an increased rate of congestive heart failure and cardiac mortality when these were used in heart failure clinical trials. Aging per se has been described by some as a state of chronic low-grade inflammation that has been termed “inflamm-aging,” which may play a role in frailty and sarcopenia in both normal aging and chronic inflammatory conditions such as RA (see Chapter 4 for further details).

A disease-associated inflammatory state, chronic use of steroids, and the lack of exercise owing to arthritis-associated disability may

all contribute to the high incidence of osteoporosis in older patients with rheumatic diseases. Since these are chronic conditions, aggressive treatment with antiresorptive agents, adequate calcium intake, and vitamin D to prevent and treat osteoporosis and fracture is critical.

Many RA therapies involve significant immunosuppression that may affect the patient’s ability to mount an antibody response to immunization, worsening the already-impaired immune reaction as a result of immune senescence in older patients. It is, therefore, important that these patients are given their age-appropriate immunizations such as pneumococcal and flu vaccines preferably prior to receiving therapy with biologics. Patients already on biologics should avoid receiving any live vaccines.

### Surgical Interventions

Surgeries can be useful to restore function and in many cases reduce pain in end-stage RA joints. These procedures include small-joint arthroplasty, joint fusion, and resection of metatarsal heads. Improvements in surgical techniques, prosthetic materials, perioperative care, and rehabilitation in the past two decades have resulted in much better outcomes in patients undergoing surgical treatments. However, it should be noted that there are very little long-term data examining the outcome of small joint arthroplasty. A number of ongoing National Institute of Health-sponsored studies will provide much needed data in the near future. Synovectomy and tendon repairs are important surgical procedures to prevent and treat tendon rupture that can have disastrous functional consequences in patients with RA. Careful planning and timing of various joint procedures in patients with RA are important. For example, it may be wise to first correct upper extremity deformities before lower-extremity surgery is performed to allow the use of the upper extremities to assist in transfer, rising from a chair, and stair climbing during rehabilitation.

### Prevention

A major problem in attempting to prevent the disease is identifying those who are at risk of developing the disease in the first place. Although genetic studies provide some clues as to which segment of the population may be at risk, the available information is not precise enough to be of practical use. There is some evidence that oral contraceptive pill and hormone replacement therapy may reduce the risk of developing RA. Conversely, epidemiologic data suggest that smoking is associated with a slightly increased risk for the disease. During the past decade, there has been considerable interest in developing T-cell receptor peptide vaccines for RA. This approach has shown some promising results in an animal model of chronic inflammatory arthritis. Whether this will eventually lead to useful human vaccine is unclear. One study suggests that the use of aggressive drug therapy in patients with inflammatory arthritis but who do not yet fulfill the criteria for full-blown RA may reduce the number developing the disease. Whether this applies to EORA is unknown.

### Special Issues

#### Patient Preference and Comorbidity

The choice of therapy should be made in conjunction with the patient and the caregivers. Although exercises are important to maintain joint and muscle functions in patients with RA, some elderly patients are unable to perform regular exercises because of their other

medical conditions, or if they have lived an inactive lifestyle for many years and are reluctant to adopt any change. In these situations, emphasizing the positive aspects of exercise (physical, psychological, and social), setting realistic goals, and recommending exercise programs specially tailored for the elderly population are helpful. In this regard, finding a physical and occupational therapist accustomed to working with older adults is important. Too often the author has seen patients who refuse to return to their therapist because of unrealistic short-term exercise goals.

The importance of assessing a patient's risk of developing GI, renal, cardiac complication, and osteoporosis prior to starting NSAIDs and corticosteroids has already been emphasized. Patient preference is important when deciding on a specific DMARD. Elderly patients with poor eyesight are often reluctant to begin antimalarials out of fear of potential ocular complications, however small the risk may be. These drugs are contraindicated in elderly patients who cannot be monitored for retinal toxicity, including individuals with macular degeneration or untreated cataract. Older adults who do not want to give up drinking alcohol may choose not to take methotrexate. Some older women have refused to take methotrexate because the drug was part of their breast cancer chemotherapy in the distant past. Intramuscular methotrexate can be used in elderly patients who experience dyspepsia or who have difficulty swallowing. Methotrexate and biological response modifiers must be used with extreme caution or not at all in patients with chronic or active infection. Elderly patients with RA should have received all the appropriate immunizations prior to receiving DMARDs. Whether elderly patients with chronic lung disease taking DMARDs should receive *Pneumocystis carinii* prophylaxis is unclear. Assessment of the patient's tuberculosis status should be done prior to beginning anticytokine therapy. The appropriate use of biologics has already been discussed extensively.

### Care Settings

The physician's choice of therapy has to take into account the patient's overall state of health and mobility, and the care setting. In

most cases, home laboratory monitoring for DMARD toxicity can be arranged for patients with significant mobility problems. Instead of DMARDs, the use of corticosteroids (oral, intra-articular, or parenteral; low- or high-dose "pulse" treatment) may be a good option in patients with RA with active disease in the end stages of their lives. Therapeutic goals may also be different in a patient near the end of life, when either long-term treatment outcome or side effects may not be important considerations. An example will be a patient with RA who has end-stage dementia when judicious use of corticosteroid rather than high-dose immunosuppression for active disease may be more appropriate.

## SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a prototypic autoimmune disease that predominantly affects the female population. The incidence of lupus has been increasing in the past few decades, with an estimated a quarter of a million patients now with the disease in this country. Late-onset lupus (LOL) is defined as symptoms beginning after the age of 55 years, representing approximately 10% of all cases of lupus. However, the United Kingdom General Practice Research Database (a population database covering 5% of the United Kingdom) has surprising data that the peak incidence of lupus in females occurs at age 50 to 54 years and for males it is 70 to 74 years (Figure 120-4). Comparable data are not available for the United States, since previous lupus surveillance studies have been confined to relatively small geographic areas. It is anticipated that an ongoing Centers for Disease Control and Prevention-sponsored study in southeastern Michigan will eventually provide a better estimate of the true age-specific incidence of this disease in the United States. Finally, improved therapies and greater appreciation of the importance of treating comorbid conditions such as coronary artery disease have resulted in more patients with lupus surviving into old age.

**FIGURE 120-4.** Incidence of systemic lupus erythematosus in the United Kingdom, 1990–1999. (Reproduced with permission from Somers EC, et al. *Arthritis Rheum.* 2007; 57(4):612.)

**TABLE 120-5****Revised Classification Criteria for SLE**

Serositis	Pleuritis, pericarditis, or peritonitis
Oral or nasal ulceration	Oral ulcers are often painless and occur in unusual parts of the oral cavity
Arthritis	Nonerosive polyarthritis involving the small joints
Photosensitivity	Skin rash when exposed to sunlight
Blood dyscrasia	Hemolytic anemia, leukopenia/lymphopenia, or thrombocytopenia
Renal disease	Proteinuria (>0.5 g/d), cellular casts, unexplained hematuria
ANA	≥ 1:160 titer in the absence of lupus-inducing drug
Immunological abnormalities	Anti-dsDNA, anti-Smith, or antiphospholipid antibody
Neuropsychiatric illness	Seizures or psychosis
Malar rash	Tends to spare the nasolabial folds
Discoid rash	Often scarring

ANA, antinuclear antibody; dsDNA, double-stranded deoxyribonucleic acid; Sm, Smith (antigen).

Data from Berney SM. *Systemic lupus erythematosus. Hospital Physician. 1998; 1(3):2–12*. Berney SM (1998).

## Diagnosis

The diagnosis of SLE is based on the presence of signs, symptoms, and laboratory features of autoimmunity. The 1982 ACR Classification Criteria for SLE was recently revised to include the presence of antiphospholipid antibodies (Table 120-5). It is important to recognize that these criteria were designed for research purposes and have not been validated in LOL. Low-titer ANA may be present in up to one-third of the elderly. Positive ANAs (titer ≥ 1:160) have high sensitivity but poor specificity for SLE when measured by indirect immunofluorescence using the standard Hep-2 substrate. In contrast, the presence of anti-dsDNA (double-stranded deoxyribonucleic acid) or anti-Smith (Smith) antibodies is highly specific for SLE. However, these antibodies are only detected in 31% to 86% and 0% to 24% of patients with LOL, respectively.

## Pathogenesis

The cause of SLE is unknown. The concordance rate of SLE in monozygotic twins is between 25% and 50%, suggesting that genetic and environmental factors are both important. Human SLE is a polygenic disease. Genetic studies have identified at least 50 susceptibility or resistance loci in human and murine lupus (e.g., *sle1*, 2, 3). A defect or deficiency in gene product(s) regulating immune complex clearance, such as in some cases of inherited complement (C1, C4, and C2) deficiencies, is associated with a high likelihood of the development of SLE. Variability in the Fcγ receptor alleles is believed to play a role in determining the susceptibility to SLE in some racial and ethnic populations. Defective apoptosis as a consequence of mutations of the Fas or Fas-ligand gene is the central mechanism responsible for the lupus-like disease seen in the MRL/*lpr* and MRL/*gld* mice. However, such defects are exceedingly rare in humans, and, when present, these cause a much more limited autoimmune disease (the Canale–Smith syndrome).

Hormonal factors are important in the pathogenesis of SLE. The disease often affects females of childbearing age. The decline in fe-

male sex hormones in postmenopausal years was believed to be an important reason for a lower incidence of SLE in this age group, but the United Kingdom General Practice Research Database study raises questions about the validity of this association. There are also data showing that exogenous estrogens (hormone replacement therapy and oral contraceptive pill) may impose a small risk for developing lupus. The SELENA (Safety of Estrogens in Lupus Erythematosus National Assessment) trial showed that postmenopausal women receiving hormone replacement therapy have a slight increase in the number of mild-to-moderate lupus flares, but there was no increase in the number of severe flares. Similar to other autoimmune diseases, an inciting role for microbial organisms has been postulated but not proven.

An unanswered question is whether LOL is a different disease than the one that occurs at a younger age. It is well accepted that many older adults have a low level of circulating autoantibodies. Additionally, measures of various markers of immunosenescence suggest that patients with autoimmune diseases have accelerated aging of the immune system. Given the apparent high incidence of lupus in middle-aged and late life, a better understanding of how immune senescence can affect the normally tightly regulated process that prevents the development of autoimmunity is needed. One hypothesis is that defective T-cell activation in aging may result in suboptimal immune response to foreign antigen, which, in turn, may allow these cells to cross-react with self-antigens. Secondly, thymic involution and the accumulation of memory T cells in aging may “force” the proliferation of naïve T cells with high affinity for self-antigen. Thirdly, epigenetics, which refers to the regulation of gene expression through cellular processes including DNA methylation, histone modification, and RNA interference, has been shown to be affected by aging. Both DNA methylation and histone acetylation are important mechanisms for the development of lupus and potentially other autoimmune diseases. Whether the age-dependent epigenetic changes also affect genes that are important in the development of autoimmunity in aging is unknown. Finally, it has been postulated that age-related DNA methylation changes may “reawaken” X-chromosome genes that have previously been inactivated in females. This, in turn, may help to explain the gender differences in a disease such as lupus in the elderly population.

## Presentation

Because of the lack of awareness of this disease in older people, the average time it takes from the onset of symptoms to the diagnosis of LOL is long, averaging between 2 and 3 years. The female:male ratio of LOL is approximately 4:1, much lower than the 9:1 ratio seen in the younger age group. It has been reported that the high prevalence of SLE in African-Americans is not so apparent in LOL. However, whether this merely reflects the demographics of the study locations is unclear.

The clinical features of patients with LOL are quite different from those who develop their lupus at a younger age (Table 120-6). The patients with LOL tend to have a milder disease and are less likely to develop alopecia, malar rash, photosensitivity, oral/nasal ulceration, glomerulonephritis, and lymphadenopathy. Patients with LOL may be more prone to develop cytopenias, serositis, and interstitial pneumonitis. Interestingly, the incidence of cancer, with the exception of non-Hodgkin’s lymphoma, may be lower in LOL

**TABLE 120-6****The Frequency of Symptoms and Signs of SLE in the Older Adults**

SYMPTOMS/SIGNS	FREQUENCY (%)
Arthritis/arthralgia	60
Rash	47
Cytopenias	45
Interstitial pneumonitis	41
Serositis	32
Raynaud's phenomenon	28
Neuropsychiatric	25
Peripheral neuropathy	25
Glomerulonephritis	24

*Adapted with permission from Kammer GM, Mishra N. Systemic lupus erythematosus in the elderly. Rheum Dis Clin North Am. 2000;266:475.*

than in younger patients with lupus. The cause of death in patients with LOL is usually related to complications of treatment such as infections, cardiovascular disease, and stroke.

## Management

The choice of therapy is largely dictated by the specific disease manifestations. Antimalarials (see above) are useful for many lupus symptoms including arthritis, serositis, mucositis, and skin disease. Available evidence strongly supports the long-term use of antimalarials in patients with lupus. Quinacrine, available from many compounding pharmacists, does not cause retinal damage and may be used in elderly patients who cannot take potentially retinotoxic drugs. NSAIDs are used by the majority of patients with lupus for symptomatic relief of arthralgias, myalgias, serositis, fever, and headaches. Their use in elderly patients must be weighed against their potential side effects. This class of drugs is best avoided in patients with lupus having renal involvement.

Local corticosteroid treatments such as (short-term) topical or intradermal injections can be helpful in cutaneous lupus. Systemic steroids are often reserved for more severe disease such as lupus pneumonitis, carditis, hemolytic anemia, or new-onset renal disease. Intravenous "pulse" methylprednisolone in doses of 1 g/d for up to 3 consecutive days can be lifesaving in rapidly progressive or fulminant disease.

The use of cytotoxic drugs such as cyclophosphamide has significantly reduced the morbidity and mortality associated with lupus nephritis. Monthly intravenous pulse cyclophosphamide is generally well tolerated and has fewer side effects than daily oral administration of the drug. Azathioprine, chlorambucil, or nitrogen mustard may be used in lupus patients with renal disease who are unable to tolerate high-dose corticosteroids or cyclophosphamide. Mycophenolate mofetil has gained significant acceptance in the treatment of many lupus manifestations and may be better tolerated than azathioprine. Cytotoxics should not be withheld from elderly patients with lupus with major organ involvement. The use of alkylating agents is associated with an increased risk of future cancer development. However, this may be a more important consideration in younger patients with a longer life expectancy. Gonad toxicity is not a very important issue in the elderly population.

## SJÖGREN'S SYNDROME

### Definition

Sjögren's syndrome is a chronic inflammatory autoimmune disease characterized by progressive lymphocytic and plasma cell infiltration of the exocrine glands, leading to dry mouth (xerostomia) and dry eye (keratoconjunctivitis sicca). The syndrome can occur in isolation (primary) or in association with other autoimmune diseases (secondary) such as RA, SLE, or polymyositis. In addition to the sicca symptoms (dry eyes and dry mouth) serologic evidence of autoimmunity and objective assessment of oral and ocular involvement need to be documented before the diagnosis of Sjögren's syndrome is made. The Schirmer test, in which a strip of Whatman No. 41 filter paper is placed in the lower conjunctival sac, is considered positive if less than 5 mm of the paper is wet after 5 minutes. Ocular involvement can also be documented by staining the conjunctiva with 1% Rose Bengal stain and slit-lamp eye examination. Minor salivary gland biopsy is the most commonly performed test used in diagnosing salivary gland involvement in Sjögren's syndrome. The test is considered positive when there is more than one focus (aggregate of  $\geq 50$  lymphocytes) per 4 mm<sup>2</sup> of biopsy specimen. Biopsy of the parotid, rather than of a minor salivary gland, should be done in patients complaining of parotid gland swelling. Saliva production is measured after overnight fasting without oral stimulation (brushing of teeth, smoking, etc.). A normal person should produce at least 1.5 mL of saliva in 15 minutes. Parotid sialography and salivary gland scintigraphy are alternate procedures for documenting salivary gland involvement.

### Epidemiology

Depending on the definition and the age of the population studied, the prevalence of Sjögren's syndrome has been estimated to be between 0.04% and 4.8%, making it the second commonest autoimmune disease after RA. The disease is likely underdiagnosed as patients often fail to discuss their symptoms with their physicians or believe that the symptoms are part of the inevitable consequence of aging. One study on a geriatric population suggests that subclinical disease may occur in up to 3% of the nursing home population. Although the prevalence of sicca symptoms increases with age, the peak incidence of primary Sjögren's syndrome occurs in the fourth and fifth decades of life, with a 9:1 female:male ratio.

### Pathogenesis

Most cases of Sjögren's syndrome occur sporadically, although there are examples of familial aggregation. An association with HLA antigens has been reported, including HLA-DR3, HLA-DR2, and HLA-DRw52 in white populations. In addition, HLA-DR3 and HLA-DQw2.1 are linked to the development of anti-Ro antibodies. Like most other autoimmune diseases, an environmental or viral trigger has been proposed for Sjögren's syndrome. One theory suggests that autoimmune lymphocytes are "homed" to salivary and lacrimal glands. This is followed by clonal expansion of the autoreactive cells in the glands, upregulation of major histocompatibility complex and adhesion molecules by epithelial cells, and secretion of

proinflammatory cytokines by lymphocytes and epithelial cells. Defective apoptosis causing the failure to delete autoreactive cells has been proposed as a central mechanism explaining the lymphoid aggregates seen in the exocrine glands.  $\alpha$ -Fodrin, a cytoskeletal protein, was recently identified as a candidate autoantigen in Sjögren's syndrome. Interestingly, neonatal immunization with this antigen can prevent the development of the disease in an animal model of Sjögren's syndrome.

## Presentation and Clinical Features

Most patients with Sjögren's syndrome have a slowly progressive and benign course. The onset of the disease is insidious, and it may take up to 10 years for the full-blown disease to develop. Older patients with Sjögren's syndrome usually present with sicca symptoms. They may complain of difficulty chewing and swallowing dry foods, the frequent need to drink liquid especially at night, difficulty wearing dentures, abnormal taste, sore/burning sensation in the mouth, and intolerance to spicy foods. Xerostomia also predisposes these patients to dental decay and the development of oral candidiasis. Instead of the classical white candida plaque, patients with Sjögren's syndrome may have erythematous oral candidiasis. In addition to the feeling of dryness in the eyes, patients with ocular involvement may complain of an itching or burning sensation, the feeling that there is a foreign body in the eye, and photosensitivity. Unilateral or bilateral parotid gland swelling occurs in one-third of all patients with primary Sjögren's syndrome and is more commonly seen in the younger age group. The differential diagnosis of unilateral or bilateral parotid gland swelling includes viral (including HIV-1) and bacterial infections, sarcoidosis, salivary gland ductal obstruction, and neoplasm.

Approximately 60% of patients with Sjögren's syndrome develop extraglandular disease (Table 120-7). Nonerosive arthritis/arthralgia is the commonest extraglandular manifestation and may precede sicca symptoms. Any part of the pulmonary tree from the trachea to the pleural lining may be involved, causing cough, hoarseness, and

shortness of breath. Pseudolymphoma and lymphoma should be suspected when an unexplained pulmonary nodule or lymphadenopathy is seen on chest radiograph. Patients with Sjögren's syndrome may experience dysphagia because of dryness of the oral pharynx or abnormal esophageal motility. Chronic atrophic gastritis, gastric lymphoma, vitamin B-12 deficiency, and antibodies to parietal cells have all been described in this disease. Autoimmune thyroid disease is present in 13% to 45% of patients with Sjögren's syndrome. Patients with Sjögren's syndrome often have elevated liver enzyme profile, especially if antimitochondrial antibodies are present. Interestingly, sicca symptoms are present in 50% of patients with primary biliary cirrhosis. Renal disease occurs in approximately 10% of patients with Sjögren's syndrome. Lymphocytic infiltration and immune complex deposition, proximal tubular acidosis with Fanconi syndrome, renal stones, electrolyte imbalance, and cryoglobulinemia have all been reported.

The association of RA and Sjögren's syndrome was first described by Henrik Sjögren in 1933. Although it is believed that RA is the commonest cause of secondary Sjögren's syndrome, its true prevalence in RA is unknown. Patients with secondary Sjögren's syndrome have milder disease with primarily sicca symptoms (dry eyes and dry mouth). Systemic complications such as salivary gland swelling, central nervous system disease, renal disease (interstitial nephritis or glomerulonephritis), and lymphoproliferative disease are uncommon.

Patients with Sjögren's syndrome often have polyclonal hypergammaglobulinemia, as well as selective increased production of specific autoantibodies. ANA and RFs are present in more than 75% and 66% of patients with Sjögren's syndrome, respectively. Anti-Ro and anti-La antibodies are detected in 70% and 40% of the affected patients. Interestingly, anti-La antibodies are less common in the secondary form of the disease.

## Management

Simple lifestyle changes such as air humidification and avoidance of cigarette smoke are helpful. Nasal dryness can be treated with saline drops or gel. Vaginal dryness can be reduced using water-soluble lubricants and estrogen cream. Dry skin can be improved by using moisturizers and bath oil. Lipstick and lip balm can be used to reduce lip dryness. Meticulous oral hygiene and frequent dental visits are important to prevent complications such as dental decay and oral candidiasis. Frequent fluid replacement, topical fluoride treatment, the use of non-alcohol-based mouthwash, and sugarfree chewing gum can all be helpful. Unfortunately, artificial saliva substitutes that are currently available are not very helpful. Oral candidiasis can be treated with a prolonged course (1–4 months) of a noncariogenic antifungal drug (e.g., nystatin vaginal tablets 100 000 units two to three times a day), with separate treatment of dentures.

The mainstay of treatment for dry eye remains artificial tears. Preparations now available can penetrate into the epithelial cell layer, extending duration of action. However, these may occasionally cause blurring and leave residue on eye lashes. Because patients with Sjögren's syndrome generally require long-term tear replenishment, preservative-free artificial tears should be used. Topical low-dose cyclosporine can be used for Sjögren's eye disease. Tear drainage can also be reduced by the placement of occlusive elements (e.g., silicon implants) in the puncta or permanently by laser or thermal cautery. Soft contact lenses may be used to protect the cornea, especially

**TABLE 120-7**

### Extraglandular Manifestations of Sjögren's Syndrome

Cutaneous	Xerosis (including dryness of nasal passage, skin, and vagina), Raynaud's phenomenon, and cutaneous vasculitis
Pulmonary	Desiccation of the tracheobronchial tree, lymphocytic infiltration (alveolitis, interstitial pneumonitis, pseudolymphoma, and lymphoma), pleuritis/pleural effusion, vasculitis, and pulmonary hypertension
Gastrointestinal	Dysphagia, atrophic gastritis, malabsorption, pancreatic dysfunction and pancreatitis, hepatomegaly and hepatitis, and primary biliary cirrhosis
Renal	Interstitial nephritis, glomerulonephritis, distal renal tubular acidosis, and kidney stones
Hematological	Anemia and cryoglobulinemia
Neuromuscular	Sensory and trigeminal neuralgia, vasculitis; mononeuritis multiplex, neuropsychiatric disorders, seizures, encephalopathy, myelitis, aseptic meningitis, dementia, myopathy, and myositis
Endocrine	Autoimmune thyroid disease

in the presence of keratitis filamentosa. Because the contact lenses require wetting, the patient needs to be careful not to introduce infection to the eyes. Plastic wrap or swimming goggles can be used at night to reduce tear evaporation.

Whenever possible, drugs with significant cholinergic side effects should be discontinued. Muscarinic agonists (pilocarpine and cevimeline) may be helpful in alleviating dry mouth symptoms in patients with Sjögren's syndrome. Systemic corticosteroid and immunosuppressive drugs (e.g., cyclophosphamide) are sometimes used for severe extraglandular diseases such as interstitial pneumonitis, interstitial nephritis, and vasculitis. Musculoskeletal symptoms are often alleviated by the judicious use of NSAIDs, hydroxychloroquine, or sulfasalazine. IFN- $\alpha$  may improve salivary flow in a subset of patients with Sjögren's syndrome. Unfortunately, while treatments are helpful for symptomatic relief, the destruction of exocrine gland continues despite best current effort.

## DRUG-INDUCED RHEUMATIC SYNDROMES

Polypharmacy and iatrogenic diseases are important geriatric issues. Medications are also increasingly recognized as common causes of rheumatic syndromes. These can be broadly categorized into drug-induced lupus (DIL), drug-induced myopathy/myositis, and drug-induced vasculitis.

### Drug-Induced Lupus

More than 100 drugs have now been implicated in DIL (Table 120-8). However, specific criteria for the diagnosis of DIL have not been established. Compared to the idiopathic disease, patients with "classical" DIL have a milder illness and a more restricted autoantibody profile. Antihistone antibodies are present in high frequencies in DIL associated with drugs such as procainamide or hydralazine but are not as frequently seen in patients with drugs such as minocycline or anti-TNF agents. The incidence of DIL has been estimated to be approximately 15, 000 to 20, 000 per year, with between 30, 000 and 50, 000 patients currently affected in the United States.

Procainamide (procainamide-induced lupus, PIL) and hydralazine (hydralazine-induced lupus, HIL) are drugs historically associated with DIL and are well-defined DIL models. Patients with DIL are usually older and more likely to be men, reflecting the age and sex of the population receiving these drugs. One-third of patients receiving procainamide for more than a year will develop symptoms, and almost all will become ANA positive after 2 years. In contrast, fewer than 20% of hydralazine-treated patients will develop DIL. The risk for developing HIL is dose dependent and is highest in patients taking more than 200 mg/day and in those who have taken more than 100 g cumulative dose. Compared to patients with idiopathic lupus, patients with PIL and HIL have fewer renal, neuropsychiatric, and skin manifestations. Pleuropulmonary complaints are particularly common in PIL, while immune cytopenias are uncommon in DIL in general. By definition, all patients with DIL are ANA positive (mostly homogenous pattern). More than 90% of patients with PIL and HIL have antihistone antibodies, and 20% to 40% are RF positive.

Up to 19% of patients treated with IFN- $\alpha$  develop some form of autoimmunity. Approximately 12% of patients receiving this drug develop positive ANA, and between 0.15% and 0.7% will develop a

TABLE 120-8

### Drugs Implicated in Drug-Induced Lupus

Acebutolol	Infliximab	Phenylbutazone
Aminoglutethimide	Interferon ( $\alpha$ , $\gamma$ )	Phenylethylacetylurea
Amiodarone	Interleukin-2	<i>Phenytoin</i>
Amoprofan	<i>Isoniazid</i>	Practolol
Anthiomaline	Labetalol	Prazosin
Atenolol	Lamotrigine	Primidone
Benoxaprofen	Leuprolide acetate	Prinolol
Canavanine (L-)	Levodopa	<i>Procainamide</i>
Captopril	Levomeprazole	Promethazine
<i>Carbamazepine</i>	Lithium carbonate	Prophthiouracil
<i>Chlorpromazine</i>	Lovastatin	Psoralen
Chlorprothixene	Mephenytoin	Pyrazinamide
Clonidine	Mesalazine	Pyrimethamine
Clozapine	Methimazole	<i>Quinidine</i>
COL-3	<i>Methyldopa</i>	Quinine
Danazol	Methylsergide	Rifampin
Diclofenac	Methylthiouracil	<i>Sulfasalazine</i>
1,2-Dimethyl-3-hydroxypyridine-4-1 (II)	Metrizamide	(5-amino) salicylic acid
Disopyramide	<i>Minocycline</i>	Simvastatin
Etanercept	Minoxidil	Spironolactone
Ethosuximide	Nalidixic acid	Streptomycin
Flutamide	Nitrofurantoin	Sulindac
Fluvastatin	Nomifensine	Sulfadimethoxine
Gold salts	Oral contraceptives	Sulfamethoxyypyridazine
Griseofulvin	Olsalazine	Terbinafine
Guanoxan	Oxyphenisatin	Tetracycline
<i>Hydralazine</i>	Para-aminosalicylic acid	Tetrazine
Hydralazine	<i>Penicillamine</i>	Thionamide
Hydroxychloroquine	Penicillin	Thioridazine
Ibuprofen	Perazine	Timolol eye drops
	Perphenazine	Tolazamide
	Phenelzine	Tolmetin
	Phenopyrazone	Trimethadione
		Zafirlukast

Drugs with the strongest associations are in italic.

Adapted with permission from Yung RL, Richardson BC. Drug-induced rheumatic syndromes. *Bull Rheum Dis.* 2002;51(4):1.

lupus-like illness. Anti-dsDNA antibodies occur in 8%, and almost all the patients with IFN- $\alpha$ -induced lupus have elevated anti-dsDNA antibodies. The development of autoimmunity appears to be dependent on the dose and duration of treatment. Other rheumatic syndromes associated with IFN- $\alpha$  include RA, polymyositis, psoriatic arthritis, Reiter's syndrome, and sarcoidosis. Autoimmune thyroid diseases are common following IFN- $\alpha$  treatment. It is important to differentiate this from idiopathic hypothyroidism that is prevalent in the elderly population.

Patients receiving TNF antagonists often develop serologic evidence of autoimmunity. In one study, new ANA and anti-dsDNA antibodies were found in 33% and 9% of infliximab recipients, respectively. However, there is clear discordance between the development of autoantibodies and clinical autoimmunity, with only a handful of symptomatic patients reported, mostly with skin diseases. Approximately 13% of patients exposed to infliximab develop infliximab-specific antibodies. Patients receiving concurrent immunosuppressants such as methotrexate or azathioprine are less likely to develop these antibodies. The presence of antibodies to

infliximab increases the likelihood of an infusion reaction but does not predict the development of autoantibodies or DIL.

### Drug-Induced Myopathy/Myositis

Drug-induced muscle diseases include myopathy/myositis and rhabdomyolysis. In addition, drugs that impair consciousness (e.g., sedatives and hypnotics) and those that cause seizures (e.g., theophylline), hyperthermia (e.g., halothane and cocaine), malignant neuroleptic syndrome (e.g., haloperidol and phenothiazines), and dystonia (e.g., butyrophenones) can also result in muscle necrosis and elevated creatine phosphokinase (CPK).

Hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (the “statins”) are well known to cause different muscle complications varying from myalgias without elevated CPK, elevated CPK without any clinical symptom, to myopathy and rhabdomyolysis. The incidence of statin-induced myopathy (defined as a greater than 10-fold increased in CPK and muscle pain or weakness) is approximately 1 in 1000 patients taking the drug. The risk is greater when these drugs are used in conjunction with gemfibrozil, cyclosporin, niacin, erythromycin, itraconazole, and diltiazem. Other risk factors include renal insufficiency, hypothyroidism, advanced age, and serious infection. The mechanism of statin-induced myopathy is unclear. These agents may interfere with mitochondrial metabolic pathways. Myopathy associated with one statin does not predict the development of a similar problem with a different statin. However, there are rare reports of statin-induced rhabdomyolysis in patients with a previous history of statin-induced myopathy.

A number of drugs rheumatologists prescribe can cause significant muscle disease. Neuromyopathy occasionally develops in patients receiving colchicine. Older patients and those with renal impairment may develop this complication even if they are taking conventional doses of the drug. Patients receiving either chloroquine or hydroxychloroquine are at risk of developing a proximal myopathy and rarely cardiomyopathy. Steroid myopathy usually occurs when greater than 20 mg of prednisone is prescribed. The onset can be acute or insidious, involving the proximal muscle groups (especially the thighs and hip girdle). Serum creatine kinase level is usually normal, but urine creatine may be elevated. Biopsy of the affected muscle classically shows type 2b fiber atrophy. Corticosteroid use is also associated with rhabdomyolysis when it is administered in the intensive care unit, often in the setting of concurrent paralytics or sedatives (“critical care myopathy”). Penicillamine used in the treatment of RA and Wilson’s disease may cause polymyositis, myasthenia gravis, and other autoimmune disorders, including lupus, pemphigus, and Sjögren’s syndrome.

Interest in over-the-counter “complementary” medicine has exploded in recent years. Several of these oral supplements have now been linked to the development of musculoskeletal syndromes. The best example is the eosinophilia–myalgia syndrome, believed to be caused by one or more contaminant(s) (the identity of which is still unclear) introduced during the manufacturing process of L-tryptophan by a single manufacturer from Japan. Patients who consumed the product developed peripheral eosinophilia, incapacitating myalgias, and tight skin and/or fasciitis. DL-Carnitine is sold in health food stores and is being promoted as a supplement to increase muscle strength. Although L-carnitine may improve fatigue and muscle strength in some individuals, the DL-carnitine preparation may rarely cause muscle weakness and a myasthenia-like syndrome.

### Drug-Induced Vasculitis

Ingestion of a number of drugs is associated with the development of antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis, including hydralazine, propylthiouracil, methimazole, penicillamine, and minocycline. Renal involvement is surprisingly common. The ANCAs often lack specificity and may have activity against myeloperoxidase, elastase, or antiproteinase 3 (PR-3). Discontinuation of the offending drug results in resolution of the clinical disease and a fall in the ANCA titer. Drug-induced vasculitis should be differentiated from drug-induced ANCA production, which is much more common.

Administration of hematopoietic growth factors, including granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor, has been associated with the development of cutaneous and rarely systemic vasculitis. Interestingly, there is a particularly high prevalence of vasculitis among patients with chronic benign neutropenia receiving these growth factors. The risk of vasculitis increases when the absolute neutrophil count rises above 800/mm<sup>3</sup>, and the problem almost always subsides with decreasing absolute neutrophil count. A number of vasculitis mimics may also develop in association with hematopoietic growth factors, including Sweet’s syndrome and pyoderma gangrenosum. Finally, the use of colony-stimulating factors in the settings of Felty’s syndrome and malignancies is associated with a flare of preexisting RA.

There are numerous reports of postvaccination vasculitic syndromes (Table 120-9). Symptom onset usually occurs within days or weeks. Most cases resolve spontaneously or with steroid therapy. Some of these cases may be related to an infectious agent or coincidental primary/idiopathic disease. It is also possible that vaccination may trigger the onset of an underlying autoimmune process. The overall incidence of vaccination-induced vasculitis appears to be low. Clinicians should not withhold the appropriate vaccination from patients with preexisting autoimmune diseases or vasculitis based on these reports.

There are a number of reports linking the development of Churg–Strauss syndrome with the use of leukotriene inhibitors (particularly Zafirlukast) in patients with asthma. Onset of Churg–Strauss syndrome is often associated with exposure to the offending drug during a steroid taper. Many pulmonologists now believe that these cases represent unmasking of undiagnosed Churg–Strauss syndrome with tapering of the steroids, rather than a drug-induced disease.

**TABLE 120-9**

#### Vaccines Associated with Vasculitis

Hepatitis B	Takayasu’s, polyarteritis nodosa, cutaneous leukocytoclastic vasculitis, Churg–Strauss, cryoglobulinemia, and GCA
Influenza	PMR, GCA, HSP, cryoglobulinemia, microscopic polyangiitis, and cutaneous leukocytoclastic vasculitis
<i>Pneumococcus</i>	Cutaneous leukocytoclastic vasculitis
Varicella	Hypersensitivity vasculitis
Measles	HSP
BCG	PMR, GCA, urticarial vasculitis, and Kawasaki’s disease
Tetanus	GCA
Meningococcal C	HSP

GCA, giant cell arteritis; HSP, Henoch–Schoenlein purpura; PMR, polymyalgia rheumatica.

Nevertheless, in the absence of further information, it remains possible that some cases of Churg–Strauss syndrome represent an idiosyncratic eosinophil-based response to leukotriene inhibitors.

## RHEUMATIC SYNDROMES AND CANCER

Clinicians are often concerned that a patient's rheumatic complaints may represent the early systemic presentation of an occult tumor. Patients with autoimmune diseases are also at higher risk of developing cancers. Finally, immunosuppressive therapies used for treating autoimmune diseases may predispose the patients to malignancies as well.

### Musculoskeletal Symptoms Associated with Cancer

An extensive search for an occult malignancy is not recommended in patients with most rheumatic syndromes unless there are specific symptoms or findings suggesting the possible presence of a tumor. Nevertheless, the possibility of metastatic disease should be considered in an elderly patient presenting with severe pain in or around a joint. Metastatic joint disease caused by lung or breast cancer is usually monoarticular or oligoarticular (two to five joints). Pain and synovitis are caused by synovial inflammation in response to tumor cells in and around the joint. Large joints (e.g., knee and hip) are most commonly affected. However, asymmetric polyarthritis can occur at the late stages of cancer. The vertebral column is a common place for metastatic disease. A malignancy workup should be done if an elderly patient presents with intractable or nocturnal back pain that is increasing in severity and if the patient has constitutional symptoms such as fever or weight loss. Multiple myeloma frequently causes lytic lesions and pathologic fractures. Light-chain amyloidosis occurs in 15% of these patients and is associated with a symmetric small-joint arthropathy. In addition, amyloid infiltration in the shoulder joint produces the classical "shoulder pad sign." Hyperuricemia and gout may develop in patients with large tumor bulk, especially during chemotherapy.

Hypertrophic osteoarthropathy is the most common rheumatic syndrome associated with malignancy and is almost always caused by metastatic lung cancer in the western world. Ankles, wrists, knees, and fingers are the sites most frequently affected. The cause is unknown, but a neurally mediated mechanism is suggested by improvement with vagotomy and atropine. Carcinomatous polyarthritis can precede or follow the diagnosis of the underlying cancer, most commonly breast in women and lung in men. The classical description is an acute-onset asymmetric seronegative polyarthritis in an elderly patient that resembles EORA. The arthritis often improves with cancer therapy and may relapse with tumor recurrence. A polymyalgia rheumatica-like disease has been linked to metastatic cancer. This is suggested by a younger age of onset, prominent constitutional symptoms, asymmetric involvement of proximal muscle groups, a relatively low sedimentation rate, and an incomplete response to prednisone. The Lambert–Eaton syndrome is characterized by an antibody-mediated defect in acetylcholine release at the neuromuscular junction. It is most commonly associated with small cell carcinoma of the lung. Ptosis, distal muscle involvement, and characteristic electromyogram findings distinguish the disease from common inflammatory myopathies. The combination of palmar fasciitis and polyarthritis is associated with gynecologic tumors,

in particular, ovarian carcinoma. This is usually associated with late metastatic disease and carries a poor prognosis. Panniculitis with synovitis and serositis is a well-known accompaniment of pancreatic cancer. Finally, there are sporadic reports of steroid-resistant eosinophilic fasciitis associated with hematologic malignancies.

### Rheumatic Diseases and Cancer

Patients with autoimmune diseases are at an increased risk of the development of a variety of malignancies. This tendency may be exacerbated by the use of specific immunosuppressive drugs. Patients with RA have a two- to fivefold increased risk of developing hematologic malignancies, including Hodgkin's and non-Hodgkin's lymphomas. The risk is even higher if secondary Sjögren's syndrome or a serum paraprotein is present. An increased risk for oral–pharyngeal cancers has been described in geographic locations where these tumors are prevalent. Interestingly, there are epidemiologic data showing that patients with RA may be at a lower risk of developing colorectal cancer. Whether this is related to the regular use of NSAIDs in this population is unknown. Patients with Sjögren's syndrome are 44 times more likely to develop lymphoma than are age-, sex-, and race-matched normal subjects. The risk may be higher if the patient is anti-Ro or anti-La positive. In some of these patients, there appears to be a progression from benign exocrinopathy to pseudolymphoma to lymphoma. These tumors are almost exclusively B-cell lymphomas with a high frequency of a t(14;18) chromosomal translocation. The malignant transformation is likely the result of chronic B-cell stimulation. The presence of a monoclonal IgM spike on serum protein electrophoresis may herald the transformation to malignant lymphoma. Hypogammaglobulinemia and loss of autoantibodies may eventually occur when the lymphoma cells replace the normal antibody-producing plasma cells.

Patients with polymyositis have a twofold increased risk of developing cancer, particularly in the 1 to 5 years following the diagnosis of the muscle disease. The risk of cancer in patients with dermatomyositis is much higher (four to five times), and the cancer may be discovered years before or after the muscle disease is diagnosed. Older age, the presence of digital vasculitis, and normal serum creatinine kinase level have been cited as possible risk factors for cancer development in patients with inflammatory myositis. Patients with overlap syndromes and those with myositis-specific antibodies do not appear to have a higher incidence of cancer than other patients with polymyositis or dermatomyositis. The cancers associated with inflammatory myositis are those that are commonly seen, including breast, lung, gynecologic, and GI malignancies. Interestingly, nasopharyngeal carcinomas are the dominant cancers associated with myositis in countries that have a high prevalence of these malignancies.

It is controversial whether patients with other autoimmune diseases are more likely to develop cancer. Some reports have described an increased risk of lymphoma (particularly non-Hodgkin's lymphoma) and possibly lung, breast, and cervical cancers in patients with SLE. Patients with scleroderma may be predisposed to skin cancer, and patients with systemic sclerosis who have pulmonary fibrosis are at risk of developing lung cancer.

### Risk of Cancer with Immunosuppression

Epidemiologic studies have reported that patients with RA treated with methotrexate may be at increased risk of developing cancer

and lymphoma. This is unclear, however, because most studies only examined the relative risk compared to that of the general population. Nevertheless, there are a large number of case reports or case series linking the occurrence of lymphoma (mostly diffuse large-cell non-Hodgkin's lymphomas) in patients with RA receiving low-dose weekly methotrexate. In most cases, cessation of therapy is associated with complete regression of the lymphoid cancer, suggesting a causative relationship. DNA analysis shows that approximately 50% of these lymphomas harbored the Epstein–Barr virus genome. It is, therefore, possible that the drug regimen may promote the malignant transformation of normal lymphoid tissue by the oncogenic virus. Patients with RA on azathioprine and cyclosporin A have a twofold increased risk of lymphoma relative to control patients with RA. A real association between the use of immunosuppressive therapy and the development of lymphoproliferative disorders is also supported by studies of patients with organ transplantation. The incidence of non-Hodgkin's lymphoma is 50-fold greater in patients with renal transplant, especially if they receive cyclosporin A as part of their immunosuppressive regimen.

The issue of cancer risk in patients on anti-TNF agents has already been discussed. Cyclophosphamide is commonly used to treat severe lupus manifestations, including nephritis and cerebritis. Patients with lupus on cyclophosphamide are more likely to develop

bladder cancer, lymphoma (primarily non-Hodgkin's lymphoma), and possibly skin cancer. A small increased cancer risk has also been reported in patients with RA treated with the drug.

# Back Pain and Spinal Stenosis

*Leo M. Cooney, Jr.*

## EPIDEMIOLOGY

Low back pain is a common problem in older individuals, but its etiology, natural history, and therapy are not well defined. Epidemiologic studies have reported the prevalence of back pain in older individuals from 6% to 47%. A recent Israeli study found that 44% of 70-year-olds and 58% of 77-year-olds reported back pain.

In the United States, back pain is the third most frequent symptom in those aged 75 years and older visiting their physicians. This pain is associated with depression, dependence in daily living activities, female gender, and poor self-reported health. The association of back pain and physical function has been quantified; the number of months with restricting back pain is associated with such markers of frailty as worsening rapid gait, chair stands, and foot tap performance. In the study of Medicare beneficiaries 65 years and older, back pain was second only to shortness of breath while climbing stairs in its association with impaired general physical health status.

Back pain is also becoming a substantial drain on health-care resources for older adults. While there was a 42% increase in total Medicare patients from 1991 to 2002, there was 131.7% increase in patients diagnosed with low back pain, and a 387% increase in low back pain charges.

It is clear that low back pain is a common problem for older individuals, is associated with poor outcome, and consumes a significant percentage of health-care resources. Our knowledge of the natural history and outcomes of this problem is limited. The studies during the past two decades that have helped to outline the natural history and outcome of back pain have been conducted exclusively in individuals younger than 60 years of age.

## ETIOLOGY OF BACK PAIN

There is very little information in the literature on the natural history, associated features, and the etiology of older patients with back pain.

The clinician must first determine whether the problem is in the hip or back. It can be difficult to distinguish these conditions, as both can give buttock and low back pain. Pain that occurs when going from the supine to sitting position is more apt to be from the back, while groin pain, worsened with weight bearing, favors the hip. A complete examination of the passive range of motion of the hip, done with the patient in the supine position, should reveal 40 degrees of hip abduction, more than 100 degrees of flexion, 50 to 60 degrees of external rotation, and 20 degrees of internal rotation. In addition, a manual muscle examination of the lower extremities, which demonstrates mild weakness of the L4, L5 (hip abductor and great toe extensor) and L5, S1 (hip extensors) innervated muscles of the lower extremities, favors the back as the cause of pain. One recent study demonstrated that the presence of groin pain, a limp, and limited internal rotation of the hip all favored the hip as the cause of pain.

A number of discrete conditions may cause back pain in older individuals. These conditions include tumors, infections, vertebral compression fractures, osteoporotic sacral fractures sciatica, lumbar spinal stenosis, and mechanical causes. One approach to the assessment of back pain in older individuals is to evaluate those patients for the historical, physical, and diagnostic imaging features of these discrete conditions and then to appraise the patient with nonspecific low back pain without one of these conditions.

## Tumor

The clinician must always be alert to nonmechanical, either referred or systemic, causes of low back pain. Visceral causes of back pain, such as abdominal aortic aneurysms or pancreatic cancer, are usually nonpositional, progressive, and associated with a normal examination of the lumbar spine and hip.

Tumors usually present with a gradual onset and progressive course, with persistent worsening of the pain over weeks and months. This insidious onset of pain, which is initially mild but progressive

in severity, is quite distinct from the abrupt onset and positional characteristics of mechanical low back pain. Tumor pain is often nonpositional, lasts longer than 4 weeks, and is associated with systemic symptoms. One study found that an abnormal CBC and ESR are the best screening tests for tumor as a cause of back pain.

## Infection

Although a rare cause of back pain, vertebral and disc infections can be difficult to distinguish from a mechanical cause of back pain; disc infections can cause the same abrupt onset, positional changes, and L4, L5 and L5, S1 neurologic abnormalities seen in mechanical disc disease.

Back pain is the most common musculoskeletal complaint seen in endocarditis. Because the disc is often involved in this condition, the signs and symptoms can mimic mechanical disc disease. Fever can be absent in older patients with infection. The clinician must be alert to a possible infectious cause of back pain for patients with a high risk of endovascular infection (artificial heart valves, indwelling venous catheters, intravenous drug abuse, etc.) and in patients with systemic symptoms and signs of inflammation.

## Vertebral Compression Fractures

The abrupt onset of severe back pain, especially in a patient with risk factors for osteoporosis, should always call for a spinal x-ray to rule out a vertebral compression fracture (Table 121-1). At times, the initial x-ray is normal and the changes of vertebral collapse appear several days to weeks after the onset of pain. As there is no dislocation with osteoporotic vertebral fractures, neurological signs and symptoms are quite rare. Pain may be referred, however, into the chest, abdomen, or leg. Any movement, even rolling in bed, usually exacerbates the pain for the first several days. Pain then gradually improves over the next several weeks and resolves in 6 weeks.

Only approximately 30% to 40% of vertebral compression fractures are symptomatic. Most symptomatic fractures are in the lower thoracic and lumbar spine. Most mid and upper thoracic fractures are asymptomatic.

The presence of a vertebral fracture does increase the risk of a subsequent fracture. In a multicenter study of osteoporosis, the presence of a fracture increased the risk of subsequent fractures in the next year from 6.6% to 19.2%.

The role of osteoporosis and vertebral fracture in chronic back pain and disability is not clear. The finding that fractures are associated with increased mortality from pulmonary disease and cancer indicate that these fractures may be markers of frailty. While some studies have shown increased disability in patients with vertebral fractures, a British population-based study found no correlation between minor vertebral deformities and back pain. A study of women

in Hawaii showed a correlation between recent fractures and back pain, but the prevalence of back pain among women with prevalent fractures was not significantly higher than those without these fractures. Finally, the Study of Osteoporotic Fractures found an increase in back pain and disability only if vertebral deformities were greater than 4 standard deviations from the mean.

## Osteoporotic Sacral Fractures

There have been a number of reports of “sacral insufficiency fractures” as a cause of back pain. Older patients, usually women, complain of dull low back pain. This pain is also felt in the buttock area. The application of pressure to the sacrum is very painful. Associated neurologic defects have not been reported. The pain usually resolves spontaneously in 4 to 6 weeks. Approximately 50% of these patients had a preceding fall, and the majority of patients have old pelvic and vertebral compression fractures on x-ray.

Plain x-rays of the sacrum are normal, but technetium bone scans demonstrate the fractures. CT scans of the sacrum usually show displacement of the anterior border of the sacrum. A sacral insufficiency fracture should be considered if a woman with osteoporosis develops sudden pain in the low back and buttock with sacral tenderness.

## Sciatica

Sciatica is usually defined as pain radiating to one leg below the gluteal fold. It is often felt in the buttock area, radiating into the posterior aspect of the leg down to the ankle. It may, however, be incomplete, as in the calf pain seen in the “pseudoclaudication” syndrome with lumbar spinal stenosis. The natural history of this condition is well defined in younger adults. Fifty percent of these patients have full resolution of symptoms within 6 weeks. While there are no studies of the natural history of sciatica in older patients, many clinicians do find that sciatica, which develops abruptly and occurs in all positions, usually has a good natural history, similar to that seen in younger individuals. Patients who develop sciatica as part of the lumbar spinal stenosis syndrome, with gradual progression of pain with shorter and shorter periods of standing and walking, have a more prolonged and persistent natural history.

## Lumbar Spinal Stenosis

Narrowing of the lateral recess of the vertebral canal, as well as the anterior–posterior diameter of the canal, is frequently seen on diagnostic imaging tests of the lumbar spine in older individuals. These abnormalities have clinical significance only if the typical history of lumbar spinal stenosis is present (Table 121-2).

Changes in spinal dynamics with movement explain some of the clinical features of lumbar spinal stenosis. Flexion of the lumbar spine decreases the intraspinal protrusion of the disc, decreases the bulge of the yellow ligaments within the canal, and stretches and decreases the cross-sectional area of nerve roots, resulting in an increase in spinal canal volume in relation to nerve root bulk. Extension of the lumbar spine causes bulging of the disc into the canal, enfolding and protrusion of the yellow ligaments into the spinal canal, and a relaxation and increase of the cross-sectional diameter of nerve roots. Extension of the canal thus produces a decreased volume of the spinal canal in relation to nerve root bulk.

**TABLE 121-1**

### Characteristics of Vertebral Compression Fracture

Severe pain with lower thoracic and lumbar fracture
High and mid-thoracic fracture often asymptomatic
Pain resolves in 4–6 weeks
Increased risk for subsequent fracture

**TABLE 121-2****Characteristics of Lumbar Spinal Stenosis**

Pain with extended spine
Prolonged standing
Walking
Walking down hill
Pain relieved on flexing spine
Sitting
Leaning on walker or grocery cart
Sciatic pain on walking
Incomplete sciatica—"pseudoclaudication"

These changes in dynamics explain the clinical picture of lumbar spinal stenosis. Positions that extend the spine (standing, walking down hill, prone lying, and extending the back) worsen symptoms, while positions that flex the spine (sitting, bending forward, placing weight on a walker or cart, and lying in a flex position) relieve the symptoms.

Patients with lumbar spinal stenosis present with pain, either in the lower back or legs, which comes on with prolonged standing and walking and is relieved with sitting. Individuals with this condition will often bend their spine more as they walk and find that they can walk further in a grocery store, supported by a cart. The leg pain can present with a classic picture of sciatica (pain radiating from the posterior aspect of the buttock down to the foot) or an incomplete "pseudoclaudication" syndrome, in which the patient feels pain only in the calf while standing and walking.

Lumbar spinal stenosis should not produce pain when going from lying to sitting and should not produce severe pain with bending, stooping, or lifting objects. In a masked study comparing radiologic and electrodiagnostic diagnoses to clinical impression, MRI findings and their interpretation did not relate in any important way to the clinical diagnosis of lumbar spinal stenosis.

### Mechanical Low Back Pain

The majority of older people with low back pain do not have tumors, infections, lumbar spinal stenosis, or vertebral compression fractures (Table 121-3). They are best described as patients with mechanical low back pain of uncertain etiology. Because the nucleus pulposus loses water content with aging, herniation of this structure is unusual beyond the age of 55 years.

A good deal of back pain in younger individuals is probably caused by displacement of the outer annulus fibrosis or inner nucleus pulposus of the intervertebral disc. The disc does not contain pain fibers: the perivertebral structures with the most sensitive pain fibers are the posterior longitudinal ligament and the dura mater, which lie

**TABLE 121-3****Characteristics of Mechanical Low Back Pain**

Intermittent sharp back pain
Pain comes on and subsides rapidly
Pain going from lying to sitting and with bending
Asymmetric loss of motion of lumbar spine
Weakness of L4, L5, S1 innervated muscles

posterior to the vertebrae and discs. The sinuvertebral nerve innervates these structures. Irritation of this nerve causes reflex spasms of the paravertebral muscles of the lumbar spine. It is, thus, logical to assume that soft-tissue displacement in this area will cause pain and limitation of some, but not all, of the planes of movement of the lumbar spine, spasm of the paravertebral muscles, and subtle weakness of the muscles innervated by the appropriate nerves roots (L4, L5, and S1—in most cases).

In a young lumbar spine, the central nucleus pulposus often herniates outside the annulus fibrosis and indents the pain-sensitive posterior longitudinal ligament and dura mater, producing pain that often lasts for several weeks and occasionally causing sciatica owing to nerve root irritation. Because of decreased water content, the nucleus pulposus becomes less gel-like as one ages and rarely herniates after the age of 55 years.

Older patients often have a syndrome of sharp pain in the lumbar area, worsened with bending movements, which comes on and subsides rapidly but recurs frequently. On physical examination, these patients often have asymmetric loss of range of motion in the lumbar spine, paravertebral muscle spasm, weakness of the L4-, L5-, and S1-innervated muscles, and pain going from the flexed to the erect position. Clinicians often use the term "unstable lumbar spine" to describe this syndrome, although the evidence for specific mechanical instability is lacking. Patients with this condition often have one intervertebral disc space narrowed and sclerotic out of proportion to other disc spaces, and anterior displacement of one vertebra on another (spondylolithesis). Maneuvers such as going from lying to sitting and bending forward often produce pain. Before considering major interventions, it is important to distinguish this condition, in which pain results from movement of the lumbar spine (e.g., lying to sitting), from lumbar spinal stenosis, in which pain results from prolonged extension of the spine (standing and walking).

### Diffuse Idiopathic Skeletal Hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH) is a condition characterized by calcification of prevertebral and peripheral ligaments. Ossification of spinal ligaments is often confused with osteophytes, and the condition is frequently mislabeled as disc degeneration or osteoarthritis. Spinal involvement is characterized by the following: (1) the presence of flowing calcification and ossification along the anterolateral aspect of at least four contiguous vertebral bodies, (2) relative preservation of intervertebral disc height in the involved area, and (3) the absence of apophyseal joint bony ankylosis or other features of ankylosing spondylitis.

Most studies have not found any association with DISH and back pain, while other studies have noted an increase in ligamentous tenderness, stiffness, and immobility of the cervical, thoracic, and lumbar spine in individuals with this condition. The condition should be distinguished from disc disease with vertebral osteophytes and is a cause of significant spinal immobility in older individuals.

### EVALUATION

The evaluation of the older patient with back pain must depend heavily on the history, physical examination, and observation of the patient. The history and physical examination remain the most helpful tools in the assessment of back pain in older persons, particularly because of the very high false-positive rate of spinal diagnostic imaging

**TABLE 121-4****History Items That Help Differentiate Causes of Back Pain**

tests in this age group. Laboratory tests and diagnostic imaging studies have a secondary role in the assessment of these patients. The clinician must make sure that the clinical presentation of the patient fits the results of the diagnostic imaging tests before proceeding with interventions.

The role of the clinician in assessing and managing back pain in older individuals must thus focus on (1) identifying those conditions that require immediate attention (e.g., infections and tumors), (2) recognizing the usual patterns of pain for defined causes of back pain, (3) assisting the patient with therapy for these specific conditions, and (4) advising the patient on the natural history, precipitating events, and therapeutic approaches to nonspecific mechanical low back pain.

## History

Patients with a mechanical cause for pain usually have intermittent, positional pain, often with the peak intensity of pain at the beginning of the syndrome (Table 121-4). Pain that is worse on going from lying to sitting and with bending, that occurs when one suddenly changes position, and that resolves quickly but recurs frequently, suggests mechanical disease of the lumbar spine as a result of soft-tissue displacement. Severe pain in any position, which comes on abruptly and is aggravated by even rolling over in bed, suggests a vertebral compression fracture. A woman with sacral and buttock pain, sacral tenderness, and osteoporosis should be evaluated for a sacral insufficiency fracture. Gradually worsening progressive pain, lasting more than a month, which is nonpositional and associated with systemic symptoms and signs, should suggest tumor. Hip disease can often mimic back problems. Pain that is worse when going from sitting to standing and that causes a limp indicates possible hip disease.

## Physical Examination

Several findings on physical examination can be useful in determining discrete causes of back pain (Table 121-5). The physical examination of the lumbar spine is an essential component of the assessment of a patient with back pain (Figure 121-1). This is best done in

**TABLE 121-5****Physical Examination Findings That Help Differentiate Causes of Back Pain**

Paravertebral muscle spasm
Mechanical low back pain
Vertebral compression fracture

Lumbar spinal stenosis

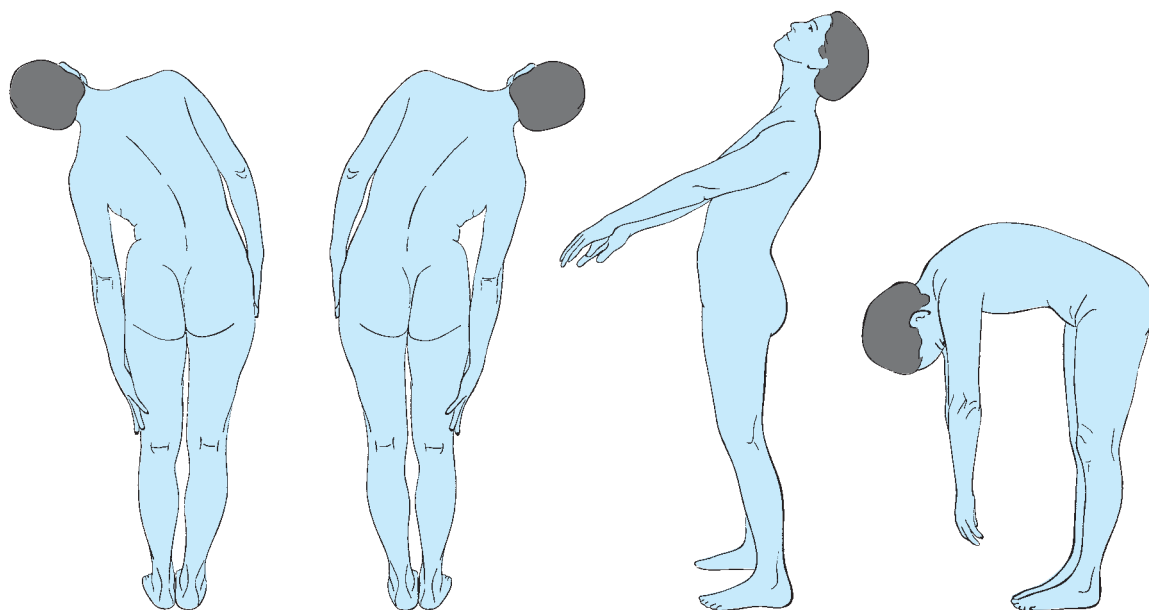

the erect position. The examiner observes the patient for kyphosis or scoliosis and then palpates for paravertebral muscle spasm. The patient is then brought through the four ranges of motion of the lumbar spine, side flexion to the right, side flexion to the left, forward flexion, and extension, observing for asymmetric limitation of motion or reproduction of the patient's pain by these maneuvers (Figure 121-1). In the supine position, straight leg raise tests can indicate nerve root irritation if positive, but a negative test does not exclude any condition. The hips should be examined by testing the passive range of motion. The examiner should be able to abduct the leg to 40 degrees before the pelvis tilts. There should be 60 degrees of external rotation (heel toward the midline) and 20 degrees of internal rotation (heel away from the midline) of each hip (Figure 121-2).

Manual muscle testing of the lower extremity gives much useful information, as subtle L4, L5 and L5, S1 weakness is common in patients with mechanical back pain. L4, L5 is tested by resisting the patient's abducted leg at the lateral upper thigh (gluteus medius muscle) (Figure 121-2), by resisting the patient's ability to dorsiflex the foot (tibialis anterior muscle), and by resisting the great toe extensor (extensor hallucis longus) (Figure 121-3). L5, S1 (gluteus maximus muscle) is tested by trying to overcome hip extension (trying to pull the leg off the examining table, when the patient has been instructed to hold the leg firmly on the table). One can also test L5, S1 by resisting the patient's ability to evert the foot (peroneus longus and peroneus brevis).

Most patients with lumbar disc disease or lumbar spinal stenosis will have some abnormalities of the examination of the lumbar spine or of the muscles innervated by L4, L5 or L5, S1. Patient with vertebral compression fractures may have a good deal of tenderness in the lumbar spine but should have no neurologic abnormalities. Patients with osteoporotic sacral fractures will have sacral tenderness, but a normal lumbar spine examination and no lower extremity muscle weakness. Patients with sciatica almost always have L4, L5 and L5, S1 weakness. A patient with persistent, severe back pain, but with a normal examination of the lumbar spine, sacrum, and hips and no evidence of L4, L5 or L5, S1 muscle weakness, should be evaluated thoroughly for a possible neoplasm or infection.

## Laboratory Tests and Imaging

The interpretation of diagnostic tests in older patients with back pain is a challenge, given the high rate of abnormal tests in asymptomatic individuals in this age group. As noted above, a CBC and an ESR

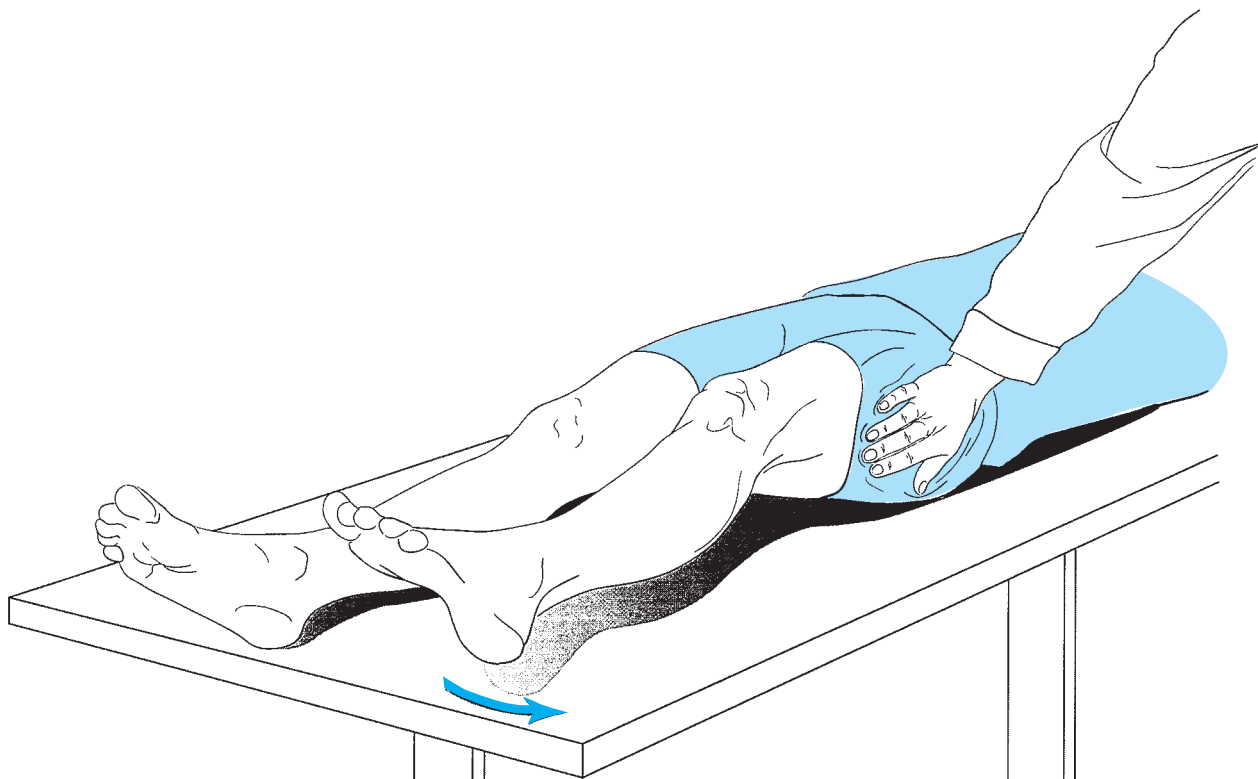

**FIGURE 121-1.** Range of motion of lumbar spine.

are reasonable screening tests if the patient's history and physical examination suggests a tumor or infection. A plain roentgenogram of the lumbar spine is more helpful in the evaluation of older patients than younger ones, as it may demonstrate a vertebral compression fracture, DISH, or spondylolithesis.

The clinician must be aware that changes in the lumbar spine are ubiquitous in older individuals and not well correlated with back pain. Kellgren and Lawrence's classic epidemiological study

in Leigh, England, found that 89% of the males and 57% of the females between the ages of 55 to 64 years had disc degeneration of the lumbar spine. A 1984 study of lumbar sacral spine x-rays found no association between back pain and Schmorl's nodes, the disc vacuum sign, traction spurs, and disc space narrowing between the third and fourth lumbar vertebrae, or between the fifth lumbar and first sacral vertebrae. There was an association between acute low back pain and disc space narrowing, and traction spurs between

**FIGURE 121-2.** Resisting abduction of the leg.

**FIGURE 121-3.** Resisting great toe extensor.

the fourth and fifth lumbar vertebra. A Lahey Clinic study found no correlation between vertebral osteophytes and low back pain but did find increased back pain in individuals with spondylololthesis (pars interarticularis defect and frontal slippage of one vertebra on an adjacent vertebra).

In a 1967 study, myelograms were performed on the lumbar spine in individuals who were undergoing these studies in the posterior fossa to evaluate acoustic neuromas. Thirty-seven percent of patients with no back pain had abnormal myelograms of the lumbar spine.

MRIs of the lumbar spine often demonstrate anatomic abnormalities in asymptomatic individuals, especially in the elderly. In a 1994 study of MRIs of the lumbar spine in patients without back pain, only 36% had a normal examination; 52% of these individuals had a disc bulge in at least one level, and 27% had disc protrusions. In another study of asymptomatic individuals, 36% of subjects older than 60 years had a herniated nucleus pulposus, 21% had spinal stenosis, and 93% had degenerative disc disease. A 1998 study found that 56% of asymptomatic individuals had tears of the annulus fibrosis of the lumbar disc. In a VA study of 198 subjects who had had no back pain for at least 4 months, 83% had moderate-to-severe degeneration of the disc, 64% had at least one bulging disc, and 32% had at least one disc protrusion. In individuals older than 65 years, 100% had disc degeneration and desiccation, 83% had a disc bulge, and 38% had facet joint degeneration.

The above findings indicate that the clinician cannot depend on imaging studies to diagnose the cause of back pain in elderly persons. These studies are used to confirm a diagnosis, indicated by the history, physical examination, and by the clinician's knowledge of applied anatomy.

## MANAGEMENT

Therapy of tumors and infectious causes of low back pain is straightforward albeit often difficult. Appropriate management of vertebral compression fractures, lumbar spinal stenosis, and mechanical low back pain is less clear.

## Vertebral Compression Fractures

The traditional treatment for vertebral compression fractures is bed rest until the patient can roll and sit without too much pain, avoiding prolonged bed rest; analgesia; and extensor exercises when the patient can participate. Calcitonin does have some additional analgesic effect in the acute stage. Bracing is not needed, as neurological sequelae are extremely rare, and pain is the sole parameter of recovery.

There is much interest in the new techniques of vertebroplasty and kyphoplasty in the management of vertebral compression fractures. In a vertebroplasty, extension positioning opens the cleft within a fractured vertebral body, and methylmethacrylate cement is injected into the vertebral body and stabilizes the fracture in this position. In a kyphoplasty, an inflated bone balloon displaces vertebral trabeculae and elevates the superior end plate, allowing some restoration of the height of the vertebral body. The balloon is then removed and methylmethacrylate injected into the vertebral space.

Vertebroplasty is now used frequently for management of acute vertebral compression fractures. Although uncontrolled studies show encouraging relief of pain, the good natural history of the pain from compression fractures, and the potential complications and expense of this procedure, should lend caution to its use. Randomized controlled trials of this procedure are lacking. In a nonrandomized trial, the control patients were those who elected not to have the procedure. The pain score was significantly decreased in the vertebroplasty group as compared to the conservative therapy group in the first few days, but there were no significant differences in clinical outcomes at 6 weeks or 6 to 12 months. In a study of patients who had pain for greater than 1 year associated with compression fractures, kyphoplasty was performed on 40 patients, with 20 control patients who elected not to have the procedure. At 1 year, the patients with kyphoplasty had fewer new fractures, fewer back pain-related physicians' visits, and greater improvement in pain scores. Again, neither of these studies were randomized controlled trials. Most experts in this field suggest analgesics, calcitonin, and exercise in the acute phase, and moving on to vertebroplasty or kyphoplasty only if patients have persistent severe pain.

## Lumbar Spinal Stenosis

The decision to proceed with extensive back surgery on an older patient is always a difficult one. A recent Cochrane review of surgery for degenerative lumbar spondylosis found that "there is still insufficient evidence of the effectiveness of surgery to draw any firm conclusions." On the other hand, the Maine Lumbar Spinal study did show that spinal surgery can be effective. This study is an observational analysis of patients treated by orthopedic surgeons and neurosurgeons in community-based practices throughout Maine. This study followed patients treated surgically or medically, at the choice of the patient and surgeon. In this cohort, patients initially treated surgically demonstrated better outcomes in all measures than those treated nonsurgically. After 10 years, however, the relative difference between surgery and conservative therapy was no longer significant.

Another observational study from four surgical centers found that the most powerful predictors of the good outcomes of greater walking capacity, milder symptoms, and greater satisfaction were the patient's report of good or excellent health before surgery, as well as low cardiovascular comorbidity.

The choice of nonsurgical treatment is difficult, as there are few randomized controlled trials of these therapies. Epidural steroid injections have been used for more than 50 years for sciatica. While there are a number of uncontrolled studies suggesting a good outcome with these injections for lumbar spinal stenosis, randomized controlled trials have had inconsistent results.

Physical therapy is advocated for this condition, but there are few controlled trials to validate this approach, and little evidence to justify advocating one treatment regimen over another. In a recent study of a relatively small number of patients (58), a program, which included thrust and nonthrust manipulation of the spine and lower extremities, manual strengthening, muscle strengthening exercises, and a body-weight-supported treadmill ambulation program, had better short- and long-term results than a regimen of lumbar flexion exercises, performance of a progressive treadmill walking program, and subtherapeutic ultrasound.

A recent randomized controlled multicenter trial of an intraspinal process decompression system did find that patients who underwent this procedure had a statistically significant improvement in neurogenic intermittent claudication versus controls.

In summary, it does seem reasonable to treat patients with lumbar spinal stenosis with a conservative approach including epidural steroid injections, physical therapy, and perhaps manipulative therapy. If this approach does not give relief in a reasonable period of time, then a surgical approach, decompressing the stenotic canal space, should be strongly considered. Those patients with high self-reported health and low cardiovascular morbidity seem to achieve the best surgical results. The role of the locally implanted intraspinal process decompression system is yet to be determined.

### Mechanical Low Back Pain

The management of back pain in the older persons requires a logical, if not yet evidence based, approach to the patient, based on both an anatomical understanding of the most likely cause and precipitants of the patient's pain. For pain that is exacerbated by spinal movement (lying to sitting, bending, etc.), spinal instability is the most likely explanation, and thus attempts to stabilize the spine make the most sense. Stabilization may be achieved by isometric abdominal strengthening exercises, lumbar sacral corsets with metal stays, and back protection maneuvers (lifting with one's knees with the back straight, etc.). Spinal fusion is reserved for intractable cases of severe low back pain.

There is no therapy needed or indicated for DISH. The pain from sacral insufficiency fractures resolves in 4 to 6 weeks, and analgesics should suffice. Antiresorptive therapy for osteoporosis should be initiated to prevent future fractures.

Spontaneous sciatica improves without therapy in most older individuals. Epidural steroids may be helpful in the management of sciatica. Surgery should be considered only if the pain persists after 3 months of nonsurgical therapy.

Prolonged bed rest should be avoided in older persons, given the complications of this intervention in this age group. Patients should,

however, avoid those activities that appear to precipitate their pain. Firm corsets should be considered to allow patients to stay mobile and active.

Analgesics should not be spared in the management of pain, but these must be used with care. There is little evidence that anti-inflammatory drugs are any better than simple analgesics, and these are associated with a high incidence of complications in this age group. Pain that occurs only with movement often does not respond well to analgesics. While narcotics may be very helpful with severe pain, the patient should be watched closely for confusion and constipation. Adjunctive pain therapy, with such agents as tricyclic antidepressants with limited anticholinergic side effects (nortriptyline and desipramine) and gabapentin, may be helpful. The use of multiple analgesic classes may be effective at reducing pain while keeping side effects to a minimum.

# Primary Considerations in Managing the Older Patient with Foot Problems

*Arthur E. Helfand*

## INTRODUCTION

Diseases and disorders of foot and their related structures in the older patient represent a significant health concern. The immobility that results from local foot conditions and the focal complications of systemic diseases have a significant impact on individuals' ability to maintain their independence, retain a quality of life, and become financial concerns for society in general. Two important factors involved in the older patient's ability to remain as a vital part of society are a keen mind and the ability to retain their mobility through ambulation.

The human foot is both a static and a mobile organ of function. It provides support for the body at rest and during propulsion and ambulation. It supports our ability to walk upright, which is a specific characteristic of modern humans. The ability to remain mobile and functional in society is a key activity of daily living and may well be the primary catalyst to independence for the older population. The loss of the ability to walk owing to some foot problem or change not only produces physical limitations but also has a significant impact on the patient's mental, social, and economic status. On average, 90% of the adult population older than 65 years will demonstrate some evidence of foot pain that alters independent activity. Foot and related complications also represent a significant factor for many hospital admissions, especially related to complications associated with diabetic and vascular ulceration and infection.

The goal of this chapter is to provide the geriatric health-care provider with a foundation of knowledge about the aging foot in health and disease. There is an extensive and unique comprehensive podiatric assessment and a medical vocabulary associated with the field of podiatry. An example of a comprehensive assessment and a list of podiatric terms are provided as appendices available in the online version of this text.

## ETIOLOGICAL AND EPIDEMIOLOGICAL FACTORS

There are multiple factors that contribute to the etiology of foot problems in older patients. The primary factors include the aging process itself, years of use and abuse, repetitive stress, neglect, foot deformity, and the presence of multiple chronic diseases. Other significant factors include the degree of ambulation, limitation of activity, prior institutionalization, as well as prior and improper self-care. Foot problems are also affected by impaired vision, obesity, the inability to bend, and peripheral sensory loss. Local foot factors include altered biomechanics and pathomechanics, soft-tissue atrophy and plantar fat pad displacement, limited joint mobility, and contractures. Discomfort, pain (podalgia), ambulatory dysfunction, and pain when walking (pododynia dysbasia) become distressing and disabling.

In addition to factors of the host, agent factors that contribute to the development of foot conditions include hard flat surfaces for ambulation, trauma, foot-covering material and fabrication, foreign bodies, and foot-to-shoe-last incompatibilities. Environmental factors that affect the foot include customs and shoe styles; low income; adequate care and referral; nutrition; poor foot health education; cultural barriers; physical changes such as climate, flooring materials, and covering; the health-care system and insurance limitations; and the lack of school foot health programs.

## ANATOMY OF THE FOOT AND CHANGES RELATED TO AGE

Figure 122-1 illustrates the major anatomic components of the foot. The human foot is an organ that is static and mobile. It provides support for the body at rest and during propulsion and ambulation.

**FIGURE 122-1.** Anatomy of the foot. (Adapted with permission from Pedorthic Footwear Association. *Pedorthic Reference Guide*. Columbia, MD; 1992, 1999, 2006.)

The human foot from a morphological standpoint is basically a modified rectangle that is also three dimensional.

The human foot is complex. Each foot has 26 bones (together constituting one-fourth of the body's total), ossicles, ligaments, muscles, tendons, arteries, veins, nerves, and its covering of skin. The foot normally bears weight on a triangular base, with the long sides being the inner and outer longitudinal arches and the metatarsal arch consisting of the bias along the five metatarsal heads. Weight is transferred from the calcaneus to the fifth and first metatarsal heads initially.

The talus, with the tibia and fibula, comprises the ankle joint. The talus has no muscular attachments and thus with the tendons and muscles, which parallel it, controls activity. The talus articulates with the calcaneus. The Achilles tendon attaches to the superior-posterior segment and is a significant structure to foot function. The cuboid is anterior to the calcaneus and is rectangular in shape, which adds to the structural support to the foot. The navicular is anterior to the talus and is coin shaped, which also provides muscular attachments to aid in function and stabilization. Anterior to the navicular and lateral to the cuboid are three wedge-shaped bones called the first, second, and third (medial, middle, and lateral) cuneiforms. These help provide stability to the foot. These bones comprise the "rear foot." The arches do not fall. The foot does rotate, pronate, supinate, invert, evert, and elongate and changes structurally in relation to Wolff's law (bone is deposited and resorbed in accordance with the stresses placed upon it) and Davis's law (soft tissue mod-

els itself along its imposed demands). The mid-foot consists of the remaining five tarsal bones, that is, the navicular, cuboid, and three cuneiforms.

Anterior to the cuneiforms and cuboid bones are the five metatarsals. Each metatarsal consists of a base, a shaft, and a head. These are anatomically classed as long bones. Anterior to the metatarsals are the phalanges. Each of the lesser toes contains three phalanges. The first or great toe comprises two phalanges. The metatarsals and phalanges represent the forefoot.

Each osseous structure attaches by ligaments to another to form the joints of the foot. Their functional role is to maintain proximity by keeping the segments of bone articulating with each other. Their properties are strength and rigidity with limited elasticity, which permit the joints to maintain some degree of motion or movement. The basic change that occurs in aging bone is a loss of calcium (osteopenia and/or osteoporosis) and, in foot ligaments, the transition from elasticity to rigidity. The lateral longitudinal arch is formed by the calcaneus, cuboid, fourth, and fifth metatarsals. It is the lower structural arch. The medial longitudinal arch is formed by the calcaneus, talus, navicular, three cuneiforms, and the first, second, and third metatarsals. It is higher with its summit at the head of the talus and navicular. The pitch of the calcaneus (the angle formed by the plantar surface of the calcaneus and plane of support) determines, to a great degree, the height of that segment. The transverse arches of the foot include the posterior metatarsal arch, formed by the bases of the metatarsals and is reasonably firm, and the anterior metatarsal

arch, formed by the five metatarsal heads, is flexible, and flattens during gait phases, with weight bearing, pronation, and supination.

The most predominant and significant membranous covering of the foot is known as the plantar fascia. It attaches to the plantar posterior segment of the calcaneus or tuberosity and fans out anteriorly to the metatarsal area. The plantar fascia covers all of the foot muscles, all of the ligaments, and all of the bones on the plantar aspect of the foot. It acts as a spring to aid in function as well as offers protection to plantar structures. It is a very elastic or flexible mass in youth, which becomes wasted and rigid with age. The dorsum of the foot does not have a strong fascial attachment. Most of the structures are subcutaneous.

The muscles that control the major functions of the foot have their origin in the leg. The posterior muscles include the tibialis posterior, flexor digitorum longus, flexor hallucis longus, plantaris, and calcaneal or Achilles tendon (formed by the gastrocnemius and soleus muscles). The lateral muscles include the peroneus longus and peroneus brevis. The anterior muscles include the tibialis anterior, extensor hallucis longus, and extensor digitorum longus. As individuals age and chronic disease becomes evident, there is a decrease in muscle strength that can result in ambulatory dysfunction, imbalance, foot drop, and a higher risk for falls.

The muscle on the dorsum of the foot is the extensor digitorum brevis. The muscles on the plantar surface of the foot are covered by the plantar fascia and are organized in four layers from superficial to deep. The muscles of the deepest fourth layer include the dorsal interossei (four), plantar interossei (four), and the tendons of the peroneus longus and tibialis posterior muscles. It is the atrophy of the interossei muscles that is a major factor in the development of hammertoes in the aging patient.

The nerves that control the foot include the lateral sural cutaneous, superficial and deep fibular (peroneal), medial dorsal cutaneous, dorsal digital, tibial, lateral calcaneal, medial plantar, lateral plantar, and saphenous nerves.

The arterial supply to the foot follows the femoral artery, to the popliteal artery, and divides to become the anterior and posterior tibial arteries. The anterior tibial artery becomes the dorsalis pedis artery on the dorsum of the foot, whose terminal branches are the dorsal metatarsal and dorsal digital arteries. The posterior tibial artery becomes the medial and lateral plantar arteries in the foot. The lateral calcaneal artery supplies the lateral segment of the calcaneal area of the foot. The venous return includes the dorsal venous arch, plantar cutaneous venous plexus, medial and lateral plantar veins, and the greater and lesser saphenous veins.

The skin of the foot is made up of fitted, flexible, elastic inner dermis, covered by a much less sensitive outer epidermis. The skin varies in thickness from one-half a millimeter (as in the eyelid) to 4 or 5 mm, in the sole of the foot. The skin of the foot undergoes many changes during the aging process. It becomes thinner, even parchment like; loses its elasticity, usually atrophies; and loses hair. It loses its hydration or water content because there is generally less perspiration and lubrication. The skin loses its suppleness, becomes brittle and dry, and injures easily. This condition, accompanied by a diminished blood supply, can be quite serious.

The normal toenail includes the nail matrix, nail bed, nail plate, lunula, eponychium, cuticle, and nail folds. The nail plate is a sheet of keratin and is important in clinical medicine, as it reflects the health events of the previous months. The nail plate grows slowly

forward until it breaks free of the nail bed at the free edge. The tissue below the free edge is termed the hyponychium. The matrix is the area under the proximal nail fold, cuticle, and lunula. The arterial supply to the nail bed stems from small arterial branches from the dorsal and plantar anastomoses. Nail growth is affected by age, trauma, chemicals, environment, and disease.

### Foot Changes with Age and Disease

The skin is one of the first structures to demonstrate change. There is a loss of hair below the knee and on the dorsum of the foot and toes. Atrophy follows with the skin appearing parchment like and xerotic. Brownish pigmentations are common and related to the deposition of hemosiderin. Hyperkeratotic lesions are associated with keratin dysfunction (hypertrophy and hyperplasia), with a residual to repetitive pressure, with atrophy of the subcutaneous soft tissue, and/or as space replacement as the body attempts to adjust to the changing stress placed on the foot.

Toenails undergo degenerative trophic changes (onychopathy), thickening (onychauxis and onychogryphosis), and/or longitudinal ridging (onychorrhaxis) related to repeated microtrauma, disease, and nutritional impairment. Deformities of the toenails become more pronounced and complicated by xerotic changes in the periungual nail folds as onychophosis (hyperkeratosis) and tinea unguium (onychomycosis). These conditions are usually longstanding, chronic, and very common in the elderly and, in the case of onychomycosis, present a constant focus of infection.

Progressive loss of muscle mass and atrophy of soft tissue decreases function and a lack of activity that increases the susceptibility of the foot to injury, so that even minor trauma can result in a fracture and a marked limitation of activity. Atrophy of the interossei is a precipitating factor in the development of digital contractures (hammer toes), metatarsal prolapse, atrophy, and displacement of the plantar fat pad.

Peripheral vascular disease and arterial insufficiency produce trophic changes, rest pain, intermittent claudication, coldness, and color variations, such as rubor and cyanosis. There may be a loss of sensation and other changes related to neuropathy. The presence of hemorrhage subungually or in subhyperkeratotic tissue indicates marked vascular disease.

## CLINICAL ASSESSMENT AND MEDICARE CONSIDERATIONS

The podiatrist provides clinical management based on important principles of podogeriatric assessment; recognizing primary changes in the aging foot; identifying complications related to systemic diseases and, in particular, diabetes mellitus and peripheral arterial occlusive disease; risk stratification; understanding Medicare reimbursement policies, serving as the patient's advocate; and being knowledgeable about primary management procedures. Given the many risk factors for foot diseases and conditions in older adults, specialized foot care is often required. Reasons to refer to a podiatrist for specialized foot care are listed in [Table 122-1](#).

The Pennsylvania Department of Health's Diabetes Prevention and Control Program working with Temple University's School of Podiatric Medicine's Department of Community Health, Aging, and Health Policy and the Pennsylvania Diabetes Academy developed

**TABLE 122-1****Reasons to Refer to a Podiatrist**

- Signs suggesting generalized disease that include neuropathy, vascular disease infection, etc., and focal neoplastic disease
- In those cases where concomitant therapy is indicated
- Where initial management is not effective
- In the presence of skin, toenail, postural and structural deformities of the feet, and related structures
- In the presence of diabetes mellitus, neurosensory, peripheral vascular, and other risk diseases
- In the presence of foot problems combined with walking problems and/or a history of falls
- Where orthotics are indicated
- If the patient is unable to obtain and/or provide foot care
- If the patient complains of foot problems or has specific questions about care including information on footwear

a Comprehensive Clinical Podogeriatric and Chronic Diseases Assessment Protocol (Helfand Index—see online appendix). The format provides a methodology to assess foot problems associated with aging and chronic diseases, stratify those patients most at risk to develop complications, maintain a surveillance instrument related to patient care, and provide a means to evaluate data for outcome measurement, which would be valid, accurate, consistent, and relevant. The protocol instrument served as an adjunct to develop prevention and management programs for individual patients and their communities and as a component for comprehensive geriatric assessment. The protocol's application includes elements of primary, secondary, and tertiary prevention and stresses a need for patient and professional education as well as the need for appropriate multidisciplinary patient management.

As a part of the current Medicare regulations for coverage, there are a number of diseases and disorders that have been categorized as special risk conditions that qualify for coverage for “routine foot care.” In Medicare terms, primary foot care refers to the débridement of hyperkeratotic lesions (heloma and tyloma) and hypertrophic onychodystrophy. Those patients who demonstrate neurosensory and vascular deficits and who present with clinical findings represent an exemption to the exclusion and become eligible for coverage, within utilization guidelines. Medicare has indicated that although not intended as a comprehensive list, the following metabolic, neurological, and peripheral vascular diseases commonly represent the underlying conditions that might justify coverage for “routine foot care.” Table 122-2 lists the primary diseases and disorders that meet current Medicare requirements for routine foot care. This list is not comprehensive but illustrates major conditions.

The podiatrist obtains a history of present illness and past medical history and screens for risk conditions. The foot examination includes a dermatological, an orthopedic, a vascular, and a neurological examination. A full assessment is described in the online appendix and is summarized briefly here.

The basic dermatologic evaluation of the foot includes, but is not limited to, the following: focal hyperkeratotic lesions, onychia, bacterial infection, ulceration, onychomycosis, onychodystrophy, onychocryptosis, cyanosis, xerosis, tinea pedis, verruca, hematoma, rubor, discoloration, and preulcerative changes.

Coverage for the débridement of onychomycosis also includes documentation of mycosis/dystrophy causing secondary infection

**TABLE 122-2****Conditions That Medicare Considers Qualifying for Routine Foot Care**

Amyotrophic lateral sclerosis (ALS)
Arteriosclerosis obliterans (A.S.O., arteriosclerosis of the extremities, and occlusive peripheral arteriosclerosis)
Arteritis of the feet
Buerger's disease (thromboangiitis obliterans)
Chronic indurated cellulitis
Chronic thrombophlebitis*
Chronic venous insufficiency
Diabetes mellitus*
Intractable edema—secondary to a specific disease (e.g., congestive heart failure, kidney disease, and hypothyroidism)
Lymphedema—secondary to a specific disease (e.g., Milroy's disease and malignancy)
Peripheral neuropathies involving the feet
Associated with malnutrition and vitamin deficiency*
Malnutrition (general and pellagra)
Alcoholism
Malabsorption (celiac disease and tropical sprue)
Pernicious anemia
Associated with carcinoma*
Associated with diabetes mellitus*
Associated with drugs and toxins*
Associated with multiple sclerosis*
Associated with uremia (chronic renal disease)*
Associated with traumatic injury
Associated with leprosy or neurosyphilis
Associated with hereditary disorders
Hereditary sensory radicular neuropathy
Angiokeratoma corporis diffusum (Fabry's)
Amyloid neuropathy
Peripheral vascular disease
Raynaud's disease

\*These conditions also must have been seen by their medical physician for management within 6 months prior to their foot care management.

and/or pain, which results or would result in marked limitation of ambulation. The specific clinical findings include discoloration, hypertrophy, subungual debris, onycholysis, secondary infection, limitation of ambulation, and pain. In addition, evidence of dystrophy, onychodysplasia, onychia, and onychogryphosis are also frequently noted.

The initial foot orthopedic assessment includes an evaluation of the primary deformities related to biomechanical and pathomechanical changes that commonly cause pain and contribute to ambulatory dysfunction. Specific conditions are listed in online appendix. The foot type, muscle strength, and ranges of motion should be noted.

There should be some identification of gait and movement changes, including the use of mobility aids and if the patient is able to reach and see their feet. An evaluation of footwear is also performed. (See section “Footwear and Orthoses.”)

As part of the assessment, the patient is evaluated for biomechanical risk for foot ulcers. Factors that increase pressure and stress should be considered. Those factors include body mass, gait (particularly antalgic), ambulatory speed, evidence of repetitive micro tissue trauma, change in weight diffusion, and weight dispersion.

Imbalance is the force on the foot that produces abnormal stresses. These factors include force (alteration in physical condition, either shape or position), compression stress (one force moves toward another), tensile stress (a pulling away of one part against another), shearing stress (a sliding or gliding of one part on the other), friction (the force needed to overcome resistance and usually associated with a sheering stress), elasticity (weight diffusion and weight dispersion), and fluid pressure (soft-tissue adaptation and conformity to stress).

The primary peripheral vascular assessment evaluation should include coldness, trophic changes, and palpation of the dorsalis pedis and posterior tibial pulses. If pulses are not present, the popliteal and femoral pulses should be identified. A history of night cramps, intermittent claudication and deep venous thrombosis, edema, atrophy, varicosities, and atrophy should be noted. Any amputation or partial amputation should be noted and the etiology identified, particularly related to diabetes mellitus, arterial occlusion, and/or infection.

The primary neurological assessment should include the following: Achilles, patellar, and superficial plantar reflexes; vibratory sense (pallesthesia); response to a loss of protective sensation using a 5.07 (10 g) nylon monofilament at bilateral and multiple sites; sharp, dull, and light touch reaction; joint position; burning; two-point discrimination; and related findings. The response to heat, cold, pain, and two-point discrimination are also important considerations. A Tip Therm can measure temperature sensation.

For Medicare purposes, the assessment for the evaluation and management of a diabetic patient with diabetic sensory neuropathy, resulting in a loss of protective sensation must include the criteria listed in Table 122-3.

The final segment of the assessment process is providing an initial impression and/or diagnosis and indicated referrals for management to include podiatric referral, medical specialty referral, patient education, special footwear, orthotics, vascular studies, clinical laboratory referrals, radiographic and other imaging studies, prescriptions as indicated for the management of diseases, and disorders of the foot and its related structures.

All of the assessment components including the focal diseases and disorders of the foot, its related structures, and the pedal manifestations and complications of acute and chronic diseases represent the multiple covariants involved in managing and treating older patients with foot conditions. One mandatory legal key to management includes the requirement for licensure by the individual providing and prescribing indicated medical and surgical care components.

**TABLE 122-3**

**Medicare Coverage for Evaluation of the Patient with Loss of Protective Sensation (LOPS)**

1. A diagnosis of LOPS
2. A patient history of diabetes mellitus
3. A physical examination consisting of findings regarding at least the following elements:
  - a. Visual inspection of the forefoot, hindfoot, and toe web spaces
  - b. Evaluation of protective sensation
  - c. Evaluation of foot structure and biomechanics
  - d. Evaluation of vascular status
  - e. Evaluation of skin integrity
  - f. Evaluation and recommendation of footwear
4. Patient education

## PRIMARY MANAGEMENT—GUIDELINES AND PRINCIPLES

The management of foot problems in the older patient requires a review of their etiology, symptoms, signs, and clinical manifestations, including related diagnostic studies. The covariant complications, sequelae, relevant treatment, prognosis, and the overall management of the geriatric patient should reflect a reasonable approach that will reduce pain, improve the functional capacity of the patient, maintain that restored function, and provide for the comfort of the patient in activities of daily living and permit the individual to live life to the end of life. Management strategies include radiographs and other imaging studies, nonsteroidal anti-inflammatory drugs, local steroid injections, the use of physical modalities, exercise, and shoe modifications.

## SKIN

A concern for older patients is dryness of the skin and/or xerosis. The etiology is as a result of a lack of hydration and lubrication and, to some degree, is a part of the normal aging and degenerative process. Keratin dysfunction can be associated with xerosis. Fissures develop as a result of stress and repetitive microtrauma and, when present, usually on the heel, present a potential hazard for the development of ulceration. Initial management includes the use of an emollient following hydration of the skin. Twenty percent urea is helpful to aid as a mild keratolytic. Creams and ointments containing lanolin can be used as long as the patient does not have an allergy to wool. A plastic or Styrofoam heel cup can be of assistance in minimizing trauma to the heel, reducing the potential for complications. Pruritus is common in the older adult patient and is usually more severe in the colder weather. It is related to dryness, scaliness, decreased skin secretions, keratin dysfunction, environmental changes, and defatting of the skin, which is usually precipitated by the constant use of hot foot soaks. The patient will scratch with excoriations noted on examination. Chronic tinea and allergic, neurogenic, and/or emotional dermatoses should be considered as part of the differential diagnosis and treated accordingly. Management consists of hydration, lubrication, protection, topical steroids if indicated, and judicious use of antihistamines in minimal doses to minimize the itching, which is usually the primary complaint. Particular care should be taken in the male patient with a history of prostatic hypertrophy. If excoriations are infected, proper antibiotic therapy should be instituted.

Hyperhidrosis and/or bromidrosis when present should be managed based on the etiology. If local, measures should be undertaken to control the excessive perspiration and odor. Hydrogen peroxide, isopropyl alcohol, and astringents may be used topically. Neomycin powder will help control the odor by reducing the bacterial decomposition of perspiration. Recommendations on footwear and stocking modifications should be considered. Particular care should be provided on colder climates, as dampness can predispose a patient to the vasospastic effects of cold.

Contact dermatitis may be the result of reactions to chemicals used in shoe construction, footwear fabrics, and/or stockings. Tannic acid, nickel, and synthetic fabrics are the common primary irritants. The skin lesions are usually well demarcated, self-limiting and usually bilateral in distributions. Skin testing can be employed

to identify the primary irritant. The general principles of management include removing the cause, mild wet dressings, and the use of topical steroids.

Stasis dermatitis is the residual of venous insufficiency and chronic ulceration. It is more common in patients with dependent edema. Hemosiderin deposition may also be noted with discoloration and induration. Management locally consists of elevation, mild wet dressings, topical steroids, antibiotics as indicated, and supportive measures needed in the management of venous disease. Pyodermias and superficial bacterial infections should be managed locally in a similar manner and, when present with tinea, treatment directed toward both etiologies.

Tinea pedis in the older patient may be an extension of onychomycosis that serves as a focus of infection. It is more common in warmer climate and related to hyperhidrosis. Chronic keratotic tinea (dry squamous type) is more prevalent in older patients, with scales forming a moccasin pattern on the foot. Interdigital infection demonstrates pruritus, scaling, and fissuring and may macerate with excessive perspiration. The acute vesicular form demonstrates bullous lesions that can rupture and produce raw sensitive skin, which makes the patient more prone to secondary bacterial infection. Poor foot hygiene and the inability to bend or see their feet may delay the patients from seeking care until the condition becomes clinically significant and cellulitis is present. In a patient with diabetes or peripheral arterial disease, this complication can be limb threatening. There are a variety of topical medications, such as terbinafine, clotrimazole, butenafine, miconazole, ketoconazole, ciclopirox, naftifine, econazole, sertaconazole, etc., that can usually control this fungal infection. Solutions, powders, and/or creams (water washable or miscible) are best when the patient is unable to easily remove an ointment base. Other common dermatological manifestations that can be demonstrated in the older patient include atopic dermatitis, nummular eczema, neurodermatitis, lichen planus, and psoriasis.

Solitary and/or hemorrhagic bullae are related to shoe trauma and friction or are related to systemic diseases such as diabetes mellitus. Management is directed toward eliminating pressure, protection, and drainage when appropriate. Supportive dressings and shoe modifications should be used as indicated. Gait changes in the older patient magnify many of the foot-to-shoe-last incompatibilities that can result in local foot lesions. Hemorrhagic bullae related to diabetes mellitus are usually indicators of pending ulceration.

Hyperkeratotic lesions, such as tyloma (callous) and heloma (corn), and their varieties, such as hard (*durum*), soft (*molle*), vascular (*vasculare*), neurofibrous (*neurofibrosum*), seed (*miliare*), and subungual, are usually painful and secondary to repetitive stress, bony abnormality, deformity, keratin dysfunction, and a lack of hydration and lubrication to the skin. Intractable keratoma, eccrine poroma, porokeratosis, and verruca must be differentiated from these keratotic lesions, although each may present initially as a hyperkeratotic area. The biomechanical and pathomechanical factors that help create these problems are those associated with stress, i.e., compressive, tensile, and/or shearing. The loss of soft tissue as part of the aging process and atrophy of the plantar fat pad increase pain and limit ambulation. Contractures, gait changes, deformities, and the residuals of arthritis are all additional factors that need to be considered in management. The incompatibility of the foot type (inflare, straight, or outflare) to the shoe last is another factor to be considered. It is important to recognize that there is usually not one factor,

but a multiplicity of conditions including skin tone and elasticity, which results in the development of painful keratotic lesions in the elderly. Their management is not routine, and the term management signifies a period of continuing care, as with any other chronic condition in the elderly, to provide for ambulation and comfort.

The common sites for the development of hyperkeratotic lesions include dorsal or distal digital, plantar metatarsal heads, marginal calcaneal, and with deformities such as hammertoes, digital rotations, contractures, hallux valgus, bunion, and/or tailor's bunion (bunionette). These deformities are precipitating factors to foot-to-shoe-last incompatibilities that produce excessive pressure on segments of the foot. Management and treatment should be directed toward the functional needs of the patients and daily living activities. Considerations include débridement, padding, emollients, shoe modifications, last changes, orthoses, and surgical revision as indicated. Materials to provide soft-tissue replacement, such as Plastazote, Professional Protective Technology (PPT), foam, and silicone, produce weight dispersion diffusion as indicated. It is also important to recognize that keratotic lesions of long standing represent a hyperplastic and hypertrophic pathology. Even when weight bearing is removed, these tend to persist for some time. In a sense, hyperkeratotic lesions are a form of body protection to pressure and are symptoms of an abnormal condition. If permitted to remain untreated, enlarge, and condense, these become primary irritants. With pressure such as weight bearing and ambulation, these produce local avascularity, which can precipitate ulceration and their resultant sequelae. Ulcers in the foot usually begin with subkeratotic hemorrhage. Once débrided and managed properly, these usually heal but may be repetitive, unless adequate measures are instituted to reduce the pressure to the localized areas of stress and ulceration. The application of a topical emollient is also an important home or self-care measure. Even with all measures, the problem may persist because of residual deformity and systemic diseases, such as diabetes mellitus. Thus, management and monitoring are similar to any other chronic condition in the older adult and can have a significant impact on the social elements of society, for, without mobility and/or ambulation, the older patient is clearly institutionalized in some form.

## TOENAILS

The onychial changes that occur with aging are the result of dystrophic changes, systemic complications, infection, long-term disorders, injury, and/or functional modification. Onychia is an inflammation involving the posterior nail wall and nail bed. It is usually precipitated by local trauma or pressure and a complication of systemic diseases, such as diabetes mellitus, and is the primary clinical sign of impending infection. Mild erythema, swelling, and pain are the most prevalent findings. Treatment should be directed to removing all pressure from the area and the use of tepid saline compresses. Topical antibiotics can be used as a dressing. Lambs wool, tube foam, or shoe modification should be considered to reduce pressure to the toe and nail. If the onychia is not treated early, paronychia may develop with significant infection and abscess of the posterior nail wall. The infection progresses proximally and deeper structures become involved. The potential for osteomyelitis is greater in the presence of diabetes mellitus and vascular insufficiency. Necrosis, gangrene, and the potential for amputation become reality.

Management includes establishing drainage, culture and sensitivity, radiographs and scans as appropriate, saline compresses, and appropriate systemic antibiotics. Follow-up is essential to prevent cellulitis.

Deformities of the toenails are the result of repeated microtrauma, degenerative changes, and/or disease. The continued friction of the toenails over the years, against the inferior toe box of the shoe, is sufficient trauma to produce dystrophic change. The initial thickening is termed onychauxis. Onychorrhexis with accentuation of normal ridging, trophic changes, and longitudinal striations are onychopathic when related to disease and/or nutritional etiology. When débridement is not completed on a periodic basis, the nail structure elongates, continues to thicken, and becomes deformed with shoe pressure. Onychogryphosis or “ram’s horn nail” is usually complicated by fungal infection. The resultant disability can prevent the elderly from wearing shoes. Pain is usually associated with shoe pressure and the deformity. Traumatic avulsion of the nail is a complication. The exaggerated curvature (onychodysplasia pincer toenails) may even penetrate the skin, with resultant infection and ulceration. Management should be directed toward periodic débridement of the onychial structures, both in length and in thickness, with as little trauma as possible. The degree of onycholysis (freeing of the nail from the anterior edge) and onychoschizia (splitting) helps determine the level of débridement. With the excess pressure of deformity, the nail grooves tend to become onychophosed (keratotic). Débridement and the use of mild keratolytics and emollients, such as ammonium lactate and 10% to 20% urea preparations provide some measure of home care for the patient. With onycholysis, subungual debris and keratosis develop, which increases discomfort and may generate pain. However, the patient may not present complaints of pain and discomfort caused by a loss of protective sensation.

Patients with neurosensory and vascular deficits usually demonstrate some form of onychodystrophy, such as onychorrhexis, onychophosis, deformity, hypertrophy, incurvation or involution, subungual hemorrhage (nontraumatic), onycholysis (freeing from the distal segment), onychomadesis (freeing from the proximal segment), autoavulsion, and onychomycosis. These individuals are at greater risk of infection, necrosis, gangrene, and possible amputation.

The most common nonbacterial infection of the toenails is onychomycosis. It is defined as a chronic, communicable disease. Culture, KOH microscopic examination, and the clinical presentation are of diagnostic importance. The clinical forms include distal-lateral subungual, white superficial, proximal subungual, total dystrophic, and candida onychomycosis. The superficial white form presents with fungal growth on the superior surface of the nail plate. Left untreated, invasion of the nail bed occurs with trophic changes. With the distal-lateral, proximal, and total dystrophic forms, the nail bed is primarily infected, with the possibility of paronychia and subsequent dystrophy. Onycholysis (freeing of the nail from the distal edge) and subungual keratosis occur owing to the long-standing chronic nature of this condition in older patients. The posterior nail wall and eponychium demonstrate xerotic changes and hypertrophy, as does the nail plate. Candida is most common in patients with some form of chronic mucocutaneous manifestation.

The older patient usually presents with a chronic infection, involving one or more of the nail plates. The entire thickness of the nail plates is usually involved with resultant hypertrophy and deformity because of the delay in management. Pain may be present with paronychia or deformity or diminished because of sensory deficits.

Mycotic onychia; paronychia; autoavulsion; subungual hemorrhage; a foul, musty odor; and degeneration of the nail plate are common findings. The options for treatment include oral antifungals such as terbinafine, itraconazole, and fluconazole and topical medications such as ciclopirox. A 50% urea-lactic acid combination in gel form will assist to chemically débride the infected nail structures. As a result of the chronicity of onychomycosis, matrix involvement enhances hypertrophy and deformity. Multiple prescriptions, diabetes mellitus, and vascular impairment may limit systemic management. Periodic débridement, topical urea, and topical fungicides are usually indicated for continuing management. Surgical excision may be indicated with excessive pain, as indicated. Onychomycosis must be viewed as a chronic infectious disease, deserving management as any other chronic condition, such as hypertension and/or diabetes mellitus.

Ingrown toenails (onychocryptosis) in the older patient are associated with deformity, trauma, and inappropriate self-care. When the nail penetrates the skin, an abscess and an infection result. If not managed early, periungual ulcerative granulation tissue may form, which increases the risk of serious complications. Deformity and involution (onychodysplasia) also increase the potential for penetration. In the early stage, a segment of the nail can easily be removed using an English nail splitter and an onychotome, drainage established, saline compresses employed, and antibiotics used as indicated. Measures should be taken to prevent the problem in the future. When ulcerative granulation tissue is present, excision, fulguration, desiccation, or the use of caustics is employed to reduce the granulation tissue. In all cases, removal of the penetrating nail is primary. Partial excision of the nail plate and matrix can be completed using regional anesthesia, followed by chemical cautery of the matrix area with CP Phenol. With this procedure, postoperative management includes isopropyl alcohol Zcompresses and topical steroid solutions. With aging, changes in the nail plate may occur, which, when viewed distally, appear “C” shaped (onychodysplasia). This abnormal curvature is incurvation or involution. When present, the pressure of the nail plate on the nail bed and folds produces onychophosis (hyperkeratosis in the nail folds) and discomfort, with complaints similar to an ingrown toenail. The condition may precipitate pressure ulcerations and infection. When this condition is severe, early and total removal of the nail plate and matrix should be considered to avoid complications as the patient ages.

Subungual heloma, when present, is usually associated with a subungual exostosis, spur or hypertrophy of the tufted end of the distal phalanx. Initial treatment consists of débridement and protection of the toe involved, as well as the use of a shoe with a high toe box. Surgical excision of the osseous deformity may be indicated if the condition cannot be managed in a conservative manner. A primary differential diagnosis is subungual melanoma that requires biopsy and prompt management. In all cases of suspected bone pathology, radiographs properly positioned to isolate the area of pathology will provide an appropriate diagnostic approach.

There are multiple onychopathies that occur in the older adult, which are associated with cutaneous and systemic disease. The most common ones include, but are not limited to, psoriasis, mucocutaneous lichen planus, anemia, diabetes mellitus, chronic obstructive pulmonary disease, myocardial infarction, Raynaud’s disease, hyperthyroidism, hypothyroidism, vasospastic states, endocarditis, cardiac disease, hypertension, malignancy, rheumatoid arthritis, cirrhosis,

alcoholism, peripheral arterial diseases, systemic medications, and local contact agents.

## PATHOMECHANICS AND BIOMECHANICS

The human foot is primarily a rigid structure that supports heavy physical workloads that are static and dynamic. The foot itself is shaped like a modified rectangle and bears static forces in a triangular pattern. The transmission of weight and force starts at heel strike, proceeds anteriorly along the lateral segment of the foot, medially across the metatarsal heads, to the first metatarsal segment for the push-off phase of the gait cycle. The social activities of life, occupation, and disease produce morphological variations in both the structure and the function of the foot, in keeping with Wolff's and Davis' law, as the body adapts to the stress placed on it. The environment itself, that is, flat and hard surfaces, force the foot to absorb shock, creating prolonged periods of micro and repeated trauma.

As individuals age the problems magnify, by changing stance, gait, and the ambulatory status of the elderly. The primary considerations include balance; a shuffling gait; broadening the base of gait and stance; reduced toe clearance; changes related to hip, knee flexion, degenerative joint disease, and obesity; as well as specific gait change including circumduction, festinating, steppage, cerebellar, and sensory ataxic gait. Pain, slow speed, short step length, and a narrow stride and width are also important factors. The stress created on the foot and the inability of the patient to adapt to stress produces inflammatory changes in bone and soft tissue, such as osteitis, periostitis, synovitis, capsulitis, fasciitis, myositis, fibrositis, neuritis, and arthritis. Structural modifications of an external nature need to be considered along with the use of physical modalities and appropriate medication as indicated.

Foot problems of a pathomechanical or biomechanical nature usually arise from the interaction between normal morphological variations, the capacity to adapt to stress, and the stressors acting on the foot itself. Morphologic variations may be intrinsic, i.e., within the foot itself, or extrinsic, such as changes in the physiologic relationship of the legs, knees, thigh, hip, and back of the human foot. These changes may be bone and/or soft tissue. The common intrinsic changes include elements such as a hypermobile segment, pes cavus, atrophy of the interossei muscles producing *digitus flexus* or hammer toes, and the development of *hallux valgus*, or the so-called "bunion deformity."

The management of pathomechanical and/or biomechanical disorders should be directed toward eliminating the cause and redistributing weight to nonpainful areas of the foot, through weight diffusion and weight dispersion. In addition, the variations in an individual's capacity to adapt to change, particularly when surgical revision is considered, are significant. The primary treatment goals are to relieve pain, to restore maximum function, and to maintain that restored function once achieved. Bilateral weight- and non-weight-bearing radiographic and imaging studies are indicated as patient management needs are considered from both a static and a dynamic phase.

The ability to adapt to stress is dependent on two major systems, the neuromuscular and vascular, which may be significantly comprised as part of the aging process and disease. The mechanical stressors are two in nature. The first is macrotrauma, which results from sudden injury, such as a fall, resulting in a fracture. The second

might be termed microtrauma, which accounts for the hundreds of thousands of repetitive injuries to the foot from occupational activities, obesity, poor stance, modified gait, and foot-to-shoe-last incompatibilities. The systemic stressors are those factors affecting the foot as complications of diseases such as diabetes mellitus, all forms of arthritis, arteriosclerosis, etc. It is also obvious that the foot cannot be divorced or segmented from the body, nor can the foot itself be segmented. It is thus evident that the foot must be considered as a total "end" organ of locomotion and that the resultant mechanical, rotational, and/or positional changes comprise parts of a syndrome or a chain of events of a chronic and progressive process. Once a link in the chain breaks, every effort must be made to prevent further damage and minimize the associated complications of chronic disease. As such, chronic foot problems take years to develop and become significant when these create pain and affect ambulation, the activities of daily living, and the quality of life.

## FOOT ORTHOPEDICS

There are a variety of residual foot deformities that can be present in multiple combinations in the older adult. These include, but are not limited to, *hallux valgus*, *hallux varus*, splay foot, *hallux flexus*, *digitus flexus* (hammer toe), *digitus quinti varus*, overlapping toes, underriding toes, prolapsed metatarsals, *pes cavus*, *pes planus*, pronation, *hallux limitus*, and *hallux rigidus*. Many of these changes are the result of and are related to degenerative joint disease (osteoarthritis), rheumatoid, and gouty arthritic changes.

Conservative modalities include shoe last changes, shoe modifications, orthoses, digital braces, physical medicine, exercises, and mild analgesics for pain. Surgical revision, arthroplasty, and joint replacement are also treatment options that should be considered with chronic pain, limitation of the quality of life, and as indicated. Age itself should not be the singular indication of contraindication for surgical consideration. Other factors must also be given to the patient's overall health, medical condition, mental status, and the ability to adapt to change in relation to ambulation, for to have an anatomically corrected joint and a patient who cannot ambulate without pain defeats the treatment needs of the elderly. Foot conditions need to be managed medically, physically, mechanically, and surgically, to keep the patient ambulatory and pain free.

Fractures of the foot and toes may be the result of direct trauma and/or stress, related to bone loss. Most uncomplicated and closed fractures that are in good position should be appropriately immobilized as indicated. Open fractures need surgical management. Digital fractures can usually be managed with silicone mold and surgical shoes and supportive dressings, as long as the joints distally and proximally are immobilized.

## FOOTWEAR AND ORTHOSES

See [Figure 122-2](#) for an overview of the anatomy of the shoe. Shoe selection should be based on the functional needs of the patient, a shoe last that conforms to the foot, the complications of other diseases and disorders, shoe size that is based on internal and external measurements, and fabrication of materials that will provide protection and support and permit maximum foot function. For example,

**FIGURE 122-2.** Components of a shoe. (Adapted with permission from *Pedorthic Footwear Association. Pedorthic Reference Guide. Columbia, MD; 1992, 1999, 2006.*)

the stylish dress shoe has different social needs than a shoe for daily use and for walking and exercise.

For the most part, a shoe that provides some flexibility to allow for free mobility usually feels most comfortable unless there are deformities or other special conditions that require rigidity. The foot is basically a modified rectangle; thus, a quadrangular shoe would be the best last, to conform to the shape of the foot. With deformity, special lasts may be indicated. The shoe should have an acceptable heel height to avoid forcing the toes into the end of the shoe. The material of construction should be porous to allow for the evaporation of moisture. There should be some degree of moderate sole friction to avoid slippery and adhesive sole material. This consideration also needs to be evaluated in comparison to flooring surfaces and, in particular, high pile carpets. The shoe should be lightweight to reduce energy expenditure on the part of the patient. The wearing of shoes should be socially acceptable in appearance to the patient. Cost is a factor, and a reasonable price for the particular patient becomes essential given the limited incomes of older patients. For long-term care patients, these suggestions may well change for the incontinent nursing home patient; a soft washable foot covering may be the most practical solution.

Shoes are constructed over a last or model of the foot. The last may be inflare, straight, or outflare. It is essential that the flare of the foot match the flare of the shoe to avoid a foot-to-shoe-last incompatibility and permit abnormal pressure to develop. Shoe generally consist of an outsole, heel, rand, counter, quarter, vamp, back stay, quarter, filler, lining, upper, tip, toe cap, foxing, welting, insole, sock lining, tongue, eyelet, and laces or other closure.

Some of the basic shoe types include standard lasts, basic orthopedic shoe with its long counter and Thomas Heel, rigid shank shoes, high top lasts, extra-depth shoes, shoes with moldable interiors, custom-molded and fabricated footwear, and athletic footwear.

The basic shoe modifications that may be used for the older patient include medial (for valgus deformity) and lateral (for varus) heel seat wedges. Sole wedges are for alignment and support and to

help maintain a better gait pattern. Calcaneal wedges limit motion and alter gait. Metatarsal bars are used to shift or transfer weight from the metatarsal heads to the shaft. In addition, the bar produces a moderate heel rise to push off without additional metatarsal head weight bearing. Examples include the Denver, Hauser, Comma bar, etc. The Thomas Heel and long counter provide improved balance, increase calcaneal support, and increase the stability of the shank area. Long shoe counters are used to increase mid-foot support and control foot direction. Heel flares increase ankle stability either medially or laterally. The heel may be reversed to provide lateral stability.

A shank filler provides for a total contact shank area, increases stability, and enhances the weight-bearing surface. They can also be used for excessive valgus and varus. The spring extension can be used to increase push-off. The steel splint or plate is used to limit motion, usually at the first metatarsal-phalangeal joint, in relation to hallux limitus or rigidus. The rocker bottom, which is an extension of the metatarsal bar, is designed to prevent flexion and extension of the shoe. Shoe elevations can compensate for limb length discrepancies. The solid ankle cushion heel improves extension (plantar flexion) or ankle motion. The solid ankle cushion heel can also be used with a metatarsal bar, rocker bar, springs, or double sole, which then limits some motion. The KEEL heel is used to eliminate lateral forces. Steel springs, cork, or wooden buildups may also be employed as indicated.

Internal shoe modifications include medial longitudinal pads or cookies, metatarsal pads, balance pads, calcaneal bars, heel pads and lifts, Barton and Thomas wedges, and tongue or bite pads, heel elevations, cushions, and wedges. Excavations and stretching or relasting are also important. Shoe selection and last determination as well as fit are essential for the older patient, particularly when orthoses are to be used.

Orthoses are used to protect, restore, and/or improve function that support, align, prevent, or modify deformities. Foot orthotics may or may not include a shoe and/or any modification to make an orthotic functional and effective. Orthoses are prescribed by health-care professionals and are fabricated to meet the specific needs of the patient.

The primary prescription objectives include modifying foot function, compensate for existing deformities, weight dispersion, weight diffusion, soft-tissue supplementation, shock absorption, support, realignment, improved performance, restriction of motion, enhancement of motion, prevention of injury, reduction of weight load, stabilization, and the relief of pain.

The available orthoses include rigid, semirigid, and flexible forms, using a variety of materials. In addition, replaceable pads, insoles, heel orthoses, functional orthoses, latex shield, silicone molds, and digital orthoses are also used as indicated. The foot orthosis is a form of durable medical equipment that does provide support and compensate for malalignment, which may be present in the older patient. The orthosis is used to improve function and provide support. It may be used to evenly redistribute weight, as is the case of the total contact orthoses. It may accommodate painful areas and provide for filler in the postamputation period. For the older patient, correction is many times modified to become compensation and may limit motion, compensate for abnormal foot position, help equalize limb length discrepancy, and control position and motion.

Orthoses may be over-the-counter, custom-made, or customized and modified prefabricated components. They may be full length, to sulcus, to metatarsal head area, or may have extensions to compensate

for metatarsal length discrepancies. Rigid orthoses are usually fabricated from metal or thermoplastics. With thermoplastics, the degree of rigidity and flexibility can be modified by the thickness and material selection, the weight and functional needs of the patient, and the use of soft material as a part of a top cover. Semirigid orthoses are usually fabricated from leather, rubber, cork, polypropylene, and celastic and may include steel springs in the shank area. Soft orthoses usually consist of materials that provide weight diffusion and weight dispersion or is multidensity to encompass both concepts. Silicone also is used both for plantar orthoses and as digital orthoses in the form of silicone molds. These custom-designed digital braces have a significant role to play in the management of the older patient, as these provide a great deal of flexibility, are cost effective, can easily be modified and/or changed, and can be custom designed to meet individual patient needs and diagnostic indications.

The general types include calcaneal orthoses such as heel stabilizer/cups, heel protectors, and shock-absorbing calcaneal seats. The full-length orthoses are usually soft and may have some degree of semirigid characteristics for stability. Multidensity and total contact orthoses usually fit this category. Schaffer, Whitman, and Mayer designs are still used, based on the indications and ability of the patient to adapt to this form of shell design. Metatarsal extensions and modifications are incorporated into these primary classifications and include, but are not limited to, the following examples: heel pad, heel spur pad, cutouts for weight dispersion, scaphoid pad, longitudinal arch reinforcement, wedges, Morton's extension, rear foot post, forefoot post, metatarsal pad, and heel lifts.

For the geriatric patient, the usual prescription includes some degree of flexibility to provide a functional accommodative orthotic. Some of the newer rigid materials, used in a thinner plate, do provide some flexibility and do permit a myotatic reflex to function. Geriatric orthoses usually provide some form of cushioning material that is both weight diffusive and weight dispersive. Keys are also strength, semiflexibility, and resiliency that compensate for change in the multiple systems involved in gait and the changes related to aging and chronic diseases.

The final determination of appropriate form and material depends on the weight of the patient, findings at examination, general functional needs, activities of daily living, and the physiological adaptability of the patient. Clinical needs and appropriate indications are essential considerations for relief of pain, restoration of a maximum degree of function, and maintaining that level of function, once achieved.

It is important to remember that footwear, as protection and foot covering, needs to be compatible with the foot and the patient's functional requirements. Shoe modifications enhance these requirements. The foot orthosis adds another link in the chain needed to keep the patient pain free and ambulatory. The foot, shoe, and orthoses must function as a unit and as a part of the patient's ambulatory system.

### Therapeutic Shoes for Diabetics

The importance of footwear and appropriate orthoses for the older population has been clearly delineated in relation to the "at-risk" diabetic under Medicare. The "therapeutic shoe" provisions as currently projected demonstrate, in this singular disease, the important relationship between shoes and orthoses in the diabetic patients. It is important to note that this is just one example of need. See

**TABLE 122-4**

#### Criteria for Coverage for Special Diabetic Shoes

1. The patient must have diabetes mellitus
2. The patient has one or more of the following conditions:
  - a. previous amputation of the other foot or part of either foot, or
  - b. history of previous ulceration of either foot, or
  - c. preulcerative callus formation of either foot, or
  - d. peripheral neuropathy with a history of callus formation of either foot, or
  - e. foot deformity of either foot, or
  - f. poor circulation in either foot
3. The physician who is managing the patient's systemic diabetes condition has documented that indications 1 and 2 are met and certifies that the patient is being treated under a comprehensive plan of care for the diabetes and that the patient needs special shoes

Table 122-4 for criteria for coverage for diabetic shoes. Following the above, a podiatrist or other qualified physician knowledgeable in the fitting of therapeutic shoes and inserts may write the prescription. The footwear must be fitted and furnished by a podiatrist or other qualified individual such as a pedorthist, an orthotist, or a prosthetist.

### ULCERATIONS

The management of ulcerations in the older patient depends on the etiology and the related complications associated with tissue loss. General principles include supportive measures to reduce trauma and pressure to the ulcerated area, such as dressings, orthoses, shoe modifications, and special shoes. The prevention and control of infection and maintaining a clean, healthy base to permit healing are essential. Issues that need to be considered include perfusion, size, depth of tissue loss, infection, and neuropathy including a loss of protective sensation. The débridement of keratosis when indicated is essential to prevent roofing of the ulcer. The use of physical modalities and measures such as low-voltage therapy (contractile currents) and exercises can assist in improving the local vascular supply to the ulcer and in helping to establish a clean base. Pressure ulcers of local origin are usually associated with a bony prominence, biomechanical abnormality, and external trauma as the result of stress associated with gait change. Atrophy of soft tissue and the residuals of arthritis provide a focus for the development of ulcerations. Tissue loss associated with systemic diseases is usually related to sensory loss, neuropathic joint change, and vascular insufficiency, as with diabetes mellitus and peripheral arterial disease. Management focuses on identifying the underlying diagnosis, local supportive measures, adequate treatment of the related systemic diseases, and efforts to minimize the potential for osteomyelitis and amputation risk, and maintaining the ambulatory status of the patient for as long as possible.

Methods to remove pressure from weight-bearing areas can be attained by the use of orthoses and/or shoe last changes; the use of pads, bars, wedges, and other modifications; increasing the sole thickness and using shock-absorbing material; and surgical shoes, total contact orthosis, special foot and ankle walkers, and ortho or heel wedge surgical shoes. Older patients who avoid the use of footwear at home, owing to their inability to bend, expose themselves to the potential of foreign bodies and foot injury.

## DIABETIC AND PERIPHERAL ARTERIAL CONSIDERATIONS

Foot complications relating to diabetes have a significant impact on the quality of diabetic patients. The older diabetic presents with a covariant set of syndromes including dermopathy, onychopathy, vasculopathy, neuropathy, and myopathy. The symptoms are similar to those of aging in general but appear at an earlier age. Foot complications are also a major cause of hospitalization, and 50% to 75% of these amputations can be presented when the diagnosis is made early and interventions made that can affect outcomes. Emphasis is placed on preventing lower extremity amputations that can produce major life style changes and have a significant economic impact on the patient, their families, the health care system, and society in general. Programs such as “LEAP” (lower extremity amputation prevention, Department of Health and Human Services) and “PACT” (Prevention, Amputation, Care, and Treatment, Department of Veterans Affairs) are examples of these efforts. The older diabetic patients present the greatest risk for ulceration, infection, hospitalization, and amputation because of the multiple systems involved in the disease. Similar changes can be demonstrated with peripheral arterial disease, hemophilia, cardiac disease, chronic renal failure (dialysis), obesity, post stroke, and chronic obstructive pulmonary disease. Tissue loss in the elderly and amputation can terminate the patient’s independent life of usefulness to themselves and society.

The pathogenesis of a diabetic foot ulceration in the older patient includes diabetes mellitus itself; trauma (direct and/or repetitive microtrauma); neuropathy—motor (weakness, atrophy, deformity, abnormal stress, high plantar pressure, and hyperkeratosis), sensory (loss of protective sensation), and autonomic (anhidrosis, xerosis, fissures, and decreased sympathetic tone); peripheral arterial disease—macrovascular (atherosclerosis and ischemia) and microvascular (structural and/or functional); osteoarthropathy (Charcot’s joints); impaired response to infection; and reduced nutrient capillary blood flow, with subsequent ulceration and potential amputation. The risk increases with sensory deficits, altered biomechanics and neuropathy, increased tissue pressure (erythema and subkeratotic hematoma), bony deformity, decreased or absent pedal pulses, prior ulcerative history, and toenail pathology.

Hyperkeratotic lesions form as space replacements and provide a focus for ulceration caused by increased pressure on the soft tissues with an associated localized avascularity from direct pressure and counterpressure. Tendon contractures and hammertoes increase pressure. A warm foot with pulsations in an older diabetic with neuropathy is not uncommon. When ulceration is present, the base is usually covered by keratosis, which retards and many times prevents healing. Necrosis and gangrene are related to infection with eventual occlusion and gangrene. Foot drop and a loss of position sense are usually present. Pretibial lesions are indicative of this change as well as microvascular infarction. Arthropathy gives rise to deformity, altered gait patterns, and a higher risk for ulceration and limb loss.

In addition to the relationship of vascular and neuropathic changes, ulcerations must be related to trauma and, in particular, the effects of repeated microtrauma. Hyperkeratosis related to keratin dysfunction, space replacement, bony abnormality, and/or pathomechanics would react to pressure and trauma, which may be mechanical, thermal, and/or chemical in nature. Subhyperkeratotic hemorrhage is usually an early clinical sign of tissue breakdown. Regardless

of the cause, the general principles of management include a decrease of local trauma by the use of orthotics, shoe modifications, specialized footwear, and efforts to maximize weight diffusion and weight dispersion techniques. Physical modalities, medication, and exercise can be employed to improve the vascular supply to the part, following adequate evaluation by Doppler and other techniques. Appropriate invasive techniques and bypass surgical procedures should be considered. Local débridement of the ulcerative site and adequate home wound care, appropriate antibiotics, topical enzymes, and tissue stimulants should be considered. Radiographs and bone scans should be ordered early on in the management process to deal with infection at its first signs. Culture and sensitivity, appropriate antibiotic therapy, and hospitalization should be considered to prevent, where possible, amputation. Wound care includes medical débridement, special dressings, autologous and epidermal grafts, and recognizing limb-threatening infection (deep ulceration, bone and/or joint involvement, systemic toxicity, ischemia, gangrene, and gas gangrene). Negative pressure wound therapy, hyperbaric oxygen, and transcutaneous oxygen measurement is additional considerations.

Asymptomatic diabetic older patients should be evaluated at least twice a year to identify problems at their earliest development. Patients with foot conditions requiring primary management should be followed every 30 to 60 days, depending on the degree of complications. A multidisciplinary care approach, which includes patients and their families, is an essential element in managing the elderly diabetic patients with foot problems.

## CONCLUSION

The ability to retain ambulation is directly related to foot health as individuals age. Regardless of the care setting, that is, home, ambulatory facilities, long-term care programs, mental health facilities, assisted living, or other models, all practitioners must think comprehensively and recognize that team care must be an essential part of the management of the older individual. Foot health education, such as programs developed by the Pennsylvania Department of Health (Feet First and If the Shoe Fits), is available to both patients and professionals and should be employed as a part of all geriatric patient education programs. With the high prevalence and incidence of foot problems in the older patient, the ability to live life to the end of life will depend, to a great deal, on the ability to remain alert and mobile and to retain the qualities that make individuals want to live.

# Fibromyalgia and Myofascial Pain Syndromes

Cheryl D. Bernstein ■ Debra K. Weiner

Fibromyalgia and myofascial pain (MP) are among the most common musculoskeletal disorders from which older adults suffer. These disorders represent opposite ends of the pain spectrum with the discrete character of MP at one extreme and the widespread symptoms of fibromyalgia at the other. MP may be acute or chronic, and is associated with taut muscle bands and hypersensitive areas called trigger points. Fibromyalgia syndrome includes symptoms of sleep disruption, fatigue, and psychological distress in addition to widespread pain. Both fibromyalgia and MP syndromes may result in significant functional impairment and cause suffering and disability comparable to that of rheumatoid arthritis and osteoarthritis. Diagnosis of these disorders is grounded in appropriately targeted history and physical examination; these are the tools required to avoid unnecessary ordering of “diagnostic” tests and foster implementation of appropriate management strategies.

## FIBROMYALGIA SYNDROME

### Definition and Epidemiology

While a number of fibromyalgia classification criteria have been proposed, the criteria developed by the American College of Rheumatology are used most commonly. These criteria, which are 81% sensitive and 88% specific, allow fibromyalgia patients to be distinguished from patients with widespread pain caused by other rheumatological disorders (e.g., systemic lupus erythematosus, rheumatoid arthritis). They include a history of generalized body pain (i.e., pain in at least three of four body quadrants) for at least 3 months duration and at least 11 out of 18 specific tender points on physical examination. Although initially developed for classification of fibromyalgia, practitioners tend to regard them as required for diagnosis, although this is not accurate. Older adults who present with widespread pain and other supportive clinical features (see below) should be considered

to have fibromyalgia even if they do not precisely fulfill the ACR criteria. These criteria are best used as a general guide and to allow for study enrollment, not for strict use in the office setting.

The incidence of fibromyalgia syndrome (the proportion of new cases or first ever episodes) is difficult to measure in part because symptoms seem to ebb and flow over time. According to five large population studies, approximately 10% of the population has widespread pain. Of those with widespread body pain, approximately 2% meet ACR diagnostic criteria for fibromyalgia. Women are four to seven times as likely to have fibromyalgia compared to men, with the greatest prevalence in those 60 to 79 years of age. Patients with fibromyalgia also have been estimated to have a two- to sevenfold greater risk of suffering from depression, anxiety, headache, irritable bowel syndrome, chronic fatigue syndrome, systemic lupus erythematosus, and rheumatoid arthritis compared to healthy individuals.

### Pathogenesis

While recent studies have added to our understanding of the pathogenesis of fibromyalgia, the exact cause is still unknown. Most studies suggest that abnormal central nervous system pain processing, known as central sensitization, plays a key role in fibromyalgia pathogenesis. Abnormal peripheral pain processing, peripheral sensitization, also contributes to fibromyalgia pathogenesis. The cause of sensitization is not known, but a variety of neuroendocrine and biochemical abnormalities are believed to be involved.

### Peripheral Tissue Abnormalities

Early studies of fibromyalgia patients failed to consistently show abnormalities in the peripheral tissues. However, reexamination of this issue has uncovered differences between muscle samples from fibromyalgia subjects and healthy controls. One difference is higher levels of nitric oxide in muscles of fibromyalgia patients that may

result in increased cell death. Other abnormalities that have been identified in muscles of fibromyalgia patients as compared with healthy individuals include lower phosphorylation potential and oxidative capacity as evidenced by lower levels of muscle phosphocreatine and ATP, as well as increased substance P, DNA fragmentation, interleukin-1, and perfusion deficits (see Staud reference). While the exact meaning of these abnormalities is unclear, the findings suggest an underlying difference in muscle metabolism of fibromyalgia patients as compared to people without fibromyalgia. Further study is needed to establish a relationship between these findings and the pain and fatigue fibromyalgia patients report.

### Central and Peripheral Sensitization and Pain Amplification

Abnormalities of peripheral and central pain processing are well established in fibromyalgia. In the periphery, tissue sensitization results from changes in primary nociceptive afferents, increased neuronal excitability, and enlarged neuronal receptive fields. Central sensitization involves neuroplasticity in the brain and spinal cord. “Windup,” a normal finding of increased pain sensations after repeated exposures to a painful stimulus, is an example of central sensitization. In studies of fibromyalgia patients, the “windup” response is exaggerated compared to controls. Staud and colleagues studied fibromyalgia patients and healthy controls after repeated exposure to heat stimuli. While both groups had higher pain ratings after repeated exposures to heat, the degree of windup and temporal summation was significantly greater in fibromyalgia subjects. In addition, the fibromyalgia subjects had more prolonged after sensations compared with control subjects. Peripheral and central sensitizations contribute to the exaggerated pain response of fibromyalgia patients.

### Neuroendocrine Abnormalities

Altered activity of the hypothalamic–pituitary–adrenal axis (HPA), and abnormal levels of adrenocortical trophic hormone (ACTH) and urinary cortisol have been demonstrated in patients with fibromyalgia. Evidence suggests that the HPA axis may be less resilient than normal in fibromyalgia patients and that this and other HPA axis abnormalities may underlie the impaired response to stress that many of these patients exhibit. The review by Crofford provides an expanded discussion of the neuroendocrine abnormalities in fibromyalgia syndrome.

### Biochemical Abnormalities

While there are no serologic tests to assist practitioners with making a diagnosis of fibromyalgia, a number of biochemical abnormalities have been identified in the context of research studies. Russell and colleagues have identified lower levels of serum serotonin and norepinephrine in patients with fibromyalgia compared to controls. Low platelet serotonin levels have also been identified. While cerebrospinal fluid (CSF) serotonin has not been measured in patients with fibromyalgia, its precursor and metabolic products have been demonstrated to exist at significantly lower levels in the CSF of fibromyalgia patients compared to controls. Norepinephrine’s metabolite, methoxyhydroxyphenylglycol, and dopamine’s metabolite, homovanillic acid, are also reduced in fibromyalgia patients.

Further discussion of the biochemical abnormalities found in fibromyalgia patients is found in the review by Mease.

Abnormal levels of nociceptive neurochemicals have also been found in patients with fibromyalgia. Several studies have shown that substance P, a neuropeptide involved in pain transmission, exists in significantly higher levels in the CSF of fibromyalgia patients compared to those without fibromyalgia (see the Russell reference). Nerve growth factor (NGF), which promotes production of substance P, also is elevated in the CSF of fibromyalgia patients.

### Functional Imaging of Pain

Researchers have used functional magnetic resonance imaging (fMRI) to help understand fibromyalgia pathogenesis. Functional MRI measures regional blood flow in the central nervous system in response to various environmental stimuli and fMRI studies have demonstrated increased central nervous system activity that corresponds to fibromyalgia patients’ subjective pain reports. In response to stimuli, which do not cause pain in controls, fibromyalgia patients report high pain scores and have augmented regional cerebral blood flow on fMRI.

### Genetics

Mounting evidence points to fibromyalgia as a heritable disorder. This evidence includes familial aggregation of fibromyalgia as well as a reduced pain threshold in the first-degree female relatives of fibromyalgia patients, even in those without overt clinical symptoms. Gene polymorphisms in the serotonergic and dopaminergic systems and a higher prevalence of polymorphisms in the promoter region of the serotonin transporter gene (5HTT) in fibromyalgia patients as compared to healthy controls also have been identified.

### Clinical Presentation

#### Patient History

Fibromyalgia patients often report that they feel pain “all over.” Pain diagrams, on which patients are asked to shade painful areas of a human figure, are helpful in making a diagnosis. For fibromyalgia patients, these diagrams show diffuse shading on the right and left sides of the body as well as above and below the waist. We observe that some fibromyalgia patients shade, circle, or put an X through the entire figure. Patients generally rate their pain as moderate to severe in intensity. Over time, pain will fluctuate in severity but typically does not resolve completely. The quality of the pain may be variably described as deep aching, mild tenderness, or sharp sensations. Symptoms are generally constant throughout the day but often are worse in the morning and the evening. Triggers, including stress, cold weather, illness, and unaccustomed exertion, will likely increase pain. In addition to pain, 75% of patients report stiffness and over 50% report a sensation of swelling. Low back pain and chronic whiplash are relatively common, affecting 20% to 30% of the patients with fibromyalgia.

Fibromyalgia patients are likely to report a wide variety of non-musculoskeletal symptoms, most commonly fatigue and difficulty sleeping. Sixty percent of patients report psychological and neuropsychological symptoms including anxiety, mental distress, and cognitive dysfunction. Thirty percent of patients report current

Sjogren's syndrome

depression with over 50% of patients reporting a history of depression. Headaches are also common. Uncommon symptoms (<20% prevalence) include tinnitus, dizziness, vertigo, and Raynaud's phenomenon. Fibromyalgia may also coexist in 20% of rheumatoid arthritis patients, 30% of patients with systemic lupus erythematosus, and 50% of those with Sjögren's syndrome. [Table 123-1](#) lists the symptoms and syndromes commonly associated with fibromyalgia.

Up to 80% of fibromyalgia patients report debilitating fatigue. This complaint encompasses mental fatigue and impaired concentration commonly referred to as "fibro fog," physical fatigue after exertion, and general sleepiness. In fibromyalgia patients, these symptoms most often occur in the absence of other medical illnesses. Poor sleep quality seen in fibromyalgia patients is known as nonrestorative sleep. Patients awaken feeling unrefreshed even after a full night's sleep. Other complaints include light sleep, frequent awakenings, and insomnia. As with other aspects of fibromyalgia, the cause of poor sleep and chronic fatigue is not fully known. Studies of sleep architecture in fibromyalgia patients have revealed abnormalities, which may account for daytime fatigue. One such finding is alpha wave intrusion into stage four sleep. In fibromyalgia patients, alpha waves, typically seen in stage one light sleep, are found in stage four slow wave deep sleep. In addition, fibromyalgia patients have a relative rapid eye movement (REM) sleep deficiency com-

pared to healthy controls. These abnormalities, while not specific to fibromyalgia, may cause significant fatigue.

## Physical Examination

When evaluating the older adult with widespread chronic pain, the practitioner should be cognizant of multiple rheumatological disorders in addition to fibromyalgia syndrome such as generalized osteoarthritis, pseudogout, gout, rheumatoid arthritis, systemic lupus erythematosus, and polymyalgia rheumatica, as summarized in [Table 123-2](#). A careful history and thorough physical examination for synovial and extrasynovial findings can help differentiate these conditions from fibromyalgia. [Table 123-2](#) lists a number of key features on history and physical examination that may aid in the diagnosis. Other diagnostic considerations include hypothyroidism, vitamin D deficiency, demyelinating polyneuropathies, and paraneoplastic syndromes. A targeted laboratory panel may be helpful in teasing out these differential diagnostic considerations.

The characteristic physical examination finding in patients with fibromyalgia is the presence of tender points at the specific locations outlined in [Table 123-3](#). A tender point is defined as a spot on the body that is painful with 4 kg of pressure (the amount of pressure required to blanch the examiner's thumbnail when palpating the palm of her own hand). Palpation of the tender points with 4 kg of pressure is needed, as below this level, most subjects will not report pain. Those who report pain when tested with 4 kg of pressure demonstrate a lower than normal pain threshold. Patients reporting pain in fewer than the 11 of 18 tender points included in the American College of Rheumatology classification criteria may still be diagnosed with fibromyalgia if they have otherwise supportive clinical features (e.g., sleep disturbance, fatigue, morning stiffness). Tender points exist in a number of conditions other than fibromyalgia, including cervical and lumbosacral facet arthrosis syndrome, sacroiliac joint syndrome, and chronic whiplash and therefore a careful history and examination are key diagnostic elements.

## Treatment

A variety of pharmacologic and nonpharmacological interventions are available for the treatment of fibromyalgia. While many of these treatments are beneficial anecdotally, controlled research is limited and the optimal treatment remains unknown. Available research is limited by small sample size, short duration, and lack of blinding and randomization. Nonetheless, we have successfully employed a number of management approaches in our older adult patients with fibromyalgia. Medications, particularly antidepressants and some antiseizure medications, may be beneficial, particularly if therapy is aimed at addressing associated symptoms such as disrupted sleep, depression, and/or anxiety ([Table 123-4](#)). For improving overall function and well being, most experts agree that nonpharmacologic therapies have greater success and should be considered as essential to any well-formulated treatment plan.

## Medications

### Antidepressants

Antidepressants are among the most widely studied medications for the treatment of fibromyalgia. The analgesic effect of antidepressants

**TABLE 123-2****Differentiation of Osteoarthritis from other Common Rheumatological Disorders: History, Physical Examination, and Other Diagnostic Features**

DISORDER	HISTORY		PHYSICAL EXAMINATION		OTHER DIAGNOSTIC FEATURES/COMMENTS
	AM Stiffness	Location of Pain	Synovitis	Extrasynovial Disease	
Osteoarthritis	Generally short-lived, e.g., < 30 min	Weight-bearing appendicular joints, cervical and lumbar spine, DIPs, PIPs and first CMC. MCP and wrist involvement go against OA	Absent or mild	None related to arthritis itself.	Since OA is ubiquitous in older adults, x-rays should be used to rule out other disorders, not to diagnose OA.
Pseudogout	Pseudorheumatoid pattern may be associated with prolonged AM stiffness	Knee and wrist are most common locations; disease is often symmetrical	Acute flares are intensely inflammatory	Chondrocalcinosis on x-rays; eye deposits, bursitis, tendonitis, carpal and cubital tunnel syndromes may occur.  Tophaceous soft tissue deposits uncommon.	Chondrocalcinosis may be asymptomatic. Identification of intracellular CPPD crystals offers a definitive diagnosis in acute flares. Acute and chronic forms occur.
Gout	Pseudo-rheumatoid pattern may be associated with prolonged AM stiffness	Joints of the lower extremities are most often involved, especially first MTP; disease is typically asymmetrical	Acute flares are intensely inflammatory	Tophi may deposit in soft tissues.	Hyperuricemia may be asymptomatic. Serum uric acid cannot diagnose gout. Identification of intracellular monosodium urate monohydrate crystals offers a definitive diagnosis in acute flares.
Rheumatoid arthritis	Prolonged, e.g., > 30 min. Duration of stiffness is used as one parameter of disease activity	Any synovial joint. The lumbar spine is typically spared.	Present	Not uncommon; rheumatoid nodules can develop in soft tissues. Many other possible manifestations including anemia, vasculitis (skin lesions, peripheral neuropathy, pericarditis, visceral arteritis, palpable purpura), pulmonary disease, etc.	Patients may be seronegative. If disease is suspected, patient should promptly be referred to a rheumatologist to retard disease progression.

Systemic lupus erythematosus	Not a prominent feature	Depends upon tissues involved—may or may not be limited to joints. Comorbid fibromyalgia is not uncommon.	Generally absent; arthralgias are more common than arthritis	Common—e.g., anemia, skin rash, pleuritis, peritonitis, pericarditis, nephritis, meningitis, etc.	Anyone with suspected SLE should promptly be referred to a rheumatologist.
Fibromyalgia syndrome	Generally short-lived, e.g., < 30 min	Typically diffuse. Worst symptoms often involve the axial skeleton.	Absent. Joints themselves are not involved, although patients experience pain in joints and soft tissues	Many other disorders may coexist (see <a href="#">Table 123-4</a> ).	Fibromyalgia syndrome is not a diagnosis of exclusion, but one based upon careful history and physical examination (see text).
Polymyalgia rheumatica	Maybe prolonged, lasting several hours	Typically proximal—e.g., shoulder girdle, hip girdle, neck. If headaches, jaw claudication, and/or prominent systemic symptoms (e.g., fever), consider temporal arteritis.	May occur, especially in small joints of hands	Occurs if comorbid temporal arteritis and relates to involvement of arteries (e.g., Raynaud's phenomenon, bruits, claudication).	Because the erythrocyte sedimentation is very nonspecific, this test should be used to assist with confirmation of a suspected diagnosis. Note that cases of PMR and TA with a normal ESR have been reported.
Vitamin D deficiency	Absent	Typically described as diffuse, deep pain. Bony pain is often present.	Absent	Fatigue is a common feature with proximal muscular weakness (pelvic-girdle myopathy). Tenderness with palpation of bony structures.	Fatigue and difficulty climbing stairs are common complaints. Gait imbalance and falls may be seen. In severe cases, the profound weakness results in need for a wheelchair. Radiologic findings include fractures and Looser-Milkman pseudofractures (osteomalacia giving a striped appearance to bones). Direct measurement of serum 25(OH)D is the best marker for vitamin D deficiency.
Hypothyroidism	Absent	Diffuse myalgias and arthralgias.	Joint swelling may be present with noninflammatory joint effusions. Hand, knee, and wrist involvement. Avascular necrosis, gout and or pseudogout may co-exist	Myalgias, generalized weakness, and carpal tunnel may exist.	Fatigue, mental slowing, and depression often seen. Associated symptoms include hair loss, edema, cold intolerance, dry skin, constipation and weight gain.

CMC, carpometacarpal joint; CPPD, calcium pyrophosphate dehydrate; DIP, distal interphalangeal joint; ESR, erythrocyte sedimentation rate; MCP, metacarpophalangeal joint; MTP, metatarsophalangeal; OA, osteoarthritis; PIP, proximal interphalangeal joint; PMR, polymyalgia rheumatica; SLE, systemic lupus erythematosus; TA, temporal arteritis.

TABLE 123-3

## Physical Examination in Older Adults with Low Back and Leg Pain: Detection of Soft Tissue and Biomechanical Abnormalities

FINDING	OPERATIONAL DEFINITION	EXAMINATION TECHNIQUE
Fibromyalgia tender points	Presence of pain when approximately 4 kg of force (i.e., enough force to blanch examiner's thumbnail bed) is applied to defined tender points	Have patient sit comfortably on examination table, arms resting in lap. Tell patient that you are going to apply pressure at several points on the body, and that you want to know if pressure on any point causes pain. Examine the following points bilaterally, using enough pressure to blanch thumb nail: (1) Occiput at suboccipital muscle insertions (2) Low cervical at the anterior aspects of the intertransverse spaces at C5-C7 (3) Trapezius, midpoint of upper border (4) Supraspinatus at origins, above the scapular spine near the medial border (5) 2nd rib at the 2nd costochondral junction, just lateral to the junction on the upper surfaces (6) Lateral epicondyle 2 cm distal to the epicondyle (7) Medial fat pad of the knee, proximal to joint line (8) Greater trochanter, just posterior to the trochanteric prominence (9) Gluteal at upper outer quadrant of buttocks in anterior fold of muscle
Functional leg length discrepancy	Pelvic asymmetry	Have patient stand with both feet on floor, shoes removed. Ask him to stand with feet together, and as erect as possible. Kneel behind patient. With palms parallel to floor, and fingers extended, place lateral surface of index finger of both hands atop pelvic brim bilaterally. Level of eyes doing the examination should be level with hands. Determine if right and left hands are at different heights.
Scoliosis (lateral/rotational)	Lateral/rotational curvature of thoracolumbar spine	Have patient stand on floor with shoes removed. Stand behind patient. Run index finger along spinous processes (do not lift hand between vertebrae) a series of 3 times. If you do not detect scoliosis, then: Ask patient to bend forward. Determine if there is asymmetry in height of paraspinal musculature.
Sacroiliac joint pain	Pain with direct palpation of sacroiliac joint or with Patrick's test	<i>Direct palpation:</i> Have patient stand on floor with shoes removed. Stand behind patient. Exert firm pressure over sacroiliac joint, first on one side, then the other. Palpate right joint with right thumb, standing to left side of patient; palpate left joint with left thumb, standing to right of patient. <i>Patrick's (Fabere) test</i> —Have the patient lie supine on the examining table and place the foot of involved side on opposite knee Then slowly lower the test leg in abduction toward the examining table If patient reports pain in back ( <i>not</i> groin, buttocks or leg), then test is positive
Myofascial pain, piriformis	Presence of pain on deep palpation of piriformis	Have patient lay supine on examination table Have patient flex right hip and knee, keeping sole of foot on table Cross bent leg over opposite leg; again place sole on table and exert mild medially directed pressure on lateral aspect of knee to put piriformis in stretch Exert firm pressure (4 kg) over middle extent of piriformis Repeat examination on opposite side
Myofascial pain, TFL ± iliotibial (IT) band pain	Presence of pain on deep palpation of tensor fascia lata and/or IT band	Have patient lying supine on examination table. Using thumbs of both hands, exert firm pressure (4 kg) over full extent of TFL and IT band. Repeat examination on opposite side.
Kyphosis	Deformity of thoracic spine creating forward flexed posture	Have patient stand on floor with shoes removed. Ask him to stand fully erect. Inspect posture from the side.
Myofascial pain of paralumbar musculature	Presence of pain on deep palpation of paralumbar musculature	Have patient stand on floor with shoes removed. Stand behind and to left of patient and brace him in front with left arm and palpate full extent of right paravertebral musculature with right thumb. Exert approximately 4 kg force. Repeat, palpating the left paravertebral musculature.
Vertebral body pain	Presence of pain on firm palpation of lumbar spinous processes	Position yourself behind patient, as for examination of paravertebral musculature above. Using dominant thumb, firmly palpate spinous processes L1-L5.
Hip disease	Pain and restricted motion of hip	<i>Hip internal rotation</i> —have patient lie supine on examining table with hip and knee bent to 90 degrees. Put the hip into maximum internal rotation and ask patient if he experiences pain. <i>Patrick's test</i> —As above.

may result from increased central nervous system serotonin and norepinephrine, which act to block pain signals from the periphery. In addition to reducing pain, antidepressants may improve sleep and emotional well-being. Those used most commonly are the tricyclic

antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), and serotonin norepinephrine reuptake inhibitors (SNRIs).

Among these classes of antidepressants, tricyclics are the oldest and have the strongest evidence for efficacy in fibromyalgia. Two

TABLE 123-4

## Medications Used in Fibromyalgia Treatment

DRUG	RECOMMENDED DOSE	COMMENTS
<i>Antiepileptic medications</i>		
Gabapentin	100–600 mg daily max dose 1800 mg daily	Titrate slowly May cause sedation or dizziness Dose adjustment for renal failure
Pregabalin	150–300 mg daily max dose of 450 mg	
<i>Tricyclic antidepressants (TCA)</i>		
Nortriptyline	10–50 mg nightly	Sedation and confusion Avoid in narrow angle glaucoma Recommend baseline EKG to evaluate Q-T prolongation If present, avoid use
<i>Serotonin reuptake inhibitors (SSRI)</i>		
Fluoxetine	20–80 mg daily	SSRIs have superior tolerability compared to TCAs
Citalopram	20–40 mg daily	
<i>Serotonin norepinephrine reuptake inhibitors (SNRI)</i>		
Venlafaxine	75–100 mg daily	Avoid in those with uncontrolled hypertension Avoid in patients with liver disease Avoid in those with narrow angle glaucoma
Duloxetine	30–60 mg daily	
<i>Analgesics</i>		
Tramadol	50–100 mg every 6 h as needed	May cause sedation and confusion Avoid in patients with seizures May cause serotonin syndrome in combination with SSRIs or other antidepressants Dose adjustment for renal failure
<i>Muscle Relaxants</i>		
Cyclobenzaprine	5–10 mg nightly	Likely to cause sedation Similar side effects to tricyclic antidepressants

of the earliest placebo-controlled clinical trials demonstrated modest effectiveness of amitriptyline at doses of 25 to 50 mg nightly. Cyclobenzaprine, a muscle relaxant with structural similarity to the tricyclics, has shown efficacy in several short-term clinical trials. A recent meta-analysis of the literature on cyclobenzaprine has shown effectiveness in treating some symptoms and providing overall improvement but did not show reduction of fatigue or tender points (see Goldenberg reference).

While tricyclic medications may benefit patients with fibromyalgia, side effects may limit their use, even in low doses. The anticholinergic effects of this class are responsible for most of the adverse effects including sedation, confusion, constipation, and palpitations. As demonstrated by Dr. Weiner and colleagues, impaired mobility and falls have also been described in older adults. TCAs may also prolong the QT interval, which in the worst-case scenario results in torsade de pointes and death. Prior to their initiation, therefore, an EKG should be obtained and if there is evidence of QT prolongation, these medications should be avoided. Secondary tricyclic amines, desipramine, and nortriptyline have fewer side effects but are not as well studied.

The SSRIs and SNRIs may have fewer adverse effects than the TCAs, but there is only modest evidence for their efficacy. The SSRIs increase serotonin levels at lower doses and both serotonin and norepinephrine levels at higher doses. The first double-blind, randomized, placebo-controlled trial of fluoxetine failed to show any benefit compared to placebo. A crossover study found improvement in pain, function, and overall well-being after treatment with fluoxetine 20 mg daily or amitriptyline 25 mg daily compared to placebo, and a combination of both drugs produced a superior result compared to either drug alone. Two studies have evaluated citalopram. While one study failed to show benefit of citalopram, Anderberg and col-

leagues demonstrated improvement in depression and overall well-being in fibromyalgia patients treated with citalopram (20–40 mg) compared to those in the placebo group.

Studies have also examined the dual serotonin and norepinephrine reuptake inhibitors (SNRIs) for the treatment of fibromyalgia. While benefits of venlafaxine were found in open-labeled studies, a randomized placebo-controlled trial showed no benefits of low-dose venlafaxine (75 mg daily) over placebo. The new SNRI duloxetine has been recently FDA approved for the treatment of FMS at 60 mg daily. Milnacipran, a new SNRI and a mild *N*-methyl-D-aspartate (NMDA) inhibitor, has demonstrated efficacy in the context of a large multicenter trial. It is available in Europe and Asia but not in the United States.

### Antiepileptics

Aside from the antidepressants, very few drug classes have evidence for efficacy in the treatment of fibromyalgia. There is some support for the use of antiepileptic drugs. While the mechanisms of action of antiepileptic drugs are largely unknown, especially for the newest agents, it is believed that they reduce neuronal excitability, decrease ectopic neuronal discharge, and modulate the levels of a variety of neurotransmitters. A large study of pregabalin, an antiepileptic drug that binds to the alpha(2)-delta subunit of the voltage-gated calcium channel, found that fibromyalgia patients treated with pregabalin experienced significant improvement in pain, fatigue, social functioning, vitality, and general health perception compared to controls (see Crofford reference). Pregabalin is the first medication approved for fibromyalgia syndrome at a dose range of 300–450 mg daily. While the efficacy of gabapentin to treat fibromyalgia has not been rigorously examined, our clinical experience suggests that low-dose

gabapentin (e.g., 100 to 600 mg/day) may be beneficial for reducing pain and improving sleep.

### Analgesics

With the exception of tramadol, there are no data that demonstrate efficacy of analgesics for the treatment of fibromyalgia. Tramadol, a weak mu receptor agonist with dual serotonin and norepinephrine reuptake inhibition, is unique in its mechanism and has been shown to be effective in three randomized controlled trials. As with other opioids, prolonged use of tramadol may be linked to abuse and dependence and should be considered judiciously. Because of the sometimes refractory nature of pain in fibromyalgia, these patients not infrequently are treated with more potent opioids, which may result in a number of adverse effects including dysmobility and falls, delirium, increased depression, sedation, nausea, and vomiting. If opioids are being considered, a pain specialist's evaluation is often helpful.

### Hormonal Supplements and Other Agents

Studies of hormonal supplements for patients with fibromyalgia have had mixed results. One study of 9 months of subcutaneous growth hormone showed benefit in fibromyalgia patients who had low insulin-like growth factor levels. Because this medication is quite costly (\$1500 per month) and because the study results cannot be broadly generalized (i.e., most patients with fibromyalgia do not have low levels of insulin-like growth factor), it cannot be recommended for routine use. A number of other hormonal supplements have been tried anecdotally including thyroid hormone, dehydroepiandrosterone, and calcitonin but the absence of randomized controlled trials precludes recommending these agents for the treatment of fibromyalgia. Similarly, nutritional supplements, herbal medications, and vitamin therapy are not accompanied by rigorous data to support their use. While some studies and anecdotal reports suggest benefit from guaifenesin, a 12-month randomized controlled trial of this medication showed no benefit for pain or symptom reduction.

Improving sleep and treating fatigue is often difficult. Sleep hygiene education, which includes keeping regular schedules, elimination of daytime naps, establishment of a restful sleep environment and exclusion of caffeine, is helpful for many patients. Benzodiazepines are typically not recommended for long-term use as they have addictive qualities when used long term and may disrupt the normal sleep cycle. Sedative antidepressants and muscle relaxants including cyclobenzaprine or tizanidine are useful in promoting sleep and well as improving other fibromyalgia symptoms.

### Nonpharmacological Therapies

Nonpharmacological therapies for fibromyalgia include cognitive-behavioral techniques, exercise, acupuncture, balneotherapy (i.e., bathing), and massage. Exercise programs, particularly those that include an aerobic component, have been shown to reduce pain and improve function and well-being. Most therapists recommend individualizing programs based on patient abilities and symptoms. During pain flares, which may occur after physical exertion, programs should be modified but not ceased. Water aerobics may also be beneficial. Finally, strength training is beneficial to fibromyalgia patients who are typically deconditioned and may be up to 30% weaker than control subjects.

Data support the benefits of coupling exercise programs with educational sessions and cognitive-behavioral techniques. Cognitive-

behavioral therapy (CBT) is useful for fibromyalgia patients who tend to catastrophize their painful symptoms. Patients can alter pain perception and manage pain flares through the use of coping skills and relaxation techniques. CBT is most useful as part of an interdisciplinary program that includes education and exercise. Both inpatient and outpatient interdisciplinary programs have been found beneficial.

The benefits of local therapies and complementary techniques for the treatment of fibromyalgia have also been evaluated. Several randomized controlled trials of acupuncture have shown effectiveness for relieving fibromyalgia symptoms although none have been performed exclusively in older adults. These data are encouraging, however, given the overall safety of this treatment modality. Weak evidence supports chiropractic treatment, massage therapy, interferential current and ultrasound for the treatment of fibromyalgia syndrome. Further studies are needed to determine the potential impact of all these modalities, and to identify potential long-term treatment benefits.

### Assessing Response to Treatment

A number of standardized questionnaires are available to assess response to treatment. One of the most efficient and useful is the 20-question Fibromyalgia Impact Questionnaire (FIQ), which takes only a few minutes to complete and quantifies physical function, painful symptoms, and emotional well-being specifically in fibromyalgia patients (Figure 123-1, see Burckhardt reference).

## MYOFASCIAL PAIN SYNDROMES

### Background and Epidemiology

Myofascial Pain (MP) syndromes, that is, pain originating in physiologically abnormal muscles, affect a majority of older adults with chronic pain and can be the sole cause of pain or one of several contributors. MP may be localized or generalized and is characterized by motor and sensory abnormalities, with the hallmark features being taut bands and trigger points. Since the muscular system is the largest and most extensive organ system in the body, MP can occur in virtually any location. These disorders were originally described by Drs. Janet Travell and David Simons, the authors of the most authoritative text on this subject.

### Pathogenesis

MP can be the result of direct or indirect muscular trauma, or aberrant neuronal input. Direct muscle trauma can take multiple forms, including disruption of normal muscular anatomy by surgery, for example, chronic chest wall pain following thoracotomy or chronic abdominal pain following abdominal surgery. Indirect trauma commonly results from abnormal body mechanics that place inordinate stress on certain muscles. Examples include tensor fascia lata (TFL) MP related to quadriceps weakness in patients with knee osteoarthritis. That is, when the quadriceps is weak, the TFL is relied upon more heavily to stabilize the leg when a person stands. Tensor fascia lata MP can also result from scoliosis or leg length discrepancy. This can be seen following total knee or hip replacement. Another

example of abnormal body mechanics causing MP is trapezius MP related to shoulder dysfunction (e.g., adhesive capsulitis or shoulder arthritis).

A number of explanations have been offered to clarify the pathogenesis of MP. Proposed etiologies for the apparent sustained muscular contraction that occurs with MP include neuronal sensitization in the spinal dorsal horn after tissue injury, primary muscle spindle dysfunction, and inflammatory changes in the muscle following injury. Electromyography has demonstrated “end-plate noise,” or spontaneous electrical activity, within the taut bands of trigger points. More recently Gerwin and colleagues have hypothesized that facilitation of acetylcholine (ACh) release, inhibition of ACh breakdown, and removal from ACh receptors combined with upregulation of ACh receptors may underlie the persistent contraction of muscle fibers that plays a central role in myofascial pathology.

Central nervous system mechanisms also play a role in the pathogenesis of MP. These mechanisms are thought to explain the phenomenon of pain radiation in patients with myofascial dysfunction. As summarized in a recent review by Borg-Stein, “it is known from experimental data that under pathologic conditions, convergent connections from deep afferent nociceptors to dorsal horn neurons are facilitated and amplified in the spinal cord. Referral to adjacent myotomes occurs owing to spreading of central sensitization to adjacent spinal segments. This pattern results in referred pain and expansion of the region of pain beyond the initial nociceptive region.” The process of central sensitization, as described in the section on fibromyalgia syndrome above, is also thought to play a role in MP syndromes.

Aberrant neuronal input in older adults can also result from axial spondylosis that injures spinal nerves, disrupts generation of neurotrophic factors, and results in muscle shortening and pain. This condition, formally described by Chan Gunn, is referred to as neuropathic MP. Axial spondylosis is ubiquitous in older adults, thus it is not surprising that MP commonly occurs in older adults with axial arthritis, even in the absence of frank radiculopathy (e.g., MP of the sternocleidomastoid and trapezius in patients with cervical spondylosis).

### Clinical Presentation and Evaluation

MP may occur in virtually any body location and the pain may be relatively discrete or cover a large area. Patients may describe MP as dull, aching, or burning. Symptoms may mimic radiculopathy and other neuropathic pain syndromes. A number of features of the patient's history may point toward a diagnosis of MP. These include characteristic exacerbating and relieving factors. Patients with MP often report that the following factors exacerbate their pain: (1) excessive physical activity, (2) firm pressure over the painful muscle, (3) cold exposure, (4) psychological stress, (5) acute illness (e.g., viral infection). Patients report that the following factors tend to alleviate their pain: (1) mild activity, (2) gentle stretching, (3) gentle pressure (e.g., massage), (4) moist heat, (5) a brief rest period following activity. In addition to pain, patients with myofascial dysfunction typically experience restricted range of motion in involved areas. Myofascial pathology also may be associated with autonomic phenomena (e.g., piloerection, sweating, temperature changes), weakness, and depression. Myofascial taut bands (see below) also can entrap nerves that cause neuropathic symptoms such as paresthesias and numbness. Appetite and sleep disturbance and decrements in cognitive func-

tion can be part of any chronic pain disorder from which older adults suffer, including MP.

Physical examination is required to elicit the pathognomonic features of MP syndromes, that is, *taut bands* and *trigger points*. A taut band is a group of taut muscle fibers extending from a trigger point to the muscle attachments and a trigger point is defined as a hyperirritable spot in skeletal muscle that is associated with a hypersensitive palpable nodule in a taut band. Trigger points may be latent or active. A *latent trigger point* is one that is painful when compressed, but it is not associated with spontaneous pain (i.e., the patient does not report pain in this region when the practitioner is taking a history). Latent trigger points exist not uncommonly in contralateral muscle groups, perhaps because of compensatory muscle activity (e.g., pain in one leg related to myofascial pathology of the tensor fascia lata may cause a relatively antalgic gait with compensatory overuse of the contralateral tensor fascia lata). *Active myofascial trigger points* are those that are responsible for clinical symptoms. These points are always tender and prevent full muscle lengthening. When these points are compressed, typically a radiating pain pattern is elicited that corresponds to the pain that the patient reports in the context of the history of present illness. Sometimes a “jump sign” is elicited on physical examination, that is, a general pain behavior response demonstrated by the patient that may include verbal as well as non-verbal expression (e.g., crying out, grimacing, withdrawing). The examiner may also appreciate a “local twitch response,” that is, a transient contraction of a taut band that traverses a trigger point and that occurs in response to stimulation of the trigger point (e.g., with needling or snapping palpation).

Accurate diagnosis of MP syndromes requires the use of precise physical examination technique, summarized in [Table 123-5](#). Because effective treatment of MP involves recognition and treatment of the underlying cause (e.g., axial and appendicular arthritis, kyphosis, scoliosis, leg length discrepancy, Parkinson's disease) before examining the painful muscles, a general physical examination including comprehensive musculoskeletal, neurological, and mobility examinations must be performed. These examinations must be carried out with an eye toward identifying abnormalities that create muscular dysfunction. Examples in the neurological examination include abnormalities of resting muscle tone such as Parkinson's disease and poststroke changes. Examples in the musculoskeletal examination include decreased range of motion of the hips, knees, cervical spine, and shoulders; scoliosis; kyphosis; and functional leg length discrepancy (i.e., discrepancy in the height of the iliac crests, observed when standing behind the patient with the hands on top of the crests). Techniques used to comprehensively examine the lower back are described in [Table 123-3](#). Examination of the patient's gait, allows an integrated assessment of body mechanics. Examination for underlying visceral pathology should also be performed, particularly in the presence of MP of the pelvic or abdominal musculature.

The most important aspect of preparing for the muscular examination is ensuring that the examiner and the patient are in a comfortable and relaxed position. When palpating the musculature of the upper body (e.g., trapezius, sternocleidomastoid), generally the patient should be sitting, with hands folded in the lap and the examiner should be standing squarely in front of him. When palpating the musculature of the lower back, the patient should be standing and the examiner should be standing to his side, bracing the front of the body with one arm and palpating the muscles with the other

**TABLE 123-5****Physical Examination Technique for Examining the Patient with Myofascial Pain**

1. Perform a general musculoskeletal examination looking for contributors to myofascial pain (e.g., spinal malalignment, leg length discrepancy, arthritis).
2. Place the patient in a comfortable and relaxed position.
  - a. When examining the upper body, the patient should be sitting with forearms resting in lap.
  - b. When examining the lower back, the patient may be standing, sitting, or side-lying.
  - c. When examining the lower extremities, the patient should be lying in the supine position.
3. Place yourself in a comfortable and relaxed position.
  - a. When examining the upper body, the examiner should be standing squarely in front of the patient.
  - b. When examining the lower back, the examiner should be standing to the side of the patient, allowing for the use of one arm to brace the patient from the front and the other hand to palpate. If the patient is lying or sitting, stand to the side of the exam table and behind the patient.
  - c. When examining the lower extremities, the examiner should be standing at the bedside.
4. When there is unilateral pain, always palpate the nonpainful side first.
5. Assess the movement of the skin over the subcutaneous tissue before palpating the muscles.
6. When palpating taut bands, sweep the examining hand firmly across the involved muscle, in a direction that is perpendicular to the orientation of the muscle fibers and in the same plane as the fibers.
7. When palpating trigger points, palpate firmly over the muscle in a direction that is perpendicular to the orientation of the muscle fibers and in a plane that is perpendicular to the fibers.
8. Physical examination targeting potential visceral pathology of the abdomen and/or pelvis should be performed if myofascial pain of these regions is diagnosed.

hand. If the patient is unable to stand, the paraspinal muscles can be palpated by having the patient in a side-lying position or sitting on the examining table with the examiner standing behind the patient. When palpating the musculature of the lower extremities, the patient should be in the supine position, with the examiner standing to the side of the patient.

Prior to palpating the musculature, the examiner should assess the movement of the skin over the subcutaneous tissues using very light palpation and simply gliding the skin in a direction of movement that is perpendicular to the orientation of the involved muscle fibers. Patients with chronic MP commonly have reduced movement of the skin over the involved region. After palpating the skin, the muscles should be examined. The nonpainful side of the body should be palpated prior to palpating the painful area. This strategy serves two purposes. First, it helps the patient to relax. Second, it allows comparison of normal with abnormal. Palpation of taut bands requires proper orientation of the examiner's hand in relation to the orientation of the muscle fibers. The hand should be placed perpendicular to the orientation of the fibers and the fingers swept firmly across the fibers. This motion allows for the tautness of the fibers to be appreciated. To elicit the radiating pain that is a pathognomonic feature of trigger points, the examiner should palpate the area firmly.

While a sweeping hand motion is needed to appreciate taut bands, this is not required to appreciate trigger points. Often, but not always, trigger points are associated with a "nodule." Depending on the location of the pain, the palpation technique may need to be modified. Travell and Simons offer two other techniques: (1) "pincer palpation," that is, palpation accomplished by grasping and rolling the muscle between the thumb and one or more fingers and (2) "deep palpation," that is, palpation accomplished by deep palpation through intervening tissue and application of pressure primarily in a direction that is perpendicular to the tissue plane. Following successful treatment of trigger points, taut bands and trigger points typically resolve, thus baseline examination is critical not only to arrive at a proper diagnosis, but to assess response to treatment.

Some examples of common MP syndromes include cervicogenic headaches, piriformis syndrome, trapezius MP (sometimes associated with "tension neckache"), pseudotrochanteric bursitis, upper and lower back pain, and postherpetic pain. These syndromes are discussed below.

### Cervicogenic Headaches

Cervicogenic headaches are characterized by neck and pericranial pain and are often associated with structural abnormalities of the cervical spine including osteoarthritis and facet arthrosis. Typically, cervicogenic headaches are unilateral in location and range from moderate to severe in intensity. While cervicogenic headaches lack the pulsating quality of migraine headaches, they may have migraine-associated features such as photophobia, phonophobia, nausea, vomiting, and dizziness. Triggers of cervicogenic headache include a variety of neck postures and movements as well as pressure applied to the cervical paraspinal muscles, the suboccipital muscles, and the trapezius. Palpation of these muscles produces pain, which radiates over the head and may extend to the ipsilateral shoulder and arm.

Making the diagnosis of cervicogenic headache may be difficult especially if structural lesions of the cervical spine are not present. A careful history and examination that clearly implicate the cervical spine and its musculature as the source of the pain are essential for diagnosis. Some studies suggest that diagnostic blockade of cervical structures may be useful in patient evaluation; however, this is not typically needed.

### Piriformis Syndrome

The piriformis muscle originates from the pelvic surface of the sacrum, passes through the greater sciatic foramen, and inserts into the medial side of the upper end of the greater trochanter. The fibers of the sciatic nerve course through the piriformis. Piriformis syndrome describes the occurrence of sciatica in association with piriformis MP that results from nerve entrapment by the myofascial taut bands in the piriformis. Patients with piriformis MP also may describe intense buttocks discomfort without sciatica. Because the piriformis acts to externally rotate the thigh at the hip joint, patients with piriformis MP sometimes demonstrate external rotation of the leg when standing or lying supine. Palpation of the piriformis can be performed with the patient standing or lying supine. The technique recommended for examining the patient in the supine position is described in [Table 123-3](#). MP of the piriformis may involve the low back, buttock, and posterior thigh. Typically this MP is increased by sitting, standing, and walking.

### Trapezius MP

The trapezius is a very large muscle and, therefore, associated MP can have a number of presentations. The fibers originate from the occiput, the ligamentum nuchae, and the vertebral spinous processes of the seventh cervical vertebra and all of the 12 thoracic vertebrae and they insert onto the distal third of the clavicle, the acromion, and the length of the spine of the scapula. The upper fibers elevate the scapula, the middle fibers pull the scapula medially, and the lower fibers pull the medial border of the scapula downward. The upper and lower fibers also assist the serratus anterior muscle in rotating the scapula when the arm is raised above the head.

Patients with MP of the trapezius typically do not complain of limitations in movement, but full rotation of the head and neck to the opposite side is often painful, and opposite side bending may be somewhat restricted. Radiating pain patterns vary according to which of the trapezius fibers contain trigger points (i.e., upper, middle, or lower). Trigger points that occur in the upper trapezius may cause pain that radiates up the posterolateral part of the neck to the mastoid process, causing so-called “tension neckache.” Sometimes this pain may radiate to the angle of the jaw and/or the temple and back of the orbit. Dizziness also can occur. Trigger points of the middle fibers of the trapezius may be associated with a superficial burning pain very close to the spinous processes of the seventh cervical and the third thoracic vertebrae or with aching on the top of the shoulder or acromion process. Trigger points of the lower fibers of the trapezius, typically located along the lower border of the muscle, may refer pain to the high paracervical spinal musculature, the mastoid and the acromion, as well as aching and tenderness of the suprascapular region. Perpetuating factors include anything that causes abnormal biomechanics of the upper body such as a whiplash injury or prolonged computer work in an ergonomically unfriendly workspace.

### Upper and Lower Back Pain

These syndromes may be caused by MP of the thoracolumbar paraspinal musculature. Numerous muscles constitute the paraspinal group, including both superficial and deep muscles. The superficial group is collectively referred to as the erector spinae and is the largest muscular mass of the back. It originates from the sacrum, the iliac crest, and the spinous processes of most of the lumbar and the last two thoracic vertebrae and insert into the ribs, the transverse processes of the cervical vertebrae, the thoracic vertebrae, and the mastoid process. The deep group comprises the semispinalis, multifidus, and rotatores. The primary function of the paraspinal musculature is spinal extension. Patients with parathoracic MP may experience pain that radiates to the region of the scapula or more medially, and sometimes to the anterior lower chest; patients with paralumbar MP may experience pain that radiates to the buttocks or the lower abdomen. Precipitation of MP may be caused by sudden muscular overload, for example when lifting objects using poor body mechanics, or associated with a vertebral compression fracture. Multiple vertebral compression fractures may also accumulate to cause hyperkyphosis and associated muscular strain. Physical examination typically reveals diminished spinal range of motion. Treatment of postural abnormalities is an important component of treating paraspinal MP. Physical therapy geared toward strengthening of paraspinal muscles is a key component of treatment, not only for the pain itself,

but also for reducing the risk of future vertebral compression fractures.

### Pseudotrochanteric Bursitis

This syndrome is caused by MP that involves the tensor fasciae latae (TFL) muscle. The TFL originates from the outer edge of the iliac crest between the anterior superior iliac spine and the iliac tubercle and inserts into the iliotibial tract. It assists the gluteus maximus in maintaining the knee in extension when a person stands. It also flexes the hip. Patients with TFL MP experience pain in the region of the hip and thigh, sometimes extending to the knee. The pattern of pain radiation is not uncommonly confused with trochanteric bursitis and is thus sometimes referred to as pseudotrochanteric bursitis. Patients may also complain of poor sitting tolerance, difficulty walking rapidly, and lying on the involved side. They may also have difficulty lying on the opposite side unless a pillow is placed between the knees because of the tight iliotibial band. Physical examination may reveal restricted hip extension and adduction and TFL trigger points. When standing, patients with TFL MP tend to maintain the hip in slight flexion. Other disorders that should be considered in the differential diagnosis include L4 radiculopathy and meralgia paresthetica.

### Postherpetic Pain

While postherpetic neuralgia is commonly thought of as a purely sensory phenomenon, MP has recently been described as a possible component of this disorder. The explanation for this association may be several-fold. The varicella zoster virus (VZV) can directly infect the ventral ventral horn of the spinal cord, but this mechanism is thought to be extremely uncommon. A more likely explanation for MP in the setting of postherpetic neuralgia lies in axial spondylosis (i.e., neuropathic MP, described above) or in guarding behavior.

We hypothesize that a spinal nerve already vulnerable from spondylosis that has caused muscle shortening may be particularly prone to the generation of MP following an acute insult such as VZV. The myofascial pathology that results may then further exacerbate neuropathic pain by entrapping the spinal nerves as they course through the taut bands of the muscles afflicted by myofascial dysfunction. This results in a feedback loop, as shown in Figure 123-2.

Myofascial pathology may also develop in the setting of postherpetic neuralgia as a result of guarding behavior. That is, the pain associated with reactivation of VZV can be excruciating, causing the patient to move their body in ways to protect the painful area. When

**FIGURE 123-2.** Theoretical relationship between reactivation of varicella zoster virus (VZV), neuropathic pain, and myofascial pain.

this type of behavior occurs over a prolonged period of time, muscles may develop contractions knots that are characteristic of MP. Whatever the mechanism by which postherpetic neuralgia may be complicated by the development of myofascial pathology, treatment of both the myofascial pathology and the neuropathy may be needed to afford optimal pain relief.

### Other MP and Dysfunction Syndromes

Since muscles cover virtually the entire body, any body region may be affected by MP. Thus, MP should always be included in the practitioner's list of differential diagnoses for regional pain syndromes. Just as importantly, the practitioner must be aware that MP syndromes may occur in response to visceral disease; when myofascial dysfunction is identified in the abdomen and pelvis, the possibility of underlying visceral pathology must be kept in mind. Sometimes after the visceral pathology has been eradicated, MP may persist, which further complicates evaluation and treatment.

Some less common causes of MP syndromes include pelvic floor myofascial dysfunction causing chronic pelvic pain in both men and women, pelvic myofascial dysfunction causing urologic pain (e.g., interstitial cystitis and the urgency-frequency syndrome), masticatory myofascial dysfunction causing toothache, abdominal wall myofascial dysfunction causing chronic abdominal pain (e.g., following abdominal surgery or a gastrointestinal illness), and intercostal myofascial dysfunction causing postthoracotomy pain. As noted earlier in this chapter, myofascial dysfunction is not always associated with complaints of pain (i.e., in the case of latent trigger points). For example, masticatory myofascial dysfunction has been associated with tinnitus and myofascial dysfunction of the trapezius with dizziness. Cervical myofascial dysfunction may also be associated with dizziness, a sense of imbalance and tinnitus, and treatment (as outlined below) may alleviate these symptoms. Thus the practitioner must keep MP on his list of key differential diagnoses for the older adult who presents with a chief complaint of dizziness. For a more extensive discussion of these and other MP and dysfunction syndromes, the reader is referred to the authoritative two-volume text by Janet Travell and David Simons, *Myofascial Pain and Dysfunction—The Trigger Point Manual*. Another less detailed but very useful introductory text that practitioners may want to consider is *Trigger Point Therapy for Myofascial Pain—The Practice of Informed Touch*, 2005, edited by Finando and Finando; www.InnerTraditions.com

### Management

The most important aspect of treating MP is attending to factors that perpetuate muscle dysfunction. Treatment of these factors and treatment of the trigger points themselves should occur in parallel. Ultimately a strengthening program to enhance muscular resilience should be implemented, and an aerobic program may also be beneficial to prevent recurrence. A summary of the overall approach to treating MP is provided in Table 123-6 and detailed discussion is provided below.

#### Treatment of Perpetuating Factors

A distinction must be made between *perpetuating factors* and *precipitating factors*. The factors that *perpetuate* MP in older adults typically are multiple and develop over a long period of time, creating an

**TABLE 123-6**

#### Approach to Treating Myofascial Pain Syndromes

1. Identify and treat perpetuating factors. e.g., correct leg length discrepancy after total joint replacement, inject rotator cuff and provide physical therapy for rotator cuff tendonitis, treat knee osteoarthritis, begin or optimize medications for Parkinson's disease, prescribe rolling walker for those with kyphosis.
2. Refer to a physical therapist who is experienced in treating patients with chronic pain for *gentle* stretching and strengthening, treatment of perpetuating factors, and for education regarding activity pacing and flare self-management techniques.
3. Perform trigger point injections or dry needling to achieve a local twitch response.
4. If psychological stressors are identified as a perpetuating factor, refer for cognitive-behavioral therapy.
5. Prescribe systemic analgesics only as adjunctive therapy, not as the primary mode of treatment.
6. Refer patients who do not respond to these treatments for interdisciplinary management in a pain clinic.
7. Prescribe aerobic exercise for cardiovascular fitness and prevention of pain flares.

cumulation of factors that must be addressed as comprehensively as possible to afford an optimal therapeutic response. In the older adult with low back pain, for example, a combination of lumbar spondylosis, degenerative scoliosis, and hip arthritis may contribute to the injury pool. The physical factors that *precipitate* MP may be overt such as a fall with direct trauma to the piriformis that causes piriformis syndrome or they may be more subtle such as a flare of knee osteoarthritis that alters gait and precipitates tensor fasciae latae pain. Psychological stressors may also precipitate flares of MP or they may act as perpetuating factors.

As part of the search for perpetuating factors, the practitioner should specifically identify any repetitive movements that contribute to muscular dysfunction such as those that occur in wheelchair users and computer operators. Proper body mechanics during sitting, standing, walking, and sleeping should be taught by an occupational or physical therapist and efforts to modify repetitive movements and/or other mechanical stressors should be instituted. Direct or indirect acute trauma also should be identified. For example, if a patient has a sudden leg length discrepancy, such as that which may occur following total hip or knee replacement, prescription of a shoe lift by a physical therapist may be helpful. For patients with long-standing leg length discrepancy, a shoe lift may disrupt the patient's established compensatory strategies and lead to mobility dysfunction and falls. In these patients, the muscle dysfunction of the pelvis and lower extremities should be first addressed by a physical therapist before considering an orthotic device. Abnormal posture also should be corrected. This can be particularly helpful for the patient with cervicogenic headaches. In the older adult with severe kyphosis related to multiple vertebral compression fractures, restoration of normal posture may not be possible, and prescription of a walker to alleviate strain on the lower back musculature should be considered strongly.

To the extent that psychological stressors are playing a role in perpetuating MP, CBT may be useful. Vitamin D deficiency also should be identified and treated given its association with musculoskeletal pain (see Plotnikoff reference) although randomized controlled

clinical trials evaluating its efficacy in patients with MP have not been performed. Patients who do not respond to these approaches in combination with trigger point treatment should be referred to an interdisciplinary pain clinic.

### Trigger Point Treatment

Treatment of trigger points utilizes noninvasive and minimally invasive techniques. The goal of both forms of treatment is deactivation or release of the trigger points. Noninvasive treatment typically consists of gentle, sustained stretching of involved muscles perhaps with application of a vapocoolant spray. Stretching and correction of perpetuating factors are the mainstays of therapy. Trigger points also can be deactivated with injection of a local anesthetic (and sometimes a corticosteroid, although rigorous data attesting to the efficacy of this approach are lacking) or “dry needling” using a hypodermic or acupuncture needle. While trigger point injection has never been shown to be more effective than dry needling, injections may be associated with less pain during the procedure and less postneedling soreness. Regardless of which technique is utilized, achieving a local twitch response, as discussed above, is thought to be the essential therapeutic element of the procedure. It should be emphasized that the duration of pain relief following trigger point injection is largely dependent upon patient compliance, that is, the patient’s willingness to maintain a stretching program and to eliminate perpetuating factors. An essential element of any physical therapy program for the treatment of MP, therefore, is instruction in a home exercise program that includes a daily stretching routine, identification and elimination of movements that may perpetuate myofascial dysfunction, and techniques to manage pain flares.

For the past decade, trigger point injections with botulinum toxin have been used to treat a variety of myofascial pain disorders. The effectiveness of botulinum toxin is often attributed to its paralytic effects. Antinociceptive effects of botulinum toxin, independent of chemical denervation, also have been suggested. Some studies have shown benefit of botulinum toxin injections in the treatment numerous MP syndromes including temporomandibular joint dysfunction, as well as myofascial neck and low back pain. The doses of botulinum toxin range from 25 to 100 units depending on the size of the muscle. Some research suggests that trigger point injections with botulinum toxin may provide a longer duration of relief than those with lidocaine and methylprednisolone. Use of botulinum is not FDA approved for the treatment of MP syndromes, and this off-label use should be explained to patients as part of obtaining informed consent.

Systemic analgesics should be regarded as adjunctive for the management of MP. Clonazepam is the only medication that has been found to help relieve pain in the context of a randomized controlled trial. Amitriptyline may benefit patients with tension-type headaches associated with MP. Both of these medications, however, are fraught with a number of serious adverse drug events such as delirium and falls. We have had some success with low-dose gabapentin (e.g., 300 mg twice a day) for the treatment of neuropathic MP, for example in patients with cervical spondylosis and MP of the paracervical musculature. Judicious use of cyclobenzaprine (e.g., 5–10 mg at bedtime) may be helpful for the patient with cervicogenic headaches.

A number of other treatments have been tried for MP, including topical medications such as capsaicin, lidocaine, and EMLA cream; repetitive magnetic stimulation; transcutaneous electrical

nerve stimulation; biofeedback; massage; ultrasound; laser therapy; traditional Chinese acupuncture and Japanese acupuncture; nerve blocks; and cervical spine dorsal root rhizotomy for the treatment of cervicogenic headaches. The quality of evidence at the present time cannot recommend for or against prescription of any of these treatments.

## CONCLUSION

Our understanding of the pathogenesis, diagnosis, and treatment of fibromyalgia and MP syndromes has grown significantly. We now understand fibromyalgia as a central sensitivity syndrome with patients demonstrating increased sensitivity to a variety of stimuli, especially pain. While the pathogenesis of fibromyalgia needs further study, there seems to be a genetic predisposition and a clear familial aggregation. Lower levels of central neurotransmitters and nociceptive chemicals are believed to be involved with fibromyalgia pathogenesis. Keys to the pathogenesis of MP syndromes lie in identifying perpetuating biomechanical factors.

For both fibromyalgia and MP syndromes, individualized approaches to treatment are recommended. Medications alone do not typically improve function, but may improve mood, sleep, and pain. Stretching and local modalities as well as identification and treatment of perpetuating factors should be considered first line for MP and aerobic exercise is a key component of the approach to treating fibromyalgia. While multidisciplinary treatment programs that include education, CBT, and exercise may be very effective for both fibromyalgia and MP syndromes, they are not widely offered and may be costly. Further studies are needed to advance the treatment of patients with these disorders, reduce the associated risk of functional compromise, and improve overall quality of life.

# Infection in the Elderly

*Kevin P. High*

## PREDISPOSITION OF THE ELDERLY TO INFECTION

There are a number of factors that increase the risk of infection in older adults when compared to young adults. The relationships between these risk factors, whether they are comorbidities, waning immunity, or age itself, may be very complex. For example, many older individuals have latent infection with *Mycobacterium tuberculosis* (i.e., asymptomatic infection) and do not manifest clinical illness despite an aging immune system and the presence of various comorbid conditions. However, superimposing malnutrition, perhaps caused by an intervening stress, may be the last insult necessary to tip the scales toward illness, resulting in clinical manifestations. This complex interplay of risk factors makes it difficult to determine the attributable risk of any one characteristic, and any risk factor in isolation cannot be considered “the cause” of infectious risk in the elderly. However, several well-recognized features associated with advanced age clearly do increase risk for clinical infection; these are reviewed in this chapter.

### Comorbidities

In the elderly individual, the increased incidence of infection and mortality for many infectious diseases (Figure 124-1) is likely a direct result of the comorbid conditions (e.g., diabetes, renal failure, chronic pulmonary disease, edema, immobility) that accompany advanced age. Comorbidity most often results in reduced innate immunity, defined as those responses that are not specific to a given organism or antigen. These include nonspecific barriers such as skin integrity, cough, and mucociliary clearance, and those immune responses triggered by recognition of patterns of microbial products (e.g., endotoxin, lipoteichoic acid) without the need for prior exposure such as complement, tissue phagocytes, and toll-like receptors (TLRs). Perhaps the best clinical example in which comorbidity contributes heavily to infection risk is chronic obstructive pulmonary disease (COPD). This disease, most often caused by prolonged ex-

posure to tobacco smoke, has a high prevalence in older adults. The impaired mucociliary clearance, alveolar macrophage dysfunction, and suppressed cough mechanism that accompany COPD substantially increase the risk for lower respiratory tract infection in the elderly. Comorbid diseases in elderly individuals with infection can also be more important predictors for worse outcomes. For example, community-acquired pneumonia (CAP) is typically treated on an outpatient basis and rarely causes mortality in patients younger than 50 years of age. However, multiple comorbid conditions and advanced age greatly increase the risk of mortality associated with CAP. In fact, while age itself dominates many CAP prognostic indices, advanced age alone is not a predictor of mortality in those persons older than 75 years of age where comorbidity dominates. Furthermore, cognitive decline and other barriers that reduce adherence to medical regimens often necessitate hospitalization of older adults in circumstances where their younger counterparts are often treated as outpatients, further increasing costs and enhancing the rate of complications.

### Waning Immunity

While comorbidities substantially predispose older adults to infection, there are also age-related fundamental changes in the immune response that may predispose the elderly to infection (see Chapter 3), so called immune senescence. Immune senescence is not merely a global state of reduced immunity, but a dysregulation of immune responses at multiple levels. Some aspects of immunity are upregulated, including the inflammatory response, which demonstrates constitutive activation in older adults, as evidenced by elevated C-reactive protein and interleukin (IL)-6 blood levels, and cellular activation of nuclear factor-kappa B (NF- $\kappa$ B). However, other innate immune responses (e.g., natural killer [NK] cell activity) are frequently reduced in older adults, and though originally thought to be normal, more recent data suggest polymorphonuclear neutrophil (PMN) function may also be impaired with reduced microbial phagocytosis and killing.

## Host Factors

### Comorbidities

Diabetes, Lung Disease,  
Renal Failure, Peripheral  
Vascular Disease

### Medication Use

Frailty/Impaired Cognition  
Physical Changes (dry mucous  
membranes/reduced gag reflex)

### Immune Senescence

## Social Factors

### Poor Nutrition

Crowding/Long-term Care Facility Residence

Poor Understanding/Acceptance of Prevention

**FIGURE 124-1.** Multiple determinants model of infection risk in older adults. The relative contribution of host versus social factors varies by individual and it is the accumulation of multiple risk factors that results in higher infection risk.

The most consistent immune deficit identified in advance age is a reduction in adaptive immune responses. There are decreases in naïve T-cell subsets, marked depression of cytokine production (particularly IL-2) and important cellular surface receptors (IL-2 receptor and CD28), and suppression of T-cell responses by inflammatory cytokines that inhibit T cell immunity such as IL-10 and prostaglandin E<sub>2</sub>.

Although there is little doubt that immune senescence exists, the clinical role of this phenomenon in the predisposition of the elderly person to infection remains uncertain. Many flaws plague the published observational studies, despite herculean efforts to minimize confounding using very strict criteria for entry (in most cases via use of the SENIEUR criteria). Ironically, less than 15% of the aged population meets SENIEUR criteria, and the generalizability and clinical relevance of the accumulated data remain in doubt. Is immune senescence irrelevant in patients with overwhelming comorbidity? Or is it the key factor that shifts the balance toward infection when young adults with comorbidity remain relatively well? A recent superb review highlights the confusing and often contrary results of human studies (see Castle, 2000).

## Nutrition

Nutritional status is a major confounder in studies of immunity in the elderly population. Protein–energy malnutrition (PEM) is present in 30% to 60% of patients older than 65 years of age who are admitted to the hospital, and is linked to delayed wound healing, pressure ulcer formation, CAP, increased risk of nosocomial infection, extended lengths of stay, and increased mortality. In community-dwelling older adults, PEM frequently goes unrecognized, but even older adults with mild PEM (i.e., those with a serum albumin of 3–3.5 g/dL) demonstrate poor vaccine responses and diminished cytokine responses to immune stimuli. Despite the strong epidemiologic evidence linking PEM to infection in the elderly, the role of nutritional supplements for preventing infection remains controversial. Some studies of residents who live in long-term care facilities suggest use of supplements may increase caloric intake, but other reports indicate meal-time calorie consumption may reciprocally decrease, leading to no net change in protein or calories. Despite this controversy, there is widespread agreement that adequate nutrition should be encouraged and provided to debilitated elderly individuals, and that adequate nutrition is essential for proper wound healing, and may speed functional recovery from serious infectious diseases (i.e., pneumonia).

Specific micronutrient deficiencies are also common in older adults, and several have been linked to poor immune function (e.g., vitamin B-12 deficiency and inadequate pneumococcal vaccine responses). Several micronutrient supplementation trials have been performed that highlight the potential importance of adequate nutrition even in apparently healthy elderly. Vitamin E supplementation ( $\geq 200$  mg/day) in healthy elderly individuals enhances delayed-type hypersensitivity (DTH) and vaccine responses for a primary T-cell–dependent antigen (hepatitis B), but has no effect on T-cell-independent vaccine responses (pneumococcal vaccine) or the booster response to tetanus. A word of caution, however: a recent meta-analysis of vitamin E supplementation suggested increased mortality in those taking  $\geq 400$  mg/day, highlighting the dangers of megadose therapy with some vitamins (vitamins A, D, E, K). Multivitamin/mineral supplements have been examined in healthy, free-living elderly persons and consistently demonstrate improved serum vitamin levels, but results are inconsistent with regard to preventing clinical infection or boosting vaccine responses. Other studies in elderly residents of long-term care facilities suggest zinc (20 mg/day) plus selenium (100  $\mu$ g/d), or specific commercial formulas may reduce the risk of infection, but more work is required to define the role of vitamin or mineral supplementation for augmenting immune response in the elderly population, and to determine whether there are specific subpopulations that could help identify target groups for therapy.

## Social and Environmental Factors

There is an increasing recognition that the health of seniors is not only a function of biomedical variables but also socioeconomic status, biophysical environment, and delivery of health care services. This “determinants of health” perspective combines biomedical, behavioral, social, and environmental explanations of illness and health (Figure 124-1). Probably the best example of this with respect to infectious diseases in the elderly individual is that of respiratory tract infections. Population-based studies reveal that lower income is associated with higher rates of CAP and invasive pneumococcal infections among elderly individuals. Lower socioeconomic status may predispose to infection either because of increased exposure to infectious agents (e.g., crowding) or because of increased susceptibility. Although the evidence is limited, this might be a result of worse nutritional status, more frequent exposure to air pollution or tobacco smoke, or inadequate vaccination.

Long-term care residents highlight the concept of “multiple determinants of health,” and the physical environment plays a particularly important role in infections in older adults who reside in long-term care facilities. This subset of the aging population has a particularly high incidence of respiratory and other infections (mainly urinary and skin infections). The close contact residents have with other residents plays a key role in the spread of respiratory infections such as influenza or with bacterial infections such as group A streptococcus (i.e., *Streptococcus pyogenes*). This combination of frail older individuals in a confined setting can lead to severe outbreaks with high mortality rates. The close proximity of residents, poor adherence to basic infection control measures, and the intense use of antibiotics are factors that lead to the spread of antibiotic-resistant bacteria such as methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), and multiresistant gram-negative rods. Although the actual infectious threat many of these organisms pose to individual residents is uncertain, the potential reservoir creates a problem when such residents are transferred to acute care hospitals where these organisms can spread to other susceptible hosts.

## DIAGNOSIS AND MANAGEMENT OF INFECTIONS IN THE ELDERLY PATIENT

### Presentation of Illness

Infectious diseases frequently present with atypical features in older adults. Serious infections may be heralded by nonspecific declines in functional or mental status, or anorexia with decreased oral intake. Underlying illness (e.g., congestive heart failure [CHF] or diabetes) may be exacerbated, leading the elderly patient to seek medical attention. The most common sign that triggers the clinician to look for infection, fever, is often absent in the elderly patient. Several studies show that frail elderly individuals have lower mean baseline body temperatures than the currently accepted normal of 98.6°F (37°C). Animal models of aging demonstrate that temperature elevations in response to endogenous pyrogens (IL-1, IL-6, tumor necrosis factor [TNF]- $\alpha$ ) are diminished with advanced age. The decline in basal temperature and blunted response to inflammatory stimuli make it less likely that a frail, older adult will achieve a body temperature commonly recognized as fever. It has been suggested that fever in frail older adults should be defined as (1) persistent elevation of body temperature of at least 2°F (1.1°C) over baseline values, or (2) oral temperatures of 99°F (37.2°C) or greater on repeated measures, or (3) rectal temperatures of 99.5°F (37.5°C) or greater on repeated measures. The sensitivity of detecting fever and infection in the nursing home setting has been improved using this definition, and reasonable specificity maintained. The importance of a “normal” or reduced temperature in the face of significant infection cannot be overemphasized. A blunted febrile response often leads to delayed diagnosis, and is an indicator of a poor prognosis.

Cognitive impairment also heavily contributes to the difficulty in diagnosing infection in the elderly. Subjects are often unable to communicate symptoms and clinicians should have a lower threshold to pursue objective assessments (e.g., laboratory and radiologic evaluations) in cognitively impaired elderly with changes in functional status.

Finally, age- and comorbidity-related changes in anatomy and physiology may confound interpretation of diagnostic evaluations.

Perhaps the best example of this is the diminished sensitivity for trans-thoracic echocardiography (TTE) for detecting vegetations on the heart valve in endocarditis. Studies suggest the additional echoes present as a result of age-related calcium deposition reduces sensitivity of TTE from 85% to 90% in adults aged 55 years and younger, to <50% for those older than 70 years of age.

### Antibiotic Management

The profound physiologic changes associated with aging and comorbidities alter drug distribution, metabolism, excretion, and interactions (see Chapter 8). Antibiotic dose reductions are occasionally required in the elderly adult because of changes in renal function or predisposition of the elderly adult to important side effects such as changes in mental status (e.g., fluoroquinolones). In addition, antibiotic interactions are more frequent because most elderly persons are taking multiple medications. Digoxin, warfarin, oral hypoglycemic agents, theophylline, antacids, and proton pump inhibitors all have significant interactions with commonly prescribed antibiotics. Drug concentrations can increase (e.g., enhanced digoxin toxicity associated with macrolides, tetracyclines, and trimethoprim) or decrease (e.g., reduced quinolone absorption with concomitant administration of antacids) with concomitant drug administration. These changes and the increased incidence of side effects in the elderly often lead clinicians to the dictum of “start low, go slow” when administering new medications in older adults. However, for antibiotics, this is not an appropriate strategy. Altered gastric motility, decreased absorption, increased adipose tissue, and coadministration of other drugs can decrease blood levels of antimicrobials in the elderly patient, and since systemic antibiotics reach tissues via blood flow, poor vascular perfusion to the site of infection, particularly in skin and soft-tissue infections of the lower extremities, may reduce efficacy. Adherence may be limited by poor cognitive function, inadequate understanding of the drug regimen, impaired hearing or vision, and polypharmacy, and studies suggest that any regimen requiring greater than twice daily dosing is associated with very poor adherence rates. Finally, there are data that suggest higher antibiotic levels are particularly important for efficacy in older adults. This is true for antibiotics that are “concentration-dependent” (i.e., the higher the concentration in relation to the minimal inhibitory concentration (MIC), the better the antibiotic kills). The activity of fluoroquinolones is concentration-dependent and the relationship between bacterial clearance and the serum/MIC ratio for levofloxacin suggests drug concentrations must be nearly twice as high in older adults than in young adults to clear infection. The reason for this is unclear, but may be caused by impaired defense mechanisms described above that aid clearance of bacteria.

Many ethical dilemmas surround antibiotic use in frail elderly persons and terminally ill patients. The 1998 American Medical Association (AMA) Council of Ethical and Judicial Affairs included antibiotics, along with mechanical ventilation, as “life-sustaining” treatment. Others argue that antibiotics are part of ordinary care, even those who are designated to be receiving “comfort measures only.” While every clinical situation is unique, and no blanket recommendation can be made for the use or nonuse of antibiotics in the terminally ill, it seems prudent to include antibiotic administration in the discussion of advanced directives as a potentially life-sustaining maneuver and to treat it no differently than any other medical intervention such as surgery or mechanical ventilation.

Finally, although older adults are at the greatest risk for illnesses that are indications for outpatient parenteral antibiotic therapy (OPAT) (e.g., for treatment of endocarditis or osteomyelitis), OPAT was infrequently used in older adults primarily because of the fact that Medicare did not cover the cost of OPAT and older adults frequently had to be admitted to nursing homes or stay in acute care hospitals to obtain appropriate therapy. With the institution of Medicare Part D in 2006, OPAT is now covered, although navigating the system to obtain reimbursement for both the antibiotic and the necessary supplies for administration takes considerable skill. A recent study and accompanying editorial outline the safety, efficacy, and patient selection criteria for OPAT in older adults, and provides Web links to sites that assist with reimbursement issues (see Malani, 2008).

## CLINICAL SYNDROMES IN THE ELDERLY

### Infective Endocarditis

Although infective endocarditis (IE) was primarily a disease of young and middle-aged adults and associated with post-rheumatic fever and congenital valvular lesions, it has become a disease of the elderly population, associated with degenerative valvular disorders and prosthetic valves (prosthetic valve endocarditis [PVE]). Furthermore, temporary and permanent pacemakers, pulmonary artery catheters, and other invasive devices are more frequently used in older adults and predispose subjects to IE.

Native valve IE in young adults is typically caused by viridans streptococci, *S. aureus*, and occasionally by HACEK organisms (*Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, *Kingella*). These same organisms predominate in the elderly patient, but comorbidities and prosthetic devices change the profile of causative agents; gastrointestinal (GI) and genitourinary (GU) organisms such as enterococci and gram-negative rods become more common in native valve IE. Coagulase negative staphylococci are a frequent cause of PVE, both from contamination at the time of surgery and from occult or documented bacteremia during the hospital stay. Other nosocomial bacteremias, often with more resistant organisms (e.g., *Enterobacter* spp.), can also result in PVE.

Endocarditis is difficult to diagnose in the elderly patient. Fever and leukocytosis are less common (55% and 25%, respectively, for elderly patients vs. 80% and 60%, respectively, for younger patients). As stated above, the prominence of degenerative, calcific valvular lesions and prosthetic valves lowers the sensitivity of TTE. Transesophageal echocardiography (TEE) may be more sensitive, and in at least one study, TEE improved the diagnostic yield by 45% over that of TTE. Age alone is not a major risk for mortality, with a 2-year survival of 75% for IE in all age groups unless major comorbidities exist.

Antibiotic treatment of IE is directed at identified pathogens or the most likely causes if blood cultures are negative (Table 124-1). Therapy is administered intravenously for 2 to 6 weeks. Combination regimens with aminoglycosides are particularly problematic in the elderly patient because of toxicity (both renal and ototoxicity), but is occasionally unavoidable in certain circumstances (e.g., enterococcal IE). Surgical therapy is required only when specific criteria are met, primarily recurrent embolic events or worsening heart failure.

Antibiotic prophylaxis is available for bacterial endocarditis for all “at-risk” patients and should be provided for dental, upper respira-

tory tract, GI, or GU procedures. Although the evidence supporting this practice is relatively weak, it has become the standard of care. Current recommendations for IE prophylaxis are available in sources listed in the references.

### Bacteremia and Sepsis

Bacteremia rates are much higher in elderly patients than in younger patients, comprising up to 14% of all admissions in some geriatric units. Older patients with bacteremia are less likely than younger patients to have systemic signs such as fever, chills, or diaphoresis. Bacteremia in the elderly patient is more likely to arise from a GI or GU source than in young adults. Thus, the causative agent is more likely to be a gram-negative rod.

Despite a similar initial cytokine response to that of young adults with sepsis, the prognosis of sepsis in the elderly is worse. The 28-day mortality for sepsis in young adults is 26% to 33% versus 35% to 42% in adults older than age 65 years. Nosocomial gram-negative bacteremia carries a mortality rate of 5% to 35% in young adults, but 37% to 50% in older adults. A major contributing factor is reduced physiologic reserve because of age and comorbidities that reduce the ability of older adults to recover from a septic episode.

Antibiotic management of bacteremia and sepsis in the elderly patient is similar to that of younger adults, and the importance of initially broad coverage must be emphasized. Mortality is greatly reduced if an antibiotic that covers the eventually isolated organism is included in the initial regimen, whereas waiting to identify the organism and switching the antibiotic at that time has little to no effect on overall survival. Thus, it is imperative to include coverage for MRSA, resistant gram-negative rods, enterococci, and other resistant organisms when there is a high clinical suspicion for resistant organisms and the elderly, particularly nursing home residents, represent a high risk population. Immunomodulatory/adjunctive therapy for sepsis, activated protein C, has been approved and should be considered for those patients with sepsis and evidence of dysfunction in at least two organ systems. A subset analysis of the trial that led to FDA approval for activated protein C, demonstrated that elderly persons have a statistically greater chance of clinically important bleeding as an adverse event yet the benefit for in-hospital and long-term survival was even greater in older adults than in young persons.

### Prosthetic Device Infections

As the prevalence of the U.S. population older than age 65 years has increased, permanent implantable prosthetic devices have become common. Prosthetic joints, cardiac pacemakers, artificial heart valves, intraocular lens implants, vascular grafts, penile prostheses, and a variety of other devices are primarily placed in the elderly. Foreign bodies interact with bacterial and host immune factors, often leading to infection. While it is impossible to review all prosthetic device infections in this chapter, several general concepts are presented. Prosthetic device infections are usually categorized by causative agents that typically present early (<60 days from implantation) or late (>60 days). Early infections are primarily caused by contamination at the time of surgery or events associated with the implantation hospitalization (e.g., bacteremia caused by IV or urinary catheters). Thus, the causative organisms for early prosthetic device infections are primarily skin and nosocomial flora. Coagulase-negative

TABLE 124-1

## Suggested Empiric Antimicrobial Therapy for Common Infections in Older Adults

INFECTION	THERAPY	COMMENTS
Community-acquired		
Outpatient Therapy		
Acute sinusitis	Amoxicillin	Amox/clav or new macrolide (clarithromycin or azithromycin) if refractory; new macrolide if penicillin allergic
Chronic bronchitis	Amoxicillin-clavulanate	Infectious exacerbations only; new macrolide if penicillin allergic
Pneumonia	[Azithromycin or Clarithromycin + 2nd gen Ceph or Amox/clav] or Resp-FQ	Smoker/COPD most common
Cellulitis	Amox/clav or Cephalexin	Community-acquired MRSA much more common since 2005; include TMP-SMX or Minocycline if suspected (e.g., recurrent boils, very aggressive or abscess-forming skin/soft-tissue infection)
Infected neuropathic ulcer	Amox/clav	Initial outpatient treatment of diabetic foot infection
Symptomatic UTI	FQ, TMP-SMX	Uncomplicated cystitis or pyelonephritis
Infectious diarrhea	FQ	Oral rehydration is key
<i>C. difficile</i> diarrhea	Metronidazole (Vancomycin for serious disease)	Elevated white blood cell count common
Inpatient Therapy		
Pneumonia	[Ceftriaxone + Azithromycin or Clarithromycin] or Resp-FQ alone	Seriously ill (intensive care unit) combination therapy 3rd gen ceph + Resp-FQ consider <i>Pseudomonas</i> if severe COPD or structural lung disease
Pyelonephritis (no catheter)	3rd gen Cephalosporin or FQ	
Urosepsis (with catheter)	3rd gen Cephalosporin + ampicillin or vancomycin	Catheter-related urosepsis often polymicrobial; have to consider enterococcal species, in addition to gram-negative bacilli
Acute bacterial meningitis	Ceftriaxone + Vancomycin + ampicillin	Vancomycin needed because of small % of ceftriaxone-resistant <i>S. pneumoniae</i> ; give dexamethasone with or prior to antibiotics if gram stain of CSF reveals bacteria
Intra-abdominal infection	[Ampicillin/sulbactam + Gentamicin] or Ampicillin + Gentamicin + Metronidazole] or Pip/tazo or carbapenem	Surgery often indicated for appendicitis, cholecystitis, ischemic colitis, abscess drainage, but rarely required for diverticulitis; tigecycline for patients with significant beta-lactam allergy
Native valve endocarditis	Penicillin + Nafcillin	Vancomycin for penicillin-allergic patient
Infected diabetic foot ulcer	Ticar/clav or Pip/tazo	3rd gen Ceph and clinda for penicillin allergy; tigecycline for significant beta-lactam allergy
Cellulitis	Ampicillin/sulbactam	Add clinda if high suspicion for GAS; vancomycin if MRSA suspected; vancomycin + FQ for $\beta$ -lactam allergy
Septic shock syndrome; with no obvious focus	Carbapenem; add clindamycin if GAS suspected	Aggressive supportive care; consider activated protein C if two or more end-organs with dysfunction; consider intravenous immunoglobulin if streptococcal toxic shock syndrome
Nursing home-acquired		
Infected pressure ulcer	FQ + clindamycin (po); ticar/clav or Pip/tazo (IV)	Pressure-relieving devices, nutrition, débridement essential; culture/x-ray to identify osteomyelitis or MRSA; NEVER do swab culture of surface to identify organism(s) – only surgical cultures of value
Pneumonia	Resp-FQ or (Ceftriaxone + Azithromycin)	Consider tuberculosis (primary or re-activation)
Urosepsis	Ciprofloxacin (po) Ceftriaxone (IM/IV)	Add enterococcal coverage if catheter
<i>C. difficile</i> colitis	Metronidazole (Vancomycin for serious disease)	Close attention to infection control as nosocomial spread documented; spores not killed by alcohol-based antiseptics, must wash hands with soap/water
Nosocomial/hospital		
Pneumonia	Cefepime or carbapenem or pip/tazo	Decision influenced by numerous factors: underlying medical conditions, mental status, respiratory support, prior antibiotic exposure, aspiration, risk of MRSA (add vancomycin)
Catheter-associated urosepsis	Vancomycin plus 3rd gen ceph or FQ	Culture to guide subsequent therapy
Intravenous catheter-associated infection (cellulitis, phlebitis, abscess, bacteremia)	Vancomycin	If immunocompromised, add cefepime or ceftazidime; surgery required for septic thrombophlebitis
<i>C. difficile</i> -related diarrhea	Metronidazole (Vancomycin for serious disease)	Discontinue the implicated antimicrobials if possible; attention to infection control and hand washing as noted above
Postoperative wound infection; incision/deep with cellulitis, abscess, or bacteremia	Cefazolin (mild infection) Vancomycin + 3rd gen ceph (severe infection)	Reopen and explore wound; definitive therapy guided by smears/cultures

2nd gen, second generation; 3rd gen, third generation; Amox/clav, amoxicillin-clavulanate; Carbapenem, imipenem-cilastatin or meropenem; ceph, cephalosporin; clinda, clindamycin; COPD, chronic obstructive pulmonary disease; FQ, Fluoroquinolone; GAS, group A streptococci (*S. pyogenes*); MRSA, methicillin-resistant *S. aureus*; Pip/tazo, Piperacillin-tazobactam; Resp-FQ, respiratory fluoroquinolone (gatifloxacin, levofloxacin, moxifloxacin); Ticar/clav, ticarcillin-clavulanate; TMP-SMX, trimethoprim-sulfamethoxazole; vanco, vancomycin.

staphylococci predominate; *S. aureus* and diphtheroids are common as well. Gram-negative bacilli, fungi, or polymicrobial infection are rare causes of early infection except when the material itself or associated products such as dressing material are contaminated. Late infections tend to be caused by the same organisms that cause community-acquired bacteremia in the elderly population, and bacteremic seeding of the device is likely the mode of infection in these cases. Staphylococci, including coagulase-negative staphylococci, are the exception to this rule, playing a major role in prosthetic device infections in both the early and late periods. Thus, empiric anti-staphylococcal therapy is imperative in either early or late prosthetic device infection.

It is difficult to cure prosthetic device infections (i.e., eradicate the organism) with the device in place. However, in some instances, early antibiotic intervention combined with aggressive surgical débridement may result in cure without removing the device. Because prosthetic device infections often include biofilms and occur in the setting of other factors that limit antibiotic efficacy (e.g., poor circulation), it is preferable to use bactericidal antibiotics, and combinations with a second agent that penetrate these areas well (e.g., rifampin) may be most effective. If early, aggressive therapy is ineffective in controlling the infection, it is imperative that the device be removed. In prosthetic joint infection (the clinical entity of device-related infection most well-studied) two-stage procedures, where the device is removed and antibiotics given for an extended period (usually  $\geq 6$  weeks) with delayed reimplantation have the highest success rate. However, for life-saving devices, such as mechanical valves or implantable defibrillators, this is not an option.

A recent analysis of surgical débridement and long-term suppressive antibiotics versus two-stage removal/reimplantation for prosthetic hip infection used functional assessment, not just cure rate, as an important indicator outcome. Using Markov modeling, the two-stage procedure was preferred if the relapse rate in the débridement strategy was assumed to be  $>60\%$  or the age of the patient with the infected arthroplasty was  $<79$  years. However, débridement and suppressive antibiotics strategy were favored when these conditions were not met. Relapse rates of the débridement/retention with long-term antibiotic strategy are approximately 30% overall, but depend on the organism, duration of symptoms, which joint is infected, the susceptibility of the organism, and many other factors known and unknown. This model gives some guidance, but allows clinicians freedom to adjust strategy based on baseline functional status and infecting agent.

Prevention of prosthetic device infection is facilitated by the use of clean air systems and/or personal isolator systems in the operating room. Although there are limited data for efficacy, typical antimicrobial prophylaxis for clean surgery seems appropriate; prophylaxis other than at the time of surgery remain contentious. Perioperative antimicrobial prophylaxis for dental procedures is clearly indicated for prosthetic valves and is frequently employed for vascular grafts, particularly within the first few months after placement. There is no evidence to demonstrate benefit for prophylaxis in patients with prosthetic joints, intraocular lens implants, intracoronary artery stents, cerebrospinal fluid shunts, breast implants, or other less-commonly used prostheses. The American Dental Association (ADA) recommends “considering” antibiotic prophylaxis for patients with prosthetic joint at “high risk,” which the ADA defines as joints within 2 years of placement, immunosuppressed patients (including immune compromise as a result of diabetes mel-

litus, rheumatoid arthritis, and malnourishment), or those with a previous joint infection.

## Tuberculosis

Tuberculosis rates are again increasing in the United States after several years of decline, in large measure, caused by disease present in immigrants and the aging population. It has long been established that advanced age is a major risk factor for developing tuberculosis, and even with the increasing populations of young adults at risk as a result of the HIV epidemic and increasing immigrant populations, older adults still comprise approximately one quarter of all tuberculosis cases reported in the United States. Tuberculosis often presents differently in older adults than in young adults. Several studies have demonstrated that, when compared to young adults, older adults are less likely to present with fever, night sweats, cough, or hemoptysis, and more likely to present with nonspecific symptoms of dizziness, nonspecific pain or mental “dullness,” a prior history of tuberculosis, and a concomitant diagnosis of underlying cancer. Radiographic and laboratory differences also occur with older adults being more likely to have widespread pulmonary parenchymal infiltrates whereas young adults are more likely to have isolated upper lobe infiltrates, and older adults are more likely to have evidence of malnutrition (i.e., reduced serum albumin).

Probably the most important issue in older adults remains the imperfections of diagnostic testing for tuberculosis. Using the tuberculin skin test (TST) in classic studies, William Stead and colleagues at the University of Arkansas defined the prevalence of TST positivity in older adult residents of long-term care facilities, the risk for reactivation of *M. tuberculosis* with and without prophylactic therapy, and the survival of older adults in each of these situations. Overall conclusions from these studies suggest that the sensitivity of the TST to detect latent infection declines with age, that tuberculosis is rare ( $<0.2\%$ ) in older residents in whom the TST is never positive, that TST-positive individuals develop clinical disease 2% to 5% of the time (much higher if the TST represents a recent conversion—7% to 12% incidence of clinical disease), and that isoniazid (INH) prophylaxis (usually provided as 300 mg daily for 12 months in the studies by Stead and colleagues) in TST-positive subjects reduces the risk of clinical disease to  $\leq 0.3\%$  for most subjects (the exception being those who are TST-positive and previously had active tuberculosis—in those cases, isoniazid therapy reduced the risk from 2–5% to 1.5–2%). The benefits of isoniazid prophylaxis are long-lasting with improved survival in TST-positive treated subjects (vs. untreated TST-positive subjects) apparent at 1.5 years and persisting up to at least 8 years.

From these data, it is clear that identifying TST-positive older adults is important for preventing active tuberculosis through INH prophylactic treatment. The confounding issues, however, surround interpretation of the TST. In the most recent guidelines from the American Lung Association, a TST is considered positive if  $>5$  mm induration in HIV-positive persons, recent TB contacts, those with fibrotic changes on chest radiograph consistent with prior TB, and immunosuppressed patients (including those on  $\geq 15$  mg/day of prednisone for at least one month);  $>10$  mm is considered positive for recent immigrants, injection drug users, residents and employees of healthcare facilities (including nursing homes), and persons with high-risk conditions (silicosis, diabetes mellitus, chronic renal failure, leukemia/lymphoma, head and neck or lung cancer, weight loss

$\geq 10\%$  of ideal body weight, s/p gastrectomy); for all other persons a TST  $> 15$  mm is considered positive.

New diagnostic tests for tuberculosis have been developed and include quantitation of interferon- $\gamma$  release from whole blood or Elispot assays both measured after ex-vivo *M. tuberculosis* antigen stimulation. Unfortunately, these newer assays have only demonstrated modestly improved sensitivity or specificity. The pooled sensitivity from multiple studies appears to be 71% for TST, 76% for interferon- $\gamma$  release assays, and 88% for the Elispot assays. The specificity for the three tests is 66%, 97%, and 92%, respectively. None of the tests appears to be useful for following response to therapy.

The treatment of tuberculosis in older adults does not differ from that of young adults, but older adults are more susceptible to adverse effects and drug-drug interactions. Latent disease (TST-positive only without clinical signs and symptoms), if not previously treated, should be treated with 9 to 12 months of INH, whereas patients with clinical illness should initially receive four drugs (usually INH, rifampin, pyrazinamide, and ethambutol) pending culture and susceptibility testing. The duration of therapy is dependent on many factors including the site of infection, susceptibility test results, and clinical response.

## Fever of Unknown Origin

Fever of unknown origin (FUO), classically defined as temperature  $> 101^\circ\text{F}$  ( $38.3^\circ\text{C}$ ) for at least 3 weeks and undiagnosed after 1 week of medical evaluation, has different causes in elderly adults and in young adults (Table 124-2) that should influence the diagnostic workup. The cause of FUO can be determined in virtually all cases and approximately one third of cases will have treatable infections (e.g., intraabdominal abscess, bacterial endocarditis, tuberculosis, or occult osteomyelitis). In contrast to young adults, connective-tissue disease (CTD) is a more frequent cause of FUO in adults older than age 60 years. A compilation of several recently published series suggests that 25% of all FUOs in the elderly patient are caused by CTDs. However, the CTD most likely to cause FUO in young adults is systemic lupus erythematosus (SLE), whereas SLE was absent in series of elderly patients and replaced by temporal arteritis

(TA) and polyarteritis nodosa (PAN). Neoplastic disease accounts for another 20%, most often a result of hematopoietic malignancies (e.g., lymphoma and leukemia). Importantly, however, multiple myeloma, a disease much more likely in older adults than in young adults, is almost never a cause of FUO. Drug fever is a common cause of FUO in the elderly, and Wegener's granulomatosis, deep venous thrombosis with or without recurrent pulmonary emboli, and hyperthyroidism occasionally cause FUO in older adults.

A reasonable approach to FUO in the elderly can be inferred from the most likely causative entities. A thorough history and physical examination; basic laboratory evaluations of complete blood counts with differential, serum chemistries and hepatic enzymes, thyroid function studies, erythrocyte sedimentation rate (ESR), placement of a purified protein derivative (PPD) skin test, a chest x-ray, and initial blood and urine cultures should begin the search. If the diagnosis continues to be elusive and the ESR is elevated, temporal artery biopsy even in the absence of typical history or objective physical findings should be strongly considered. If the source remains obscure, or if there is a low suspicion for TA, abdominal imaging with computed tomography (CT) or magnetic resonance imaging (MRI) should be performed. Further invasive diagnostic procedures, such as bone marrow and liver biopsy, or laparoscopy, should be considered in specific cases, but are low yield unless there are significant clues for involvement (e.g., cytopenias or hepatomegaly).

## IMMUNIZATION OF THE ELDERLY

Immunization recommendations for older adults are constantly being updated. The latest consensus recommendations can be found online at the Centers for Disease Control (CDC) Web site at: <http://www.cdc.gov/vaccines/recs/schedules/adult-schedule.htm>

### Pneumococcal Vaccine

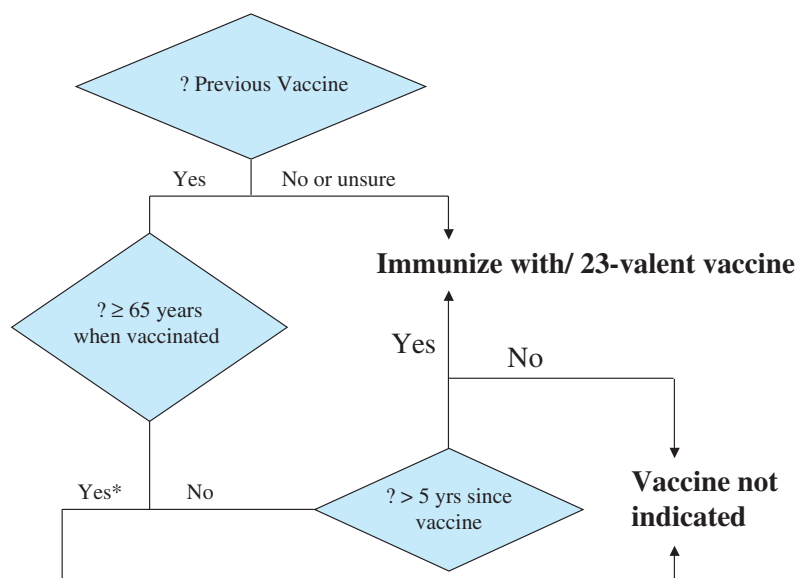

Many reviews and meta-analyses have been performed to help assess the benefit of pneumococcal immunization in older adults. Although many have failed to reach statistical significance indicating benefit, the confidence intervals of negative studies have not ruled out benefit, particularly when only invasive disease end points (i.e., bacteremia and meningitis) were the outcomes selected. Some of the lack of clear benefit may be a result of waning of efficacy at the extremes of old age ( $> 85$  years), unrecognized immune compromise in many older adults, and the fact that the pneumococcal vaccine is really 23 different vaccines (i.e., 23 serotypes) and failure of any one serotype is considered a failure of the vaccine. Despite these ongoing scientific discourses, pneumococcal immunization for persons age 65 years and older has become standard practice, as well as for many patients younger than age 65 years with comorbid conditions. If more than 5 years has elapsed since the first dose and the patient was vaccinated prior to the age of 65 years, repeat vaccination is recommended and safe (Figure 124-2). The 23-valent polysaccharide vaccine, when given to adults older than age 65 years, is similar in cost-effectiveness to many procedures commonly employed in older adults (e.g., multiple screening procedures, angioplasty and coronary artery bypass grafting), even when one limits consideration of efficacy to only invasive disease (i.e., blood-borne infection), making no assumption for any benefit with regard to pneumonia. Pneumococcal

**TABLE 124-2**

### Fever of Unknown Origin (FUO) in the Elderly Patient

MAJOR CAUSES	% OF CASES*
Infections	35
Intra-abdominal abscess	12
Tuberculosis	6
Infective endocarditis	10
Other	7
Collagen vascular disorders	28
Temporal arteritis/polymyalgia rheumatica	19
Polyarteritis nodosa	6
Other	3
Malignancy	19
Lymphoma/other hematological	10
Solid tumors	9
Other (pulmonary emboli, drug fever)	10
No diagnosis	8

\*Percentages represent pooled data from three studies of FUO in the elderly patient.

\*re-vaccination not indicated for persons vaccinated at age  $\geq 65$  yrs.

**FIGURE 124-2.** Decision analysis for pneumococcal vaccine per current Advisory Committee on Immunization Practices recommendations.

vaccine can be given concurrently with other vaccines at a different anatomic site.

Implementing current pneumococcal vaccine recommendations remains the greatest obstacle to prevention of fatal *S. pneumoniae* disease in the elderly. According to CDC estimates, only 40% to 50% of eligible elderly persons receive pneumococcal vaccine. Many unvaccinated elderly patients diagnosed with invasive pneumococcal disease saw a medical practitioner within the prior 6 to 12 months. The CDC and its Advisory Committee on Immunization Practices (ACIP) have outlined several strategies for improving vaccine administration including (1) age-based: review immunizations in all persons at age 50 years, vaccinating those with qualifying comorbid conditions; (2) organizational (e.g., standing orders): routine administration in elderly and at-risk patients in office, nursing home, and hospital settings by a blanket order for all patients (this is the single-most effective strategy); (3) community-based: public health promotions focusing on underserved, often inner-city populations and community outreach programs (senior centers, civic organizations, etc.); and (4) provider-based: physician-reminder systems (chart checklists, computer "flags," prehospital discharge, etc.).

Protein-polysaccharide conjugate pneumococcal vaccines may be more effective and are approved for use in children. Conjugate vaccines reduce nasopharyngeal carriage of pneumococcus, thus reducing the incidence of both mucosal (i.e., otitis media) and invasive disease in children. Importantly, the conjugated pneumococcal vaccine reduces nasal carriage of pneumococci and has led to sharp declines in disease in older adults since many infections in older adults are acquired from children (Figure 124-3). This concept of "herd immunity," reducing the risk of disease in the most vulnerable older adults by immunizing children may have important implications for public health strategies to reduce the risk of infection in older adults who coincidentally are the most likely to experience poor responses to the currently available vaccines (see High, 2007).

## Influenza

The current influenza vaccine is a killed virus that is modestly immunogenic with estimated efficacy rates of 60% for illness and 50% to 60% for mortality. Annual influenza immunization reduces rates

of respiratory illness, hospitalization, and mortality in the elderly population, and current ACIP recommendations are for all patients older than the age of 50 years or with underlying medical illnesses to be immunized just prior to influenza season each year. Medical personnel and caregivers for high-risk patients should also be immunized to reduce transmission to those at increased risk for complications. A live, attenuated influenza vaccine has been under development for years and appears to be more effective, but has not yet been approved for widespread use nor adequately studied in older adults (see Chapter 130 for additional details).

## Zoster

Zoster is much more common, and the devastating effects of postherpetic neuralgia much more frequent in older adults than in young

**FIGURE 124-3.** Reduction in the incidence of invasive pneumococcal disease in older adults after introduction of the conjugated pneumococcal vaccine in children. Presumably, the reduction in circulating pneumococcus in the community induced by protective immunity in children by the conjugated vaccine reduced exposure in older adults and consequently serious pneumococcal disease. All declines from 1998–1999 to 2003 are significant (–28%, –35%, –29% in the >84-, 75–84-, and 65–74-yr age groups, respectively). (Data from JAMA. 2005;294:2043.)

adults. In 2006, the FDA approved a vaccine that reduces the risk of zoster by about 50% and the risk of clinically significant postherpetic neuralgia by about 60%. The FDA approved the vaccine for use in those aged 60 years and older without a prior history of zoster. The ACIP however recommends the vaccine for all adults aged 60 years and older regardless of prior zoster history citing the safety of the vaccine and the unreliability of a zoster history (see Chapter 129 for additional details).

## Other Vaccines

The elderly population is the group most at risk for tetanus in the United States, with older women being particularly susceptible because of a lower likelihood of receiving boosters associated with minor/moderate trauma. Subprotective levels of tetanus antibody (<0.01 U/mL) have been found in 43% to 61% of men and in 48% to 71% of women older than age 50 years. A complete vaccine series is indicated for persons with an uncertain history of tetanus immunization and for those who have received fewer than three doses. Boosters should be given at 10-year intervals, or more frequently with high-risk injuries such as burns, puncture wounds, or extensive soft-tissue injury.

Hepatitis vaccines may also be considered for the elderly patient under certain circumstances. Hepatitis B vaccine is indicated for all persons at risk for percutaneous or mucosal exposure to infected blood or body secretions. Older adults may have comorbidities (e.g., renal failure) that place them at risk, but they also commonly volunteer at health care facilities and should be considered at risk if they engage in any patient contact. Hepatitis A vaccine is indicated in more limited circumstances such as chronic hepatitis C, travel, and for men who have sex with men. Unfortunately, the efficacy of hepatitis A and B vaccines in older adults is unknown, but may be much lower than in young adults. Age-related declines in antibody titers to levels below those considered protective begin as early as age 35 years and by age 70 years, less than half of adults administered the hepatitis B vaccine, and only two thirds of those given the hepatitis A vaccine will produce serum antibodies to levels considered protective.

## TRAVEL RECOMMENDATIONS FOR THE ELDERLY PERSON

Elderly persons are among the most widely traveled members of our society. The Centers for Disease Control and Prevention Web site (<http://wwwn.cdc.gov/travel/content/Vaccinations.aspx>) has information on recommended vaccines. Many countries require cholera and yellow fever vaccines prior to entry, but a specific note of caution must be sounded for elderly adults. The yellow fever vaccine is a live-virus vaccine and recent data suggest that older adults are six times more likely than young adults to experience a serious adverse event. Furthermore, although still quite rare, reactions requiring hospitalization or resulting in death are 3.5- and 9-fold higher in adults aged 65 to 74 years and older than 75 years, respectively, when compared to young adults. Because the incidence of yellow fever in travelers is very low, particularly when travel is limited to urban centers, a compelling case to administer the vaccine should be elicited prior to administering yellow fever vaccine in older adults. Often the most compelling reason is that countries may deny access to those who

cannot prove recent immunization, but a physician's letter of exemption is often acceptable.

Other recommended immunizations include hepatitis A vaccine, which has replaced intramuscular immunoglobulin as the preferred method of prevention for hepatitis A. Hepatitis A immunization is strongly encouraged for individuals anticipating prolonged travel (usually longer than 3 weeks) in areas where water and sanitary conditions are uncertain. Similarly, typhoid vaccine may be indicated for travel for extended periods of time to rural areas with poor sanitation. Other considerations include rabies (particularly when traveling to rural areas of Southeast Asia where stray dogs are commonly encountered), hepatitis B, Japanese encephalitis, and meningococcal vaccines (particularly for travel to sub-Saharan Africa).

Malaria chemoprophylaxis can be difficult in the elderly. Side effects are more common for many agents (e.g., mefloquine may produce dizziness, change in mental status, and bradycardia or prolonged QT intervals), and coadministration may be difficult in those taking cardiac medications or with significant heart disease. There are multiple alternative regimens for malaria prophylaxis but recognition of current resistance patterns is critical. Clinicians are directed to the CDC Web site ([www.cdc.gov/travel](http://www.cdc.gov/travel)) for the most up-to-date information.

Diarrhea occurs in 25% to 50% of travelers to developing countries. Primary treatment consists of fluid and electrolyte replacement, but antimicrobial therapy with a quinolone is indicated when diarrhea is accompanied by fever, bloody stools, or is prolonged. Antimotility agents are safe when coadministered with antibiotics.

# General Principles of Antimicrobial Selection

Maureen Bolon ■ Stephen G. Weber

## INTRODUCTION

When treating infection in older patients, selection of an antimicrobial regimen often precedes the identification of the causative pathogen and may sometimes be necessary even before the specific site of infection has been established. In these cases, the choice of therapy is typically based on the clinician's estimation of the most likely causative organism as well as properties of the available antimicrobial agents. This method of antimicrobial selection is described as "empiric," as opposed to "pathogen-directed," in which the causative organism has already been determined by the results of clinical cultures and antimicrobial susceptibility testing. This chapter addresses the unique challenges of selecting optimal empiric antimicrobial therapy for older patients with known or suspected infection.

To provide both a framework for discussion as well as a practical tool to be applied at the bedside, the process of selecting empiric antimicrobial therapy for older patients may be considered in three steps. First, to determine the potential causative pathogen as well as the appropriateness of initiating antimicrobial therapy, clinical and epidemiological clues are examined in order to establish the most likely site of infection. Next, estimation of the likelihood of antimicrobial resistance, together with consideration of the seriousness of the patient's infection and overall clinical status are used to determine the most appropriate breadth of antimicrobial coverage. Finally, pharmacological issues, including the pharmacokinetics of the available agents, potential toxicities and drug interactions are considered in order to facilitate the final selection of the most appropriate antimicrobial agent or agents. Once empiric therapy is initiated, the patient's clinical progress is closely followed and the antimicrobial regimen is broadened or narrowed according to the results of testing in the clinical microbiology laboratory. This process of choosing empiric therapy is summarized in [Table 125-1](#).

In the section that follows, this systematic approach to the management of older patients with known or suspected infection is re-

viewed in greater detail. Thereafter, the strategy is applied to the discussion of specific recommendations for antimicrobial therapy for a variety of infectious syndromes.

## Identifying the Causative Pathogen

### Clinical Features

When evaluating any patient with possible infection, determination of the most likely site of infection is a critical first step for the clinician who wishes to establish the causative pathogen in order to select the most appropriate antimicrobial regimen. The unique and often enigmatic manifestations of infection in older patients serve to complicate this endeavor. An understanding of the physiological factors that influence the clinical presentation of infection in older patients provides clinicians caring for this group with the necessary tools and increased sensitivity to detect evidence of infection in these vulnerable patients and lower the threshold to initiate empiric therapy even when only subtle signs or symptoms of infection are present.

The factors that increase vulnerability to infection and those that result in atypical or blunted manifestation of infection are often the very same in the elderly patient. These issues are addressed in greater detail in Chapter 124.

### Epidemiological Context

Once clinical clues have raised the suspicion of infection and the decision has been made to initiate empiric antimicrobial therapy, epidemiological factors may offer additional information as to the most likely etiological agent. For example, a history of recent hospitalization or long-term care facility residence should increase concern for a wider diversity of infecting strains. For patients with this history, the relatively innocuous gram-positive flora that typically resides on

**TABLE 125-1****Rational Stepwise Approach to the Selection of Antimicrobial Therapy for Older Patients**

- I. Estimate the most likely causative pathogen if not known**
  - Review clinical and epidemiological clues
  - Identify the most likely site of infection
- II. Determine the appropriate breadth of initial antimicrobial therapy**
  - Estimate the likelihood of antimicrobial resistance
  - Consider the severity of patient's condition and comorbid diseases
- III. Integrate pharmacological data to select the empiric choice of therapy**
  - Evaluate pharmacokinetic and pharmacodynamic data
  - Consider the risk of drug toxicity and interactions
- IV. Monitor clinical course and laboratory data to refine and narrow antimicrobial regimen**
  - Direct efforts at confirmation of microbiological diagnosis

the skin may be replaced by more aggressive gram-negative species that are more likely to infect surgical wounds, intravascular catheters and the urinary tract.

When considering epidemiological clues, knowledge of local outbreaks of infection should inform the diagnostic evaluation of a new case of illness in an individual patient. Seasonal factors should also be considered. For example, influenza may be an exceptionally common cause of respiratory infection from October to March, whereas other causes are more likely at other times of the year. The known geographic distribution of certain pathogens and infectious syndromes is also important for the clinician to keep in mind. The pathogen responsible for fever in a traveler returning from the Amazon Basin (malaria) is apt to be different than the organism causing the same presentation in an elderly resident of the desert Southwest (coccidiomycosis) or Martha's Vineyard (babesiosis).

## Determining Breadth of Coverage

### Severity of Infection

Following the identification of the site of infection and determination of the most likely causative organism, the next step in the management of the infected older patient is an evaluation of the severity of infection. While an accurate assessment of the severity of infection will inform a clinician's decision as to whether or not to start empiric therapy, the same information should influence the breadth of antimicrobial coverage once therapy is initiated. In general, the most appropriate response to evidence of a severe infection in an older patient on the part of the treating clinician should be rapid administration of one or more potent antimicrobial agents with efficacy against the most likely causative pathogen. There is evidence that rapid delivery of the first dose of therapy is particularly critical for the treatment of serious infections in older patients, such as sepsis, meningitis and pneumonia.

The severity of infection not only influences the choice of antimicrobial regimen, but may also influence antimicrobial dosing and the route of delivery selected. In all cases of severe infection, the goal is to ensure delivery of an adequate level of the antimicrobial agent to the site of infection in a sufficient concentration that will result in the killing of the pathogen. In general, parenteral administration of antimicrobial agents must be employed for serious

infections. Parenteral therapy may not be necessary for the entire duration of treatment, but should at least be used until the patient has demonstrated some response to therapy, such as resolution of fever or normalization of leukocytosis.

In general, use of an agent with a broad antimicrobial spectrum may be most appropriate in the early stages of treating a serious infection in an older patient. This should ensure that the agent is active against the pathogen, the identity of which is usually unknown at the time that therapy is initiated. Once the causative pathogen is identified, an agent with a narrower spectrum of activity can be used to more specifically target the pathogen without the attendant consequences of broad-spectrum therapy, such as disruption of the normal bacterial flora and selection of pathogens with antimicrobial resistance.

### Antimicrobial Resistance

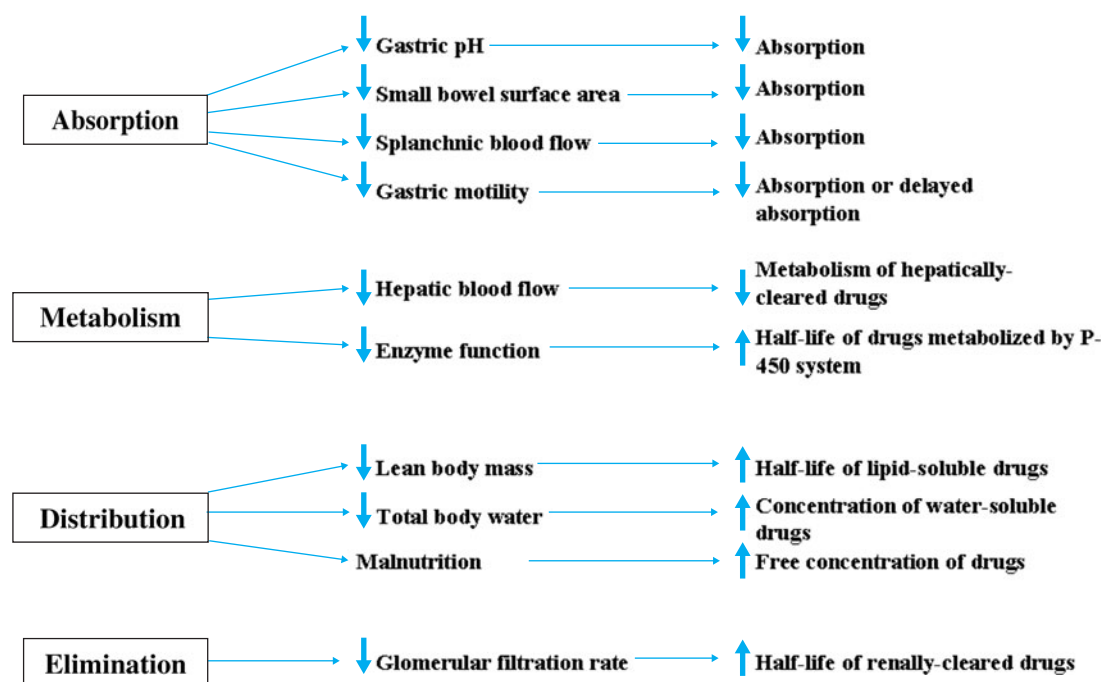

In addition to considering the severity of infection, the clinician pursuing a rational approach to antimicrobial selection for an older patient will incorporate the likelihood of antimicrobial resistance into their thinking. This is particularly an issue for patients in long-term care facilities or acute care hospitals where transmission of pathogens between patients is a particular concern. The high rates of antimicrobial use in long-term care and acute care facilities also leads to the selection of antimicrobial-resistant organisms. Inappropriate prescription of antimicrobials, reported to approach fifty percent of prescriptions in these settings, is a major contributor to the continued escalation of this problem.

In all cases of known or suspected infection with antimicrobial-resistant pathogens, knowledge of local susceptibility profiles for common pathogens should inform all decisions about antimicrobial choice. Institutions and laboratories should be encouraged to provide data on local susceptibilities to clinicians. Consideration should be given to an antimicrobial regimen with a broader spectrum of coverage until the causative pathogen is identified.

When infection with an antimicrobial-resistant pathogen is anticipated, it may be appropriate to consider the use of combination therapy—the concurrent use of two or more agents from different antibacterial classes. The rationale for the use of combination therapy is to increase the likelihood that the administered antibacterials are effective against the known or suspected pathogen, whether the increase in antimicrobial activity of the combination is additive or synergistic. The decision to initiate combination therapy must be weighed against the possibility of increased toxicity, additional expense, and further selection of resistant organisms. In general, while combination therapy may be appropriate for empiric therapy for a seriously ill older patient, the regimen can generally be narrowed to a single effective agent once a pathogen is isolated, identified and susceptibility results are available.

### Pharmacological Considerations

Having established the need for empiric antimicrobial therapy and the most likely causative pathogen through careful examination of clinical and epidemiological clues and after considering the patient's severity of illness and the likelihood of antimicrobial resistance to determine the appropriate breadth of coverage, the clinician treating the infected older patient may still have a number of therapeutic options from which to choose. In making a final decision regarding the optimal antimicrobial regimen, he/she will need to draw

**FIGURE 125-1.** Pharmacokinetic issues to consider when prescribing antimicrobials to elderly patients.

upon an up to date knowledge of pharmacological principles, especially as they apply to this vulnerable population. While the recommended antimicrobial agent and dosing schedule for a particular infection should apply to most populations, there are unique pharmacological issues that affect the choice of therapy for older patients (Figure 125-1).

### Pharmacokinetics

Theoretically, oral drug absorption may be reduced by physiological changes common in elderly populations, such as elevated gastric pH or reduced splanchnic blood flow. It is more likely, however, that coadministered medications are the primary culprits that interfere with the absorption of certain antimicrobial agents in this population. It may be appropriate to review timing of administration of medications such as antacids when a new antimicrobial agent is prescribed. While administration of parenteral therapy should avoid potential problems with oral absorption, the increased risk of intravascular catheter infection in this population must be weighed against the benefits of this approach.

Once absorbed, drug metabolism may be affected in the older adults. Age-related changes in hepatic function, such as reduced hepatic blood flow, smaller hepatic mass, and reduced enzyme function may lead to inefficient drug metabolism, which, in general, slows drug clearance. Patients prescribed other medications that interfere with antimicrobial metabolism may experience either higher or lower levels of antimicrobial than anticipated.

In many older patients, the volume of distribution of medications is altered. This can be because of the reduction in lean body mass, increase in proportion of adipose tissue, or reduction in total body water. Changes in protein-binding caused by malnourishment can also affect volume of distribution. These changes can lead to unpredictability in medication levels and are particularly important to keep in mind when choosing loading doses of antimicrobial agents.

### Toxicity and Polypharmacy

Geriatric patients may be more prone to certain medication toxicities because of the vulnerability of the end organ. For example, exacerbation of hearing loss or impairment of the vestibular system is more likely to occur in geriatric patients treated with aminoglycosides. Renal impairment is of particular concern following aminoglycoside therapy, especially in older patients with pre-existing renal dysfunction. A list of frequently encountered adverse effects associated with specific antimicrobial agents is provided in Table 125-2.

The problem of polypharmacy in the geriatric population is thoroughly reviewed in Chapter 72. It is appropriate here, however, to consider the contribution of antimicrobial agents to this problem. In some respects, the individuals most susceptible to polypharmacy are also those at greatest risk for infection—frail older adults with multiple comorbid conditions. Drug–drug interactions are of primary concern when adding a new prescription for an antimicrobial to an already long medication list. A comprehensive list of potential interactions is presented in Table 125-3.

### Final Considerations: Narrowing and Withholding Therapy

Ideally, microbiological cultures will have been obtained at the time infection is initially suspected in an older patient and the identity of the causative organism will be confirmed after 2 to 3 days of empiric therapy. With this information, the clinician will have the opportunity to narrow the breadth of coverage based on knowledge of antimicrobial susceptibility data. Optimally, the more focused regimen that is chosen demonstrates excellent penetration into affected tissue, is highly active against the causative pathogen, exhibits limited activity against commensal bacteria that are not implicated in the infection, and limits exposure of the patient to drug toxicity. In other words, therapeutic benefit is maximized with respect to

**TABLE 125-2****Common Drug-Drug Interactions Involving Antimicrobial Agents and Drugs Prescribed to Elderly Patients**

<b>ANTIMICROBIAL CLASS/AGENT</b>	<b>INTERACTING DRUGS</b>	<b>ADVERSE EFFECT(S)</b>
Acyclovir	Aminoglycosides Narcotics	Increased nephrotoxicity/neurotoxicity Increased meperidine effect
Aminoglycosides	Acyclovir Oral anticoagulants Bumetanide Cephalosporins Cyclosporine Digoxin Furosemide Magnesium sulfate Vancomycin	Inreased nephrotoxicity/neurotoxicity Potentiation of anticoagulation effects Increased ototoxicity Increased nephrotoxicity Increased nephrotoxicity Decreased digoxin effect (oral aminoglycosides only) Increased nephrotoxicity/ototoxicity Increased neuromuscular blockade Possible increased nephrotoxicity and ototoxicity
Azithromycin	Aluminum/magnesium antacids Digoxin	Decreased peak concentrations Increased digoxin concentrations
Cephalosporins	Aminoglycosides Furosemide	Increased nephrotoxicity Increased nephrotoxicity
Clarithromycin	Oral anticoagulants Benzodiazepines Carbamazepine Corticosteroids Cyclosporine Digoxin Phenytoin Rifampin	Potentiation of hypoprothrombinemia Increased CNS toxicity Increased carbamazepine toxicity Increased effect and possible toxicity of methylprednisone Increased cyclosporine toxicity Increased digoxin concentrations Possible increased or decreased effect Decreased clarithromycin concentrations
Erythromycin	Oral anticoagulants Benzodiazepines Carbamazepine Corticosteroids Cyclosporine Digoxin HMG-CoA reductase inhibitors Loratadine Phenytoin Valproic acid	Potentiation of hypoprothrombinemia Increased CNS toxicity Increased carbamazepine toxicity Increased effect and possible toxicity of methylprednisone Increased cyclosporine toxicity Increased digoxin concentrations Increased risk of rhabdomyolysis Increased loratadine toxicity Possible increased or decreased effect Increased valproic acid toxicity
Fluconazole	Benzodiazepines Coumarin anticoagulants Cyclosporine HMG-CoA reductase inhibitors Phenytoin Rifampin Sulfonylureas Thiazides	Increased CNS toxicity Increased prothrombin times Increased cyclosporine concentrations Increased risk of rhabdomyolysis Increased phenytoin concentrations Increased fluconazole concentrations Increased plasma concentrations and decreased metabolism of sulfonylureas Increased fluconazole concentrations
Fluoroquinolones	Antacids Oral anticoagulants Cyclosporine Iron NSAIDs Sucralfate	Decreased fluoroquinolone effect Prolonged prothrombin times Increased risk of nephrotoxicity; increased serum cyclosporine concentrations Decreased serum fluoroquinolone concentrations Possible increased risk of CNS stimulation Decreased serum fluoroquinolone concentrations
Linezolid	SSRIs	Increased risk of serotonin syndrome
Metronidazole	Oral anticoagulants	Increased anticoagulant effect
Nitrofurantoin	Antacids Fluoroquinolones	Possible decreased nitrofurantoin effect In vitro antagonism of quinolone activity
Rifampin (and other rifamycins)	Analgesics Oral anticoagulants Anticonvulsants Beta-blockers Clarithromycin Corticosteroids	Possible decreased concentrations and activity Possible decreased concentrations and activity Possible decreased concentrations and activity Possible decreased concentrations and activity Decreased clarithromycin concentrations/increased rifamycin toxicity Possible decreased concentrations and activity

## Common Drug–Drug Interactions Involving Antimicrobial Agents and Drugs Prescribed to Elderly Patients (Continued)

ANTIMICROBIAL CLASS/AGENT	INTERACTING DRUGS	ADVERSE EFFECT(S)
	Diazepam	Possible decreased concentrations and activity
	Digoxin	Decreased digoxin effect
	Fluconazole	Decreased fluconazole effect
	HMG-CoA reductase inhibitors	Decreased HMG effect
	Isoniazid	Possible increased hepatotoxicity
	Narcotics	Possible decreased concentrations and activity
	Verapamil	Possible decreased concentrations and activity
Sulfonamides	Oral anticoagulants	Increased anticoagulant effect
	Hypoglycemics	Increased hypoglycemic effect
Tetracyclines	Antacids	Decreased oral tetracycline effects
	Oral anticoagulants	Increased anticoagulant effect
	Bismuth subsalicylate	Decreased oral tetracycline effects
	Carbamazepine	Decreased doxycycline effect
	Digoxin	Increased digoxin effect
	Lithium	Increased lithium toxicity
	Phenytoin	Decreased doxycycline effect
	Rifampin	Possible decreased doxycycline effect
Vancomycin	Aminoglycosides	Possible increased nephrotoxicity and ototoxicity

NSAIDs, nonsteroidal anti-inflammatory drugs; SSRIs, selective serotonin reuptake inhibitors; CNS, central nervous system; HMG, hydroxy-3-methylglutaryl.

infection while the risk of toxicity and subsequent resistance is minimized. As an added benefit, narrow therapy is often less expensive than the broad-spectrum agents typically used for empiric coverage.

There are a number of scenarios in which it is appropriate to consider not initiating antimicrobial therapy. First and foremost, antibiotics may be specifically named in advanced directives and withheld when indicated in such documents. Withholding antibacterial agents is often justified for upper respiratory infections, as these are typically caused by viral pathogens. This is also true of many diarrheal illnesses. Some entities, such as asymptomatic bacteriuria, are not felt to represent true infection and, as such, affected patients do not benefit from therapy. There are a number of other instances in which a culture may demonstrate growth of bacteria in the absence of a clinical infection. Single blood cultures positive for skin flora, such as coagulase negative staphylococci, are generally felt to have been contaminated during the process of obtaining the culture and need not prompt initiation of treatment. Clinicians also must recognize that some positive culture results represent microbial colonization rather than invasive infection, such as bacteria that may grow from a culture swab of a skin ulcer without associated purulence, inflammation or cellulitis. Finally, for a clinically stable patient with a fever, it may be appropriate to follow closely while monitoring for signs and symptoms that clarify the source of the fever rather than initiating therapy. The caveat to this advice is that it is always appropriate to initiate empiric therapy in a patient with poor physiological reserve and/or evidence of sepsis with end organ dysfunction if there is a suspicion of infection.

## SPECIFIC INFECTIOUS SYNDROMES

### Pneumonia and Other Respiratory Infections

The physiology, microbiology, and management of pneumonia in older patients are discussed at greater length in Chapter 126. A lim-

ited discussion of the specific factors that influence the selection of antimicrobial therapy for older patients with respiratory infection is offered here in order to demonstrate the application of the paradigm for antimicrobial selection outlined in Table 125-1.

Anticipation of the causative pathogen is central to the appropriate selection of empiric antimicrobial therapy for older patients with respiratory infection. To this end, a number of clinical features have been associated with specific causative pathogens. However, these associations generally do not stand up to more rigorous scrutiny, especially in older patients. Of greater utility in predicting the causative pathogen in community-acquired pneumonia are the epidemiological features that distinguish one patient from the next, including nursing home residence and recent hospitalization.

In the absence of unique clinical or epidemiological features to suggest chronic respiratory infection (such as that cause by *M. tuberculosis*) or viral pneumonia, clinicians caring for older patients must make every effort to optimize their management of community-acquired pneumonia. For older patients, as for younger patients with pneumonia, there are a number of suitable therapeutic options to address the suspected pathogens (Table 125-4). These regimens are generally well tolerated, although clinicians must be alert to common toxicities, such as gastrointestinal distress caused by macrolides or mental status changes caused by fluoroquinolones.

The most appropriate duration of therapy for community-acquired pneumonia in the older patient has not been rigorously assessed. Conventionally, most patients will receive between 10 and 14 days of treatment.

### Skin and Soft Tissue Infections

The skin of older patients is especially vulnerable to infection with a wide range of microorganisms as a result of the physiologic and physical changes to the integument that accompany aging. As is true for younger patients, the majority of skin and soft tissue infections in the older adults are caused by the gram-positive bacteria that normally colonize the skin. Streptococcal and staphylococcal species

TABLE 125-3

## Adverse Effects of Antimicrobials Commonly Used in the Elderly Population

ANTIMICROBIAL CLASS/AGENT	COMMON ADVERSE EFFECTS
Acyclovir	Nephrotoxicity, CNS toxicity
Amantadine/rimantadine	CNS toxicity
Aminoglycosides	Nephrotoxicity, ototoxicity, vestibular toxicity
Azithromycin	GI toxicity (diarrhea, nausea, vomiting, abdominal pain), candidiasis/vaginitis
Beta-lactam agents	Rash, hypersensitivity reactions, bone marrow toxicity, CNS toxicity (seizure), interstitial nephritis, antibiotic-associated diarrhea, <i>C. difficile</i> -associated diarrhea
Clarithromycin	GI toxicity (diarrhea, nausea, vomiting, abdominal pain), CNS toxicity
Clindamycin	GI toxicity (esophagitis, gastritis, nausea, vomiting, abdominal pain), antibiotic-associated diarrhea, <i>C. difficile</i> -associated diarrhea
Erythromycin	GI toxicity (diarrhea), hepatotoxicity, QT prolongation, torsade de pointes, ototoxicity
Fluconazole	Hepatotoxicity
Fluoroquinolones	QT prolongation, torsade de pointes, CNS toxicity, peripheral neuropathy, tendon rupture, <i>C. difficile</i> -associated diarrhea
Isoniazid	Hepatotoxicity, peripheral neuropathy
Linezolid	Bone marrow suppression (thrombocytopenia), GI toxicity (nausea, vomiting, diarrhea), headache, peripheral neuropathy
Metronidazole	Dysgeusia, anorexia, GI toxicity (nausea, vomiting), CNS toxicity (dizziness, lightheadedness, headache), peripheral neuropathy, disulfiram-like effects when alcohol is ingested
Nitrofurantoin	Pulmonary infiltrates, peripheral neuropathy
Rifampin	Rash, hypersensitivity reactions, nephrotoxicity, reddish-orange discoloration of the urine, tears, perspiration, saliva, hepatotoxicity
Sulfonamides	Rash, hypersensitivity, Stevens-Johnson syndrome, GI toxicity (nausea, vomiting), hyperkalemia, bone marrow suppression
Tetracyclines	Photosensitivity, GI toxicity (nausea, vomiting, diarrhea), hepatotoxicity, CNS toxicity (ataxia, dizziness, vertigo)
Vancomycin	Infusion-related histamine release (Red neck syndrome), ototoxicity, vestibular toxicity, nephrotoxicity (primarily when used in combination with other nephrotoxins), bone marrow toxicity (neutropenia)

predominate. However, it is important to recognize the potential for disruption of the native skin flora as a result of certain comorbidities, such as diabetes mellitus, or recent antimicrobial therapy which may lead to a greater proportion of cutaneous infections caused by other less common pathogens. In such patients, cellulitis, furunculosis, or

folliculitis may be caused by gram-negative bacteria, including *Escherichia coli* and *Klebsiella* spp. Less commonly, *Pseudomonas aeruginosa* may be isolated as the cause of skin infection in an older patient.

The increased breadth of pathogens associated with skin and soft tissue infections among older patients is further complicated by the challenge of obtaining definitive microbiological diagnosis in such cases. Cultures of blood, skin swabs, and even skin biopsies are likely to be of low yield in establishing the causative pathogen of nonsuppurative infections like cellulitis. As a result, empiric therapy is the rule for treating patients with skin infection. When there is abscess material to be sampled, it is critical that specimens be collected as quickly as possible, preferably prior to the institution of antimicrobial therapy. Providing further rationale for incision and drainage of a furuncle is the fact that antimicrobial therapy may be unnecessary in the setting of adequate drainage. However, the decision to withhold antimicrobial therapy for furunculosis should only be contemplated in a stable patient with good baseline health without extensive soft tissue inflammation.

Once empiric therapy is started, the older patient with skin and soft tissue infection should be monitored closely for signs of improvement, as delayed recovery may be indicative of clinical failure as a result of inadequate antimicrobial coverage. Clinicians should monitor the patient for improvement in systemic signs of infection within the first 24 to 48 hours of antibiotic therapy and consideration should be given to modifying therapy for patients who appear to be failing.

Older patients, whether because of the phenomenon of immunosenescence, comorbid conditions, or immunosuppressive drug therapy, may be at increased risk for rapidly-progressive skin and soft tissue infection, including necrotizing fasciitis. In general, an older patient evaluated in the acute care setting for skin and soft tissue infection should be followed closely for early evidence of rapid spread of infection. Skin infection that measurably expands within the first hours of evaluation represents a potentially life-threatening emergency. In addition to broadening antimicrobial coverage, urgent surgical consultation is warranted.

The management of skin and soft tissue infections among all patients has been complicated in recent years by the emergence of strains of *Staphylococcus aureus*-resistant to methicillin in individuals without prior contact with the healthcare system or exposure to antibacterial agents. So-called community-associated methicillin-resistant *S. aureus* (MRSA) appears to be associated with particularly severe and recurrent skin infections. While the extent to which this emerging pathogen specifically affects older patients is not yet known, clinicians must be aware of this new epidemiological trend and adjust the choice of empiric therapy accordingly.

Despite concerns for gram-negative or antimicrobial-resistant pathogens, initial antimicrobial therapy active against streptococci and staphylococci remains appropriate for older patients with skin and soft tissue infection. Commonly-selected regimens include antistaphylococcal penicillin such as dicloxacillin (oral) or oxacillin (parenteral), or a first-generation cephalosporin such as cephalexin (oral) or cefazolin (parenteral). The rationale for choosing parenteral rather than oral therapy is based on the assessment of severity of illness. While penicillin offers adequate coverage for streptococcal infection, the typical absence of a confirmed microbiological diagnosis precludes this approach given the lack of activity of penicillin against nearly all staphylococci. For patients with allergy to  $\beta$ -lactam agents, clinicians may elect to treat with clindamycin, a macrolide or

TABLE 125-4

## Common Pathogens and Optimal Treatments for Older Patients with Community-Associated Pneumonia

CLINICAL SETTING	COMMON PATHOGENS	RECOMMENDED EMPIRICAL REGIMEN
Community-acquired, not hospitalized	<i>S. pneumoniae</i> , atypical bacteria ( <i>M. pneumoniae</i> , <i>C. pneumoniae</i> ), viral pathogens	Respiratory fluoroquinolone, or azithromycin plus high-dose amoxicillin
Community-acquired, hospitalized	<i>S. pneumoniae</i> , atypical bacteria ( <i>M. pneumoniae</i> , <i>C. pneumoniae</i> )	Ceftriaxone plus azithromycin, or respiratory fluoroquinolone
Community-acquired, hospitalized in ICU	<i>S. pneumoniae</i> , <i>Legionella</i> spp.	3rd generation cephalosporin plus respiratory fluoroquinolone
Community-acquired, LTCF resident	<i>S. pneumoniae</i> , influenza, enterobacteriaceae, <i>P. aeruginosa</i>	3rd generation cephalosporin plus respiratory fluoroquinolone plus vancomycin (if <i>S. aureus</i> or MRSA suspected)
Hospital-acquired	<i>P. aeruginosa</i> , enterobacteriaceae	imipenem or piperacillin/tazobactam plus respiratory fluoroquinolone plus vancomycin (if <i>S. aureus</i> or MRSA suspected)

a tetracycline derivative (such as doxycycline). Antimicrobial agents active against MRSA are discussed in greater detail in the section on healthcare-associated infection.

Possible regimens for skin and soft tissue infection are generally well tolerated in older patients. There are limited drug interactions between these antibiotics and the pharmaceutical agents commonly prescribed to older adults. The duration of therapy should be approximately 2 weeks; however, there are limited data available comparing the effectiveness of different durations of therapy. In all cases, incision and drainage of any purulent collection offers not only the opportunity for microbiological diagnosis, but also improved likelihood of clinical resolution.

## Gastrointestinal Infections

### Infectious Diarrhea

As in other age groups, infectious diarrhea may represent nothing more than a harmless nuisance to the older patient. However, by some estimates 50–85% of the mortality associated with diarrheal illness in developed nations occurs in geriatric populations.

Certain epidemiologic factors may increase an elderly patient's risk for gastrointestinal infection with certain pathogens—such as residence in a nursing home, known to be loci of norovirus outbreaks, or recent hospitalization or antimicrobial use, which should bring consideration of *Clostridium difficile* to mind. Clinical and epidemiologic clues as to the causative pathogen may also be gained by inquiring about: how the illness began; stool characteristics (frequency and quantity); symptoms or signs of hypovolemia; travel history; whether the patient has ingested raw or undercooked meat, raw seafood, or raw milk; whether the patient's contacts are ill; the patient's sexual contacts, medications, and other medical conditions if any.

An older patient presenting with fever, tenesmus, and bloody stools should be evaluated for inflammatory or invasive diarrhea caused by *Salmonella*, *Shigella*, *Campylobacter*, *Yersinia*, or *C. difficile*. For this group, antimicrobial therapy may be appropriate. While clinicians may choose to treat empirically and not perform stool cultures, the utility of confirmatory testing for a microbiological diagnosis may be especially high in an institutional setting in which a number of individuals appear to have similar complaints. In ad-

dition, stool cultures can be beneficial to the care of the individual patient by identifying etiologic agents that do not require antimicrobial therapy (such as viral pathogens), thus avoiding unnecessary antibiotic use. Lastly, antimicrobial resistance has been observed in a number of enteric pathogens, including fluoroquinolone resistance in *Campylobacter* and multidrug resistance in *Salmonella*. As a general rule, it is probably wise to obtain stool testing from patients with diarrhea that has lasted longer than 1 day, is accompanied by fever, hematochezia, systemic illness, or dehydration, or in individuals who have recently been hospitalized or have received recent antimicrobials.

Having identified inflammatory diarrhea in an older individual and developed a suspicion about the likely pathogen based on epidemiologic clues, the next step is to determine whether or not to initiate antimicrobial therapy at all. Individuals with diarrhea caused by the *E. coli* O157:H7 strain may be more likely to develop hemolytic uremic syndrome after therapy with certain antimicrobials. Treatment of diarrhea caused by *Salmonella* spp. with fluoroquinolone agents can lead to a prolonged carrier state or relapse of symptoms. The decision to initiate antimicrobial therapy should be guided by an assessment of the patient's severity of illness as well as their comorbid medical conditions. Empiric recommendations are detailed in Table 125-5. Duration of therapy may range from 3 to 14 days depending upon the enteric pathogen, as outlined in Table 125-5. Anticipated toxicities may include exacerbation of intestinal distress by doxycycline or rash secondary to trimethoprim-sulfamethoxazole.

### *C. difficile*-Associated Diarrhea

Advanced age is a well-established risk factor for *C. difficile*-associated diarrhea (CDAD). The vulnerability to CDAD in the geriatric age group is felt to be explained by age-related changes in the fecal flora, immunosenescence, and the presence of other comorbid medical conditions.

Symptoms of CDAD can range from several loose stools a day without fever or clinical instability to a debilitating watery diarrhea associated with abdominal cramping, fever, leukocytosis with consequent dehydration and electrolyte losses. In advanced disease, a dangerous ileus may develop and the most severely ill patients may require colectomy. The range of manifestations highlights the need

TABLE 125-5

## Antimicrobial Recommendations for Enteric Pathogens

ORGANISM	OPTIONS FOR THERAPY	SPECIAL CONSIDERATIONS
<i>Aeromonas/Plesiomonas</i>	Trimethoprim-sulfamethoxazole Fluoroquinolone	
<i>Campylobacter</i> spp.	Erythromycin	
<i>C. difficile</i>	Metronidazole Oral vancomycin	Discontinue antimicrobial therapy, if possible Recurrences can be managed with repeat courses of metronidazole
<i>E. coli</i> spp.		
Enterohemorrhagic (STEC)		Role of antimicrobials unclear, avoid administration. Avoid antimotility agents
Enteroinvasive	Trimethoprim-sulfamethoxazole Fluoroquinolone	
Enteropathogenic	Trimethoprim-sulfamethoxazole Fluoroquinolone

to remain vigilant for the possibility of *C. difficile* infection in patients recently treated with antimicrobials.

Contact with the healthcare system is a known risk for acquiring *C. difficile* colonization, which can then progress to infection following the administration of antibiotics. Nearly every antimicrobial agent has been implicated as a risk factor for CDAD and outbreaks have been seen both in acute care hospitals as well as long-term care facilities.

The initial approach to the management of CDAD includes discontinuing all precipitating antimicrobial agents (if possible), replacement of fluid and electrolyte losses, and avoidance of antimotility agents. Conservative management will not be sufficient for the majority of patients, and therapy with either metronidazole or vancomycin is needed. Although oral vancomycin is the only FDA-approved agent for treating CDAD, most guidelines recommend initiating therapy with oral metronidazole. This is because of the higher cost of vancomycin, the concern that use of vancomycin will lead to selection of vancomycin-resistant enterococci, and the fact that vancomycin was not been shown to be superior to metronidazole in head-to-head studies. Vancomycin may be considered for individuals who cannot tolerate oral metronidazole or for those patients who fail to improve with metronidazole therapy. Duration of therapy of 10 to 14 days is recommended.

It is estimated that recurrence of CDAD following the completion of therapy occurs in as many as half of cases. It is recommended that recurrence be managed with a repeated course of oral metronidazole of standard duration.

Probiotics such as *Sacharomyces boulardii* and *Lactobacillus rhamnosus* are microorganisms of low pathogenicity that may be used to re-populate the normal bowel flora that has been eliminated through the use of antimicrobial agents. Unfortunately, they have not been shown to be of great benefit. Use of probiotics should be avoided

in immunocompromised individuals because of the possibility of invasive infection caused by these organisms.

## Bone and Joint Infections

### Osteomyelitis

Bone infection presents both diagnostic and therapeutic challenges in all patient populations, but especially in older patients. Because manifestations of disease may be nonspecific, the first step in making the diagnosis of bone infection is the timely recognition of predisposing factors, such as loss of overlying skin and soft tissue integrity. The forms of osteomyelitis typically seen in older patients are vertebral osteomyelitis, generally secondary to bacteremic seeding, and contiguous osteomyelitis, which may or may not be associated with vascular insufficiency. In all forms of osteomyelitis in this population, identification of the causative pathogen greatly improves the likelihood of administering appropriate antimicrobial therapy. In most cases of spine infection as well as in cases of contiguous osteomyelitis, bone biopsy is almost always necessary to establish the pathological diagnosis and to identify the causative organisms so that appropriate therapy may be chosen. See Table 125-6 for anticipated pathogens and recommended regimens for treatment of osteomyelitis.

Vertebral osteomyelitis generally presents subacutely with fever and back pain; other constitutional symptoms such as night sweats or weight loss may also be present. The presentation in an elderly individual may be subtle or atypical and the presence of preexisting back pain may delay recognition of a new infectious process at this site. Knowledge of a primary site of infection from which the bone has been seeded is a clue to the pathogen, although frequently the primary site is unknown. Skin and soft tissue pathogens, particularly

TABLE 125-6

## Subtypes of Bacterial Osteomyelitis Among Older Patients

	TYPICAL CLINICAL SETTING	COMMON PATHOGENS	RECOMMENDED EMPIRICAL REGIMEN
Spinal osteomyelitis	Bacteremic spread from other source of infection	<i>S. aureus</i> (including MRSA), streptococci	Vancomycin
Osteomyelitis from contiguous spread with vascular insufficiency	Diabetic foot ulcer	<i>S. aureus</i> , streptococci, enterococci, gram-negative pathogens, anaerobes	IV: ertapenem, ampicillin/sulbactam, vancomycin (if MRSA suspected) Orally: amoxicillin/clavulanate, fluoroquinolone plus clindamycin
Osteomyelitis from contiguous spread without vascular insufficiency	Pressure ulcer	<i>S. aureus</i> , streptococci, enterococci, gram-negative pathogens, anaerobes	imipenem, piperacillin/tazobactam, vancomycin (if MRSA suspected)

*S. aureus*, are most commonly involved, but genitourinary and respiratory infections, infected intravenous catheters, postoperative wounds, endocarditis, and dental sources are all considerations. In a patient with known or suspected exposure to tuberculosis, Pott's disease (tuberculosis of the spine) is a concern.

Because of the more chronic nature of the infection, empiric antimicrobial therapy may be safely withheld from the older patient with suspected vertebral osteomyelitis until cultures have been performed in order to increase the likelihood of identifying the infecting pathogen. A caveat to this is that patients experiencing neurological deficits, including new lower extremity sensory or motor deficits or bowel or bladder dysfunction, should receive prompt treatment with antimicrobials, as well as neurosurgical evaluation. While awaiting culture results once specimens have been collected, it may be reasonable to cover broadly for gram-positive skin and soft tissue organisms, particularly *S. aureus*, with a first-generation cephalosporin or an antistaphylococcal penicillin. In a patient with a history of MRSA or risk factors for MRSA, vancomycin is an appropriate addition. In a patient with known urinary tract infection or prostatitis, gram-negative coverage with a third-generation cephalosporin or a fluoroquinolone should be added. Once the infecting organism is identified, coverage can be narrowed and is generally continued for 4 to 6 weeks in intravenous or highly orally bioavailable form. Adverse effects associated with therapy for osteomyelitis include the complications of long-term intravenous access, such as line infection or thrombosis caused by the foreign body. Long-term  $\beta$ -lactam use may be associated with bone marrow suppression or hepatic toxicity. Prolonged vancomycin use may also result in bone marrow suppression or, infrequently, renal toxicity. Regular monitoring of blood counts and liver and kidney function is advised with prolonged use of any intravenous antimicrobial therapy, especially in older patients.

Osteomyelitis caused by contiguous spread of infection with vascular insufficiency generally refers to diabetic ulcers of the lower extremity, but may also occur in individuals with severe peripheral vascular disease. Patients typically present with a long-standing ulcer of the foot, possibly with concurrent cellulitis or purulent drainage. Polymicrobial infection is the rule; *S. aureus*, streptococci, enterococci, gram-negatives, and anaerobes are frequently seen. Bone biopsy for culture is valuable in identifying the causative organisms, as well as confirming the pathological changes of acute osteomyelitis, and is not associated with exacerbation of the infection. This infection may be slow to respond to antimicrobial therapy, particularly if

underlying issues of blood glucose control and vascular supply are not addressed. In many cases, the goal of therapy is to suppress infection and maintain functional status. Wound care and surgical management are equal partners to treatment with antimicrobial agents. Antimicrobial therapy is generally prolonged, but can often be administered orally, owing to the availability of oral agents with superior bone penetration, such as amoxicillin/clavulanate, trimethoprim-sulfamethoxazole, clindamycin, and ciprofloxacin.

Osteomyelitis caused by contiguous spread of infection without vascular insufficiency is most often associated with trauma, but pressure ulcers are a particular concern in bed-bound elderly individuals. These infections are generally polymicrobial in cause and may include staphylococci and streptococci. In the case of sacral pressure ulcers, Gram-negatives and anaerobes may be present given the proximity to the rectum and the likelihood of stool contamination of broken skin. Recommended empiric therapy should be broad, but can later be narrowed on the basis of cultures from deep tissue biopsy or debridement. Antimicrobial-resistant organisms are a concern, particularly in institutionalized patients, and culture-guided therapy may need to be administered for MRSA, VRE, or resistant gram-negatives. Surgical management is a critical component of therapy, the purposes of which include: drainage, debridement, obliteration of dead space, and wound protection. Proper wound care is also necessary, as is well described in Chapter 124.

### Septic Arthritis

Septic arthritis is an infection with high morbidity and mortality. Elderly patients are particularly at risk, by virtue of pre-existing joint disease caused by rheumatoid arthritis, osteoarthritis, and gout, which are known risk factors for septic arthritis. Patients typically present with fever, pain, warmth, swelling, and decreased range of motion at the infected joint, although these may be absent in older patients. Gonococcal arthritis is common in young adults, but fairly infrequent in the elderly population, although it should be considered in the setting of appropriate risk factors. Gram-positive organisms are prominent, both because of the pathogenesis of bacteremic seeding from compromise of the skin and because of the proclivity of these organism to adhere to the connective tissue and extracellular matrix proteins of the joints. As such, *S. aureus* is the most commonly implicated organism and is associated with notably poor outcomes. Group B beta-hemolytic streptococcus (*S. agalactiae*) is seen in association with diabetes, cirrhosis, advanced age, and

TABLE 125-7

## Common Pathogens and Optimal Treatments for Older Patients with Septic Arthritis

CAUSATIVE PATHOGEN	EPIDEMIOLOGICAL CLUES AND RISK FACTORS	OPTIMAL THERAPY
<i>S. aureus</i>	Usually bacteremic spread from other site of infection	Vancomycin if MRSA is suspected. Otherwise nafcillin or oxacillin
<i>N. gonorrhoea</i>	Sexually active patient	3rd generation cephalosporin
<i>S. pneumoniae</i>	May follow pulmonary infection	3rd generation cephalosporin
Group B streptococcus	Diabetes, cirrhosis, neurological disease	Penicillin G or 3rd generation cephalosporin

neurologic disease. *S. pneumoniae* may occur following invasive pulmonary infection, but also occasionally in the absence of pneumonia. Gram-negative infections may occur following genitourinary infection, and are also associated with intravenous drug use, particularly *P. aeruginosa*. Coagulase negative staphylococci may be seen following joint arthroscopy.

Joint aspiration is necessary both to confirm the presence of septic arthritis and identify the causative organism. Gram stain of fluid is not particularly sensitive, so empiric therapy should be instituted before cultures results are available. Because the infection is rapidly destructive and has a high mortality, therapy should be initiated rapidly. If Gram stain is negative, an antimicrobial agent that covers staphylococci and streptococci as well as gram-negatives should be initiated, such as ceftriaxone. Many would also advise initial vancomycin therapy for the possibility of MRSA. Intravenous therapy is typically used for a 3-week duration. Surgical therapy is an important component of management, and joint drainage and irrigation should be performed to allow for decompression of the joint, improvement in blood flow, and removal of bacteria, toxins, and proteases. Open drainage should be considered in the case of a slow clinical response or inaccessible joint, such as the shoulder joint. See Table 125-7 for common pathogens and suggested empiric treatment for septic arthritis.

## Prosthetic Joint Infection

This issue is covered in more detail in Chapter 116, but certain points will be highlighted here as they serve to illustrate key issues of antimicrobial management in the elderly population. One of the foremost of these is the well-established association between timing of infection relative to surgery and likely organisms isolated, an excellent example of how epidemiologic clues can help guide empiric antimicrobial therapy in older patients. The presentation of prosthetic joint infection is typically divided into 3 stages based on how soon after joint implantation the infection occurs (see Table 125-8).

TABLE 125-8

## Bacteria Associated with Prosthetic Joint Infection by Time of Presentation

TIMING	MOST COMMON PATHOGEN(S)
Early 0–3 months postoperative	<i>S. aureus</i> (including MRSA), gram-negative bacteria
Delayed 3–24 months postoperative	Coagulase-negative staphylococci, <i>Propionobacterium</i> spp.
Late >24 months postoperative	<i>S. aureus</i> (including MRSA), other pathogens from bacteremic spread

Early infections occur within the first 3 months following joint implantation and are typically caused by highly pathogenic organisms, such as *S. aureus* or Gram negatives that were inoculated during the original surgery. Delayed infections, occurring 3 to 24 months following surgery, are also felt to have been inoculated during the original surgery, but involve less virulent pathogens, such as coagulase negative staphylococci and *Propionobacterium* that present in a subacute manner. Late infections, occurring more than 24 months after surgery, are felt to arise through hematogenous seeding of the prosthetic material, and, as such, involve virulent organisms typically associated with bacteremias, such as *S. aureus* from skin sources, and the appropriate organisms from respiratory, dental, and genitourinary sources.

Identification of the infecting organism may be facilitated by blood cultures, but often requires direct culture of joint fluid or tissue obtained from operative debridement or prosthetic removal. In the case of delayed infection, which is generally subacute, it is appropriate to withhold antimicrobial therapy until after cultures are obtained or if therapy has been initiated to stop therapy 2 to 4 weeks prior to obtaining operative cultures to improve the diagnostic yield of these cultures. Multiple tissue cultures are useful to confirm the pathogen status of organisms of low virulence like coagulase negative *Staphylococcus* or *Propionobacterium*. Empiric choice of antimicrobials should include coverage for resistant gram-positive organisms like MRSA or coagulase negative staphylococci—generally, vancomycin is used. Gram-negative coverage with a third-generation cephalosporin may be utilized if these less common culprits are suspected.

Once the causative organism is identified and directed therapy is chosen, it is necessary to consider addition of an agent like rifampin for its ability to penetrate biofilms. Bacteria growing on prosthetic material often form a biofilm—a community of bacteria growing within a polymeric matrix. Antimicrobials diffuse poorly through biofilms and bacteria within them assume a stationary growth phase that makes them less susceptible to antimicrobials with activity against dividing bacteria. Antimicrobial therapy for prosthetic infections must be prolonged in order to counter the resistance to therapy imparted by the biofilm. While intravenous agents such as antistaphylococcal penicillins, first-generation cephalosporins, or vancomycin are typically used along with rifampin, several older studies found that oral combinations of fluoroquinolones and rifampin also successfully treated prosthetic joint infections. Unfortunately, resistance to fluoroquinolones has become so prevalent in staphylococci that this is no longer a reliable combination. Rifampin should be used cautiously given its effect on hepatic metabolism and numerous consequent drug–drug interactions.

The most appropriate duration of therapy for prosthetic joint infection is typically prolonged and may range from several months

to life-long therapy depending upon whether the infected prosthesis is removed.

## Central Nervous System Infection

The manifestations of infection of the central nervous system (CNS) among both older and younger patients range from self-limited and benign to abrupt and lethal. Careful review of the patient's presenting complaints, history, examination and initial laboratory and radiographic data should permit a clear distinction between the infectious syndromes of the nervous system, including meningitis, encephalitis, and brain abscess. **Figure 125-2** outlines the approach to managing an older patient with suspected CNS infection.

### Meningitis

Signs and symptoms of bacterial infection of the CNS must be recognized in a timely manner in order to ensure the best possible clinical outcome. Unfortunately, the classical signs and symptoms of meningitis may be masked among older patients, contributing to a delay in diagnosis. Generally speaking, clinicians caring for older patients are well advised to have a low threshold to aggressively pursue the diagnosis of meningitis with early lumbar puncture and cerebrospinal fluid (analysis whenever confronted with a patient with the constellation of fever and headache or mental status change. While it is optimal to collect cerebrospinal fluid for Gram stain and culture prior to the administration of the first dose of antibiotic, therapy should not be delayed for an undue period while lumbar puncture is performed or radiological evaluation is completed.

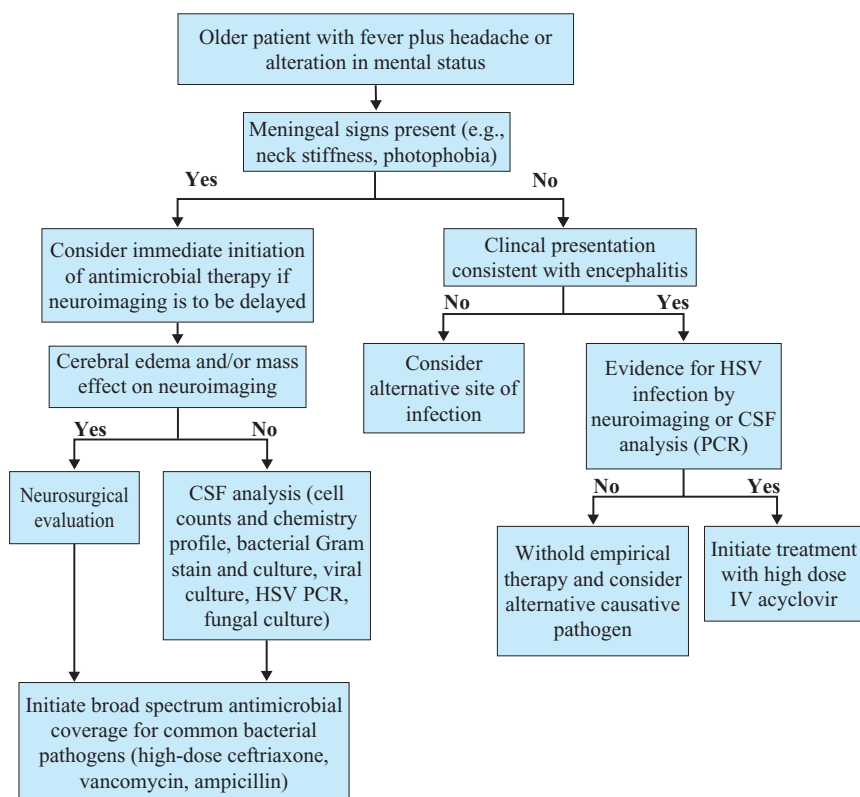

In the setting of suspected meningitis in an elderly patient, empiric antimicrobial therapy should be selected that has sufficient coverage to address all clinically relevant pathogens. While meningococ-

cal meningitis occurs less frequently in elderly patients than in young adults and children, pneumococcus remains a concern, and, in fact, is the most-commonly-isolated bacterial pathogen in this population. Older patients appear to be at increased risk for CNS infection with strains of pneumococcus that are resistant to penicillin. While third-generation cephalosporins may be effective against penicillin-resistant *S. pneumoniae* infection at other sites, these agents may not be adequate for therapy of meningitis in this setting. As a result, supplemental therapy with vancomycin should be included in the initial empirical regimen to ensure coverage of resistant pneumococci.

Elderly patients are particularly susceptible to meningeal infection with *Listeria monocytogenes*. While a number of epidemiological clues can point to infection with *L. monocytogenes*, including exposure to specific contaminated food, such clinical risk factors need not be present to raise the concern for this infection. High dose ampicillin is the most appropriate choice for CNS infection with *L. monocytogenes*. Because the clinical signs and symptoms of CNS infection with *Listeria* overlap considerably with those attributable to infection with *S. pneumoniae* and *N. meningitidis*, ampicillin should be included in the empiric regimen for all older patients even before microbiological identification and susceptibility testing has been completed.

Once the results of microbiological cultures and other laboratory studies are available, antimicrobial therapy for meningitis can be narrowed to focus on the causative pathogen while limiting toxicity and interactions with other pharmacological agents. The duration of therapy for pneumococcus should be approximately 2 weeks and for *Listeria* 3 weeks or longer depending upon clinical response.

If no causative bacterial pathogen is isolated despite the timely collection of CSF specimens and the clinical presentation (including

**FIGURE 125-2.** Approach to the older patient with suspected CNS infection.

clinical signs and symptoms as well as CSF cell counts, protein and glucose levels) is consistent with viral meningitis, antibacterial therapy should be discontinued so as to minimize the exposure to these potentially toxic drugs.

### Encephalitis

In an older patient with fever and focal neurological signs and/or change in sensorium who lacks definitive clinical, physical examination or laboratory evidence for meningeal infection, the diagnosis of encephalitis must be considered swiftly. As was true for meningitis, prompt initiation of antimicrobial therapy may be critical to the recovery of affected individuals.

HSV encephalitis remains a prevalent cause of CNS infection among older patients. Clinicians should remain vigilant for the diagnosis, even in patients without other evidence of herpes virus infection or a known history of prior cutaneous involvement. Suspicion for this etiology is strengthened by characteristic in the temporal lobes visualized on MRI. Confirmatory diagnosis requires detection of HSV DNA by PCR of the spinal fluid. Because this testing may take several days in some centers, therapy should be initiated upon first suspicion of infection. The optimal therapy is parenteral acyclovir, which should be continued for 2 to 3 weeks.

### Healthcare-Associated Infections

The approach to antimicrobial therapy for the older patient infected as a consequence of hospitalization or other contact with the health-care system is sufficiently unique to warrant separate consideration. The same general themes that have been discussed regarding the management of other infections in the older adults apply to the special case of healthcare-associated infections. Clinical features of the patient's presentation and epidemiological clues should be integrated to deduce the most likely causative pathogen. Specimens should be collected expeditiously for microbiological testing prior to the initiation of antimicrobial therapy if possible. Finally, the overall severity of infection, along with understanding of the unique pharmacological challenges of treating older patients should be considered prior to the final decision regarding antimicrobial treatment.

The goal in all cases of suspected healthcare-associated infection is to determine the likely pathogen responsible for the patient's signs and symptoms. For hospitalized patients, the anticipated microbiology will be influenced not only by the actual site of infection, but by the geographical and temporal trends in antimicrobial flora and susceptibility within the institution itself. Integrating epidemiological and microbiological data from the hospital antibiogram is critical to the selection of empirical therapy for the treatment of healthcare-associated infections in the older adults.

In general, the breadth and intensity of antimicrobial coverage for hospitalized older patients will tend to be greater than that provided to even debilitated older patients in the outpatient setting. This need for broader, more potent therapy is a consequence of the extensive comorbid conditions and generally poorer physiological reserve of hospitalized older patients.

In addition to their generally weakened physical condition, hospitalized older patients are commonly exposed to multiple medical interventions. As a result, the risk of complicated and potentially severe drug interactions is greatly increased in this population. Lastly, because of comorbid conditions or other therapies, the volume of distribution, renal and hepatic clearance and other pharmacokinetic

parameters may be significantly altered when older patients are hospitalized.

### Healthcare-Associated Pneumonia

The microbiology of respiratory infection among hospitalized patients is fairly distinct when compared to that associated with community-acquired pneumonia. Specifically, commensal gram-positive and anaerobic bacteria are replaced by Enterobacteriaceae, including *E. coli* and *Klebsiella* spp, after an older patient is hospitalized for several days. Such changes in the oral flora coupled with the possibility of aspiration of oral contents into the lower respiratory tract should lead to the inclusion of therapy active against Enterobacteriaceae in an empirical regimen for healthcare-associated pneumonia. Agents with activity against *P. aeruginosa* are generally included as well because of the relatively high incidence and clinical severity of nosocomial infection caused by this organism. MRSA is also seen increasingly commonly in healthcare-associated pneumonia. Finally, while patients with witnessed or high-risk for aspiration generally are prescribed an antimicrobial agent with activity against oral anaerobes, the available literature and recent guidelines do not specifically support this intervention.

The specific choice and breadth of antimicrobial therapy will be strongly influenced by the severity of the patient's pneumonia. Common choices include combination  $\beta$ -lactam/ $\beta$ -lactamase inhibitors such as piperacillin/tazobactam, ceftazidime, and combinations of third-generation cephalosporins with fluoroquinolones. Vancomycin or linezolid should be included when there is concern for MRSA involvement. Recent guidelines have recommended a 7-day course of therapy for healthcare-associated pneumonia not caused by *P. aeruginosa*. Extending therapy to 10 to 14 days may be reasonable in individuals with poor baseline health or particularly severe manifestations of pneumonia.

### Skin and Soft Tissue Infections

For surgical wound infections in older patients, the approach is similar to that described earlier for cellulitis and other soft tissue infections in the outpatient setting. Anticipation of the causative organism is also comparable in that gram-positive bacteria predominate, specifically streptococcal and staphylococcal species. In the hospital, clinicians must be particularly vigilant for skin and soft tissue infections caused by MRSA, owing to the relatively high incidence and the risk of aggressive disease associated with this pathogen. Occasionally certain clinical features or epidemiological clues will suggest a less common pathogen (such as nontuberculous mycobacteria as a cause of chronic nonhealing surgical site infection).

As is always the case, systemic signs and symptoms, including evidence of sepsis, suggest the need for selection of broader empiric coverage and even consideration of less common pathogens, including Gram negatives. In addition, rapid progression of a skin or soft tissue infection may be evidence for a more complicated infection, such as necrotizing fasciitis. Management of this entity mandates rapid initiation of therapy that provides broad coverage for Gram positives, Gram negatives, and anaerobes. In addition, use of an antimicrobial that inhibits protein synthesis, such as clindamycin, is recommended in an attempt to disrupt the production of bacterial toxins responsible for this potentially life-threatening infection.

TABLE 125-9

## Antimicrobial Agents with Activity Against MRSA

	ROUTE OF ADMINISTRATION	NOTES
Trimethoprim/sulfamethoxazole, clindamycin, doxycycline	Orally or IV	Effective against many strains of community-associated MRSA. Ineffective against most hospital-acquired MRSA.
Vancomycin	Orally only (for systemic treatment)	Widely effective against nearly all MRSA strains isolated to date. Requires therapeutic monitoring to ensure efficacy and avoid toxicity
Daptomycin	IV only	Not effective for primary pulmonary infections
Linezolid	Orally or IV	Demonstrated effectiveness in skin and soft tissue infections. Associated with thrombocytopenia when administered for extended duration

While the optimal therapeutic regimen for patients with skin and soft tissue infection is subject to debate, a regimen with broad efficacy against gram-positive cocci and MRSA is requisite (see Table 125-9). Historically, the most common choice has been vancomycin. Familiar agents, such as clindamycin, trimethoprim-sulfamethoxazole, and minocycline, can be utilized for their activity against MRSA, but may have toxicities or limitations in coverage against streptococci, in the case of trimethoprim-sulfamethoxazole, that limit their use in all situations. The role to be played by newer agents such as linezolid and daptomycin remains to be seen. The toxicity and expense associated with these agents may preclude their use as the first choice of therapy. Additionally, it is recommended that linezolid not be used in combination with selective serotonin reuptake inhibitors (SSRIs) because of the concern for precipitating the serotonin syndrome. Duration of therapy typically mirrors that for nonhealthcare-associated skin and soft tissue infections—approximately 2 weeks—but in general, should be guided by the patient's response to treatment.

### Urinary Tract Infection

Choosing antimicrobial therapy for healthcare-associated infections of the urinary tract presents several unique challenges. Standard culture methods enable detection of bacteria in the urine of hospitalized patients with a high sensitivity. In fact, the high sensitivity of culture results may even prove to be misleading. A large proportion of urine samples obtained from hospitalized older patients, particularly those with bladder catheters, may be found to be colonized with bacteria. In several studies, the prevalence of bacteriuria among catheterized patients has been found to approach 100% after 1 month with the catheter. As a result of these issues, in the setting of a sepsis-like syndrome occurring in an older hospitalized patient with bacterial growth in the urine as the sole evidence for the urinary tract as the primary site of infection, it is recommended that the search continue for a definitive source. Multiple cultures of the blood are essential to the informed management of such patients.

There are few unique clinical or epidemiological factors that influence appropriate selection of empiric antimicrobial therapy for older hospital patients with known or suspected urinary tract infection. For the most part, the antimicrobial regimen should include coverage for the Enterobacteriaceae that are most commonly associated with ascending urinary tract infections. Among the available agents, those that concentrate in the urine are particularly useful. Fluoroquinolones are frequently utilized in this capacity, although the rise of resistance to these agents mandates that therapy be guided by the bacterial susceptibility results obtained from urine cultures. A 3-day duration is appropriate for uncomplicated bladder infections.

However, in older hospitalized patients, the urinary tract infection will often be considered “complicated,” necessitating a prolongation of therapy to 2 weeks.

### Bacteremia

Bloodstream infection in hospitalized older patients can arise as a primary event affecting only the bloodstream or as a secondary manifestation of infection at a specific body site, such as bacteremic pneumococcal pneumonia. Among the former group, bloodstream infections complicating intravascular access devices remain most common. In all cases, the most common pathogens tend to be streptococci or staphylococci. However, when the endogenous flora that normally colonizes the skin and digestive tract of older patients are replaced by hospital-acquired pathogens, the diversity of pathogens causing bloodstream infection expands to include gram-negative bacteria and fungi.

Principal among the clinical and epidemiological factors that might influence the choice of empiric therapy is the detection of a primary site of infection in these patients. If infection of the lung, bladder, or a surgical wound is detected, therapy should be chosen to cover those pathogens most commonly associated with infection of that specific body site. Alternatively, clinical evidence of infection of a vascular access device, such as drainage or inflammation at a catheter insertion site, supports the diagnosis of a primary bloodstream infection. Most such cases, as has already been noted, will be caused by common gram-positive organisms.

Empiric coverage should generally be guided by the Gram stain or preliminary culture results. For gram positives, vancomycin should be used while awaiting identification and antimicrobial susceptibility testing, assuming that there is a high institutional prevalence of MRSA. For gram-negative pathogens, coverage should be informed by local antibacterial susceptibility trends as reported in an institutional antibiogram. The use of double coverage for gram-negative pathogens (and specifically for infection with *P. aeruginosa*) remains controversial. There is little direct evidence indicating a benefit of protracted coverage with more than one agent once final susceptibility results are available.

The optimal duration of therapy for bloodstream infection in the hospitalized older patient remains somewhat uncertain, but is influenced by whether or not the bacteremia is associated with a removable focus of infection. For patients with infected vascular access devices, best practice dictates the removal of the infected line. If this step is completed in a timely fashion, clinicians may opt to treat for as little as 7 to 14 days. However, this less intensive strategy would not be appropriate for patients with more complicated infection,

including those with heart valve involvement or those with evidence of metastatic spread of infection, who may require several weeks of therapy.

# Pneumonia

Thomas J. Marrie

Pneumonia is a common, expensive (in 2002, the total cost was \$8 billion to treat pneumonia in the United States), and often serious infection with considerable morbidity and mortality. The major burden of pneumonia in a community is borne by the elderly. Successful management of pneumonia, in any patient, but especially in the elderly requires considerable skills.

## DEFINITIONS

From the viewpoint of the pathologist, pneumonia is an inflammatory response in the lung caused by an infectious agent that involves the alveoli and terminal bronchioles. It is manifested by increased weight of the lungs, replacement of the normal lung sponginess by consolidation and alveoli filled with white blood cells, red blood cells, and fibrin (Figures 126-1 and 126-2).

The clinician defines pneumonia as a combination of symptoms (fever, chills, cough, pleuritic chest pain, sputum), signs (hyper or hypothermia, increased respiratory rate, dullness to percussion, bronchial breathing, aegophony, crackles, wheezes, pleural friction rub), and an opacity (opacities) on a chest radiograph (Figure 126-3). In addition, laboratory findings; such as, increased white blood cell count and decreased level of oxygen saturation, may also be part of the definition.

The epidemiologist or clinical trialist defines pneumonia as two or more of the symptoms listed above, one or more of the physical findings listed above and a new opacity on chest radiograph that is not because of a condition other than pneumonia (such as, congestive heart failure, vasculitis, pulmonary infarction, atelectasis, or drug reaction).

Pneumonia may also be categorized according to the site of acquisition—community, hospital (nosocomial) or nursing home. Some authorities categorize nursing home acquired pneumonia as community-acquired, while others insist it more closely resembles nosocomial pneumonia and should be labeled institutionally ac-

quired pneumonia. However, nursing homes or long-term care facilities have residents who range from fully functional to those who are bedridden. We prefer to consider nursing home/long-term care facility acquired pneumonia as a separate category.

It is useful for the practicing clinician to remember definitions for the certainty with which an agent can be implicated as the cause of the pneumonia. An agent is said to be the definite cause of pneumonia if it is isolated from blood (although some blood isolates, such as coagulase negative staphylococci, are usually contaminants and not pulmonary pathogens), from pleural fluid or from pulmonary tissue; if it is isolated from sputum and is a pathogen that does not colonize the upper airway (such as *Mycobacterium tuberculosis*; *Legionella* spp.; *Nocardia* spp.); or if a microbial antigen is detected in urine (*Streptococcus pneumoniae*; *Legionella pneumophila*). Amplification of DNA or RNA of a microbial agent from pulmonary tissue or from nasopharyngeal secretions if that agent does not colonized the upper airway would allow categorization of the agent as the definite cause of the pneumonia. An agent is the presumptive or probable cause of pneumonia if it is isolated from a sputum sample which has >25 polymorphonuclear leucocytes per low power field and <10 squamous epithelial cells or if there is a fourfold or greater rise in antibody titer between acute and convalescent serum samples. Amplification of DNA or RNA of a viral agent from nasopharyngeal secretions would qualify that agent for status as a possible cause of the pneumonia.

## EPIDEMIOLOGY

Data from the National Hospital Discharge Survey in the United States indicate that between 1990 and 2002 there were 21.4 million hospitalizations among those 65 years of age and older. Infectious diseases accounted for 48% of these hospitalizations and 46% of the infectious diseases hospitalizations were caused by the lower respiratory tract infections. Death resulting from these infections was

**FIGURE 126-1.** Photograph of a lung with pneumonia (white area) involving the entire upper lobe.

reported to be 48%. There has been a 20% increase in pneumonia as a first or any listed diagnosis in those 65 years of age and older from 1988 compared to 2002. The in-hospital mortality rate was 1.5 times higher for pneumonia compared with the other most common causes of hospitalization.

Pneumonia and influenza are listed as the 6th leading cause of death, and approximately 70% of hospitalized cases of pneumonia among adults occur in the elderly. Annual hospitalization rates for pneumonia and influenza were 23.1 per 1000 men aged 75 to 84 years of age and 13.3 per 1000 women in this age group. The cor-

responding numbers for men and women, respectively, in the 65 to 74 age group were 8.3 and 5.8 per 1000. Approximately 60% of the episodes of pneumonia among those 65 years of age and older are treated in the community. The admission rate for pneumonia is subject to considerable variation from region to region within a province or state and even from hospital to hospital within a single city. This variation cannot be explained solely on the basis of severity of illness and likely reflects variation in physician practice.

In a population-based study the following were identified as independent risk factors for community-acquired pneumonia: alcoholism, relative risk (RR) 9; asthma, RR 4.2; immunosuppression, RR 1.9; and age, RR 1.5 for those >70 years of age (vs. 60–69 years of age).

The overall mortality rate for patients with community acquired pneumonia (CAP) who require admission to hospital ranges from 6% to 15%. For those who require admission to an intensive care unit (ICU) for treatment of pneumonia, the mortality rate ranges from 45% to 57%. The annual per capita cost of pneumonia from an employer perspective is five times higher than the costs for typical beneficiaries. For elderly patients there is a burden of care for family members.

In an effort to determine the risk factors for pneumonia, investigators studied 101 patients aged  $\geq 65$  years old who were admitted with CAP; each patient with pneumonia was age and sex matched with a control subject who arrived at emergency within  $\pm 2$  days of the case and was subsequently admitted. By multivariate analysis, the following were identified as risk factors for pneumonia—suspected aspiration, low serum albumin, swallowing disorder, and poor quality of life. Significant predictors of a fatal outcome were bedridden state prior to onset of pneumonia; temperature  $\leq 37^\circ\text{C}$ ; presence of a swallowing disorder; respiratory rate  $\geq 30$  breaths/minute; shock; creatinine greater than 1.4 mg/dL and  $\geq 3$  lobes involved on chest radiograph.

The attack rate for pneumonia in adults is highest among those residing in nursing homes with rates of 1.2 episodes of pneumonia per 1000 resident days. Pneumonia is the leading reason for transfer of nursing home patients to hospital. In many areas, nursing home/long-term care facility acquired pneumonia accounts for

**FIGURE 126-2.** Photomicrograph of lung showing alveoli filled with inflammatory exudate. Magnification: 445x.

**FIGURE 126-3.** Gram stain sputum showing many polymorphonuclear leucocytes and gram-positive diplococci (*S. pneumoniae* was recovered on culture of this specimen). Magnification: 1000x.

10% to 18% of all pneumonia admissions. Lower respiratory tract infections are the fourth most common infection among residents of long term care facility (LTCFs) affecting 2.1% of the residents. In a nursing home population, old age, odds ratio (OR) 1.7; male sex OR 1.9; swallowing difficulty, OR 2; and inability to take oral medication were significant risk factors for pneumonia. In another study, profound disability (Karnofsky score of <10), bedfast state, urinary incontinence, presence of a feeding tube, or deteriorating health status were risk factors for pneumonia in this setting.

For specific etiologies of pneumonia, risk factors may differ from those for pneumonia as a whole. Thus, dementia, seizures, congestive heart failure, cerebrovascular disease, tobacco smoking, and chronic obstructive lung disease are risk factors for pneumococcal pneumonia. Fifty percent of patients with bacteremic pneumococcal pneumonia were homozygous for FcγRIIa-R31, which binds weakly to IgG<sub>2</sub>, compared with 29% of uninfected controls suggesting that genetic factors may also be important risk factors for pneumococcal pneumonia.

Among HIV-infected patients the rate of pneumococcal pneumonia is up to 41.8 times higher than age matched patients who are not HIV-infected. Risk factors for Legionnaires' disease (LD) include male gender, tobacco smoking, diabetes, hematologic malignancy, cancer, end stage renal disease and HIV infection.

Both attack rates and mortality rates caused by pneumonia are highest in the winter months.

In a large study of 3474 adults hospitalized for the treatment of CAP, the mean length of stay (LOS) was  $8.6 \pm 6.3$  days and the median LOS was 6.4 days. Patients were divided into those who stayed <7 days versus those who stayed >7 days and factors associated with these LOS were examined by multivariate analysis. Older age, ex-smoker status, home care prior to admission, reduced pre-morbid functional status and longer time to first dose of antibiotic were all associated with a longer stay. In contrast male gender, pathway use (refers to use of a critical pathway for treating CAP), residence at home without home care and shorter time to receipt of first dose of antibiotic were associated with a shorter stay. LOS was also independently associated with the hospital to which the patient was admitted. Thus, there are patient, institution, and physician factors that influence LOS in elderly patients with CAP.

## ETIOLOGY

There are more than 100 microbial (bacteria, viruses, fungi, protozoa, and other parasites) causes of community-acquired pneumonia. *S. pneumoniae* is the most common cause of CAP accounting for approximately 50% of all cases. Advances in technology such as multiplex polymerase chain reaction are changing our knowledge of the etiology of pneumonia. It is apparent that viral pneumonia is more common in adults than was previously thought and in many instances a viral upper respiratory tract infection impairs ciliary clearance and pneumonia results from microaspiration of oropharyngeal microflora. Table 126-1 gives the most common causes of CAP. Table 126-2 identifies clues that might be obtained from the history to suggest a particular organism(s) as the cause of the pneumonia. It is important to remember that the relative frequency of each pathogen may vary geographically and seasonally. Many elderly persons travel

**TABLE 126-1**

### Most Common Causes of Community-Acquired Pneumonia in the Older Adults

1. *S. pneumoniae*
2. *C. pneumoniae*
3. *Enterobacteriaceae*

TABLE 126-2

## Clues to the Etiology of Pneumonia

FACTOR	POSSIBLE AGENT(S)
Travel	
Southeast Asia	<i>Burkholderia pseudomallei</i> (melioidosis); <i>M. tuberculosis</i>
Many countries	<i>M. tuberculosis</i>
Arizona, parts of California	<i>C. immitis</i>
Occupational History	
Health care workers	<i>M. tuberculosis</i> , acute HIV seroconversion with pneumonia (if recent needlestick injury from an HIV positive patient)
Veterinarian, farmer, abattoir worker	<i>C. burnetii</i>
Host Factor	
Diabetic ketoacidosis	<i>S. pneumoniae</i> , <i>S. aureus</i>
Alcoholism	<i>S. pneumoniae</i> , <i>Kelbsiella pneumoniae</i> , <i>S. aureus</i> , oral anaerobes; <i>Acinetobacter</i> spp.
Chronic obstructive lung disease	<i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>Moraxella catarrhalis</i>
Solid organ transplant recipient	<i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>Legionella</i> spp., <i>P. jirovecii</i> , (pneumonia occurring >3 mo cytomegalovirus, <i>Strongyloides stercoralis</i> after transplant)
Sickle cell disease	<i>S. pneumoniae</i>
HIV infection and CD4 cell count of <200/ $\mu$ L	<i>S. pneumoniae</i> , <i>P. jirovecii</i> , <i>H. influenzae</i> , <i>Cryptococcus neoformans</i> , <i>M. tuberculosis</i> , <i>Rhodococcus equi</i>
Dementia, stroke, altered level of consciousness	Aspiration pneumonitis
Structural lung disease (bronchiectasis)	<i>Pseudomonas aeruginosa</i>
Environmental Factors	
Exposure to: contaminated air conditioning, cooling towers, hot tub, recent travel stay in a hotel, exposure to grocery store mist machine, or visit to, or recent stay in a hospital with contaminated (by <i>Legionellaceae</i> ) drinking water	<i>L. pneumophila</i> or other <i>Legionellaceae</i>
Exposure to: mouse droppings in an endemic area	Hantavirus
Pneumonia after windstorm in an area	<i>C. immitis</i> of endemicity
Outbreak of pneumonia in shelter for homeless men or jail	<i>S. pneumoniae</i> , <i>M. tuberculosis</i>
Outbreak of pneumonia occurs in military training camp	<i>S. pneumoniae</i> , <i>C. pneumoniae</i> , Adenovirus
Outbreak of pneumonia in a nursing home	<i>C. pneumoniae</i> , <i>S. pneumoniae</i> , Respiratory syncytial virus, Influenza A virus; <i>M. tuberculosis</i>
Pneumonia associated with mowing a lawn in an endemic area	<i>Francisella tularensis</i>
Exposure to bats, excavation or residence in an endemic area (Ohio and Mississippi river valleys)	<i>Histoplasma capsulatum</i>
Exposure to parturient cats in an endemic area	<i>C. burnetii</i>
Sleeping in a rose garden	<i>Sporothrix shenkii</i>
Camping, cutting down trees in an endemic area	<i>Blastomyces dermatitidis</i>

for pleasure, placing them at risk for a variety of pathogens (Table 126-2). Vacations in the sun to Arizona or parts of California can result in acquisition of the fungus *Coccidioides immitis* by inhalation. In most instances, the infection is asymptomatic. However, atypical pneumonia, hilar adenopathy or lung nodules may result. The latter are often misdiagnosed as carcinoma and the nodules excised. Elderly women who are receiving hormone replacement therapy may be at greater risk for the pulmonary nodule presentation of coccidioidomycosis. Legionellosis is also associated with travel.

### *S. pneumoniae*

Worldwide *S. pneumoniae* continues to be the most common cause of CAP. It accounts for approximately 50% of all cases of pneumonia requiring admission to hospital for treatment and for 60% of all cases of bacteremic pneumonia. While there are more than 90 capsular polysaccharide types of *S. pneumoniae*, 80% of the strains that cause

invasive disease are present in the 23-valent-pneumococcal polysaccharide vaccine. These include serotypes 1, 2, 3, 4, 5, 6B, 7F, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19A, 19F, 20, 22F, 23F, 33F. Vaccination of children with a 7-valent protein conjugate vaccine (contains serotypes 4, 6B, 9V, 14, 18C, 19F, 23F) has resulted in a decrease in invasive pneumococcal disease not only in children but also in elderly persons as well. Recently there has been emergence of outbreaks of invasive pneumococcal disease caused by serotype 5 among homeless adults.

One of the problems facing clinicians treating patients with CAP is drug-resistant *S. pneumoniae*. If an isolate is resistant to penicillin, it is likely also that it is resistant to three or more drug classes (multidrug resistant). Currently, 12% to 25% of *S. pneumoniae* isolates in North America are resistant to penicillin—approximately half demonstrate low-level resistance (minimal inhibitory concentration 0.1–1.0 mg/L) and half have high-level resistance (MIC  $\geq$  2 mg/L). In many communities, the levels of penicillin resistance are much higher than this. In the United States and Canada, approximately

20% of isolates of *S. pneumoniae* are resistant to erythromycin and the other macrolides. This resistance may be because of an efflux pump mechanism or to alteration of the target site of erythromycin action through a mutation in the *erm* gene. Approximately 70% of pneumococcal erythromycin resistance in North America is as a result of an efflux pump mechanism and these isolates may respond to treatment with a macrolide. Isolates that are resistant as a result of the target site modification will not respond to treatment with a macrolide. Risk factors for penicillin-resistant *S. pneumoniae* (PRSP) include  $\beta$ -lactam antibiotic use within the previous 6 months; residence in a nursing home; residence in a day care center or being a parent of a resident in a day care center; and immunocompromised state. Age <5 years and nosocomial acquisition of the infection were independent predictors of macrolide resistance. Resistance among isolates of *S. pneumoniae* is also beginning to appear to fluoroquinolones, although at present it is uncommon with a 1% to 2% level of resistance. Risk factors for fluoroquinolone-resistant *S. pneumoniae* are presence of chronic obstructive pulmonary disease; nursing home residence; fluoroquinolone use within the last 12 months and nosocomial acquisition of the infection. More than 30% of *S. pneumoniae* isolates are resistant to trimethoprim-sulfamethoxazole and approximately 15% are resistant to tetracycline. In general, third-generation cephalosporins can be used to treat patients with drug-resistant *S. pneumoniae*. If central nervous system infection complicates the pneumonia, vancomycin should be added. Cefixime, cefibuten, cefaclor, and loracarbef have poor activity against *S. pneumoniae* and should not be used to treat pneumonia caused by this microorganism.

Early mortality (within the first 3 or 4 days) in patients with bacteremic pneumococcal pneumonia may not be influenced by antibiotic therapy. An APACHE II (the acute physiology and chronic health evaluation scoring system) score of  $\geq 28$  is associated with a mortality rate of 80% in patients with bacteremic pneumococcal pneumonia.

### Staphylococcus aureus

*Staphylococcus aureus* is an uncommon cause of CAP, accounting for 1% to 5% of cases. However, it is approximately the third most frequent cause of bacteremic pneumonia and it is more common in patients with severe pneumonia who require treatment in an ICU. It is also more common as a cause of pneumonia among residents of long-term care facilities. *S. aureus* pneumonia has classically been described as a secondary bacterial pathogen in the setting of a primary influenza virus upper respiratory tract infection. In the setting of bacteremic *S. aureus* pneumonia one should always exclude endocarditis (often right sided), especially if there are multiple rounded opacities on the chest radiograph (septic emboli). Methicillin resistance (Methicillin-resistant *S. aureus* [MRSA]) among isolates of *S. aureus* was first reported in 1961 and is now common in both community and hospital acquired infections caused by this microorganism. Fortunately, vancomycin resistance, while it has been reported, is uncommon. More recently, community-acquired MRSA infections have been caused by strains producing the Pantan-Valentine leukocidin (PVL). In 1932, Pantan and Valentine described leukocidin as a virulence factor. Production of this leukocidin is now known to be associated with tissue necrosis. In one study, hemoptysis was found in 38% of 16 patients with severe pneumonia associated with *S. aureus* strains carrying PVL genes compared with 1 of 33 PVL

negative patients. To date PVL *S. aureus* infections including pneumonia have been more common in young patients.

### Chlamydomphila pneumoniae

*Chlamydomphila pneumoniae* is commonly implicated serologically as a cause of CAP. It is more frequent in those with chronic obstructive pulmonary disease. In the older adults, it usually manifests as reactivation of previous infection, while in younger adults it can be a primary infection. It is not necessary to include diagnostic studies for *C. pneumoniae* in working up a patient with CAP since in more than 50% of cases it is a copathogen and patients recover without specific treatment directed at *C. pneumoniae*. Outbreaks of pneumonia in nursing homes have been caused by this agent.

### Mycoplasma pneumoniae

This microorganism is usually a cause of pneumonia in young adults; however, it can also cause pneumonia in older adults. It has rarely been responsible for outbreaks of pneumonia in nursing homes. *M. pneumoniae* has a number of extrapulmonary manifestations including—cold agglutinin induced hemolytic anemia; leukoerythrophagocytosis; encephalitis; cerebellar ataxia; stroke like syndromes; arthritis; erythema multiforme; and a maculopapular rash.

### Legionnaires' Disease

The most common cause of LD is *L. pneumophila* serogroup 1, although just under half of the more than 40 recognized species in the Legionellaceae family can cause LD. *Legionella* spp. often cause a severe pneumonia with a high mortality rate. Epidemiologically, there is frequently a history of exposure to a contaminated water source. Outbreaks have been associated with exposure to a variety of aerosol-producing devices, including showers, a grocery store mist machine, cooling towers, whirlpool spas, decorative fountains, and evaporative condensers. It is also likely that aspiration of contaminated potable water by immunosuppressed patients is also a mechanism whereby *Legionella* is acquired. Outbreaks of pneumonia caused by *Legionella* spp. appear to be uncommon in nursing homes (but they have occurred) and are more likely to occur in a community or hospital setting. In the United States, rates of LD are higher in northern states and during the summer. From 1980 through 1998, there was a change in the methods of diagnosing LD in the US with a decline in the number of cases diagnosed by culture and direct fluorescent antibody test and serology and an increase in the number of cases diagnosed by the detection of antigen in the urine. These trends were associated with a decrease in the mortality rate from 26% to 10% for community-acquired cases and from 46% to 14% for nosocomial cases. Severe headache combined with hyponatremia are features that should raise a clinical suspicion of LD although the clinical features are usually not distinctive. *L. pneumophila* serogroup 1 accounts for most cases of LD in the United States. *Legionella longbeachae* accounts for 72% of the cases of LD in western Australia. In this area, cases have occurred in active gardeners and the organism has been isolated from potting soil. When patients with LD are compared with those with community-acquired pneumonia caused by other agents the patients with LD are more likely to have myalgias, headache, diarrhea, and a higher mean oral temperature at the time

of presentation. They also present to hospital sooner after the onset of symptoms—4.7 days versus 7.7 days ( $p = 0.02$ ). When patients with LD were compared with patients with bacteremic pneumococcal pneumonia the following features were associated with *L. pneumoniae*—male sex, OR 4.6 95% confidence interval (CI) 1.48–14.5; heavy drinking 4.8 (1.39–16.42); previous  $\beta$ -lactam therapy 19.9 (3.47–114.2); axillary temperature  $>39$  C 10.3 (2.71–38.84); myalgias 8.5 (2.35–30.74); gastrointestinal symptoms 3.5 (1.01–12.18). Negative associations included pleuritic chest pain, previous upper respiratory tract infection and purulent sputum.

In a study from Barcelona, 104 patients  $<65$  years of age with LD were compared with the 54 patients who were older than 65 years of age. The older patients had more comorbidities and a greater likelihood of receiving corticosteroids while the younger patients were more likely to be male, smoke, have alcoholism and HIV. Fever, diarrhea and headache were less frequent in those older than 65 years of age. There was no difference in complications or requirement for mechanical ventilation. While the mortality rate was twice as high in the elderly, 11.2% versus 4.8%, the difference was not statistically significant.

## Enterobacteriaceae

Enterobacteriaceae are commonly isolated from the sputum of elderly patients with CAP. The problem is distinguishing colonization from infection since these microorganisms commonly colonize the upper airway of elderly persons. Elderly patients who are bacteremic (usually secondary to pyelonephritis), with *Escherichia coli* in particular may have secondary seeding of the lungs.

## M. tuberculosis

Nursing home residents account for 20% of cases of tuberculosis in older people. In the 1980s, approximately 12% of persons entering a nursing home were tuberculin positive, and active tuberculosis developed in 1% of isoniazid (INH) treated tuberculin positive patients compared with 2.4% of those who did not receive INH. The incidence of active tuberculosis among nursing home patients is 10 to 30 times greater than among community-dwelling elderly adults—thus, tuberculosis should always be considered in nursing home patients with pneumonia.

## Viruses

There are a large number of viruses that affect the respiratory tract (predominately the upper respiratory tract). These include influenza A and B viruses; parainfluenza viruses 1,2,3,4; adenovirus; respiratory syncytial virus, human metapneumoviruses (HMPVs) A and B, severe acute respiratory syndrome (SARS) CoV, coronaviruses, hantaviruses and varicella. Viruses are estimated to be the cause of adult CAP in 10% to 31% of cases. In a prospective study of 338 nonimmunocompromised adults with a diagnosis of CAP in whom paired serology for respiratory viruses were obtained, 61 patients (18%) had a respiratory virus identified. Influenza virus was the most common (37 patients), followed by parainfluenza (11 patients), respiratory syncytial virus (5 patients), adenovirus (5 patients), and mixed viruses (3 patients). In most instances the virus infects the upper airway, impairs ciliary function so that bacteria which are

microaspirated into the LRT are not cleared and bacterial pneumonia results.

## Respiratory Syncytial Virus

In eight hospital-based studies of RSV-associated pneumonia in adults the rates of this infection ranged from 2% to 14% among the five studies that used complement fixation test to make the diagnosis and from 4% to 14% for the two studies that used an enzyme-linked immunoassay test. Direct fluorescent antibody testing of nasopharyngeal swabs for RSV should not be done in adults because of low sensitivity.

## Human Metapneumovirus

HMPV was first described in 2001 in the Netherlands. HMPV can cause upper and lower respiratory tract infection in patients of all age groups, but symptomatic disease most often occurs in the young children or older adults. It is an emerging pathogen as a cause of CAP in adults in which it seems to behave like RSV.

## Severe Acute Respiratory Syndrome

In November 2002, an outbreak of severe acute respiratory infection started in Guangdong Province in southern China and spread worldwide affecting more than 8000 persons. SARS was caused by a novel coronavirus that jumped the species barrier from civet cats to man. The case fatality rate of the 2003 Hong Kong outbreak was 11%, but higher mortality was seen in the elderly ( $\geq 60$  years of age) and pregnant women.

## Other Coronaviruses

Human coronaviruses were first described in association with respiratory infections in 1935, but were largely ignored until the advent of SARS. HCoV-229E and HCoV-OC43 caused upper and lower respiratory tract infections prior to the SARS outbreaks. Since that time, human coronaviruses, HCoV-NL63 and CoV-HKU1 have been identified as additional etiologic agents in CAP.

## Hantavirus

In May 1993, an outbreak of severe respiratory illness, caused by a previously unknown virus, Hantavirus, occurred in the southwestern United States. The illness was preceded by prodromal flu-like symptoms followed by noncardiogenic pulmonary edema. The virus accounting for the initial cases, Sin Nombre Virus, is spread to humans from infected mice. Subsequently other Hantaviruses have been found to cause Hantavirus pulmonary syndrome and the disease has been described in other parts of the United States, western Canada, and South America. It is important to recognize that Hantavirus does not cause pneumonia but instead causes an ARDS like picture, because of the host response to this virus.

## Influenza A

Influenza continues to be a major cause of morbidity and mortality worldwide. Primary influenza pneumonia occurs when influenza virus infection directly involves the lung, typically producing a severe

pneumonia. Influenza pneumonia occurs most frequently in certain groups of patients with underlying chronic illnesses who are classified as “high risk” for this infection. These high-risk groups include patients with heart or lung disease, diabetes mellitus, renal disease, hemoglobinopathy, or immunosuppression; residents of nursing homes or chronic care facilities; and otherwise healthy individuals older than 65 years of age.

The last major pandemic of influenza in 1918 caused the deaths of more than 20 million persons, and made almost 1 billion people ill. Epidemics of influenza typically occur during the winter months and are responsible for an average of 20,000 deaths per year in the United States.

There is increasing concern that we are on the verge of the next great pandemic. Health Canada predicts that 4.5–10.6 million Canadians will become clinically ill and 11,000 to 58,000 will die during the next pandemic. There is wide spread concern that the current strain of influenza A, H5N1 which has been circulating in South East Asia among birds with limited spread to humans will mutate and be the agent of the next pandemic. As of July 26, 2006, there had been 232 human cases and 134 deaths, a 57% mortality caused by this virus.

### Aspiration Pneumonia

Aspiration pneumonia denotes two distinct clinical entities. (1) Aspiration pneumonitis: aspiration of gastric contents (usually sterile as long as there is gastric acid present) into the lungs with a resultant inflammatory response. (2) Pneumonia: aspiration of oropharyngeal flora into the lung with resultant bacterial infection.

In studies of medicare patients it was noted that the diagnosis of aspiration pneumonia increased 93.5% between 1991 and 1998. The mortality rate for patients with aspiration pneumonia was 23.1% compared with 7.6% for pneumococcal pneumonia. In elderly patients with CAP there is a high incidence of silent aspiration. Seventy-one percent of the elderly patients aspirated during sleep compared with 10% of control subjects. Just more than 28% of patients with Alzheimer’s disease and 51% of those with a stroke aspirated when swallowing was tested using videofluoroscopy. Furthermore, feeding tube placement in patients shown to aspirate on videofluoroscopy was associated with increased rates of pneumonia and death over those who aspirated but did not receive such a tube. The manifestations of aspiration pneumonia vary according to the volume and the nature of the material aspirated. Gastric acid results in a chemical pneumonitis that can be very severe requiring assisted ventilation. There is an acute onset of dyspnea, tachypnea, bronchospasm, and cyanosis. The chest radiograph often shows diffuse opacities. Many elderly patients are achlorhydric, so this presentation may not occur in the elderly. Indeed clinically, aspiration pneumonitis is often indistinguishable from pneumonia in this population. A history or a witnessed account of an aspiration event (one or more of vomiting, coughing while eating, and displacement of a feeding tube, vomitus, or tube feeding on bed clothes or on the patient within 24 hours of the diagnosis of pneumonia) is present in only 40% of definite aspiration events among residents of a long-term care facility.

In the setting of aspiration of oropharyngeal contents if there is poor dental hygiene anaerobic bacteria may also be present and lung abscess is not uncommon. Particulate matter may be aspirated resulting in mechanical obstruction of the airway.

### PATHOPHYSIOLOGY

There are three routes whereby pathogens gain access to the pulmonary parenchyma—hematogenous, airborne, and microaspiration. The latter is most common. Hematogenous spread may occur in the elderly patient bacteremic from a urinary tract source with secondary seeding of the lung. Most viruses and *Coxiella burnetii* cause infection via the airborne route. *Legionella* spp. may gain access to the lower respiratory tract via the airborne route or aspiration.

Once a pathogen is in an alveolus an inflammatory response is triggered. The pathogen serves as a chemoattractant for polymorphonuclear leucocytes. Pro-inflammatory mediators (tumor necrosis factor alpha, interleukins 1, 6) are liberated from the leucocytes amplifying the inflammatory response. Red blood cells, fibrin, and leucocytes fill the alveoli resulting in consolidation of the lung (see [Figures 126-1 and 126-2](#)). This inflammatory response results in fever, cough, purulent sputum, myalgia, and arthralgia, and if blood levels of the pro-inflammatory cytokines are high enough, septic shock ensues. In due course anti-inflammatory mediators, especially IL-10, are released leading to resolution of the inflammatory response.

Consolidation of the lung leads to dyspnea (as a result of decreased compliance) and hypoxemia. The latter is because of the ventilation-perfusion mismatch (consolidated lung is perfused but not ventilated).

### PRESENTATION

Pneumonia may present with a sudden or insidious onset of symptoms. [Table 126-3](#) gives the frequency of each symptom or sign of pneumonia at the time of presentation. Extrapulmonary symptoms such as nausea, vomiting, diarrhea, myalgia, and arthralgia are common. In one study, older patients with pneumonia complained of fewer symptoms than younger patients—patients aged 45 to 64, 65 to 74, and  $\geq 75$  years old had 1.4, 2.9 and 3.3 fewer symptoms than patients aged 18 to 44 years. Pneumonia can be one of the causes of insidious or nonspecific deterioration in general health and/or activities, for example, confusion or falls in the elderly; infection including pneumonia should be considered also as a cause of sudden deterioration of, or a slow recovery from, an existing primary disease in this group of patients. While these latter presentations are emphasized in teaching the care of the elderly, there is no data to indicate what percentage of elderly patients with pneumonia present in this fashion. A diagnosis of pneumonia based on physical examination has a sensitivity of 47% to 69% and a specificity of 58% to 75%; thus, a clinical diagnosis of pneumonia should be confirmed with a chest radiograph. Crackles, wheezes, and the signs of consolidation (dullness to percussion, bronchial breathing and aegophony) may be found. The most sensitive sign of pneumonia in an elderly adult is an increased respiratory rate (provided it is counted for 1 min) with a respiratory rate of  $>28$  indicating severe pneumonia. The chest radiograph can be difficult to interpret in elderly patients, especially if it is a portable antero-posterior examination. There is at least a 25% inter-observer variation in the diagnosis of pneumonia in elderly patients on chest radiographs where one observer is a radiologist and the other is the attending physician. Computed tomography of the chest is very accurate for the diagnosis of pneumonia but obviously cannot be done on everyone in whom this entity is suspected.

$\geq 40.0^\circ\text{C}$	2.0
Systolic blood pressure, <90 mm Hg	5.9

\*Altered mental status was defined as lethargy, stupor, coma or confusion representing an acute change from usual baseline state.

**EVALUATION****Site of Care**

The evaluation of a patient with pneumonia consists of an assessment of the severity of the pneumonia and use of this to guide the decision as to the optimal site of care—home, hospital (ICU or ward), or for those who are residents of a long-term care facility, whether to treat in the facility or transfer to hospital. A number of pneumonia specific severity of illness scoring systems have been developed (Tables 126-4 to 126-6). The pneumonia specific severity of illness scoring system

**TABLE 126-4****British Thoracic Society Rule for Severity of Community-Acquired Pneumonia\***

Respiratory rate >30 breaths/min
Diastolic BP <60 mm Hg
BUN >7 mM/L

\*If 2 or more of the above are present, the pneumonia is severe and patient is likely to require admission to an ICU.

**TABLE 126-5****CURB—65 Rule**

Confusion
Urea >7 mM/L
Respiratory rate >30 breaths/min
Blood pressure: systolic <90 mm Hg or diastolic < 60 mm Hg
Age >65 yr
Assign one point for each when present
Mortality rate: 0–0.7%; 1–3.2%; 2–3%; 3–17%; 4–41.5%; 5–57%.

by Fine et al. predicts mortality. This system has been used to guide the admission decision—that is, all patients in classes I to III can be treated on an ambulatory basis while those who fall into classes IV and V should be admitted. However, subsequent experience has indicated that such an approach to the admission decision is flawed and the physician's judgment should be the most important element in the admission decision. The British Thoracic society rule (Table 126-4) is the simplest and accurately predicts pneumonia severity. It has been modified to become the CURB-65 rule (Table 126-5). More recently, Finnish investigators noted that acute aggravation of a coexisting illness (such as impairment of glucose control in diabetics or deterioration of congestive heart failure), a respiratory rate  $\geq 25$  breaths/minute, and a C-reactive protein level  $\geq 100$  were independently predictive of mortality. If none or 1 of these was present, the mortality rate was 2.2% while if all three were present it was 20%. It is noteworthy that a study designed to elucidate how physicians decided on the site of care for patients with pneumonia found the most common reason given for admitting a patient to hospital was that he or she looked sick. The problem with this approach is that there is a great deal of inter-observer variability in what constitutes "looks sick."

**Transfer from a Nursing Home to Hospital**

A number of studies have provided data to help us decide who should be transferred from a long-term care facility for the treatment of pneumonia. In one study the following were associated

**TABLE 126-6****Severity of Nursing Home Pneumonia Scoring System**

Data from Naughton BJ, Mylotte JM, Tayara A. Outcome of nursing home-acquired pneumonia: derivation and application of a practical model to predict 30-day mortality. *J Am Geriatr Soc.* 2000;48:1292.

**TABLE 126-7****Criteria for Treatment of Pneumonia in a Nursing Home**

Respiratory rate <30 breaths/min
Oxygen saturation $\geq$ 92% while breathing room air
Pulse rate <90 beats/min
Temperature 36.5°C to 38.1°C
Systolic and diastolic blood pressure within 10 mm Hg of usual readings
No feeding tube present
Conscious
Severity of pneumonia score 2 or less (see Table 126-6)
Availability of medical and nursing care
Wishes of patient and family

with failure of treatment of pneumonia in the nursing home: pulse rate >90 beats/minute; temperature >100.5° F; respiratory rate >30 breaths/minute; feeding tube dependence and mechanically altered diets. If none of the above risk factors were present, the failure rate was 11%; while it was 23% for  $\leq$ 2 and 59% when 3 or more of these risk factors were present. The model was not predictive of mortality. The authors of another study concluded that the following could be used as indicators of the need for hospitalization—very dependent for activities of daily living; low body temperature; decreased level of consciousness; and white blood cell count <5 or >20  $\times 10^9$ /L. There was no significant difference in 30-day mortality rates between those initially treated in nursing homes (22%) and those initially treated in hospitals (31%); or between those treated with an oral regimen in the nursing home (21%) and those initially treated with an intramuscular antibiotic in nursing homes (25%). In a cluster randomized trial of 680 residents of 22 nursing homes with lower respiratory tract infections who were managed in the nursing home according to a clinical pathway or standard therapy, 10% of the 327 residents in the pathway were hospitalized compared with 22% in the standard therapy arm. There was no difference in mortality or health related quality of life between the two groups. However, there was a cost savings for just more than \$1000 per resident treated.

Since nursing homes vary greatly in the facilities and nursing staff available to provide care to very ill patients, any decision that is made has to be done with the knowledge of available resources. The nursing home pneumonia severity of illness score in Table 126-6 and the criteria in Table 126-7 help in making the decision regarding who should be transferred from a long-term care facility to hospital for the treatment of pneumonia.

## ICU Admission

Approximately 10% of patients admitted to hospital with pneumonia require intensive care. In this subgroup the mortality rate is approximately three times higher than the mortality rate for those patients with CAP who do not require intensive care. The decision to admit to an ICU is based on the severity of the pneumonia and often the need for mechanical ventilation (>50%); hemodynamic monitoring (30%); and shock (15%). Age alone should not be used to determine who is admitted to ICU. Elderly patients who require mechanical ventilation for the treatment of pneumonia can be weaned from the ventilator just as quickly as younger patients with pneumonia who require intubation, however, they require on

average 3 more days of ICU support and are more likely to require reintubation. ICU patients with pneumonia incur longer hospital stays (23 days vs. 9 days) and have a mortality rate that is approximately four times higher than patients with pneumonia who do not require ICU care.

## Diagnostic and Therapeutic Evaluations

### Diagnostic Evaluations

The specific evaluations that should be carried out for elderly patients with pneumonia are shown in Table 126-8. These are divided into three phases—those to be carried out in emergency department, in hospital and post discharge. The yield from blood cultures ranges from 6% to 15%. *S. pneumoniae* accounts for 60% of all cases of bacteremic CAP. *S. aureus* is the second most common cause of bacteremic CAP. The presence of *S. aureus* in the blood should prompt a search for endocarditis. MRSA is now quite common as a cause of community-acquired CAP. Aerobic gram-negative bacilli are the third most common cause of bacteremic CAP.

Sputum Gram stain and culture is perhaps the most controversial of all the diagnostic tests used in the evaluation of a patient with CAP for several reasons. Firstly, only approximately one-third of

**TABLE 126-8****Evaluation of Elderly Patients with Pneumonia**

- I. In emergency department
  - Posterior-anterior and lateral chest radiographs
  - Blood cultures: two sets
  - Complete blood count (hemoglobin, white blood cell count, platelet count)
  - Electrolytes
  - Glucose
  - Creatinine
  - Blood urea nitrogen
  - Pulse oximetry: if the oxygen saturation is <92% (at sea level) or if patient has chronic obstructive pulmonary disease blood gas analysis should be done.
  - Sputum Gram stain and culture (do not withhold antibiotics waiting for patient to produce a sputum sample)
  - In selected patients: urine for legionella antigen and for pneumococcal antigen; sputum stain and culture for acid-fast bacilli; acute and convalescent serology; serum for testing for HIV infection; nasopharyngeal swab for direct detection of influenza A, B virus antigens; nasopharyngeal swab for detection of DNA of *Legionella* spp.; *M. pneumoniae*; *C. pneumoniae*.
- II. In hospital
  - Daily assessment of pulse, temperature, respiratory rate, oxygenation status, and ability to eat and drink.
  - When the above parameters are stable assess functional and mental status.
  - Assess stability of comorbid illnesses.
  - Check for complications of pneumonia.
  - Check pneumococcal and influenza vaccination status and update if necessary.
  - If tobacco smoker offer access to smoking cessation programs.
- III. Post discharge
  - Follow up chest radiograph to ensure that the pneumonia has cleared.
  - If pneumonia fails to clear radiographically, consider bronchoscopy.

**FIGURE 126-4.** Chest radiograph showing left lower lobe opacity. This patient had Legionnaire's Disease.

elderly patients with pneumonia can provide an adequate sputum sample and one-third of these will yield a single pathogen; one-third yield multiple pathogens and one-third will be reported as negative or as showing oropharyngeal flora depending upon the reporting practice of the laboratory. The second problem is that the presence of a pathogen in sputum does not mean that it is in the lung and therefore the cause of the pneumonia. Nevertheless, sputum cultures should be done because a Gram stain on a good sputum specimen can give an immediate diagnosis (see [Figure 126-3](#)) and in some instances, a sputum stain and culture can be diagnostic such as with *M. tuberculosis* and in infection with *Nocardia* spp.

The chest radiograph is the gold standard for the diagnosis of pneumonia ([Figures 126-4 to 26-8](#)). Pneumonia on chest radiograph may be lobar, segmental or subsegmental and may be interstitial or alveolar. Remember that any disease that causes a pulmonary opacity can mimic pneumonia. Thus, pulmonary infarction, vasculitis, drug reactions, and pulmonary hemorrhage have been misdiagnosed

as pneumonia both clinically and radiographically. Suboptimal radiographs (portable single views) of elderly patients with suspected pneumonia are especially difficult to interpret. The inter- and intra-observer reliability of radiologists for the diagnosis of pneumonia is 80%.

**FIGURE 126-5.** A series of chest radiographs of a patient with pneumococcal pneumonia. The upper-left radiograph shows right lower lobe opacity. The upper-right radiograph shows apparent progression of the pneumonia. At this time, the patient had an acute respiratory distress syndrome. Subsequent radiographs show resolution of the pneumonia.

**FIGURE 126-6.** A chest radiograph showing diffuse opacification of the left lung. This patient, who had myotonic dystrophy, had a severe pneumonia caused by aspiration. Initially, this was a chemical pneumonitis but later nosocomial pneumonia developed.

**FIGURE 126-7.** Chest radiograph showing patchy right upper lobe opacity. The clinical diagnosis was tuberculosis.

Legionella urinary antigen detects only *L. pneumophila* serogroup 1, for which it is 90% sensitive. However, it detects only approximately 60% of all cases of LD (since LD can be caused by *L. pneumophila* serogroups 2 to 6 and to many of the other species of Legionellaceae). Therefore, a negative test should not lead to a change in diagnosis or management if there is a strong clinical suspicion of LD.

An immunochromatographic test is available to detect *S. pneumoniae* antigen in urine. This is done in a dipstick format with results available in 15 minutes. It is 80% sensitive when bacteremic pneumococcal pneumonia is used as the gold standard. The problem is defining the sensitivity and specificity of such tests in pneumonia where there is a presumptive diagnosis of pneumococcal pneumonia or in cases of pneumonia of unknown etiology. Currently, the test is best reserved for patients with severe pneumonia in whom blood cultures are negative and there is no sputum specimen available for culture.

Some authorities recommend drawing a blood sample for serology on all patients with pneumonia. A convalescent sample is drawn 2 to 6 weeks later. Serology remains the best way to diagnose pneumonia caused by Hantavirus, *C. burnetii* or *M. pneumoniae*.

Direct detection of influenza antigens in the upper airway is useful in making a rapid diagnosis of influenza and several commercial kits using direct immunofluorescence methodology (DFA) are available. It should be noted that a DFA assay on a nasopharyngeal swab is not useful for the detection of respiratory syncytial virus infection in adults. Amplification of DNA of respiratory pathogens from material collected via a nasopharyngeal swab using the polymerase chain reaction is useful for the diagnosis of LD. It can also be used to diagnose *Mycoplasma* or *Chlamydia* pneumonia. These latter two organisms may colonize the upper airway so detection of their DNA is only suggestive that they are the cause of the pneumonia. Multiplex nucleic acid amplification tests are now available so that a

**FIGURE 126-8.** Chest radiograph of the same patient as in Figure 126-7 but approximately 3 months later. The patient did not respond to antituberculous therapy and was readmitted with weight loss, clubbing of the fingers and this radiograph was obtained. Note the diffuse patchy airspace disease and an air fluid collection at the right base. Aspiration of the pleural fluid revealed an empyema. *Fusobacterium necrophorum* was isolated. A bronchopleural fistula had developed and the patient had a prolonged recovery.

specimen (nasopharyngeal swab, pleural fluid, or lung tissue) can be tested for *Legionella* spp.; *M. pneumoniae*; *C. pneumoniae*; influenza viruses A and B, RSV, adenovirus; parainfluenza viruses; HMPVs and coronaviruses including SARS CoV.

Human immunodeficiency virus (HIV) does not respect age. Bacteremic pneumococcal pneumonia, *Pneumocystis carini* and *M. tuberculosis* are more common in HIV-infected patients. Thus, HIV serology may be part of the workup of the elderly patient with pneumonia.

C-reactive protein, serum procalcitonin and neopterin have been used in an attempt to distinguish viral from bacterial infection. An ultrasensitive assay for procalcitonin looks promising in that at a level of  $\leq 0.25 \mu\text{g/L}$ , antibiotic therapy has been successfully discontinued in patients with pneumonia. The inference is that patients with this level of procalcitonin have viral pneumonia. Copeptin, which is cosynthesized with vasopressin is elevated in lower respiratory tract infections and the highest increase is in patients with pneumonia. However, since it is elevated in sepsis from any source it is not specific for pneumonia.

If a pleural effusion is present, a lateral decubitus film, with the affected side down, should be performed. If the effusion measures 1 cm or greater it should be aspirated and cultured for aerobes, anaerobes, fungi, and acid-fast bacilli. Cytology should always be performed on such specimens and the cell count, glucose, LDH, protein and pH determined. The specimen for pH should be collected in a blood gas syringe; the tip of the needle corked and submitted to the laboratory on ice.

Some patients will require invasive tests, such as bronchoscopy to make an etiological diagnosis. The decision to use such investigations depends upon the clinical setting.

### Therapeutic Evaluations

The most frequently used therapeutic evaluation is repeated measurement of vital signs (including pulse oximetry) and repeated physical examination. In general, it is obvious when there is failure of therapy—see discussion on attainment of physiological stability under the discharge decision. In patients who are improving clinically there is a need for only one follow-up chest radiograph. The timing of when this is carried out is important. Chronic obstructive pulmonary disease is typically associated with delayed radiographic clearance of pneumonia. However, if the pneumonia has not resolved radiographically by 12 weeks, bronchoscopy should be done. In 2% of patients with CAP, the pneumonia is a manifestation of cancer of the lung (post obstructive pneumonia). In 50% of these patients, the diagnosis is suggested radiographically at the time of presentation. Hence, the importance of a follow-up chest radiograph to ensure that the pneumonia has cleared.

Computed tomography of the chest is useful in the assessment of a patient who is not improving. It can detect loculated pleural effusions (potentially empyema) and early cavitation before they are seen on conventional chest radiograph. The better detail and assessment of hilar and mediastinal adenopathy may also be helpful in suggesting alternative diagnoses.

### Discharge Decision

This is often a complicated matter and involves not only the stability of the pneumonia but also the stability of comorbid illnesses and the

functional and mental status of the patient. Once physiological stability is achieved (temperature  $<37.5^\circ\text{C}$ ; respiratory rate  $<22$  [or a return to baseline for patients with chronic pulmonary compromise]; oxygen saturation of  $\geq 92\%$  while breathing room air; stable blood pressure; and ability to eat and drink), clinical deterioration requiring admission to a critical care unit or telemetry monitoring occurred in less than 1% of patients. Indeed, in one study if discharge occurred once physiological stability has been reached, the length of hospital stay for pneumonia could be reduced by 1 day. There is no need to observe the patient in hospital once the switch from intravenous to oral antibiotic therapy has been made and the patient is physiologically stable. However, there are other factors to be considered in the discharge decision; such as the elderly person who can no longer care for himself or herself and requires placement in a long-term care facility or home care. A mini-mental status should be done prior to discharge and further assessment performed for those who score less than 25.

## MANAGEMENT

### Drugs

#### Antibiotics

Guidelines published by several different professional bodies for the empiric therapy of CAP suggest different antibiotics according to the severity of the pneumonia and certain epidemiological features, such as the likelihood that PRSP may be causing the infection. Unfortunately, most of these recommendations are not based on data from randomized clinical trials. Suggested treatment for ambulatory pneumonia is a macrolide or doxycycline. Telithromycin, a ketolide, is no longer used to treat ambulatory pneumonia because of hepatotoxicity. Tigecycline, a glycylicycline structurally derived from minocycline, is currently undergoing evaluation as an agent for the treatment of CAP. If PRSP is common in the community a “respiratory quinolone”; such as levofloxacin, moxifloxacin or gatifloxacin can be used. The Canadian guidelines for the treatment of CAP have added a new category to the treatment of pneumonia on an ambulatory basis; that is, “outpatient with modifying factors.” This refers to patients with chronic obstructive lung disease who have received antibiotic therapy or oral corticosteroid treatment within the past 3 months. The antibiotic therapy of first choice in this setting is a respiratory quinolone; the second choice is amoxicillin-clavulanic acid with or without a macrolide; another possibility is a second-generation cephalosporin with or without a macrolide (Table 126-9). For patients requiring admission to a hospital ward, antibiotic therapy can be with a “respiratory quinolone” alone or with a macrolide plus a second or third-generation cephalosporin. For those who require admission to ICU, the recommended treatment is erythromycin or azithromycin or a fluoroquinolone with enhanced activity against *S. pneumoniae* plus cefotaxime, ceftriaxone, or a  $\beta$ -lactam/ $\beta$ -lactamase inhibitor (Table 126-9). Data from two studies (one a retrospective review of 12 945 Medicare inpatients with CAP, the other an observational study of 2963 patients with CAP) indicated that treatment with a second-generation cephalosporin plus a macrolide, or a nonpseudomonal third-generation cephalosporin plus a macrolide or a fluoroquinolone alone were associated with lower

TABLE 126-9

## Antibiotic Therapy (First and Second Choices) of Community-Acquired Pneumonia When Etiology is Unknown

- A. Patient to be treated on an ambulatory basis (previously healthy and no use of antimicrobials in the past 3 months)
1. Macrolide (erythromycin 500 mg q 6h orally × 10 days, clarithromycin 500 mg twice daily orally × 10 days or azithromycin 500 mg orally once a day then 250 mg once a day orally × 4 days)
  2. Doxycycline 100 mg twice daily orally × 10 days. \*If risk factors for PRSP or macrolide-resistant *S. pneumoniae* are present, consider a fluoroquinolone with enhanced activity against *S. pneumoniae*
- If chronic obstructive lung disease is present or antibiotics have been administered within the past 3 months.
1. Fluoroquinolone with enhanced activity against *S. pneumoniae*; e.g., levofloxacin, moxifloxacin, gatifloxacin. Levofloxacin 750 mg once a day orally or IV. If creatinine clearance <50 mL/min reduce levofloxacin dose to 250 mg once a day. Moxifloxacin 400 mg once a day orally; Gatifloxacin 400 mg once a day orally or IV
  2. Combination therapy with a  $\beta$ -lactam antibiotic plus a macrolide
- B. Patient to be treated in hospital ward
1. Fluoroquinolone with enhanced activity against *S. pneumoniae*; e.g., levofloxacin, moxifloxacin, gatifloxacin. Levofloxacin 750 mg once a day IV or orally, If creatinine clearance <50 mL/min reduce levofloxacin dose to 250 mg once a day. Moxifloxacin 400 mg once a day orally; Gatifloxacin 400 mg once a day IV or orally
  2. Ceftriaxone 1 gm once a day IV or cefotaxime 2 g q 6 h IV plus azithromycin 500 mg once a day IV.
- C. Patient to be treated in an ICU
1. Azithromycin 1 gm IV then 500 mg IV once a day plus ceftriaxone 1 gm q12h. IV or cefotaxime 2 gm q6h IV (ceftazidime and an aminoglycoside if *Pseudomonas aeruginosa* infection is suspected; piperacillin/tazobactam; imipenem, meropenem, cefipime and ciprofloxacin also have activity against *P. aeruginosa*)
  2. Fluoroquinolone with enhanced activity against *S. pneumoniae* (not recommended as first choice because of lack of clinical trial data in the ICU setting)
- If MRSA infection is suspected in any of the above settings add Vancomycin 1 gm q12h IV or Linezolid 600 mg IV or orally q12h.
- D. Patient to be treated in a nursing home
1. Fluoroquinolone with enhanced activity against *S. pneumoniae* e.g., Levofloxacin 750 mg once a day orally or Moxifloxacin 400 mg once a day orally or Gatifloxacin 400 mg once a day orally
  2. Ceftriaxone 500–1000 mg IM once a day or cefotaxime 500 mg IM q12h plus a macrolide.
- E. Aspiration pneumonitis/pneumonia
1. Pneumonitis: history of, or witnessed aspiration of gastric contents and an opacity on chest X-ray  
Wait 24 hours—if still symptomatic antibiotic therapy as given below.
  2. Pneumonia:
    - a. Poor dental hygiene and anaerobic infection suspected: metronidazole 500 mg q 12 h orally (clindamycin could be used but because of increased rate of *Clostridium difficile* with clindamycin use of metronidazole is preferred) plus one of the following: levofloxacin 500 mg once a day orally or moxifloxacin 400 mg once a day orally or gatifloxacin 400 mg once a day orally or ceftriaxone or cefotaxime.
    - b. Anaerobic infection not suspected: as above but do not include anaerobic coverage.

\*Risk factors for: PRSP—previous use (within 3 months) of  $\beta$ -lactam antibiotics, alcoholism, age <5 yr or >65 yr, in some areas residence in a nursing home; Macrolide-resistant *S. pneumoniae*—age <5 yr or nosocomial acquisition of infection.

30-day mortality rates. There is a suggestion that a  $\beta$ -lactam plus a macrolide therapy is associated with lower mortality in patients with CAP independent of severity. There are also several observational studies that suggest that addition of a macrolide to a  $\beta$ -lactam is associated with lower mortality in patients with bacteremic pneumococcal pneumonia. There is also one prospective observational study which found that the mortality for critically ill patients with pneumococcal bacteremia was 23.4% for the group that received combination therapy versus 55.3% for the group with monotherapy. In the same prospective study, investigators examined the “impact of concordant antibiotic therapy (i.e., receipt of a single antibiotic with in vitro activity against *S. pneumoniae*) versus discordant therapy (inactive in vitro) on mortality was assessed at 14 days. Discordant therapy with penicillins, cefotaxime, and ceftriaxone did not result in a higher mortality rate.” However, discordant therapy involving cefuroxime was associated with a significantly higher mortality rate. Prompt administration of antibiotics, within 4 to 8 hours of arrival at emergency department is associated with a lower mortality rate among elderly patients when compared with those who wait longer for antibiotic therapy.

The respiratory quinolones seem like ideal choices for the treatment of CAP since they are active against most of the microbial causes

of pneumonia, including: penicillin-susceptible *S. pneumoniae* and PRSP, *H. influenzae*, *M. catarrhalis*, *S. aureus*, *M. pneumoniae*, *Legionella* spp., and *Chlamydia pneumoniae*. It is very important to remember that the respiratory quinolones (especially gatifloxacin [which was withdrawn from the market]) may cause dysglycemia. One study found that levofloxacin (and by inference other respiratory quinolones) was superior to ceftriaxone/cefuroxime for the treatment of mild to moderately severe CAP. New information indicates that levofloxacin 750 mg daily for 5 days is adequate for the treatment of CAP. There is concern that the widespread use of the respiratory fluoroquinolones will lead to the emergence of resistance among these respiratory pathogens. For this reason the CDC working group on the management of CAP, in the era of pneumococcal resistance, recommended that macrolides or doxycycline should be first line therapy for the management of ambulatory pneumonia and that the new fluoroquinolones should be reserved for adults who have already failed one of the first line drugs; who are allergic to the first line drugs or who have documented infection with highly drug-resistant pneumococci. The CDC group recommends that first line treatment for moderately ill persons hospitalized with CAP should be with a parenteral  $\beta$ -lactam antibiotic; such as, cefuroxime, cefotaxime, ceftriaxone, or a combination of

ampicillin sodium and sulbactam sodium and a macrolide; such as, erythromycin, azithromycin or clarithromycin.

In an International study of CAP it was found that 85% of patients in North America received treatment for both atypical and typical pathogens compared with 49% in Europe, 45% in Latin American, and 1% in Africa/Asia.

### When to Switch from Intravenous to Oral Antibiotics in the Treatment of CAP

For patients who are treated with intravenous antibiotics, the question of when to switch to oral antibiotics arises. Studies have shown that the switch from intravenous to oral antibiotics can be safely done when the white blood cell count is returning toward normal, there are two normal temperature recordings 16 hours apart, and there is improvement in cough and shortness of breath. The respiratory quinolones are so well absorbed from the gastrointestinal tract, however, that intravenous therapy is only necessary in those who are hypotensive or who have nausea and/or vomiting.

### Nonpharmacological Management

Because of fever and increased loss of water through the lungs caused by rapid breathing, dehydration is common in patients with pneumonia. Thus, rehydration with intravenous fluids is often necessary. Hypoxemia is common and supplemental oxygen is used to correct this. In the absence of bronchiectasis, chest physiotherapy is not useful. Patients with pleuritic chest pain may require analgesia. Intubation may be avoided in some patients with severe chronic obstructive pulmonary disease, who have pneumonia and impending respiratory failure, by use of positive pressure assisted ventilation via a tight fitting facial mask (BiPAP). Anti-pyretics should not be used unless the temperature is  $>39^{\circ}\text{C}$  or unless the patient is quite uncomfortable from the fever. Twice daily measurements of temperature are useful for monitoring response of the pneumonia to treatment. Pneumonia in elderly patients frequently exacerbates baseline confusion or results in new onset of delirium. Indeed, all elderly patients with pneumonia should be assessed for the presence of delirium at the time of admission and daily for the first 4 to 5 days in hospital. Delirium requires both nonpharmacological and pharmacological management.

### Ancillary Measures

Appropriate management of comorbid illnesses, some of which can be made worse by the pneumonia, is important.

In the PROWESS trial, drotrecogin alfa (activated protein C) resulted in a 28% relative reduction in mortality among patients with severe CAP. Currently, patients with CAP and an APACHE II score of  $>25$  qualify for this drug, although the data suggest a beneficial effect beginning at an APACHE II score of 20.

Tissue factor pathway inhibitor may also have a beneficial effect in severe pneumonia, and currently trials of this compound are underway.

Low-dose corticosteroid therapy is beneficial to those seriously ill pneumonia patients who are relatively adrenal insufficient ( $<9$  mcg/mL response in cortisol level to a dose of adrenocorticotropic hormone). Hyperglycemia has been shown to be associated with higher mortality rates in patients who require hospitalization for

community-acquired pneumonia, so it is likely that control of hyperglycemia will be beneficial for patients with pneumonia and elevated blood sugar.

## PREVENTION

### Pneumococcal Vaccine

Currently, there is a 23-valent capsular polysaccharide vaccine available for use in adults; with the most common capsular polysaccharide types of *S. pneumoniae* causing bacteremic pneumonia represented in the vaccine. Elderly subjects do not mount a good antibody response to this vaccine. However, the evidence indicates a beneficial effect from this vaccine. A booster dose is given 5 years after the first dose. A polysaccharide-protein conjugate vaccine is currently undergoing clinical trials, and promises to be more effective than the currently available capsular polysaccharide vaccine.

### Influenza Vaccine

Yearly influenza vaccination of the elderly reduces the rate of admission to hospital for both pneumonia and congestive heart failure. Immunization of health care workers against influenza protects against nosocomial influenza.

### Cessation of Tobacco Smoking

Tobacco smoking is associated with a twofold increase in risk for pneumococcal pneumonia. It is likely that cessation of tobacco smoking will reduce the rate of pneumonia, but there are no data from clinical trials to indicate this. Nevertheless, this recommendation is likely to have many benefits, including slowing the age related decline in lung function and reducing the risk of lung cancer.

### Prevention of Aspiration Pneumonia

The “chin down” posture has been found to reduce the occurrence of aspiration both before and during the swallow. This posture results in a posterior shift of the anterior pharyngeal structures, narrowing the laryngeal entrance while widening the angle of the epiglottis to the anterior tracheal wall. The end result is protection of the airway. Cleaning of the teeth and gingival by caregivers after each meal reduced the latency time of the swallowing reflex and increased substance P in the saliva of patients with dysphagia caused by cerebrovascular disease. Substance P stimulates the neural pathways to improve the swallowing reflex.

## SPECIAL ISSUES

### Patient Preference

If there is a significant risk of mortality many prefer to be treated in hospital; otherwise they prefer to be treated at home. Sir William Osler termed pneumonia “Captain of the men of death.” This is one condition where it is of utmost importance to know the wishes of

your patient regarding ventilatory support and resuscitation. In one study 15% of patients with CAP, who required admission to hospital, had a do-not-resuscitate order (DNR) written within 24 hours of admission while an additional 7% had such an order written later. In multivariate analyses, the following were predictive of initial DNR: age, nursing home care, active cancer, dementia, neuromuscular disorders, altered mental status, low systolic blood pressure, tachypnea, abnormal hematocrit, abnormal blood urea nitrogen, and absence of alcohol or intravenous drug abuse. In similar analyses of DNR at any time, additional predictors included aspiration, low white blood count, chronic pulmonary disease, cerebrovascular disease, and congestive heart failure.

### Patient Education

Patients (particularly those treated on an ambulatory basis) should be given written information on the expected course of the pneumonia, warning signs that indicate a need for reassessment, (such as increasing dyspnea, pleuritic chest pain, hemoptysis), and the requirement for a follow-up chest radiograph to ensure that the pneumonia has cleared.

### Quality of Care Measures

The following have been adopted as quality of care measures for patients with CAP requiring admission to hospital: blood cultures prior to administration of antibiotics; measurement of oxygenation status; administration of antibiotics within 4 hours of presentation to emergency department; ascertainment of influenza; and pneumococcal vaccination status and administration of these vaccines as necessary. In addition, for those who smoke tobacco products, at the very least information re: cessation, and preferentially counseling regarding cessation of smoking. Two large studies have examined the quality of care in U.S. hospitals for a number of conditions including pneumonia. In one study, academic hospitals had higher performance scores for acute myocardial infarction than nonacademic hospitals and congestive heart failure but lower scores for pneumonia—69% versus 71%. Not-for-profit hospitals had significantly higher scores for all three conditions than did for profit hospitals. There were also regional differences with the Midwest and Northeast outperforming the West and the South. The number of beds was significantly associated only with pneumonia scores, with the smallest hospitals having the highest scores. Of 3484 hospitals most, approximately 98%, met the oxygenation assessment criteria; The pneumococcal vaccination criteria were very scattered—approximately 2% of the hospitals assessed immunization in 91% to 100% of cases; 18% did the assessment 0% to 10% of the time and approximately 60% of the hospitals assessed less than 50% of the patients. Only 3% of the hospitals gave antibiotics in the recommended time to 91% to 100% of the patients. In another study of U.S. hospitals, the investigators examined hospital's performance on 18 standardized indications of quality of care for four conditions one of which was pneumonia. Data were collected more than a 2-year period in more than 3000 accredited hospitals. The measures assessed for CAP were—oxygenation assessment within 24 hours after admission; pneumococcal vaccination screening, blood cultures collected before initiation of antibiotic therapy; smoking-cessation counseling or advice; mean time from arrival to initial antibiotic administration. Over the course of the study the percentage of patients who had oxygenation assessment

done rose from 95% to 99%; pneumococcal vaccination from 28% to 50%; blood cultures from 82% to 83%; smoking cessation counseling from 34% to 67%; mean time to initiation of antibiotics 266 minutes to 227 minutes. With the exception of blood cultures all the rest were statistically significant

There are now a number of studies which have examined the effect of using guidelines on patient care, and while the design of these have differed, there is a strong suggestion that following guidelines has a “halo-effect” in improving patient care and results in decreased mortality and, in some instances, reduced LOS.

## CONCLUSIONS

Management of pneumonia in the elderly is challenging yet very rewarding. Attention to vaccination status and advice regarding cessation of pneumonia can prevent many cases of pneumonia. Prompt treatment according to guidelines for empiric therapy and attention to the effect of pneumonia on comorbidities can optimize outcomes.

# Urinary Tract Infections

*Lindsay E. Nicolle*

Urinary tract infection (UTI) is the most frequent bacterial infection in elderly populations. While urinary infection in the elderly person is usually asymptomatic, symptomatic infection occurs frequently with associated serious morbidity and, rarely, mortality. Optimal management of urinary infection in the elderly patient is challenging in the face of diagnostic uncertainty, concerns with excess antimicrobial use, and increasing antimicrobial resistance in both the community and nursing home. Current limitations in knowledge and optimal management strategies for this problem must be appreciated. In addition, the heterogeneity of the elderly populations means approaches may vary for different groups. The impact and management of urinary infection differs for women and men, and for the institutionalized and noninstitutionalized elderly person. There are also unique considerations for the subgroup of institutionalized elderly persons with chronic indwelling catheters. The discussion in this chapter is relevant to individuals without long-term indwelling catheters, unless otherwise stated.

## PRESENTATIONS OF URINARY INFECTION

The bladder is normally sterile. While bacteriuria is always abnormal, it is not necessarily detrimental. “Bacteriuria”, a positive urine culture without attributable signs or symptoms, is used interchangeably with “asymptomatic UTI” in this chapter. The majority of the elderly individuals with bacteriuria have evidence for a local host response. Some authors use the term “bladder colonization” in discussing asymptomatic bacteriuria. This term has not been shown to have clinical or biological relevance in elderly populations, and is not used in this discussion.

UTI encompasses a spectrum of presentations (Table 127-1). Acute uncomplicated urinary infection, also known as acute cystitis, is usually considered relevant only for premenopausal women. However, women who experience recurrent acute uncomplicated urinary

infection prior to menopause often continue to experience these episodes after menopause. Complicated UTI occurs in either sex in the setting of a structurally or functionally abnormal urinary tract. A wide variety of genitourinary abnormalities are associated with infection, from prostatic hypertrophy and cystoceles to chronic renal failure and chronic indwelling catheters. A characteristic of complicated UTI is frequent and early post-therapy recurrence if the underlying genitourinary abnormality persists. These infections are also characterized by a wider variety of infecting organisms. The majority of functionally impaired older women and all men with urinary infection should be considered to have complicated infection.

Acute prostatitis is an infrequent, severe, febrile infection occurring primarily in young men. Chronic bacterial prostatitis occurs in older men. It is characterized by bacterial infection of the prostate with mild to moderate local symptoms, and is commonly associated with recurrent episodes of acute cystitis as organisms reinfect the urine from the prostate source. These symptoms respond to antimicrobial therapy. Presentations of chronic prostatitis/chronic pelvic pain syndrome in men without documentation of bacteria in the prostate are no longer thought to be attributable to infection, irrespective of the presence or absence of pyuria.

Recurrent urinary infection, either reinfection or relapse, is common for elderly persons. Reinfection is recurrent urinary infection with an organism isolated following antimicrobial therapy which differs from the pretherapy isolate. This is assumed to reflect entry of a new organism into the bladder during or following therapy. Superinfection is a new urinary infection (i.e., a reinfection) that occurs in the presence of existing bacteriuria, without an intervening episode of negative urine culture. Relapse is recurrent urinary infection when the organism-isolated post-therapy is similar to the pretherapy isolate. When relapse occurs, the organism has usually remained sequestered at some site in the urinary tract and was not eradicated with antimicrobial therapy.

**TABLE 127-1****Potential Clinical Presentations of UTI**

PRESENTATION	CHARACTERISTICS
Acute, uncomplicated urinary infection	Bladder infection in women with a normal genitourinary tract
Acute, nonobstructive pyelonephritis	Acute renal infection in women with a normal genitourinary tract
Complicated UTI	Bladder or renal infection in men and women with functional or structural genitourinary abnormalities
Asymptomatic bacteriuria (asymptomatic UTI)	Positive urine culture meeting standard quantitative criteria for significant bacteriuria with no signs or symptoms referable to the urinary tract, irrespective of the presence or absence of pyuria
Acute prostatitis	Febrile illness, usually with bacteremia and severe voiding symptoms associate with acute bacterial infection of the prostate
Chronic bacterial prostatitis	Symptomatic persistent relapsing documented bacterial infection of prostate, often manifested by recurrent acute cystitis

**EPIDEMIOLOGY****Asymptomatic Infection****Elderly in the Community**

There is a marked increase in the prevalence of asymptomatic bacteriuria with increasing age for women. The prevalence of bacteriuria is 2% to 3% in young women and increases to more than 10% for women older than age 65 years and 20% at 80 years or more (Table 127-2). Bacteriuria is uncommon in younger men but the prevalence of bacteriuria increases substantially with aging, particularly coincident with the development of prostatic hypertrophy. Approximately 5% of men older than age 70 years living in the community have bacteriuria. There are few studies describing the incidence of asymptomatic urinary infection in the elderly ambulatory populations. With yearly urine cultures obtained, it was reported to be 6.7/100 person years for diabetic and 3.0 for nondiabetic women aged 55 to 75 years. For 209 initially nonbacteriuric elderly ambulatory male outpatients of a veteran's hospital, 10% had at least one episode of bacteriuria during a mean of 2.8 years follow-up. Three-quarters of these episodes resolved spontaneously.

**TABLE 127-2****Prevalence of Asymptomatic Bacteriuria in Elderly Populations**

POPULATION	POSITIVE URINE CULTURE (%)	
	Women	Men
Community >70 yr of age	10–18	4–7
Long-term care	25–55	15–37

**Institutionalized Older Adults**

The prevalence of asymptomatic bacteriuria in institutionalized elderly populations is remarkably high (Table 127-2). This has been consistently observed in reports over several decades from many geographic areas of the world. It is somewhat higher in women, with 25% to 50% bacteriuric, compared to 15% to 40% of men. The variation in prevalence is primarily determined by characteristics of the institutionalized population. There may be an increased prevalence with increasing age of residents, although this is not consistent among studies. In fact, bacteriuria in the very elderly, those older than age 90 years, may be somewhat lower. The incidence of asymptomatic infection amongst these populations is also very high. In a group of previously bacteriuric women screened monthly, new infections occurred at a rate of 87 infections per 100 patient years. In elderly men resident in a veteran's hospital with urine cultures obtained every 2 weeks, an incidence of infection of 45 infections per 100 patient years was observed, with 10% of previously nonbacteriuric residents becoming bacteriuric in every 3-month period.

The remarkable occurrence of asymptomatic bacteriuria in elderly institutionalized populations has also been described in repeated prevalence surveys, with observations reported as both acquisition and loss of bacteriuria between surveys. Acquisition of bacteriuria at 1 month after initial negative screening was reported to be 11% for men and 12% for women. In another study, 8% of women acquired bacteriuria by 6 months, and 23% by 1 year. Reversion to negative urine cultures was observed in 22% of bacteriuric men at 1 year and, for women, 12% at 1 month, 31% at 6 months, and 27% at 1 year. Resolution of bacteriuria is often coincident with antimicrobial therapy.

**Symptomatic Urinary Infection****Elderly in the Community**

Clinically diagnosed urinary infection in an American community-living population older than 65 years of age was reported to be 13 per 100 person-years, 10.9 per 100 years in men and 14 per 100 years in women. The rate was 15 per 100 years in those aged 65 to 74 years, but 12 per 100 years in those older than age 75 years. In women 55 to 75 years enrolled in a group health plan in Washington State, symptomatic infection was 7/100 person years; 12/100 for women with diabetes and 6.7/100 for those without diabetes. Symptomatic infections were 0.17 per 1000 days in a cohort of 29 ambulatory elderly male veterans with bacteriuria. In initially bacteriuric residents of a geriatric apartment, the incidence of urinary symptoms was 0.9 per 1000 days during 6 months follow-up. Considering more severe presentations, hospitalization for acute pyelonephritis in persons older than 70 years was 10 to 15 per 10 000 population in one Canadian province, with hospitalization for women 1.3 times more frequent than men. An American study using 1997 administrative data reported pyelonephritis hospitalizations were 13.5/10 000 for women 60 to 79 years and 23.3/10 000 for women 80 years or older, and 6.3/10 000 and 12.9/10 000 for men, respectively.

**Institutionalized Older Adults**

The incidence of symptomatic urinary infection in long-term care facilities varies from 1.0 to 2.4 per 1000 resident days. Definitions to

identify symptomatic urinary infection are, however, often imprecise and variable among studies. The reported incidence of symptomatic infection is only 0.27 to 0.4 per 1000 days for bacteriuric men or women when restrictive clinical definitions which require localizing genitourinary symptoms are used. An incidence of 0.6/1000 days was recently reported from a group of American facilities using standardized definitions, and 1.0/1000 resident days in a German nursing home. The incidence of fever from a urinary source in non-catheterized subjects in nursing homes was reported to be 0.5 to 1 per 1000 resident days using restrictive clinical or serologic criteria for identification of invasive urinary infection.

## MORBIDITY AND MORTALITY

### Asymptomatic Bacteriuria

Long-term adverse outcomes have not been attributed to asymptomatic bacteriuria for either ambulatory or institutionalized populations. Persistent asymptomatic urinary infection is not associated with an increased risk of development of renal failure or hypertension. In addition, despite a high prevalence of infection with urease-producing organisms such as *Proteus mirabilis*, complications from renal stone disease are not a common problem in institutionalized populations. Studies from Greece and Finland in the 1970s reported an association between asymptomatic bacteriuria and decreased survival for both elderly men and women. Subsequent studies in both community and institutionalized elderly populations in Finland, the United States, and Canada have not confirmed this observation. Thus, current evidence does not support an association between asymptomatic bacteriuria and decreased survival for elderly populations.

### Symptomatic Urinary Infection

Symptomatic urinary infection is a common infection in the elderly population. Morbidity may occur along a continuum of limited voiding discomfort to disruption in daily activities or hospitalization for pyelonephritis or sepsis. An American study of 284 patients, older than 65 years of age, presenting to an emergency department reported 4.6% died during hospitalization; 9.5% required intensive care admission; 48.9% had greater than 2 days length of stay and 26.4% required more than 2 days intravenous antibiotics. Independent predictors of any of these adverse outcomes included mental status change, frequent past urinary infections, other non urinary infections, abnormal temperature, tachycardia, hypotension, elevated blood urea nitrogen, hyperglycemia, elevated white blood cell count and relative neutrophilia.

For the institutionalized population, deterioration in functional status may also contribute to morbidity, but this impact has not been rigorously evaluated. From 8% to 30% of transfers from long-term care to an acute care facility are necessitated by urinary infection. Urinary infection is the most common source of bacteremia in long-term care facility residents, although bacteremia is infrequent in residents without a chronic indwelling catheter. Antimicrobial pressure associated with treatment of UTIs, much of which may be asymptomatic, promotes emergence and persistence of resistant organisms in long-

term care facilities. Antimicrobial therapy also contributes to morbidity through adverse effects. Urinary infection, however, is an infrequent cause of mortality, even with bacteremia from a urinary source.

## PATHOGENESIS

### Route and Site of Infection

Urinary infection occurs by the ascending route. The reservoir for infecting organisms is usually the gastrointestinal flora. Organisms colonize the periurethral area and ascend up the urethra into the bladder. Infecting organisms may subsequently reach the kidney. Renal infection is determined by virulence characteristics of the infecting organism or the presence of genitourinary abnormalities such as obstruction or reflux in the host. For men, ascending infection may also lead to prostate infection. Thus, urinary infection may be localized to the bladder, may involve the kidneys as well as the bladder and, for men, may also be localized in the prostate. Infection of the upper tract (kidney) is present in 50% of elderly women with asymptomatic infection. Renal localization is more frequent with increasing age, and in residents of nursing homes. The proportion of elderly men with a prostatic site of infection is unknown, but is likely substantial. In the institutionalized population, transfer of organisms which colonize the perineum or urinary drainage devices such as indwelling or external catheters may occur between patients. Rarely, infection may be hematogenous rather than ascending, with urinary infection secondary to bacteremia from a nonurinary source.

## Microbiology

### Infecting Organisms

The most frequent infecting organism isolated from urinary infection in either asymptomatic or symptomatic ambulatory elderly women is *Escherichia coli* (Table 127-3). For women with acute uncomplicated infection, the spectrum of virulence factors in urinary *E. coli* isolates is similar to younger women. Pyelonephritis strains are associated with *P. fimbriae*, and have an increased frequency of other virulence characteristics including capsule type, adhesins, and proteins such as iron binding proteins and hemolysins. *E. coli* isolated from persons with complicated urinary infection have a lower prevalence of virulence characteristics. In men, gram-positive organisms and other gram-negative organisms, particularly *P. mirabilis*, are more frequently isolated than *E. coli*.

*E. coli* remains the most frequent organism isolated from institutionalized women, although less common than in noninstitutionalized women. *P. mirabilis* is the most frequent in men (Table 127-3). *E. coli* may be more common in bacteremic infection than other gram-negative uropathogens. *E. coli* is also more likely to persist than other organisms in women with asymptomatic bacteriuria. Many other gram-negative organisms are isolated in the institutionalized population, including Enterobacteriaceae such as *Klebsiella pneumoniae*, *Serratia* spp., *Citrobacter* spp., *Enterobacter* spp., and *Morganella morganii*, as well as *Pseudomonas aeruginosa*. *Providencia stuartii* is an organism isolated virtually only from institutionalized subjects. When this organism is isolated, it is frequently the predominant organism in the ward or facility. Thus, it has a unique propensity for

TABLE 127-3

## Distributions of Infecting Bacteria Isolated from Elderly Populations with Asymptomatic Urinary Infection and Without Indwelling Catheters

ORGANISM	POPULATION (% OF ISOLATES)			
	Community		Institutionalized	
	Women	Men	Women	Men
<i>E. coli</i>	68–72	19–50	47–77	11–27
<i>P. mirabilis</i>	0.8	0.6–4.7	2.3–27	30–36
<i>K. pneumoniae</i>	9–10	4.7–6.9	6.8–11	5.9–9.1
<i>Citrobacter</i> spp.	—	—	1.82.6	2.5–3.1
<i>Enterobacter</i> spp.	—	1.7–3.3	0.9–2	1.7–9.1
<i>Providencia</i> spp.	—	1.0	6.8	16
<i>M. morgani</i>	—	0.7	1.7	1.2–2.5
<i>P. aeruginosa</i>	—	4.7–9.4	5.1–9	13.2–19
Group B streptococci	10	—	0–13	0–1.7
<i>Enterococcus</i> spp.	4.8	18–25	4.5–8.0	5–23.7
Coagulase-negative staphylococci	5.6	8.9–39	0.9–4	1.7–4.5
<i>Staphylococcus aureus</i>	—	5.0	0–6	2.5–8.5

spread within the institutional setting. Gram-positive organisms include group B streptococci, which may be more common in persons with diabetes. *Enterococcus* spp. and coagulase-negative staphylococci are frequently isolated in men, but are seldom associated with symptomatic infection. Polymicrobial bacteriuria is common in both men and women resident in institutions, with more than one organism isolated in 10% to 25% of bacteriuric subjects.

### Antimicrobial Resistance

Bacterial isolates from urinary infection in institutionalized populations are characterized by a higher frequency of antimicrobial resistance than organisms isolated in the community population. This is a consequence of intense exposure to antimicrobials together with facilitation of transmission of organisms in the institutional setting. The prevalence of resistant isolates varies widely among facilities. Resistant organisms of particular concern in urinary infection include vancomycin-resistant enterococci, extended spectrum beta lactamase producing *E. coli* and *K. pneumoniae*, and fluoroquinolone-resistant *P. aeruginosa*. For the elderly residents with urinary infection who present to emergency departments, prior antimicrobial use with either trimethoprim/sulfamethoxazole (TMP/SMX) or a fluoroquinolone is the most important risk factor for isolation of a resistant organism. Consistent associations for identification of resistant organisms in nursing home residents also include prior TMP/SMX exposure for TMP/SMX-resistant organisms, and prior fluoroquinolone exposure for fluoroquinolone-resistant organisms. The presence of an indwelling urethral catheter is also associated with isolation of fluoroquinolone-resistant *E. coli*.

### Host Factors

#### Elderly in the Community

In the normal genitourinary tract, intermittent, complete voiding is the preeminent host defense against urinary infection. Most well-elderly women continue to empty their bladder completely. Sev-

eral host factors, however, contribute to the high frequency of urinary infection in elderly populations (Table 127-4). In ambulatory postmenopausal women associations with asymptomatic bacteriuria are urinary incontinence, increased postvoid residual urine, reduced mobility and estrogen treatment. For postmenopausal women who are diabetic, an additional risk factor is the duration of diabetes. A prospective study of risk factors for symptomatic UTI in women of age 55 to 75 years reported independent predictors were a prior history of urinary infection and diabetes. An initial case control study in the same women had reported sexual activity and incontinence to be associated with symptomatic infection, but these findings were not confirmed in the prospective study.

Any structural or functional abnormality which impairs voiding will increase the likelihood of urinary infection. Genitourinary abnormalities such as urethral or ureteric strictures, bladder

TABLE 127-4

## Contributing Factors to the High Prevalence of Bacteriuria in Elderly Populations

Women	Genetic predisposition Loss of estrogen effect on genitourinary mucosa Changes in colonizing flora Cystoceles Increased residual volume
Men	Prostatic hypertrophy Bacterial prostatitis Prostatic calculi Urethral strictures External urine collecting devices
Both	Genitourinary abnormalities Bladder diverticulae Urinary catheters (intermittent, indwelling) Associated illnesses Neurologic disease with neurogenic bladder dysfunction Diabetes

diverticulae, and cystoceles occur with increased frequency in older populations, and contribute to bacteriuria. Studies in ambulatory women have tended to confirm an association of increased postvoid residual being associated with UTI. An association between urinary incontinence and UTI is consistently reported from both ambulatory and institutionalized women, but is unlikely to be causative. Women with incontinence have abnormal voiding, and voiding abnormalities are a major predisposing factor for development of bacteriuria or urinary infection. Thus, urologic abnormalities which lead to incontinence are also likely to promote bacteriuria. In multivariate analyses of associations with urinary incontinence, urinary infection frequently does not persist as an independent variable. Current evidence does not support a role for immunologic changes of aging being important contributors to the high frequency of urinary infection.

The association of estrogen decline in elderly women with urinary infection is complex, and observations sometimes conflicting. Loss of the estrogen effect on the genitourinary mucosa in postmenopausal women is associated with an increased colonization of the vagina with potential uropathogens. Postmenopausal women are less likely to have lactobacilli colonizing the vagina, and more likely to have *E. coli* and enterococci. These changes in vaginal flora, together with the higher pH in the absence of lactobacilli, are similar to changes observed in younger women with recurrent UTI, and have been suggested to facilitate urinary infection in older women. However, both case control studies and prospective, randomized trials, have consistently reported that systemic estrogen use in postmenopausal women is associated with an increased risk of symptomatic infection. It is suggested this is because women who use estrogen are more likely to be sexually active, but this hypothesis requires confirmation. Topical vaginal estrogen maintains a vaginal environment characterized by decreased pH and predominance of lactobacilli. Prospective, randomized clinical trials have reported that vaginal estrogen may decrease the frequency of infection. However, some case control studies report an association of topical vaginal estrogen with increased risk of urinary infection. Again, these studies may be biased by inclusion of women who are receiving topical estrogen because they are experiencing recurrent urinary infection.

Prostate hypertrophy is the most important factor promoting urinary infection in elderly men. This leads to obstruction and turbulent urethral urine flow which facilitates ascension of organisms into the bladder or prostate. Once bacteria are established in the prostate they are difficult to eradicate because of poor diffusion of antimicrobials into the prostate, and the increasing presence of prostate stones with age. These stones provide a nidus from which it may be impossible to eradicate bacteria. Frequent relapse of urinary infection from a prostate source is common, although months or even years may intervene between episodes.

### Institutionalized Older Adults

The prevalence of asymptomatic bacteriuria in the institutionalized elderly population correlates with increasing functional impairment. The bacteriuric institutionalized elderly population are characterized by incontinence of bladder and bowel, immobility, and dementia. Impaired bladder emptying or ureteric reflux frequently accompany neurologic diseases which precipitate the requirement for institutional care, such as Alzheimer's disease, Parkinson's disease, and cerebrovascular disease. These voiding abnormalities promote the

acquisition and persistence of urinary infection. No association of bacteriuria with other chronic diseases, including diabetes, or with specific medication use, has been reported. In contrast to observations in ambulatory women, bacteriuria has not been associated with elevated postvoid residual urine in women or men in the nursing home population. Oral estrogen and progesterone given to incontinent women resident in a nursing home was also not associated with a decreased prevalence of bacteriuria, despite vaginal pH and cytology showing a partial estrogen effect.

The use of external condom collecting devices for management of incontinence in men also promotes bacteriuria. Men who have incontinence managed with the use of these devices have a 2-fold-increased prevalence of bacteriuria when compared to men with incontinence in whom external catheters are not used. The initiation of condom catheter drainage is frequently temporally associated with onset of bacteriuria in a previously nonbacteriuric resident. With the external catheter, bacteria colonize the periurethral area in high concentrations and may ascend into the bladder, particularly if there is kinking or obstruction of the condom or drainage tube.

In long-term care facilities, host factors that predict symptomatic rather than asymptomatic infection have not been well characterized. Trauma to the genitourinary mucosa or obstruction of the genitourinary tract in the presence of asymptomatic urinary infection frequently precipitate fever, often with bacteremia from the urinary source. Identification of other host determinants of symptomatic infection requires further study.

### Immune and Inflammatory Response

The elderly institutionalized individuals with asymptomatic bacteriuria usually have evidence for a local host response, and a substantial proportion also have evidence of a systemic response. More than 90% have pyuria. Approximately 30% of institutionalized subjects without bacteriuria, however, also have pyuria, presumably caused by other inflammatory processes of the genitourinary tract. Cytokines, such as interleukin (IL)-1 $\alpha$ , IL-6, or IL-8, are measurable in the urine significantly more often in bacteriuric than nonbacteriuric subjects. Urine antibody levels against the infecting organism are elevated in most bacteriuric subjects, and markedly increased in more than one-third of subjects. Asymptomatic bacteriuria in hospitalized, functionally impaired elderly subjects is associated with circulating tumor necrosis factor receptors and a higher number of neutrophils in the blood, but not with increases in cytokines including tumor necrosis factor  $\alpha$ , IL-6, or IL-1 receptor agonist, or with increased C-reactive protein. Approximately one-third of subjects with bacteriuria have markedly elevated serum antibody levels to their infecting uropathogens, and these elevated levels persist while bacteriuria persists. The clinical significance of the presence or degree of these abnormalities in asymptomatic subjects is unknown.

The response to symptomatic urinary infection in the elderly population is, generally, similar to that described for younger populations. There is evidence of local inflammation within the genitourinary tract with pyuria and elevated urinary cytokine and antibody levels. For systemic urinary infection, including fever and pyelonephritis, there is a systemic antibody response to the infecting organism, as well as elevated serum IL-6, C-reactive protein levels, and other inflammatory markers. These variables all decline together with resolution of systemic symptoms with appropriate treatment of the infection. Elderly individuals with systemic infection generally

**TABLE 127-5****Clinical Presentations of Symptomatic UTI in Elderly Populations**

Probable urinary infection
Acute lower tract irritative symptoms (frequency, dysuria, urgency, increased incontinence)
Acute pyelonephritis (fever, flank pain, and tenderness)
Fever with urinary retention or obstruction of the urinary tract
Fever with chronic indwelling urethral catheter
Unlikely caused by urinary infection
Fever without localizing genitourinary signs or symptoms and no indwelling catheter
Gross hematuria
Nonspecific symptoms of clinical deterioration without localizing findings
Not caused by urinary infection
Chronic incontinence
Other chronic genitourinary symptoms

have a secondary antibody response, with antibody increases against antigens of the infecting organism in both urine and blood.

## CLINICAL PRESENTATION

### Symptomatic Urinary Infection

Clinical presentations of symptomatic infection may be similar to those in younger populations (Table 127-5). Acute lower tract infection (cystitis) presents with frequency, urgency, suprapubic discomfort, and dysuria. New or increased incontinence may also be a common presenting symptom in the elderly. Acute pyelonephritis presents with the classic triad of fever and costovertebral angle pain and tenderness, with or without associated lower urinary tract symptoms. The clinical diagnosis of symptomatic urinary infection is, however, frequently problematic, particularly in the highly functionally impaired elderly population. Difficulties in communication because of mental impairment or hearing loss and the presence of chronic symptoms associated with comorbid illnesses compromise the clinical assessment of changes in resident status.

Chronic genitourinary symptoms are common in elderly persons. These may include incontinence, frequency, urgency and dysuria. With the high prevalence of bacteriuria, especially amongst the institutionalized population, a positive urine culture frequently accompanies these chronic genitourinary symptoms. However, the chronic symptoms should not be attributed to bacteriuria, and are not improved by antimicrobial therapy. An unpleasant urinary odor may be associated with bacteriuria, likely attributable to polyamine production by infecting organisms in the urine. However, not all malodorous urine is bacterial infection, and infected urine is not universally malodorous. The appropriate approach to malodorous urine is through incontinence management and, perhaps, hydration, rather than considering this a symptom for which antimicrobial treatment is indicated.

### Hematuria

Gross hematuria in institutionalized subjects occurs more frequently in men than in women. The majority of subjects with hematuria

are bacteriuric, approximately 75% in one study. However, urinary infection manifesting as hemorrhagic cystitis in this population is uncommon, and other diagnoses should always be sought. Bacterial hemorrhagic cystitis is reported to have an incidence of only 6.3 per 100,000 resident days. The most frequent causes of gross hematuria are bladder stones, tumors, or trauma associated with an indwelling catheter. Hematuria attributable to any genitourinary abnormality, however, in the presence of an infected urinary tract, is frequently complicated by secondary systemic urinary infection. As many as 30% of institutionalized subjects presenting with gross hematuria will subsequently become febrile. This is assumed to reflect organisms from the bacteriuric urinary tract entering the systemic circulation through whatever breach also produced the hematuria.

### Clinical Deterioration Without Localizing Genitourinary Symptoms

It is sometimes suggested that urinary infection should be a consideration in any elderly person with “nonspecific” decline in clinical status. Such presentations may include acute delirium or confusion, lethargy, anorexia, or increased falls. The high prevalence of positive urine cultures in the institutionalized population means a positive urine culture is common with any clinical presentation. Thus, bacteriuria has a low predictive value for symptomatic urinary infection in the absence of localizing acute genitourinary symptoms. A diagnosis of urinary infection to explain general decline without localizing signs or symptoms should be entertained with skepticism. Further study defining clinical presentations of urinary infection in the functionally impaired elderly person is needed.

Fever without localizing signs or symptoms presents a diagnostic dilemma. As the expected prevalence of positive urine cultures in the noncatheterized institutionalized population is as high as 50%, attributing fever to urinary infection because of an associated positive urine culture is usually not a correct diagnosis. Only 10% to 15% of episodes of fever in bacteriuric institutionalized subjects without localizing genitourinary symptoms and without indwelling catheters are attributable to a urinary source. The positive predictive value of a positive urine culture for a urinary source of fever in the absence of genitourinary symptoms is less than 10%. Currently, however, clinical features that discriminate between a urinary and nonurinary origin, other than the presence of a chronic indwelling catheter, have not been identified.

## LABORATORY EVALUATION

### Microbiological Diagnosis

A definitive diagnosis of urinary infection requires isolation of appropriate quantitative counts of uropathogens from an optimally collected urine specimen (Table 127-6). When symptomatic urinary infection is a diagnostic consideration, a urine specimen for culture is essential to confirm the diagnosis and determine antimicrobial susceptibilities of the infecting organism to facilitate appropriate antimicrobial therapy. A urine specimen for culture should be obtained prior to antimicrobial therapy for all institutionalized residents, for all men, and for women with a clinical presentation consistent with pyelonephritis. Pretherapy urine culture may not be

TABLE 127-6

## Quantitative Urinary Microbiology for Diagnosis of UTI

CLINICAL PRESENTATION*	QUANTITATIVE MICROBIOLOGY
Asymptomatic urinary infection	Same organism(s) $\geq 10^5$ CFU/mL on two consecutive cultures
Pyelonephritis or fever with localizing genitourinary symptoms	$\geq 10^4$ CFU/mL
Acute lower tract symptoms	$\geq 10^3$ CFU/mL of uropathogen
Specimen collected from:	
External collecting device (men only)	$\geq 10^5$ CFU/mL
Aspirated indwelling catheter	$\geq 10^3$ CFU/mL

\*For both women and men unless otherwise stated.  
CFU, colony-forming units.

indicated uniformly for well, ambulatory women presenting with symptoms consistent with cystitis and who have not recently received antimicrobial therapy. Pretherapy culture should be obtained from all women, however, in whom the diagnosis is uncertain, or who experience early symptomatic recurrence following antimicrobial therapy. While a positive urine culture cannot differentiate symptomatic from asymptomatic infection, a negative urine culture obtained prior to initiating antimicrobial therapy effectively excludes a diagnosis of UTI.

### Urine Specimen Collection

A clean catch voided urine specimen collected to minimize contamination is preferred. Functionally impaired elderly subjects frequently cannot cooperate for optimal collection of a voided urine specimen. For incontinent women urine specimens may be contaminated with organisms which colonize the vagina and periurethral mucosa, compromising interpretation of the culture. The use of “pedibags” or bedpans has been proposed for urine specimen collection from such women, but these collection methods are subject to bacterial contamination, and not recommended. In-and-out catheterization should be used for urine specimen collection where a specimen is required from a woman who cannot provide a voided specimen. Catheterization should only be used where urine specimen collection is essential for clinical management as this procedure, itself, will precipitate bacteriuria in up to 5% of episodes.

Contamination with periurethral flora is less frequent in men than in women, and a clean-catch urine specimen can usually be obtained from men with voiding. Urine specimens from men who cannot cooperate for specimen collection may also be collected using external urine collecting devices. A standard approach for specimen collection which minimizes contamination should be followed. This includes cleaning of the glans, applying a clean condom and collecting bag, and immediate specimen collection after voiding.

### Interpretation of Urine Culture

For asymptomatic urinary infection, two consecutive specimens with the same organism(s) isolated at  $\geq 10^5$  colony-forming units (CFU)/mL are necessary (Table 127-6). With symptomatic infection, a single specimen with  $\geq 10^5$  CFU/mL is sufficient. A bacterial quantitative count of  $\geq 10^3$  CFU/mL is diagnostic for specimens obtained by in and out catheter. When urine specimens are collected

through external devices, a quantitative count of  $\geq 10^5$  CFU/mL is necessary. Lower quantitative counts should be interpreted as contamination with colonizing periurethral organisms. In men with symptomatic infection, and for men or women with the clinical presentation of acute pyelonephritis, lower quantitative counts of  $\geq 10^4$  CFU/mL of a single organism are generally considered sufficient for a microbiologic diagnosis of urinary infection. In the presence of renal failure, diuretic therapy, or with selected less common infecting organisms (e.g., *Candida albicans*) lower quantitative counts may also be consistent with infection. Rarely, with unusual pathogens (e.g., *Haemophilus influenzae* or *Ureaplasma urealyticum*), or with infection proximal to a complete obstruction, the urine culture may be negative. The urine culture, of course, may also be negative if the specimen for culture is obtained after antimicrobial therapy has been initiated. As infection with more than one organism may occur, especially in institutionalized subjects, cultures with multiple organisms isolated in appropriate quantitative counts should not be assumed to represent contamination.

### Pyuria and Other Diagnostic Tests

Urinalysis or other screening tests for pyuria are not useful diagnostic tests for identification of urinary infection in elderly populations. Symptomatic urinary infection is consistently accompanied by pyuria, but pyuria also accompanies asymptomatic bacteriuria. More than 50% of bacteriuric elderly subjects living in the community have associated pyuria. In long-term care facilities, pyuria is almost a universal accompaniment of asymptomatic bacteriuria. Higher quantitative levels of pyuria are associated with renal rather than bladder infection. As many as 30% of long-term care facility residents without bacteriuria also have pyuria. The origins of pyuria in nonbacteriuric subjects have not been characterized, but are likely attributable to other inflammatory conditions within the urinary tract or, for women, contamination with vaginal secretions. Pyuria of any level with bacteriuria is not associated with poorer outcomes in elderly populations. Thus, the presence of pyuria does not identify “symptomatic” infection or indicate a need for therapy. While a finding of pyuria is not a useful diagnostic test, the absence of pyuria is helpful in excluding UTI.

Several rapid urine-screening tests have been proposed and evaluated for use in elderly populations as surrogate markers for identification of bacteriuria. The most widely used is the leukocyte esterase test, which screens for pyuria rather than bacteriuria. The nitrate-detection dipstick is also used. These tests have low sensitivity for bacteriuria and, when positive, cannot differentiate symptomatic from asymptomatic infection. None of these surrogate tests for bacteriuria have been demonstrated to have clinical utility in elderly populations, and they are not recommended for use in the management of urinary infection. A negative leukocyte esterase screen test, however, has high specificity and may be useful in excluding urinary infection.

## MANAGEMENT

### Asymptomatic Infection

As with other populations, ambulatory elderly women or men who experience recurrent episodes of symptomatic urinary infection also

have a high prevalence of asymptomatic bacteriuria. There is no evidence that the asymptomatic bacteriuria causes symptomatic infection, and studies have consistently documented that treatment of asymptomatic bacteriuria is not effective in preventing symptomatic episodes. Clinical trials directly addressing treatment of asymptomatic bacteriuria in the elderly ambulatory men or women have not been reported. However, studies of management of asymptomatic bacteriuria in ambulatory women have often enrolled postmenopausal women. For instance, a study of diabetic women with asymptomatic bacteriuria and mean age more than 50 years reported that treatment of bacteriuria had no benefits, irrespective of age. Thus, treatment of asymptomatic infection in ambulatory populations is not recommended. It follows that routine screening for bacteriuria in asymptomatic elderly ambulatory populations is also not appropriate.

Antimicrobial treatment of asymptomatic bacteriuria in the institutionalized elderly is not beneficial. Clinical trials have consistently and repeatedly shown that therapy of asymptomatic urinary infection in either women or men in these settings does not decrease the occurrence of symptomatic urinary infection, improve chronic genitourinary symptoms, or improve survival. Chronic incontinence in bacteriuric subjects, in particular, is not improved with antimicrobial therapy. The prevalence of bacteriuria in a long-term care population is not decreased by efforts to eradicate bacteriuria in asymptomatic residents. Antimicrobial therapy for asymptomatic bacteriuria is, however, associated with negative outcomes, including an increased frequency of adverse drug effects, emergence of resistant organisms, and increased cost. Thus, for the institutionalized population, asymptomatic bacteriuria should not be treated with antimicrobial therapy. Similarly, the presence of pyuria in the absence of symptoms is not an indication for therapy. Routine screening for bacteriuria or pyuria in these populations is not recommended. The only exception would be if an invasive genitourinary procedure is planned. Antimicrobial therapy is indicated as prophylaxis to prevent bacteremia and sepsis following the procedure.

## Symptomatic Urinary Infection

### Choice of Antimicrobial

Antimicrobial selection for treatment of urinary infection is similar for elderly and younger populations. Consistent alterations in antimicrobial pharmacokinetics are observed in the elderly, including increased volume of distribution and decreased renal clearance. These changes are not, however, of sufficient consistency or magnitude that differences in selection or dosing of antimicrobials is recommended routinely on the basis of age alone. Therapy may be given either orally (Table 127-7) or, when oral administration cannot be tolerated or absorption is uncertain, parenterally (Table 127-8). The specific antimicrobial selected is determined by effectiveness of the agent for treatment of urinary infection, known or presumed susceptibilities of the infecting organism, whether oral or parenteral therapy is indicated, tolerance of the patient, and renal and hepatic function. Antimicrobial cost will also usually be a factor, especially for institutionalized populations. When the clinical presentation is not severe, therapy should be delayed until urine culture results with organism susceptibilities are available.

**Oral Therapy** The preferred oral therapy for susceptible gram-negative organisms would usually be nitrofurantoin or TMP/SMX,

**TABLE 127-7**

### Oral Antimicrobial Regimens for Treatment of Acute UTI

AGENT	DOSE*
First line	
Nitrofurantoin	50–100 mg four times a day
TMP/SMX	160/800 mg, twice daily
TMP	100 mg twice daily
Amoxicillin†	500 mg three times daily
Other	
Amoxicillin/clavulanic acid	500 mg three times daily or 875 mg twice daily
Norfloxacin	400 mg twice daily
Ciprofloxacin	250–500 mg twice daily
Ofloxacin	200–400 mg twice daily
Levofloxacin	500 mg once a day
Cephalexin	500 mg four times a day
Cefaclor	500 mg
Cefadroxil	1 g once a day or twice daily
Cefixime	400 mg once a day
Cefuroxime axetil	250 mg twice daily
Cefpodoxime proxetil	100–400 mg twice daily

\*Assumes normal renal function.

†For susceptible gram-positive organisms.

as these are relatively inexpensive agents with which there is extensive clinical experience. Nitrofurantoin should not be used for renal infection, *P. mirabilis*, *K. pneumoniae* or *P. aeruginosa* infection, or in patients with renal failure. Concerns about sulfa allergy have led some countries, including Sweden and Great Britain, to restrict the use of TMP/SMX. However, there is long experience with this antimicrobial and it remains a useful agent. Where sulfa allergy precludes use of the combination, TMP alone may be used.

**TABLE 127-8**

### Parenteral Antimicrobial Regimens for the Treatment of UTI

AGENT	DOSE*
Preferred	
Gentamicin	1–1.5 mg/kg q8h or 4–5 mg/kg q24h
Tobramycin	1–1.5 mg/kg q8h or 4–5 mg/kg q24h
Ampicillin†	1 g q4–6h
Cefazolin	1–2 g q8h
Other	
TMP/SMX	160/800 mg q12h
Amikacin	5 mg/kg q8h or 15 mg/kg q24h
Piperacillin	3 g q4h
Piperacillin/tazobactam	4 g/500 mg q8h
Cefotaxime	1–2 g q8h
Ceftriaxone	1–2 g q24h
Cefepime	2 g q12h
Ceftazidime	0.5–2 g q8h
Aztreonam	1–2 g q6h
Imipenem/cilastatin	500 mg q6h
Vancomycin†	500 mg q6h or 1 g q12h
Ciprofloxacin	200–400 mg q12h
Levofloxacin	500 mg daily

\*Assumes normal renal function.

†For gram-positive organisms.

There is, however, increasing TMP and TMP/SMX resistance in some populations, and local susceptibilities must be considered in choosing empiric therapy.

Fluoroquinolones have been widely used for treatment of UTI in both ambulatory and institutionalized elderly populations. A randomized, nonblinded study of oral suspensions of ciprofloxacin or TMP/SMX enrolled both ambulatory elderly and nursing home residents and reported 10 days of ciprofloxacin was superior to 10 days of TMP/SMX, and had fewer adverse effects. The difference was more marked in nursing home residents. Despite this, widespread use of fluoroquinolones as empiric first line therapy is of concern as this may promote resistance. The early fluoroquinolones, norfloxacin and ciprofloxacin, have had extensive use in elderly populations and are well tolerated. Levofloxacin may be associated with glucose abnormalities in diabetic patients. Moxifloxacin is not indicated for treatment of urinary infection because of limited urinary excretion. These agents are still most appropriately reserved for treatment of infections with organisms resistant to first-line agents, or in individuals who cannot tolerate alternate antimicrobials.

Amoxicillin is effective for treatment of infections with susceptible gram-positive organisms, such as group B streptococci or enterococci. It is not first-line therapy for gram-negative organisms because of the high prevalence of antimicrobial resistance. Amoxicillin/clavulanic acid and oral cephalosporins are also effective in the treatment of urinary infection, but are not recommended as first-line agents because of their broad-spectrum activity and cost.

**Parenteral Therapy** When parenteral therapy is indicated, aminoglycosides such as gentamicin or tobramycin remain the antibiotics of choice. These may be given either intravenously or intramuscularly. Ampicillin or vancomycin are added for empiric therapy if enterococcal infection is a concern. After assessment of the initial response to therapy, and when the pretherapy urine culture and susceptibility results are known, a decision should be made whether aminoglycoside therapy should be continued, changed to alternate parenteral therapy, or the therapeutic course completed with oral therapy. Ototoxicity and nephrotoxicity with aminoglycoside therapy are unlikely when therapy duration is limited to 48 to 72 hours. Aminoglycosides should not be used, however, in persons with renal failure. Many other parenteral antimicrobials are also effective (Table 127-8), but these are more costly and, again, there are concerns with promoting antimicrobial resistance with widespread use.

**Resistant Organisms** For vancomycin-resistant *Enterococcus*, nitrofurantoin usually remains effective therapy and is the treatment of choice for cystitis. Alternate therapies for renal or systemic infection would include linezolid or tigecycline, but there is little clinical experience with these agents for treatment of urinary infection at any age. Extended spectrum beta lactamase producing organisms are usually also resistant to TMP/SMX, fluoroquinolones, and aminoglycosides. Nitrofurantoin frequently remains effective and should be used for cystitis. Some of these strains are also susceptible to amoxicillin/clavulanic acid. If parenteral therapy is required, most strains remain susceptible to carbapenems, and ertapenem may be appropriate. Symptomatic candida infection is uncommon in non-catheterized individuals. The treatment of choice is fluconazole—the only azole with renal excretion. For fluconazole-resistant strains, such as *C. glabrata*, there is no clear consensus on optimal therapy. Amphotericin B bladder washout, or a single parenteral dose of am-

**TABLE 127-9**

**Recommended Duration of Antimicrobial Therapy for Treatment of Symptomatic UTI**

CLINICAL PRESENTATION	DURATION
<b>Women</b>	
Acute cystitis	3–7 days
Acute pyelonephritis	10–14 days
<b>Men</b>	
Acute cystitis	7–14 days
Acute pyelonephritis	14 days
Relapsing infection (likely prostatitis)	6–12 weeks

photericin B may be considered for bladder infection. For renal or systemic infection, amphotericin B deoxycholate or as lipid complex, voriconazole or caspofungin may be options, but no specific recommendations can be made.

**Duration of Therapy (Table 127-9)**

Treatment of symptomatic lower urinary infection in elderly women is less effective than for younger women. This is consistent for all durations of therapy, but shorter courses of therapy of a single dose or 3 days are likely proportionately less effective than 7-day courses in older women. Current guidelines and meta-analyses of clinical studies suggest that short course therapy should not be used for postmenopausal women with acute uncomplicated urinary infection. Despite this, the majority of postmenopausal women with acute cystitis will be cured by 3-day therapy. A recent randomized, double blind trial documented equivalent efficacy of 3 or 7 days ciprofloxacin for the treatment of acute cystitis in ambulatory elderly women older than 65 years of age. The mean age in this study was 79 years and women were carefully selected to exclude renal failure or complicated urinary infection. Thus, for well, ambulatory elderly women, 3 days fluoroquinolone therapy is an effective option.

Short course antimicrobial therapy is ineffective for treatment of asymptomatic bacteriuria in long-term care facility residents, but has not been evaluated for treatment of symptomatic infection. Longer antimicrobial courses are also associated with very high rates of recurrence, and the comparative efficacy of short or longer courses for symptomatic infection has not been evaluated. Seven days is currently recommended for women or men with bladder infection. Renal infection should be treated with 10 to 14 days of therapy. For men, retreatment with prolonged therapy of 6 or 12 weeks may achieve higher cure rates for prostate infection.

Prolonged suppressive antimicrobial therapy may be considered where there is persistent or recurrent morbidity attributable to urinary infection, and bacteria cannot be eradicated from the urinary tract. Such circumstances are uncommon, but might include recurrent invasive infection in the presence of an underlying genitourinary abnormality that cannot be corrected, persistent infected stones where suppressive therapy may prevent further stone enlargement, frequent symptomatic recurrences from a prostatic source, or with chronic renal failure. Antimicrobial selection for suppressive therapy is individualized, based on susceptibilities of the infecting organism and tolerance. For the elderly, it is usually continued indefinitely. It must be appreciated, however, that suppressive therapy is seldom

indicated. When this approach is used, the therapy should be reevaluated regularly to ensure it remains appropriate and effective.

### Outcome Following Therapy

Bacterial cure rates of 75% to 90% at 4 to 6 weeks post-therapy are anticipated for ambulatory elderly women treated for symptomatic infection. Recurrence may be symptomatic or asymptomatic. For ambulatory men with prostate infections, cure rates are only 40% to 50% at 4 to 6 weeks, even with more prolonged therapy. Prostatic infection may also be associated with very late relapses, occurring up to a year or more after therapy.

The outcomes following treatment of urinary infection for both men and women in the institutionalized population are similar to other populations with complicated urinary infection. Recurrent infection, either relapse or reinfection, occurs by 4 to 6 weeks for at least 50% of therapeutic courses. Thus, high microbiological recurrence rates are the norm. The goal of treatment is to ameliorate symptoms, not to sterilize the urine. Post-therapy urine cultures should be obtained only when symptoms persist or recur.

### Controversies in UTI Management in Long-Term Care Facilities

UTI is one of the most frequent reasons for prescribing antimicrobial therapy in long-term care facilities. A substantial proportion of these antimicrobial courses are given for asymptomatic infection or presentations without localizing urinary symptoms. Symptomatic urinary infection is over-diagnosed and, in effect, asymptomatic bacteriuria is frequently treated on the basis of urinalysis findings or nonspecific changes in clinical status. While this problem has been appreciated for many years, limited progress toward a more rational antimicrobial approach in these facilities has been made.

Qualitative studies have characterized some variables which drive inappropriate antimicrobial use. When antimicrobial therapy is given, patients frequently are not assessed by physicians; nursing personnel are central to decision making and treatment. Ordering urine cultures and prescribing antibiotics are influenced by a wide range of nonspecific symptoms or signs in residents. The most commonly reported triggers for suspecting UTI in noncatheterized residents are changes in mental status, voiding patterns, or character of the urine. A strong odor to the urine or cloudy urine and fever are frequently assumed to be urinary infection. Dipstick analysis of the urine is often the initial testing procedure which, of course, frequently documents pyuria, and is interpreted as an indication for treatment despite the absence of acute localizing findings.

Guidelines and consensus statements recognize the problems with definitive diagnosis and have proposed management for potential urinary infection. The IDSA guidelines for evaluation of fever in long-term care facilities suggest diagnostic laboratory evaluation of suspected urinary infection in noncatheterized residents should be reserved for those with acute onset of symptoms and signs associated with urinary infection. These include fever, dysuria, gross hematuria, new or worsening urinary incontinence, and/or suspected bacteremia. A consensus conference proposed criteria for empiric antimicrobial treatment for non catheterized residents with suspected urinary infections which include presentations of either acute dysuria alone, or of fever ( $>37.9^{\circ}\text{C}$  [ $100^{\circ}\text{F}$ ] or increase of  $1.5^{\circ}\text{C}$  [ $2.4^{\circ}\text{F}$ ] above baseline) and at least one of: new or worsening ur-

gency, frequency, suprapubic pain, gross hematuria, costovertebral angle tenderness, or urinary incontinence. These criteria assume that prior to institution of antimicrobial therapy a urine specimen for culture is obtained.

Intervention studies developed to improve antimicrobial use for urinary infection in long-term care facilities have also been reported. A Swiss study addressing the diagnosis and treatment of both urinary and respiratory infection assessed the impact of interventions which included a comprehensive, multidisciplinary educational program including distribution of guidelines followed by continuing lectures and feedback compared with usual practice. The intervention program was associated with a significantly increased adherence of antimicrobial therapy to the guidelines, together with an overall 54% reduction of antibiotic consumption for urinary infection and pneumonia combined. A comparative study in 24 Ontario and Idaho nursing homes evaluated a diagnostic and treatment algorithm based on the consensus recommendations for initiating antimicrobial therapy for UTI. The intervention included small group interactive sessions for nurses, videotapes, written material, outreach visits and one-on-one interviews with physicians. The intervention homes had a significant decrease in antimicrobial courses for suspected UTI, but total antimicrobial use was similar in intervention and usual care groups. This suggested that patients with nonspecific symptoms who were previously diagnosed as urinary infection were still receiving antimicrobial treatment, but given an alternate diagnosis. Approaches to improving antimicrobial use in long-term care facilities likely must be comprehensive, rather than focusing on a single infection.

## PREVENTION

### Asymptomatic Infection

The extraordinary frequency of urinary infection in the elderly populations is primarily attributable to aging changes and associated comorbidities. Prevention of urinary infection on a population basis would require modification of these contributing factors. Optimal management of comorbid illnesses is desirable, but the potential impact on bacteriuria is unknown. It is unlikely there are interventions which could substantially decrease the prevalence of bacteriuria.

Devices used for management of incontinence, including external urine collecting devices, intermittent catheterization and, of course, indwelling urethral catheters, contribute to bacteriuria. Avoidance or limitation of use of these devices will be effective in decreasing the frequency of bacteriuria. This may not, however, be an achievable goal in the individual elderly subject. In people with bladder emptying using intermittent catheterization, the frequency of urinary infection is similar with a sterile or clean technique, so in the long-term care setting a clean technique is appropriate, and less costly.

### Symptomatic Infection

Some elderly women will experience recurrent episodes of acute cystitis, similar to younger women. Women who have recurrent symptomatic infections should be considered for referral to a urologist, as structural abnormalities in the lower urinary tract may predispose to recurrent infections. When these symptomatic episodes occur so

**TABLE 127-10****Antimicrobial Regimens for Prophylaxis of Acute, Recurrent, Symptomatic Lower Tract Infection in Ambulatory Women**

ANTIMICROBIAL	REGIMEN*
Preferred	
Nitrofurantoin	50–100 mg daily
TMP/SMX	80/400 mg daily or three times weekly
TMP	100 mg daily
Second line	
Cephalexin	125 mg daily
Norfloxacin	200 mg daily or three times weekly
Ciprofloxacin	125 mg daily

\*Medication taken at bedtime. Topical estrogen use may prevent recurrent symptomatic infections in postmenopausal women. Patients with recurrent infections should be evaluated for a structural lesion (see text).

frequently that they are distressing to the patient or interfere with daily routine, and no correctable pathology has been identified, they may be prevented with long-term low-dose prophylactic antimicrobial therapy (Table 127-10). Prophylactic therapy is usually taken at bedtime, and initially continued for 6 months or 1 year. This approach is indicated for otherwise well women in the community with no genitourinary abnormalities. It would seldom be appropriate in women residents of long-term care facilities with neurological impairment of bladder emptying. Topical vaginal estrogen therapy may also decrease the frequency of acute symptomatic infection in selected women. However, studies of efficacy are conflicting and this intervention is not as effective as antimicrobial therapy. Currently, it does not seem appropriate to prescribe continuous topical vaginal estrogen solely to prevent recurrent UTI.

Ingesting large quantities of “natural” urinary antiseptics, particularly cranberry juice, has been proposed. Cranberry juice may be effective through interference with bacterial adherence. Female residents of a long-term care facility who drank large quantities of cranberry juice daily had a decreased prevalence of bacteriuria with pyuria, but not bacteriuria nor symptomatic episodes. A double blind, placebo controlled trial of cranberry juice in a geriatric assessment and rehabilitation ward found no significant decrease in symptomatic infection with cranberry juice, and no difference in antimicrobial use. While there seems no reason to discourage drinking cranberry juice, it is premature to endorse this as a means of preventing urinary infection or its complications in elderly populations.

There is an increased risk for systemic infection from a urinary source in the presence of obstruction of the genitourinary tract, such as the elderly man with prostatic hypertrophy. Continuing evaluation and early intervention if obstruction occurs should be effective in decreasing morbidity. Prophylactic antimicrobial therapy is indicated for bacteriuric subjects who will undergo an invasive genitourinary procedure likely to be associated with mucosal trauma. This includes cystoscopy in men and transurethral resection of the prostate, but not uncomplicated replacement of a long-term indwelling urethral catheter. Antimicrobial therapy must be initiated prior to the invasive procedure, preferably within 1 hour, and usually is not continued beyond the duration of the procedure. Studies suggest a single preprocedure dose of antimicrobial, selected based on the susceptibilities of the infecting bacteria, is adequate.

**LONG-TERM INDWELLING CATHETERS****Epidemiology**

From 5% to 10% of elderly residents of institutions have urine voiding managed with a chronic (long-term) indwelling catheter. A higher proportion of women have chronic indwelling catheters. The major indications for catheterization are retention, incontinence management, and to assist in healing pressure ulcers. Subjects with long-term indwelling catheters are always bacteriuric, usually with two to five organisms at any time. Morbidity from urinary infection is increased in the presence of a long-term indwelling catheter relative to bacteriuric residents without a catheter. Renal inflammation consistent with acute pyelonephritis is also identified at autopsy more frequently in elderly residents with an indwelling catheter. A chronic indwelling catheter is the single most important risk factor for bacteremia in the institutionalized elderly. Catheter obstruction is a frequent problem, but the incidence and time to obstruction varies among patients. Obstruction is caused by struvite formation by urease producing organisms such as *P. mirabilis* or *P. stuartii*. Mucosal trauma may occur with catheter change, and in the presence of infected urine may lead to fever. However, bacteremia occurs infrequently, in less than 10% of catheter changes, and is usually asymptomatic. Residents with an indwelling urinary catheter also have an increased mortality compared to noncatheterized residents, but there is no evidence this is attributable to catheterization itself.

**Biofilm Formation**

Biofilm is uniformly present on the internal and external catheter surface. Initially, bacteria adhere to the conditioning protein film which coats the catheter immediately after it is placed. These bacteria excrete an extracellular polysaccharide material and organisms multiply and persist in colonies within this material. Urine constituents such as Tamm-Horsfall protein, magnesium, and calcium are also incorporated. Biofilm ascends the catheter surfaces within a few days of insertion of a new catheter.

The presence of the biofilm explains several clinically relevant observations. The microbiology of organisms present in the biofilm differs from that in the urine, with a greater number of organisms at higher quantitative counts isolated. Urine specimens obtained through a catheter *in situ* will sample the microbiology of the biofilm rather than urine. Biofilm formation is also responsible for catheter encrustation and obstruction through mineral deposition in the presence of an alkaline urine produced by urease producing organisms. This is the same process as struvite formation with urolithiasis. Finally, organisms grow in the biofilm in a relatively protected environment. Some antimicrobials are unable to diffuse into the biofilm. Antimicrobial therapy given to subjects with a chronic indwelling catheter encourages emergence of resistance in organisms resident in the biofilm. In addition, organisms may be relatively metabolically inactive and not susceptible to some antimicrobials. Host defenses, including neutrophils and immunoglobulins, also cannot diffuse into the biofilm and are ineffective in controlling growth of organisms in these colonies. Thus, the biofilm provides a protected environment where organisms persist despite antimicrobial therapy, and are a source of relapsing infection when therapy is discontinued.

## Clinical Presentations

Presentations of urinary infection in patients with indwelling urethral catheters differ from those without a catheter. The most common presentation of symptomatic urinary infection is fever alone without localizing genitourinary signs or symptoms. Local findings such as obstruction or leaking of the catheter or evidence of trauma to the mucosa such as hematuria may occur. In the absence of localizing findings, the urinary tract is the likely source of fever in 30% to 40% of episodes. Local presentations of infection also occur. These include purulent urethritis, tunnel site infections in patients with suprapubic catheters, or periurethral abscesses. Men may develop a urethral fistula, epididymitis, orchitis, scrotal abscess, prostatitis or prostatic abscess. Urolithiasis with bladder or renal stones may also occur. A unique, uncommon, presentation is the “purple urine bag syndrome.” This is thought to result when bacteria in the gut metabolize tryptophan to indole in the presence of decreased gut motility. The indole is absorbed and conjugated in the liver to indican, which is excreted into the urine and further metabolized to indoxyl by organisms present in the drainage bag. In an alkaline urine, indigo and indirubin are generated and dissolve in the plastic of the drainage bag, creating a purple color. While the presentation is dramatic, the condition is benign, and addressed by managing constipation and changing the drainage bag.

## Management of Symptomatic Infection

Consensus recommendations for instituting empiric antimicrobial therapy for urinary infection in the presence of an indwelling urinary catheter suggest the presence of any one of fever ( $>37.9^{\circ}\text{C}$  [ $100^{\circ}\text{F}$ ] or increase of  $1.5^{\circ}\text{C}$  [ $2.4^{\circ}\text{F}$ ] about baseline temperature), new costovertebral angle tenderness, rigors (shaking, chills) with or without identified cause, or new onset of delirium is sufficient. A urine specimen for culture should be obtained prior to antimicrobial therapy. The indwelling catheter should be changed and the specimen for culture obtained through the newly inserted catheter immediately prior to initiating antimicrobial treatment. This specimen is representative of urine rather than biofilm microbiology. Catheter replacement prior to antimicrobial therapy also leads to a more prompt resolution of fever, and a lower likelihood of symptomatic relapse post-therapy.

Considerations in choosing an antimicrobial are similar to those for subjects without indwelling catheters. When symptomatic urinary infection is diagnosed, antimicrobial therapy should be selected on the basis of the known or presumed infecting organisms and patient tolerance (Tables 127-7 and 127-8). The duration of antibiotic therapy is not well studied, but should be limited to prevent emergence of resistant organisms. Generally, only 5 to 7 days therapy is recommended if there is a prompt clinical response. There are no clinical studies, however, that define the optimal length of therapy, and clinical judgment is necessary.

## Prevention

The most important intervention is to avoid catheter use or, when an indwelling catheter is indicated, to discontinue the catheter as soon as possible. This is not feasible for some long-term care facility residents, especially women. For men, incontinence management with an external condom collecting device is an option. A recent randomized trial in a VA hospital enrolling men with a mean age of

73 years, reported a significant decrease in adverse outcomes with condom drainage compared to an indwelling catheter. When possible, intermittent catheterization is preferred to a chronic indwelling catheter for retention, and may also be associated with fewer adverse effects. Use of a suprapubic catheter is sometimes suggested, but studies are inconsistent in documenting benefits with suprapubic catheter use. The surgical procedure for insertion may itself be associated with adverse effects. A suprapubic catheter, however, may have a role for selected individuals with difficulties with urethral catheter insertion or with discomfort with the urethral catheter.

Currently, there are no specific interventions which are documented to decrease the frequency of bacteriuria or complications of urinary infection in elderly patients who require chronic indwelling catheters. Maintenance of a closed drainage system for the catheter and tubing delays onset of bacteriuria in subjects with short-term indwelling catheters and is recommended for long-term indwelling catheters as well. The drainage bag should be maintained in a dependent position. The catheter should be secured in order to minimize urethral irritation, and to avoid contact with incontinent stool. Catheter care should minimize trauma, and facilitate prompt identification of obstruction. Routine catheter change, daily periurethral catheter care with antiseptics, or catheter irrigation with saline or antiseptics does not decrease the frequency of urinary infection, and these are not recommended practices.

Morbidity of UTI associated with chronic indwelling catheters is largely attributable to biofilm formation. Thus, development of catheter materials which limit biofilm formation would be an advance in preventing complications of catheter use. Use of a silicone rather than a latex catheter may delay onset of obstruction for selected patients. These catheters are more expensive, but should be considered for patients with repeated, early obstruction, as well as those with latex allergy. Some antimicrobial catheters may minimally delay onset of bacteriuria in short-term catheterization. To date, none of these have been shown to have a benefit for patients with chronic urinary catheters.

## Summary

UTI is the most common infection which occurs in elderly populations. The management of UTI for elderly ambulatory individuals is similar to younger populations, and determined by the presentation as either acute uncomplicated urinary infection or complicated urinary infection. Treatment of symptomatic urinary infection requires optimal use of urine culture for diagnosis, appropriate antimicrobial selection, and appropriate duration of therapy. In the long-term care facility, the very high prevalence of asymptomatic bacteriuria interferes with ascertainment of symptomatic infection, especially in residents without localizing genitourinary symptoms. Bacteriuric elderly individuals who present with clinical decline without localizing findings should not be assumed to have a urinary source, despite a positive urine culture. A critical approach to diagnosis, investigation, and treatment is necessary. Further characterization of symptomatic presentations of urinary infection in the functionally disabled elderly, together with evaluation of management approaches such as non treatment with observation compared with empiric antimicrobial treatment, are needed. For residents with chronic indwelling catheters, optimal duration of antimicrobial therapy, management of complications, and evaluation of new catheter materials or alternatives to indwelling urethral catheters need to be addressed.

# Human Immunodeficiency Virus Infection

*Amy C. Justice*

Aging and human immunodeficiency virus (HIV) infection were once considered mutually exclusive conditions. Older people did not “get AIDS” (acquired immunodeficiency syndrome) and the younger people who did never had a chance to grow old. Now, thanks to the success of combination antiretroviral therapy (CART), people aged 50 years and older represent a growing proportion of all those living with HIV infection; from 2001 to 2004, the proportion grew from 17% to 23%. The U.S. Senate Subcommittee on Aging now predicts that by 2015, 50% of the U.S. population living with HIV infection will be 50 years of age or older.

As the prevalence of HIV infection grows in older population groups, the risk of new HIV infections is also likely to increase. This increased risk may be exacerbated by several factors. First, the use of sildenafil (Viagra) and related medications to effectively treat erectile dysfunction and enhance sexual performance may increase risky sexual behavior. Additionally, postmenopausal women may be less likely to request that condoms be used as they face no risk of pregnancy. Finally, age-associated erectile changes may make condom use difficult and age-associated declines in immunity may place older individuals at higher risk of transmission with each exposure.

Research in age, aging, and HIV has focused on comparing outcomes among persons aged 50 years and older to their younger counterparts. This cut point is supported in HIV for both sociological and medical reasons: people aged 50 years and older with HIV state they feel marginalized because of age and this group experiences a shortened survival and greater burden of comorbid disease. Additionally, some data suggests that chronic HIV infection causes an accelerated aging process; an HIV infected 50-year-old person may have more physiologically in common with an uninfected individual aged 60 or 70 years.

While few geriatricians are likely to choose to manage antiretroviral agents, geriatricians need to be aware of the new Centers for Disease Control and Prevention recommendations for HIV screening. Geriatricians will also be increasingly needed to comanage the effects of aging and cumulative frailty; comorbid medical and psychiatric

conditions; and drug interactions and toxicities in people with HIV infection. Further, the study of HIV infection among aging individuals may provide a template for improving the management of complex chronic disease more generally especially among special populations of aging individuals—people of color, sexual minorities, those with few socioeconomic resources, and those aging with heavy substance use histories. These groups are often ignored or understudied when more common conditions of aging are addressed.

## CLINICAL PRESENTATION

Little is known about the presentation of acute HIV infection in older patients. In younger patients, acute infection may be completely asymptomatic or present as a flu-like syndrome. Like older HIV-negative individuals, older people with HIV infection underreport symptoms as compared to younger individuals, and this underreporting may be especially pronounced in older black patients. In addition, the symptoms associated with HIV infection are also common among older patients without HIV infection.

Among those persons 50 years of age and older who are chronically infected with HIV and in care, the most common self-reported symptoms are fatigue, pain in hands or feet (peripheral neuropathy), problems sleeping, muscle or joint pain (myalgias or arthralgias), and problems with having sex. Prior to the start of antiretroviral therapy, people with HIV infection tended to have lower cholesterol values than demographically matched controls. Common laboratory abnormalities include leucopenia, anemia (predominantly normocytic), and transaminitis. Thus, unless the clinician has a high index of suspicion in the older patient, or routinely screens for HIV infection, it may be difficult to identify HIV-positive individuals. HIV-infected women enter menopause at a median age of 46 years compared to the median of 51 years among uninfected women. HIV-infected women also tend to experience more pronounced symptoms during menopause. Hypogonadism is also prevalent among men

infected with HIV. Like the symptoms, signs, and laboratory abnormalities discussed above, most of the diagnoses made in older people with HIV are not unique to HIV infection.

## DIAGNOSIS

Physicians and their older patients are likely to underestimate the risk of HIV infection. The patient may be misinformed or in denial. The physician may mistakenly believe that the patient is not having unprotected sex with multiple partners or using illicit drugs. Nationally, the median CD4 cell count at presentation for HIV care continues to indicate advanced HIV disease (counts below 200 per mm<sup>3</sup>) and delayed treatment. This is especially true among older individuals.

Because untreated individuals are more likely to infect others, the benefit from treatment is less among those presenting with advanced disease and previous targeted screening policies have not improved the situation. The Centers for Disease Control and Prevention have revised their guidelines for HIV testing as of September of 2006 to encourage near universal screening. Specifically, current recommendations now call for HIV screening among:

- All patients aged 13 to 64 years in all health care settings
- All patients initiating treatment for tuberculosis
- All patients seeking treatment for sexually transmitted diseases
- All persons at high risk for HIV (at minimum on a yearly basis)

The Centers for Disease Control and Prevention goes further to say that opt-out screening (screening after notifying the patient that an HIV test will be performed unless the patient declines) is now recommended in all health care settings. Specific signed consent for HIV testing should not be required. General informed consent for medical care should be considered sufficient to encompass informed consent for HIV testing.

Regardless of age, any patient reporting any of the following: multiple sexual partners and unprotected sex; a prior diagnosis of a sexually transmitted disease (gonorrhea, syphilis, chlamydia, or trichomonas); or illicit drug use is at high risk for HIV infection and should be tested. Note that in some cases, an individual in a monogamous relationship may present with a sexually transmitted disease because their partner has more than one partner. These individuals are at risk for HIV as well and should be tested. While, intravenous drug use is a risk factor in itself; illicit drug use, IV or otherwise, is associated with risky sexual behavior. Hazardous alcohol use is also an important risk factor for unprotected sex with multiple partners. Because older patients may not spontaneously report these behaviors and conditions, physicians should routinely ask about them (Table 128-1).

HIV testing should be conducted as part of a diagnostic workup in any patient with unexplained anemia, peripheral neuropathy, oral candidiasis, widespread herpes zoster, recurrent bacterial pneumonia, or any of the more traditional AIDS-associated conditions (*Pneumocystis carinii* pneumonia, Kaposi's sarcoma, atypical mycobacterium, or tuberculosis). Finally, any patient for whom more common causes of debilitating fatigue or weight loss have been eliminated should be tested for HIV.

The blood test is simple, accurate (sensitivity and specificity >99.9%), and widely available. It involves two steps. The first step is a screening enzyme immunoabsorbent assay for HIV antibody. If this test is positive, a western blot is used to confirm the diagnosis.

**TABLE 128-1**

### Short Sex and Drug History to Use with Older Adults

I now need to ask you some questions about some possible activities that may put you at risk for infectious diseases. Do you mind if we discuss your sexual health and other behaviors?

- Do you have sexual or intimate contact with another man or woman? If yes, with men, women, or both?
- Do you take disease precautions? If yes, explain your precautions? If no, why not?
- Do you take any recreational drugs that involve the use of needles? If yes, do you share needles? If yes, how do you clean them?
- Have you ever had a sexually transmitted disease? If yes, how was it treated?
- Do you drink alcohol before sex? Do you use any illicit drugs or other substances before sex?

Do you have any questions that you would like to ask me about your sexual health and practices?

Specifically, do you have any questions about AIDS or sexually transmitted diseases?

*Adapted from Linsk NL. HIV among older adults: age-specific issues in prevention and treatment. AIDS Reader. 10(7):430, 2000.*

If the first test is negative, the patient is considered uninfected. Even in low-risk populations such as blood donors, the false-positive rate of these combined tests is low (<0.001%). When an individual tests positive, it is important to inform them of these results with as much care as you would any other life-changing diagnoses like that of cancer or diabetes. It is particularly important that you facilitate their integration into a clinical practice with substantial experience in the treatment of HIV infection. Comanagement may be needed if the patient has a substantial burden of age-related comorbid conditions or frailty.

## PROGNOSIS

Survival without treatment from the time of first AIDS-associated diagnosis is on the order of 1 to 2 years (median). Survival with current multiclass, combination antiretroviral treatment has not been fully characterized, but estimates suggest that current treatments confer between 10 and 25 additional years of survival. Of note, prognosis is poorer among those who present late for care or fail to adhere to their treatment regimen.

Throughout the epidemic, age at seroconversion has been strongly associated with survival. This is, in part, explained by delays in treatment. When treated, older people appear to adhere to multiclass, combination antiretroviral treatment better than their younger counterparts. However it remains unclear whether their immunologic response to treatment is as good as among younger individuals. Older individuals may also be more susceptible to short- or long-term adverse drug effects from antiretroviral therapy.

## OVERLAPPING COMPLICATIONS, COMORBIDITIES, AND TOXICITY

Chronic HIV infection is a complex chronic disease in which it is often impossible to tell whether a new condition in an individual

**FIGURE 128-1.** Outcomes among people aging with HIV infection.

patient is the result of HIV disease progression, HIV treatment, or comorbidity (and/or its treatment) (Figure 128-1). In many cases, the likely answer is that there is no single etiology but rather the conditions results from a combination of some or all of these factors. Further, non-AIDS defining conditions among HIV-infected individuals tend to cluster into three main categories: medical conditions, substance use conditions, and psychiatric conditions. We are now challenged to develop diagnostic strategies and team management techniques to convert what was once a rapidly fatal disease to a well-tolerated (and well-managed) complex chronic disease.

## HIV and Related Conditions

Most HIV-associated opportunistic infections and cancers do not vary significantly in prevalence when older patients are compared with their younger counterparts (Table 128-2). It is, however, important to note that the prevalence of these conditions has dropped significantly in the era of multiclass combination antiretroviral treatment. Furthermore, the conditions that are most prevalent are no longer *Pneumocystis carinii* pneumonia, Kaposi's sarcoma, or atypical mycobacterium infection. They are instead conditions that commonly occur in people without HIV infection such as esophageal candidiasis, bacterial pneumonia, tuberculosis, and herpes simplex and zoster. Further, HIV infection itself is also associated with anemia, renal insufficiency, hepatitis, wasting, and cognitive decline.

## Benefits and Harms of Antiretroviral Treatment

As can be seen by the substantially improved survival seen with CART, individuals experience dramatic benefit from antiretroviral treatment. Some have suggested that this benefit may be muted among older individuals because of competing risk of death from comorbid conditions, to a possibly decreased immunological recovery on treatment, the likely increased risk of drug toxicity, and drug–drug interactions from cumulative organ system frailty.

**TABLE 128-2**

**Comorbid and AIDS-Defining Medical Conditions by Age Among HIV-Infected Veterans ( $n = 876$ )**

	OVERALL	<50 YEARS	50+ YEARS	<i>p</i>
<b>Comorbid Condition (%)</b>

<b>Any AIDS-Defining Medical Condition</b>	<b>69</b>	<b>68</b>	<b>71</b>	<b>0.3</b>

Early reports from Phase I and II trials of antiretroviral therapies substantially underestimated the rates of toxicity likely as a result of the exclusion of individuals with prior organ injury from the trials. Longer term, postmarketing surveillance studies of populations receiving these drugs are beginning to describe the degree to which the earlier studies underestimated these effects. Common adverse antiretroviral drug effects include gastrointestinal intolerance (gas, bloating, nausea, and vomiting), diarrhea, chemical hepatitis, hyperlipidemia, hyperglycemia, peripheral neuropathy, bone marrow suppression (anemia, thrombocytopenia, neutropenia), fat redistribution, lactic acidosis, and bleeding diathesis. A subset of antiretrovirals are associated with nephrolithiasis, renal insufficiency, and failure. There is growing evidence that these adverse effects of treatment are more common among individuals with prior organ injury. Thus, aging individuals who are more likely to have prior hepatic injury, renal insufficiency, and preexisting hyperlipidemia or glucose intolerance may be at especially high risk for adverse effects of antiretroviral therapy. Longer term observation is required to determine whether HIV treatment incurs increased risk for cancer.

## Substance Use and Abuse

As a group, patients infected with HIV who are aged 50 years or older are also more likely than their HIV-uninfected demographic counterparts to have consumed hazardous amounts of alcohol, used

illicit drugs, and smoked cigarettes. As a result of these behaviors, these patients are also more likely than the general aging population to be coinfecting with hepatitis C or B and to have liver, lung, and heart disease and to be at increased risk for a number of common cancers.

Among patients who continue to drink hazardingly and or to use illicit drugs, ongoing organ injury and adherence to antiretroviral therapy are likely to be important issues. Patients should be asked directly about alcohol, cigarette, and illicit drug use, and encouraged to stop or curtail ongoing use. Any patient reporting current drug or alcohol use should be questioned closely regarding treatment adherence and monitored for alcoholic hepatitis. Current research suggests that even moderate levels of alcohol consumption may be hazardous among those aging with HIV infection.

### Aging and Comorbid Medical and Psychiatric Disease

No one is immune from HIV infection. Nevertheless, HIV infection occurs more commonly among the homeless, members of inner-city minority or sexual minority populations, or those suffering from substance abuse and psychiatric illness as compared to the general population of people 50 years of age or older. General medical comorbidities such as hepatitis C, hypertension, diabetes, and obstructive lung disease are common in these populations. Depression and severe mental illnesses such as psychosis and posttraumatic stress disorder are also more common among older people with HIV infection than among the general population of people 50 years of age or older.

Risk for many forms of cancer may be elevated as well. Cancers that may be more common among those receiving treatment for HIV infection include liver cancer, lung cancer, and anal cancer. Finally, older people with HIV infection may have multiple reasons to have cognitive dysfunction, whether from cognitive diseases of aging (multi-infarct dementia or Alzheimer's disease) or from HIV (minor cognitive motor disorder or HIV-associated dementia). It should also be noted that older people in care for HIV infection may be on as many medications for their comorbid conditions as for HIV infection. The potential for drug–drug interactions and cumulative organ toxicity is substantial.

Thus, even before contracting HIV infection and receiving antiretroviral therapy, older people with HIV infection may be at greater risk of comorbid medical and psychiatric disease. Clearly, the prevalence of general medical comorbid conditions is high among older HIV-positive patients receiving antiretroviral treatment (see [Table 128-2](#)).

More recently, we have also come to recognize that long-term chronic HIV infection may be associated with a selective accelerated aging process. Evidence to support this theory includes the fact that, after adjustment for gender, race/ethnicity, and pack years of smoking, veterans with HIV infection have a greater risk of obstructive lung disease than uninfected veterans in every age category. Additional evidence comes from the observations that, even after adjustment for conventional risk factors for coronary artery disease, HIV-infected individuals appear to be experiencing cardiovascular events at an accelerated rate compared to uninfected control samples. Finally, a recent analysis comparing a national sample of HIV-infected veterans to 2:1 demographically matched uninfected veterans found significant positive interactions between age of 60 years or more years and HIV status for the risk of hypertension,

diabetes, and vascular disease. This suggests that HIV-infected aging individuals are at particularly high risk of multimorbidity once they reach 60 years of age.

## MANAGEMENT

The Centers for Disease Control is now recommending routine universal HIV screening, regardless of risk factors, for all individuals aged 13 to 65 years. Generalist, emergency room physicians, and geriatricians must begin to screen for sexual and drug use behavior in their older patients and to include HIV infection in their differential diagnosis of unexplained conditions.

Among aging HIV-infected individuals it will be important to help insure that they receive timely treatment for their HIV infection through opt-out screening programs and that these individuals adhere closely to their prescribed treatment regimen. It will also be important to attempt to keep the number of total medications (for HIV and non-HIV conditions) down in order to avoid drug–drug interactions and cumulative toxicity and to screen regularly for evidence of liver, kidney, and bone marrow toxicity. Antiretroviral treatment timing and choice should be made balancing the individual's cumulative organ system frailty and their likely risk of adverse events against the substantial benefit of early and aggressive HIV treatment.

Recently published Infectious Disease Society of America Guidelines suggested that, “it is imperative that all persons in the United States be managed according to standard practices appropriate for the individual's age and sex regardless of HIV status.” This statement ignores the fact that people receiving treatment for HIV infection do not enjoy a “normal” age-appropriate life expectancy. Whether or not a particular primary care practice is appropriate for an individual with HIV depends upon the frequency and impact of the condition, the degree to which outcomes associated with that condition can be modified by timely medical intervention, and the risk associated with the intervention. For example, colon cancer screening via colonoscopy has a slight risk of perforation at the time of screen and a substantial risk of discomfort for the patient. Patients probably need to live at least 5 to 7 years after their screening for the benefit of the screening in decreased risk of death from colon cancer to outweigh the risk of perforation and the pain and discomfort of the procedure. Conversely, more aggressive screening for anal cancer may be indicated because of the increased incidence of this condition among those with HIV infection. Thus, it would be unwise to apply all “age appropriate” primary care guidelines for those without to those with HIV infection without careful consideration for the individual's prognosis, preferences for care, and personal risk of these conditions.

Finally, because of the overlapping complications and comorbid medical and psychiatric disease experienced by most patients with HIV infection, comprehensive care requires a team approach. No one specialist or generalist can hope to stay on top of optimal care in all these domains. HIV specialists need to turn to generalists and geriatricians when determining the best way to manage overlapping comorbid medical disease and to psychologists, psychiatrists, and social workers when managing psychiatric diseases. The management of alcohol and drug abuse also requires the insights of generalists familiar with the medical complications of these behaviors and of psychiatrists, psychologists, and social workers familiar with methods of managing these behaviors. In turn, generalists and geriatricians will

need careful guidance from HIV specialists in determining when to start antiretroviral treatment, choosing optimal drug combinations, and in determining when to stop or change therapy. For those who must manage patients far from specialty services, frequent telephone conferencing with specialists in HIV and with those experienced in the management of comorbid conditions is recommended.

# Herpes Zoster

Jack I. Twersky ■ Kenneth Schmader

## DEFINITION

Herpes zoster is a neurocutaneous disease that is caused by the reactivation of varicella-zoster virus (VZV) from a latent infection of dorsal sensory or cranial nerve ganglia following varicella or primary infection with VZV earlier in life. Herpes zoster is characterized by unilateral, dermatomal pain and rash.

Postherpetic neuralgia (PHN) has been defined as any pain after rash healing or any pain from 1 to 6 months after rash onset. Pain experts currently define PHN as pain 90 to 120 days after rash onset to be consistent with established definitions of chronic pain and to eliminate neuropathic pain from acute inflammation. Some experts define the herpes zoster pain trajectory as an acute herpetic neuralgia that lasts for approximately 30 days after rash onset, a subacute herpetic neuralgia that lasts from 30 to 120 days after rash onset, and PHN as pain that persists 120 days and more after rash onset.

## EPIDEMIOLOGY

### Varicella-Zoster Virus Transmission

VZV is a double-stranded DNA that is transmitted from person to person via direct contact, airborne or droplet nuclei when a virus-naïve, VZV seronegative individual is exposed to the vesicular rash of varicella or herpes zoster. These exposed individuals may then develop varicella. Health care workers and staff in nursing homes and hospitals and children who have not received the varicella vaccine may not have had VZV primary infection and are potentially at risk for varicella. However, nearly all older adults are seropositive and latently infected with VZV. The exposure of a latently infected individual to herpes zoster does not cause herpes zoster or varicella.

Furthermore, there is no risk of VZV transmission when the herpes zoster rash is only maculopapular or crusted. All cases of herpes zoster are caused by the reactivation of endogenous VZV.

### Herpes Zoster Incidence and Risk Factors

In general population studies from North America and Europe, the incidence of herpes zoster in persons of all ages is 1.2 to 4.8 cases per 1000 persons per year and in persons older than 60 years old, the incidence is 7.2 to 11.8 cases per 1000 per year. The lifetime incidence of herpes zoster is estimated to be about 20% in the general population and maybe as high as 50% among those surviving to 85 years or higher.

The cardinal epidemiological feature of herpes zoster is its increase in incidence with aging and with diseases and drugs that impair cellular immunity. The increase in the likelihood of herpes zoster with aging starts around 50 to 60 years of age and increases into late life in individuals older than 80 years of age (Figure 129-1). In the herpes zoster vaccine trial (“Shingles Prevention Study”), which was prospective, used active surveillance in a community-based population, and used polymerase chain reaction (PCR) for definitive diagnosis of herpes zoster cases, the incidence of herpes zoster in the placebo group ( $n = 19\ 276$ ) was 11.8 cases per 1000 persons per year in adults 60 years of age and older. Immunocompromised patients at risk for herpes zoster include persons with human immunodeficiency virus (HIV) infection, Hodgkin’s disease, non-Hodgkin’s lymphomas, leukemia, bone marrow and other organ transplants, systemic lupus erythematosus, and those taking immunosuppressive medications. Other risk factors include white race, psychological stress, and physical trauma.

Current population figures and herpes zoster incidence data yield estimates of about 1 million new cases of herpes zoster each year in the United States, with more than half occurring in persons 60 years of age or older. The number of herpes zoster cases is expected to increase in the near future decades because of population

**FIGURE 129-1.** Incidence of zoster and postherpetic neuralgia by age. (Data from Donahue JG, Choo PW, Manson JE, et al. The incidence of herpes zoster. *Arch Intern Med.* 155:1605–1609, 1995; Choo PW, Galil K, Donahue JG, et al. Risk factors for postherpetic neuralgia. *Arch Intern Med.* 1997;157:1217–1224.)

aging and the development of immunocompromising diseases (and their therapies) associated with aging. Whether varicella vaccination of children and the subsequent reduction in varicella incidence will contribute to an increase in the number of herpes zoster cases by reduced exogenous immune boosting in individuals latently infected with wild-type VZV is under investigation.

### Postherpetic Neuralgia Incidence, Prevalence, and Risk Factors

Exact data on the incidence and prevalence of PHN are not available because of variable definitions and inadequate data in medical records and administrative databases. Useful figures for older patients who seek medical care come from a combined analysis of large trials of antiviral drugs for herpes zoster in outpatients aged 50 years and older. In this analysis, 49% to 54% of placebo recipients had pain 90 days after rash onset and 46% at 120 days after rash onset; 25% to 35% of antiviral recipients had pain 90 days after rash onset and 29% at 120 days after rash onset. In the placebo group of the Shingles Prevention Study, the incidence of PHN was 0.74 cases per 1000 person-years for subjects between 60 and 69 years and 2.14 for subjects older than 70 years (Figure 129-1). The figure illustrates that the rate of increase of PHN cases associated with aging is greater than the rate of increase of herpes zoster cases. Investigators have estimated that the prevalence of PHN ranges from 500 000 to 1 million in the United States.

Like herpes zoster, the most important epidemiological feature of PHN is its marked increase in incidence and severity with aging.

All epidemiological studies of PHN show that the risk of PHN is substantially increased in older adults. Other risk factors for PHN include the presence of prodromal pain, severe pain during the acute phase of herpes zoster, greater rash severity, more extensive sensory abnormalities in the affected dermatome and, possibly, ophthalmic nerve involvement. As the age of patient and severity of the episode of herpes zoster increases, the more likely the development of PHN.

## CLINICAL FEATURES

### Prodrome

VZV reactivates in the affected sensory ganglion and spreads in the peripheral sensory nerve, causing symptoms that frequently precede the rash by several days. These prodromal symptoms are located in the involved dermatome and range from a superficial itching, tingling, or burning to severe, deep, boring, or lancinating pain, paresthesia, or hyperesthesia. The pain can be constant or intermittent. The prodrome may be mistaken for many other conditions in older adults, particularly in those patients with cognitive impairment. The prodrome may mimic pleurisy, a myocardial infarction, cholecystitis, appendicitis, renal colic, a collapsed intervertebral disk, glaucoma, trigeminal neuralgia, or unappreciated trauma. The prodromal symptoms usually last a few days, although it has been reported to last more than a week. Zoster sine herpette is a condition

**FIGURE 129-2.** A patient with herpes zoster illustrates a range of lesions (e.g., large pustules, erythematous papules, and crusting).

when patients experience acute dermatomal neuralgia without ever developing a skin eruption.

### Rash

When VZV reaches the dermis and epidermis, the initial cutaneous presentation of herpes zoster occurs as a unilateral, dermatomal, red, maculopapular eruption. Vesicles generally form within 24 hours and evolve into pustules, which dry and crust in 7 to 10 days. The rash usually heals over in 2 to 4 weeks. In normal individuals, new lesions may continue to appear for 1 to 4 days and occasionally for as long as 7 days. The T1 to L2 or V1 dermatomes are most commonly involved (Figure 129-2). Adjacent dermatomes can show satellite lesions but multiple lesions in contiguous dermatomes are not characteristic of herpes zoster. Atypical rashes may occur in older persons. The atypical rash maybe limited to a small patch located within a dermatome or may remain maculopapular without ever developing vesicles.

### Acute Herpetic Neuralgia

Herpes zoster-associated acute neuritis produces dermatomal neuralgic pain in many older adults. Some older patients never develop pain while others may experience the delayed onset of pain days or weeks after rash onset. The neuritis is described as burning, deep aching, tingling, itching, or stabbing. A subset of patients may develop severe pain, especially those with trigeminal nerve involvement. Acute herpetic neuralgia can have a profound adverse impact on functional status and quality of life in older adults. Acute herpes zoster pain can interfere with all activities of daily living but interference is greatest for instrumental activities of daily living, as well as sleep, general physical activity, and leisure activities. As overall pain burden increases, patients experience poorer physical, role, and emotional functioning.

### Complications

Ophthalmic herpes zoster occurs in 10% to 15% of the cases. It is second in frequency to thoracic herpes zoster and is a result from VZV reactivation in the first division of the trigeminal nerve (cranial nerve V). Ophthalmic involvement may present with impaired vision as a result of local inflammation. In 30% to 40% of cases of ophthalmic

zoster, there is involvement of the nasociliary branch, which also innervates the side and tip of the nose. Symptoms and/or signs on the tip of the nose should immediately lead to a thorough search for involvement of the eye. VZV-induced damage to the cornea and uvea and other eye structures can cause corneal anesthesia and ulceration, glaucoma, optic neuritis, eyelid scarring and retraction, visual impairment, and blindness in patients who did not receive antiviral therapy. Secondary bacterial infections can cause panophthalmitis and enucleation. Ophthalmic herpes zoster is also associated with stroke occurring weeks to months after the onset of the rash. The cause of the stroke is a granulomatous arteritis of the carotid artery close to the involved first division of cranial nerve V. Arteriograms show segmental narrowing of cerebral arteries ipsilateral to the ophthalmic zoster. Herpes zoster-associated arteritis in the trigeminal distribution can also cause ipsilateral occlusion of the central retinal artery with resultant visual loss.

Herpes zoster can affect cranial nerves other than the first division of cranial nerve V in older adults. Involvement of the third division of cranial nerve V can produce lesions and pain in the mandibular area of the face and in the mouth. Cranial nerve VII and VIII involvement, or Ramsey Hunt syndrome, is characterized by facial palsy in combination with herpes zoster lesions of the ipsilateral external ear, ear canal, tympanic membrane, or hard palate. Symptoms include tinnitus, vertigo, deafness, problems with balance, and facial paresis. Involvement of cranial nerve IX, X may produce pharyngeal or laryngeal lesions and resulting pharyngitis or laryngitis. The patient may have multiple symptoms because more than one cranial nerve can be involved in an attack.

Motor paralysis is reported in 1% to 5% of patients with herpes zoster. Subclinical motor neuron involvement with herpes zoster probably occurs more frequently than reported because muscle weakness in the thoracic and lumbar dermatomes is difficult to appreciate. It results from VZV-induced destruction of motor neurons in the anterior spinal horn or motor radiculitis corresponding to the extension of VZV infection from the involved sensory ganglion. Paralysis involves muscle groups with innervation that is contiguous with that of the affected dermatome.

The most commonly observed affected muscles are those of the face with involvement of the cranial nerve VII and the extremities with herpes zoster of the accompanying dermatome. Painful Bell's palsy in an older adult strongly suggests herpes zoster. Motor deficits usually occur at the time of or within a few weeks after the onset of the rash. Full or partial recovery of motor function occurs in most patients within months of the onset of weakness but facial palsy has a much lower rate of recovery.

Herpes zoster myelitis, with detection of VZV in the spinal cord or cerebrospinal fluid, has been reported both as a complication of typical herpes zoster and of zoster sine herpette. The incidence of acute symptomatic myelitis and meningoencephalitis is low (0.2–0.5%), although lymphocytic pleocytosis, with or without an increase in the concentration of protein in the cerebrospinal fluid, is a regular feature of uncomplicated herpes zoster.

The most feared complication of herpes zoster among older adults is PHN. PHN patients describe the quality of their pain as burning, throbbing, stabbing, shooting, sharp, aching, gnawing, tiring, or tender. The pain maybe spontaneous and/or stimulus-evoked. Spontaneous pain maybe constant aching or burning and/or brief, intermittent shock-like sensations. Stimulus-evoked pain consists of allodynia or hyperpathia. Allodynia is pain elicited by an innocuous stimulus and is particularly problematic. A cold wind, clothes, or

**Box 129.1 Clinical Pearls**

There is no risk of VZV transmission when the herpes zoster rash is maculopapular or crusted i.e., there must be vesicles for VZV transmission

When Bell's palsy presents with pain think HZ. Corollary: If a patient presents with a painful facial paresis look in the ipsilateral ear for vesicles (Ramsey Hunt Syndrome).

A vesicle at the tip of the nose should raise suspicion for ophthalmological HZ

Acute and convalescent VZV IgG and IgM levels are needed to diagnose zoster sine herpette.

Increasing severity of pain and rash in herpes zoster increases the probability of developing PHN.

Patients who claim they have several episodes of shingles probably have HSV; definitive diagnosis requires microbiological testing (e.g., PCR, culture, IFA)

bed sheets against the allodynic skin may cause debilitating pain. Hyperpathia is an exaggerated pain after a mildly painful stimulus. A minor bump of the affected dermatome against an object can cause severe pain that lasts for hours. Patients may experience discomfort that is not described as pain such as numbness or itching. Postherpetic itch can be maddening and appears to be mediated by damage and dysfunction of peripheral and central itch-specific neurons.

PHN greatly interferes with the functional status and quality of life of older adults. Patients can suffer from a variety of constitutional symptoms including chronic fatigue, anorexia, weight loss, and insomnia. PHN is associated with depression and social isolation in older adults. Reduced quality of life and interference with activities of daily living (ADLs) increases significantly as pain severity increases. Instrumental and basic ADLs are all compromised by PHN. For example, the patient with allodynic skin may be forced to avoid bathing or clothing around the affected area. Instrumental ADLs commonly affected include traveling, shopping, cooking, and housework. Studies using standardized pain scales and measures of function and quality of life such as the SF-36, SF-12, EuroQol, and Nottingham Health Profile have shown that PHN significantly interferes with multiple ADLs, reduces health-related quality of life (HRQL), and impairs mental and physical health. Though most people eventually have relief of pain, some are refractory to all treatments and the pain can even get worse over time (see [Box 129-1](#) on Clinical Pearls).

**DIAGNOSIS****Differential Diagnosis**

In patients who present with prodromal pain and no rash, herpes zoster is often confused with other causes of unilateral, localized pain in older adults, as noted above. One diagnostic clue to the presence of prodromal pain is localized cutaneous sensory abnormalities (e.g., hyperesthesia, dysesthesia) in the affected dermatome. Herpes zoster is easily diagnosed when an older adult patient presents with the typ-

ical dermatomal vesicular rash and pain. In the Shingles Prevention Study of the 1308 cases of suspected herpes zoster based upon clinical evaluation, 984 cases were confirmed to be herpes zoster (75%). During the rash phase, herpes simplex has the most similar presentation to herpes zoster. Evidence supporting herpes simplex includes a presentation in a younger population, multiple reoccurrences of lesions, and the absence of chronic pain. The lesions themselves are more difficult to distinguish, particularly when herpes zoster occurs in areas commonly affected by simplex (e.g., oral, genital, buttock lesions). In the Shingles Prevention Study, 3.4% of suspected herpes zoster cases were found to be herpes simplex virus. The differential diagnosis also includes contact dermatitis, burns, and vesicular lesions associated with fungal infections but the history and examination usually makes the distinction clear.

**Laboratory Tests**

The diagnosis of herpes zoster may need laboratory diagnostic testing when differentiating herpes zoster from HSV infection is necessary, for suspected organ involvement, and for atypical presentations, particularly in the immunocompromised host. The diagnostic tests include viral culture, immunofluorescent antigen (IFA) detection, PCR, and serology ([Table 129-1](#)). The best specimen is vesicle fluid, which contains abundant VZV. Lacking vesicle fluid, acceptable specimens include lesion scrapings, crusts, tissue biopsy, or cerebrospinal fluid. Crusts cannot be used for VZV culture. VZV isolation in culture of vesicular fluid is the "gold standard," but it is slower than other tests and not very sensitive as only 30% to 60% of vesicle culture specimens are positive. VZV antigen detection by IFA tests of vesicle scrapings or tissue biopsies takes hours to get results and is both specific and sensitive. These reasons make IFA the most useful test when specimens are available. Polymerase chain reaction is highly sensitive and so it can be used to test crust or other unusual samples. As the cost of PCR decreases over time, this will likely be the most commonly used test to confirm herpes zoster in the near future. Acute and convalescent VZV IgM and IgG levels maybe useful in making a retrospective diagnosis when there are no peripheral lesions or specimens are inadequate. Tzanck smears suggest herpes zoster when multinucleated giant cells and intranuclear inclusions are seen on slides but this does not differentiate herpes zoster from herpes simplex.

**MANAGEMENT****Acute Herpes Zoster****Nonpharmacological Management**

The principal goal of the treatment of herpes zoster in older adults is to decrease the length of the acute attack and to reduce or eliminate pain. Patients should be instructed to keep the rash clean and dry to decrease the chances of developing bacterial superinfection. Topical antibiotics should be discouraged. Cool compresses, calamine lotion, cornstarch, or baking soda may help to reduce local symptoms and speed the drying of the vesicles. When the vesicles have crusted over, a bland ointment or olive oil may help separate the adherent crusts. Occlusive ointments and topical steroids should be avoided.

**TABLE 129-1****Laboratory Tests for Detecting Varicella-zoster Virus (VZV) and Diagnosing Herpes Zoster**

TEST*	DETECTS	SENSITIVITY	SPECIFICITY	TURNAROUND	PROS	CONS
Culture	Whole VZV	Low (about 40%)	Very high (near 100%)	Days	Whole virus isolation is the standard for diagnosis. Only method that yields infectious VZV for further analysis. Readily available	Slow, insensitive, VZV difficult to grow on tissue culture
Immunoassays (IFA, EIA)	VZV antigen	High (90%)	High (90%)	Hours	Readily available. Good sensitivity and specificity.	Must be done in experienced laboratory, careful interpretation to avoid false positive and negatives
PCR	VZV DNA	Very high (near 100%)	Very specific (near 100%)	Hours	Superb sensitivity and specificity. Valuable for unusual specimens or when the clinician suspects that IFA or culture has yielded false negative test results.	Expensive, not as readily available, must be done by experienced laboratory to avoid false positives
Serology (ELISA, FAMA, LA)	IgG, IgM antibody	High for antibody detection; unknown for HZ diagnosis	High for antibody detection; unknown for HZ diagnosis	Hours	Can be used to diagnose zoster sine herpete or HZ retrospectively using acute and convalescent VZV IgG titers.	Not clinically useful for diagnosing HZ at time of presentation; requires acute and convalescent (6 weeks later) samples

\*IFA, immunofluorescence antigen; EIA, enzyme immunoassay; PCR, polymerase chain reaction; ELISA, enzyme-linked immunosorbent assay, FAMA, fluorescent antibody to membrane antigen; LA, latex agglutination.

Reassurance and education directly address concerns about contagiousness, for example, who is at risk for contracting VZV, zoster pain management, and potential disability. Social support, mental and physical activity, adequate nutrition, and a caring attitude are important interventions for coping with a herpes zoster attack.

### Antiviral Therapy

The first line of drug therapy is aimed at inhibiting the replication of VZV. The guanosine analogs, acyclovir, famciclovir, and valaciclovir, are phosphorylated by viral thymidine kinase to a triphosphate form that inhibits VZV DNA polymerase and VZV replication. Valaciclovir and famciclovir are prodrugs, which have greater bioavailability, resulting in higher blood levels and a less frequent dosing schedule. Randomized controlled trials indicate that oral acyclovir (800 mg five times a day for 7 days), famciclovir (500 mg q 8 hours for 7 days), and valaciclovir (1 gm three times a day for 7 days) reduce acute pain and the duration of chronic pain in older patients with herpes zoster who are treated within 72 hours of rash onset. The kidneys excrete these medications and the dose should be adjusted for renal insufficiency. They are safe and well-tolerated among older adults. The most common adverse effects are nausea, vomiting, diarrhea, and headache. The data from current clinical trials indicate that all three drugs are acceptable agents with factors other than efficacy determining the choice, such as cost and dosing schedule (Table 129-2). The effectiveness of antiviral agents has not been evaluated for treatment after 72 hours have elapsed since the onset of rash. An exception to the 72-hour threshold for treatment is made for patients who have ophthalmic zoster or patients that continue to have

new vesicle formation. Topical antiviral therapy is not an effective treatment.

### Analgesics

Acute herpes zoster pain requires the use of standardized pain measures (e.g., 0 to 10 rating scale), scheduled analgesia, and close monitoring to adjust dosing and detect adverse effects. Opioid and nonopioid analgesia are a standard of care for the acute pain syndrome. The choice of treatment will depend on the patient's pain intensity, comorbidities, and preferences. Patients with mild pain maybe managed with acetaminophen or nonsteroidal agents. Patients with moderate to severe pain usually require treatment with an opioid analgesic (e.g., oxycodone). There is a tendency among many clinicians to undertreat the pain and particularly to use opioid analgesia sparingly. Opioids have multiple adverse effects including nausea, constipation, and sedation, which maybe intolerable in some older adults. Among frailer patients, there is an increased risk for falls and confusion. Constipation should be anticipated and managed with

**TABLE 129-2****Medications for the Management of Herpes Zoster**

MEDICATION	DOSE (MG)	FREQUENCY	COST
Acyclovir	800	5 times/day	60 cents/pill
Famciclovir	500	3 times/day	\$8.94 /pill
Valaciclovir	1000	3 times/day	\$5.19 /pill

Data from <http://www.drugstore.com>.

laxative therapy. Assessment of appropriate analgesia should include ability to sleep and manage routine activities as well as provide sufficient relief.

### Corticosteroids

The anti-inflammatory effects of corticosteroids have been postulated to reduce herpes zoster symptoms but there remains controversy over their use. Randomized, controlled clinical trials demonstrated that corticosteroids do not prevent PHN when compared to placebo or acyclovir. These findings, the risk of VZV dissemination, and the adverse effects of corticosteroids in older adults argue against the routine use of these agents in herpes zoster. However, clinical trials have shown reductions in acute pain and one randomized controlled trial showed benefits in improvement in time to uninterrupted sleep, return to routine activities, and cessation of analgesic medications among patients with no relative contraindications to corticosteroids. In the trial, prednisone was administered orally at 60 mg/day for days 1 to 7, 30 mg/day for days 8 to 14, and 15 mg/day for days 15 to 21. Therefore, corticosteroids maybe useful in reducing moderate to severe acute pain unrelieved by antiviral agents and analgesics. Corticosteroids are used to treat VZV-induced facial paralysis and cranial polyneuritis to improve motor outcomes and provide pain relief. If prescribed, corticosteroids should always be used in conjunction with antiviral agents. The use of corticosteroids in older patients with hypertension, diabetes, gastritis, osteoporosis, psychosis, or cognitive impairment needs to be weighed carefully. The most common adverse effects of corticosteroids are dyspepsia, nausea, vomiting, edema, and granulocytosis. The doses and length of treatment would put the patient at risk for bone loss.

### Adjuvant Agents

If moderate-to-severe herpes zoster pain is not inadequately relieved by antiviral agents in combination with oral analgesic medications and/or corticosteroids, then other therapies could be considered. Gabapentin or pregabalin, nortriptyline or desipramine, or neural blockade all have potential roles in the treatment of acute herpes zoster. There are no randomized controlled trials of gabapentin or pregabalin, or nortriptyline or desipramine, for acute herpes zoster pain nor are there trials showing these agents prevent PHN. The rationale for considering gabapentin or pregabalin is their known efficacy in relieving chronic neuropathic pain and a study using a single dose (900 mg) of gabapentin in acute herpes zoster pain showing pain reduction. The use of these anticonvulsant agents must be balanced against adverse effects of sedation, dizziness, ataxia, and peripheral edema. The rationale for considering nortriptyline or desipramine is their known efficacy in relieving chronic neuropathic pain and a trial using amitriptyline that showed treating acute herpes zoster resulted in a reduction in PHN at six months. This trial had major methodologic concerns including acyclovir use was unbalanced favoring the amitriptyline group and a question of whether the reduction in PHN was the result of treatment during acute herpes zoster or because the treatment with amitriptyline continued for 3 months after rash onset. The use of these tricyclic agents must be balanced against their adverse cardiac and anticholinergic effects. Neural blockade can reduce severe acute herpes zoster pain. A randomized controlled trial of antiviral therapy, oral analgesics, and a single epidural block with bupivacaine and methylprednisolone

compared to antiviral therapy and oral analgesics alone showed that neural blockade reduces acute pain but does not prevent PHN. This modality requires referral to a pain specialist. Some patients have very severe pain refractory to usual outpatient treatments and require hospitalization for parenteral opioids and/or epidural analgesia.

Ophthalmic zoster requires ophthalmological consultation. Oral antiviral and analgesic therapy is the mainstay of treatment as it is for herpes zoster presenting on the rest of the body but other ocular therapies may be necessary. These treatments are best managed by an ophthalmologist and include antibiotic ophthalmic ointment to prevent bacterial infection of the ocular surface, topical steroids to reduce ocular inflammation, mydriatics as needed for iritis, and ocular pressure-lowering drugs as needed for glaucoma. Cool to lukewarm compresses may provide some comfort and oral corticosteroids maybe useful for patients with severe pain.

## Postherpetic Neuralgia

### Oral and Topical Pharmacotherapy

The treatment for PHN is problematic because the pain may last from months to a year or more and be associated with a decline in activities of daily living and quality of life. Based upon evidence of effectiveness from clinical trials and safety in older adult population, tricyclic antidepressants (TCAs), gabapentin, pregabalin, lidocaine patch, and opioids are considered first-line therapies because one or more high-quality randomized controlled trials demonstrated efficacy with these agents. Gabapentin, pregabalin, and the topical lidocaine patch 5% are approved by the FDA for the treatment of PHN.

**Topical Treatments** The topical lidocaine patch 5% reduced PHN in randomized vehicle controlled trials. In one trial, which also included other neuropathic pain patients, the percentage of patients who obtained 50% reduction in pain was 31% with the lidocaine patch compared to 8% with placebo patch. The number needed to treat (NNT) for 50% pain reduction is 2.0. Up to three patches maybe applied over the affected area for 12 hours a day. It may take up to 2 weeks for these treatments to reach full effectiveness. Systemic lidocaine toxicity has not been reported from topical lidocaine. Capsaicin, a *trans*-8-methyl-*N*-vanillyl-6-nonenamide is known to deplete substance P, an endogenous neuropeptide that is involved in the transmission of nociceptive impulses from the sensory nerve endings to the central nervous system. This treatment has been shown to have a statistical benefit in studies but its clinical effect is small. It takes days to deplete substance P and many patients are unable to tolerate the burning it causes. Nonetheless, topical capsaicin maybe considered as a therapeutic option in PHN because it maybe effective in individual circumstances. Topical treatments should not be used in herpes zoster in the acute phase with open lesions.

**Gabapentin and Pregabalin** Gabapentin is an anticonvulsant that has become a popular treatment partly because two randomized, placebo controlled studies showed a significant clinical benefit in pain relief with gabapentin and partly because of the favorable side effect profile. In those trials, 41% to 43% of patients on gabapentin reported moderate or better pain improvement compared to 12% to 23% of those on placebo. The NNT for 50% pain reduction was 4.6 (Table 129-3). Dosing is described in Table 129-3. Patients who

TABLE 129-3

## Medication for Managing Postherpetic Neuralgia

MEDICATION	NUMBER NEEDED TO TREAT* (PERSONS)	SIDE EFFECTS OF MEDICATIONS	BEGINNING DOSE	TITRATION
Lidocaine patch	2.0	Dysesthesia vesicular rash, ulcerations, edema, or erythema at the application site.	Maximum of 3 patches daily for a maximum of 12 h	None needed
Gabapentin	4.4	Somnolence, dizziness, ataxia, peripheral edema and cognitive impairment.	100–300 mg at night	Increase by 100–300 mg a day every 1–7 days as tolerated in divided doses up to three times a day, maximum 3600 mg daily
Pregabalin	4.9	Somnolence, dizziness, ataxia, peripheral edema and cognitive impairment.	50–150 mg daily two to three times a day	Increase to 300 mg a day, given in 2 or 3 divided doses within 1 week; maximum dose generally 300 mg in older adults
Tricyclic antidepressant nortriptyline	2.6	Dry mouth, sedation, constipation and less risk for cognitive impairment and orthostatic hypotension.	10–25 mg qhs	Increase by 10–25 mg daily Every 3–7 days as tolerated; maximum dose 75–150 mg daily
Opioid oxycodone (dosage given for morphine equivalents)	2.7	Constipation, nausea sedation, impaired cognitive function, and falls.	2.5–15 mg every 4 h as needed	After 1–2 weeks, convert total daily dosage to long-acting opioid analgesic and continue short-acting medication as needed
Tramadol	4.7	Constipation, nausea sedation, impaired cognitive function, orthostasis, falls.	25 mg once daily	Increase by 25–50 mg daily in divided doses every 3–7 days as tolerated; maximum 300 mg daily in patients older than 75 yr of age

\*NNT, number of patients needed to treat to achieve 50% reduction in pain.

Data from Hemenstall K, Nurmikko TJ, Johnson RJ, A'Hern RP, Rice ASC. Analgesic therapy in postherpetic neuralgia: a quantitative systematic review. *PLOS Med.* 2(e164): 0628–0644, 2005.

do not have at least partial relief at 1800 mg are unlikely to benefit from higher doses of gabapentin. Frail elderly patients often need smaller doses because of problems tolerating higher doses. Doses should be adjusted for creatinine clearance. Adverse effects include somnolence, dizziness, ataxia, and peripheral edema. Cognitive impairment may also occur in elderly patients.

Pregabalin is an anticonvulsant that is similar in structure and action to gabapentin. In placebo-controlled trials, the proportion of patients with greater than 50% decrease in mean pain scores was 50% in the pregabalin group compared to 20% in the placebo group. The NNT for 50% pain reduction is 4.9 (Table 129-3). The adverse effect profile of pregabalin is similar to gabapentin with dizziness, somnolence, peripheral edema, dry mouth, and gait disturbances as the most common adverse effects. The drug has few drug–drug interactions, can be given less frequently than gabapentin, and has a relatively rapid onset of action. Other anticonvulsants (e.g., phenytoin, levetiracetam, oxcarbazepine, tiagabine, topiramate, zonisamide, valproate) are possibly useful but cannot be considered first-line agents because of limited data for efficacy and/or significant adverse effects.

**Tricyclic Antidepressants** TCAs modulate nerve transmission. Multiple randomized controlled trials of TCAs demonstrated significant pain relief in patients with PHN with 44% to 67% of patients treated with TCAs reporting moderate to good pain relief compared to 5% to 19% of placebo or control drug recipients.

The NNT for 50% pain reduction is 2.8 (Table 129-3). In the only head-to-head comparison, nortriptyline demonstrated equivalent efficacy and was better tolerated when compared to amitriptyline in a PHN. Nortriptyline and desipramine are preferred over amitriptyline because they have less anticholinergic effects, resulting in less dry mouth, sedation, constipation, cognitive impairment, and orthostatic hypotension. Tricyclic antidepressants are associated with cardiac toxicity in patients with cardiovascular disease. They are contraindicated in patients with QT prolongation, familial histories of long-QT syndromes, atrioventricular block, bundle-branch block, or a recent acute myocardial infarction. An EKG looking for QT prolongation or heart block should be evaluated before initiating therapy and with each change in dose. Caution is necessary in the concomitant administration of TCAs and selective serotonin reuptake inhibitors (SSRIs). Tricyclic antidepressants are metabolized by the cytochrome P450 D26 enzyme system and SSRIs, especially fluoxetine, inhibit P450 D26 so toxic TCA plasma concentration could result. Dosing is described in Table 129-3.

**Opioid and Opioid-Like Analgesics** PHN pain responds to opioid treatment. In a randomized, crossover trial showing significant pain relief with oxycodone, 67% of patients expressed preference for oxycodone compared to 11% of the placebo recipients. The NNT for 50% pain reduction is 2.6. In another crossover study of PHN comparing opioid analgesics, TCAs, and placebo, controlled-release

morphine and TCAs provided statistically significant benefits on pain relief. Patients preferred treatment with opioid analgesics compared to TCAs and placebo despite a greater incidence of side effects and more drop-outs during opioid treatment.

Although oxycodone has been shown to be an effective treatment, equianalgesic doses of other opiates are likely to be as effective. The most frequently reported adverse effects were constipation, nausea, and sedation. Impaired cognitive function, falls, and fractures are also more likely to occur in the older patients prescribed opioids. Starting at a low dose and slowly increasing the dose may reduce the probability of serious side effects. We start all patients receiving opioids on an aggressive bowel regimen. Dosing is described in [Table 129-3](#). Tramadol is a mu opioid agonist and a norepinephrine and serotonin reuptake inhibitor. One randomized controlled trial in PHN found that 77% of subjects on tramadol versus 56% on placebo reported greater than 50% reduction. The adverse effects of tramadol include all the opioid adverse effects noted above as well as orthostatic hypotension, increased risk of seizures in patients with a history of seizures, and risk for serotonin syndrome in patients who use serotonergic medications, especially SSRIs and monoamine oxidase inhibitors. Dosing is described in [Table 129-3](#).

**Combination Pharmacotherapy** Many PHN patients do not respond to single drug therapy but there are relatively few data on optimal combinations of drugs. Combination therapy may augment a partial response to a single drug or produce better analgesia at lower doses of drug. However, combination therapy in older adults increases the risk of adverse effects and makes it difficult to determine which medication is responsible for adverse effects or benefits. In one study of combination therapy that included 22 patients with PHN, investigators studied the effects of morphine alone, gabapentin alone, or morphine–gabapentin combination in a randomized, double-blind, active placebo-controlled, four 5-week period crossover trial. The results showed that gabapentin and morphine combined achieved modestly better pain relief at lower doses of each drug than either as a single agent. However, the combination was associated with higher levels of sedation, dry mouth, and cognitive dysfunction than the maximal tolerated dose of each single agent. For patients with PHN who do not have an adequate response to any of the front-line medications, other drug and nondrug treatments deserve consideration. These patients should be referred to a pain specialist or pain center for consideration of more complex drug combinations, risky second-line medications, or invasive treatments.

### Other Treatments

**Noninvasive Treatments** Transcutaneous electrical nerve stimulation (TENS), percutaneous electrical nerve stimulation (PENS), acupuncture, cold application, or psychological treatments maybe useful in some patients and have little risk, although their effectiveness in PHN has not been tested in controlled clinical trials. PHN patients who are good candidates for a trial of PENS or TENS are those that maybe experiencing associated myofascial pain in addition to neuropathic pain. The presence of myofascial pathology is indicated by taut muscle bands (i.e., a group of tense muscle fibers extending from a trigger point to the muscle attachments) and trigger point(s) (i.e., a hyperirritable spot in skeletal muscle that is painful on compression) in the affected dermatome.

**Invasive Treatments** Patients who remain in severe pain and have failed all other therapies can be considered for invasive interventions, which include neural blockade, spinal cord stimulation, and central nervous system drug delivery. Neural blockade techniques include sensory nerve, plexus, and sympathetic nerve blocks as well as epidural and intrathecal blockade with lidocaine-like drugs and/or corticosteroids. Spinal cord stimulation requires implantation of an electrode in the thoracic or lumbar epidural space and the placement of a percutaneous electrical stimulator. Central nervous system drug delivery systems place drug (e.g., morphine), as close as possible to central pain receptors in the spinal cord corresponding to the affected dermatome. In general, the risks of these interventions outweigh any potential benefits in older adults with PHN.

## PREVENTION

### Varicella Vaccine

The live, attenuated varicella vaccine is safe and effective in preventing varicella and is licensed for use in the United States. The Centers for Disease Control reported that varicella incidence declined by approximately 80% compared to prevaccination incidence rates in varicella surveillance areas in the year 2000. Vaccine uptake among children aged 19 to 35 months in the United States was 88% in 2004. These figures indicate that the varicella vaccine is having a dramatic impact on the epidemiology of varicella in the United States by markedly reducing the incidence of varicella. The effect of the varicella vaccine on older adults is a reduced likelihood of exposure to VZV and less chance of exogenous boosting of their cellular immunity against VZV. Whether this is clinically important is unknown but some experts speculate that latently infected individuals will be more likely to develop herpes zoster without this booster effect. The vaccine virus can establish a latent infection in children and reactivate at a later time. However, vaccine virus-associated herpes zoster will probably be less frequent and severe in vaccinated children as they become older adults because the vaccine virus is highly attenuated.

### Zoster Vaccine

Regardless of the impact of the varicella vaccine, millions of latently infected older adults are at risk for herpes zoster for the foreseeable future. The zoster vaccine was developed to prevent or attenuate herpes zoster. It is similar to the varicella vaccine but it is formulated to yield much higher concentrations of live attenuated VZV and antigen than the varicella vaccine. The zoster vaccine, but not the varicella vaccine, significantly boosts VZV-specific cellular and humoral immunity in older adults. The increase in VZV-specific cellular immunity in older adults by the zoster vaccine forms the scientific rationale for testing the vaccine because cellular immunity to VZV declines with age.

The Shingles Prevention Study was a randomized, double-blind, placebo controlled trial to determine if the zoster vaccine would decrease the incidence and/or severity of herpes zoster and PHN among older adults. The study randomized 38 546 community-dwelling persons  $\geq 60$  years old to vaccine or placebo and followed them for herpes zoster and adverse events for a median of three years. There

were 315 cases of herpes zoster among vaccine recipients compared to 642 cases among placebo recipients. There were 27 cases of PHN among vaccine recipients and 80 cases of PHN among placebo recipients. The vaccine reduced incidence of herpes zoster from 11.12 to 5.42 cases (51.3%) per 1000 person-years for an NNT of 59 over the 3.12 years of the study. The vaccine reduced the incidence PHN from 1.38 to 0.46 cases (66.5%) per 1000 person years for an NNT of 362 over the duration of the study. The zoster vaccine also reduced the pain burden of illness (a pain severity by duration measure) caused by herpes zoster by 61.1%. The efficacy of the zoster vaccine in reducing pain burden and PHN in the 60- to 70-year old group was mediated mostly by preventing herpes zoster, whereas efficacy in the greater than 70-year-old group was mediated mostly by attenuating herpes zoster since the vaccine was less effective in preventing HZ in that age group. Reactions at the injection site were more frequent among vaccine recipients but were generally mild. In 2006, the FDA licensed the zoster vaccine for the prevention of herpes zoster in immunocompetent adults 60 years of age and older and the Advisory Committee on Immunization Practices (ACIP) of the CDC unanimously recommended the vaccine for the prevention of HZ and PHN in immunocompetent adults 60 years of age and older.

Several key clinical questions are raised by the use of the zoster vaccine. What is the duration of the protective effect of the vaccine? The Shingles Prevention Study data indicate that vaccine efficacy persists for at least 4 years. Long-term follow-up studies are ongoing to determine the durability of the effectiveness of the zoster vaccine in a subset of study vaccine recipients. What is the effectiveness of the vaccine in very old and frail individuals? Neither the FDA nor the ACIP set an upper age limit on the use of the vaccine. These individuals are at highest risk for herpes zoster and PHN and reduction of herpes zoster pain severity and duration occurs in the “old-old” even when herpes zoster is not prevented. What is the efficacy of the zoster vaccine in individuals who have already had herpes zoster? Older adults with prior herpes zoster ask for the vaccine but the answer to this question is unknown because these individuals were excluded from the Shingles Prevention Study. Persons with recent episodes (within 3 to 5 years) of herpes zoster have a boost in immunity from reactivated wild-type VZV that is as strong or better than that obtained from the zoster vaccine so they may not benefit from the vaccine. However, other individuals with a more remote history of herpes zoster may benefit because herpes zoster can recur. The ACIP recommends the zoster vaccine for persons older than 60 years of age whether or not they report a prior episode of herpes zoster.

In summary, the incidence of herpes zoster and PHN increases greatly with aging so the majority of herpes zoster cases occur among older adults. Acute herpes zoster pain, other herpes zoster compli-

cations (e.g., ophthalmic zoster) and PHN interfere with functional status and lower quality of life in older people. Although not perfect, clinicians now have several tools to prevent and treat these conditions. Those tools include the zoster vaccine, early antiviral therapy, careful acute pain management, and a number of neuropathic pain treatments. The systematic application of these interventions will markedly reduce the suffering of older adults from herpes zoster and PHN.

# Influenza and Respiratory Syncytial Virus

*Mark B. Loeb*

## INFLUENZA

Influenza is an important threat to the health of older adults. Each year, it is estimated that 36,000 older adults in the United States die of influenza and pneumonia with the majority of these occurring in persons 65 years and older. Despite immunization, outbreaks of influenza occur regularly in nursing homes and other long-term care facilities. This section of the chapter will summarize the biological, epidemiological, and clinical features of influenza that are relevant to the elderly with a particular emphasis on prevention.

### Clinically Relevant Biological Characteristics of Influenza Virus

To properly understand the impact of influenza in the elderly, it is important to be familiar with several key characteristics of the virus. The structure of influenza consists of an envelope with a central nucleic acid core comprised of single-stranded RNA. Key structural characteristics of the virus include the presence of hemagglutinin and neuraminidase proteins on the envelope. There are three types of influenza viruses A, B, and C. However only A and B are clinically relevant. Influenza A viruses are characterized by the structure of the hemagglutinin, a surface protein whose function is to bind to a glycoprotein on the surface of respiratory epithelial cells, allowing the virus to enter into the cell by forming an endosome and then using the protein making machinery of the cell to replicate itself. Annually new mutations are selected for resulting in small changes in the hemagglutinin (“antigenic drift”) hence the reason why influenza vaccine needs to be given annually. The other surface projection, neuraminidase, cleaves terminal sialic acid residues from carbohydrate moieties on surfaces of infected cells, promoting the release of virions that go on to infect other cells. As discussed below, this is a key target for neuraminidase inhibitors, thus preventing the influenza virus from replicating.

An important feature of influenza is the segmented structure of the RNA at the core of the virus, with each of eight segments coding for a structural or enzymatic component of the virus. This gives the virus the potential to recombine with influenza viruses of animal origin, forming a virus with a novel genotype and hemagglutinin to which there is no preexisting immunity. This is known as “antigenic shift” and was responsible for pandemics in 1957–1958 and 1968–1969. A recent concern is the changes in hemagglutinin from animal strains, such as avian influenza or H5N1, maybe able to attach to the human receptors, causing direct transmission from animals to humans. This is believed to have caused the 1918–1919 pandemic and is a current concern with avian influenza (H5N1). Of note is that the highest mortality rate occurring in the 1918–19 pandemic was not in the elderly, but in 18- to 25-year-olds. This may have been because of the fact that there were similar H1 viruses circulating in the early 1900s and individuals older than 50 years of age developed partial immunity with previous exposure. At present, there are only three hemagglutinins (H1, H2, H3) and two neuraminidases (N1, N2) that have developed a stable lineage in humans.

### General Epidemiology of Influenza

Epidemics of influenza occur annually between November and April in the Northern hemisphere. A typical outbreak of influenza lasts for about 6 weeks, reaching a peak and slowly declining. However, in any given season, there maybe several strains circulating, with several peak periods of activity. It is for this reason that the annual influenza vaccine contains antigen from three influenza strains, two strains of influenza A, and one strain of influenza B.

### Important Host Considerations in the Elderly

During the interpandemic period, older adults and particularly residents of long-term care facilities are among those at highest risk for complications of influenza. Rates of hospitalization for influenza in

community dwelling elderly persons range from 125 to 228 hospitalizations per 100,000 persons. As with many other infectious diseases, the very old and the very young are at highest risk of complications. Children between the ages of 6 and 23 months similarly have high rates of hospitalization attributable to influenza, ranging from 144 to 187 hospitalizations per 1000 persons. The presence of chronic conditions, such as chronic lung disease, congestive heart failure, conditions that predispose to aspiration, and metabolic disease, increase the risk for complications following infection with influenza. Many of these conditions occur predominately in older age groups. Moreover, studies that have assessed complications have found that age older than 65 years alone is independently associated with increased risk for influenza complications.

Based on our current understanding, the cause of death as a result of influenza in the elderly in the interpandemic period is not viral pneumonia but typically a bacterial infection complicating the influenza infection. Infection with influenza virus therefore predisposes to *Streptococcus pneumoniae* or *Staphylococcus aureus* infection, resulting in bacterial pneumonia. Deficits in innate immunity (phagocytes natural killer cells) and acquired immunity (T-cell function, cytokine activity, antibody response) are all felt to play a role, as discussed in Chapter 3.

### Clinical Presentation

Young, healthy individuals with influenza characteristically present with a sudden onset of fever, cough, myalgia, sore throat, and headache. Fever and cough have been shown in a systematic review to be the best predictors of influenza in the general population. In the elderly, the presentation usually is more subtle with cough and change in baseline temperature predominating. One of the most important factors in making the diagnosis of influenza, whether on clinical grounds or through diagnostic testing, is the local influenza activity. That is, if a community is experiencing an outbreak of influenza, particularly if the incidence of influenza is at its peak, fever and cough in an older person increase the likelihood of infection with influenza. However, it is important to bear in mind that the majority of studies that have assessed the diagnostic utility of clinical symptoms were done in samples with participants aged from 18 to 45 years, so less is known about the diagnostic utility of clinical signs and symptoms in the elderly.

In the nursing home setting, it is essential to obtain prompt diagnostic testing, because, as consistently demonstrated in longitudinal studies that have compared symptoms to etiologic agents, the clinical presentation is nonspecific. Even when there are peaks of influenza in the community, respiratory syncytial virus (RSV) or other respiratory viruses can circulate. It is essential to obtain testing, because it can lead to a change in management: an outbreak of influenza A in nursing home warrants chemoprophylaxis (see below) as well as immunization of nonimmunized residents in whom it is safe to do so.

### Specific Diagnostic Tests

The traditional method to detect influenza has been viral culture. The main limitations of culture have been moderate diagnostic accuracy and delay in obtaining results, which may take 2 to 3 days. Rapid tests include direct fluorescent antigen (DFA), or direct immunofluorescence, where monoclonal antibodies labeled with fluorescent material are directed to influenza cell coat antigens. A result

can be reported within hours. Rapid enzyme-linked immunoassay (ELISA) tests are commercially available, however they are only available for influenza A and have a sensitivity of 60%. Nucleic acid amplification testing, such as polymerase chain reaction (PCR), is the most promising test since it is over 90% sensitive and specific and the turnaround time is rapid. The drawback however is that most laboratories do not have the resources to perform PCR on a routine basis.

### Infection Control Aspects

The incubation period of influenza, the period of time from initial infection to development of symptoms, is typically 2 days, but can range from 1 to 4 days. An infected individual becomes contagious 1 day prior to the onset of symptoms. In adults, viral shedding at levels high enough to cause transmission occurs over 5 or 6 days. This is the rationale for keeping patients with influenza in isolation in hospital for 5 days after symptom onset. Although the extent to which influenza can be transmitted by airborne spread is controversial, the majority of spread of influenza is large droplet caused by coughing and sneezing. In terms of practical implications, use of “respiratory etiquette,” coughing, and sneezing into tissues, for example, may help prevent spread to older adults who are susceptible to complications although supporting epidemiologic evidence is limited. In the hospital setting, the use of gloves, gowns, and a mask is recommended prior to entering a patient’s room.

### Immunization

In the United States, there are currently two types of influenza vaccine that are licensed, the inactivated trivalent vaccine, which is a split virus formulation with two strains of influenza A and one B, and a cold-attenuated live intranasal vaccine. Only the inactivated vaccine is licensed for persons older than of 65 years of age. A recent systematic review summarized randomized controlled trial and cohort study evidence for efficacy and effectiveness: 64 studies were included in assessment, resulting in 96 data sets. In nursing homes where there was a good vaccine match and high viral circulation the effectiveness of vaccines against influenza-like illness was 23% (6–36%) but it was not significant against influenza (relative risk [RR] 1.04; 95% CI 0.43–2.51). However, well-matched vaccines had a 46% (30–58%) efficacy for preventing pneumonia, 45% (16–64%) efficacy to prevent hospital, and 42% (17–59%) efficacy for preventing death from influenza or pneumonia.

In elderly individuals living in the community, the review showed that poorly matched vaccines were not significantly effective against influenza (RR 0.19; 95% CI 0.02–2.01), influenza-like illness (RR 1.05; 95% CI 0.58–1.89), or pneumonia (RR 0.88; 95% CI 0.64–1.20). Well-matched vaccines had a 26% (12–38%) efficacy for preventing hospital admission for influenza and pneumonia and a 42% (24–55%) efficacy for preventing all-cause mortality.

These data show that influenza immunization plays an important role in prevention. However, the data show only a modest effect of the influenza vaccine in community-dwelling elderly. One concern is the high effect size for preventing all cause mortality compared to the lack of significant effect for preventing influenza. A possible explanation is confounding by health status. That is, it maybe that “healthier” seniors are more likely to be immunized and as a result of their underlying health have higher survival rates than those who are not immunized. Empirical evidence of this relationship was demonstrated

in a case–control study showing that when functional status is adjusted for, the efficacy of the influenza vaccine for preventing mortality is reduced.

Studies using seasonal regression modeling with both U.S. and Italian data show no reduction in mortality among the elderly with increased influenza vaccine coverage. These studies assessed trends in excess mortality after adjusting for age. One possible explanation of the results in these studies is that the influenza vaccine failed to protect the elderly against death because of immune senescence (see Chapter 3).

### Influenza and Long-term Care

Residents of nursing homes and other long-term care facilities are at high risk for complications of influenza, including pneumonia, death, and hospitalization. This is likely because there is close contact between residents and staff in these facilities, increasing the exposure to and transmission of influenza, and because the majority of residents have comorbidities, including cognitive impairment, chronic lung diseases, and strokes. Outbreaks of influenza are well characterized in nursing homes, often described as “explosive” in that the onset is relatively abrupt. Such outbreaks are usually first detected by nursing home staff who notice a higher incidence of respiratory symptoms than usual on specific long-term units, although at least one surveillance study has shown that such outbreaks are commonly missed even when active surveillance by trained nurses is performed. Such outbreaks are best managed using a multifaceted approach that includes the following: cohorting residents, increasing adherence to hand hygiene, chemoprophylaxis with antiviral agents, and immunization of those not previously vaccinated. It should be noted that because of space limitations, it is usually not feasible to cohort ill residents together as a means of separating them from noninfected residents in long-term care facilities. Administering neuraminidase inhibitors, such as oseltamivir or zanamivir, as chemoprophylaxis to noninfected residents helps to reduce further spread. In one randomized controlled trial where long-term units were randomized to zanamivir or to rimantidine, the risk of influenza was 3% in the zanamivir arm versus 8% in the rimantidine arm ( $P = 0.038$ ). More recent data suggests that immunizing staff in nursing homes against influenza can benefit residents. There have been three cluster randomized controlled trials showing that immunizing healthcare workers against influenza reduces mortality in residents of long-term care facilities. Vaccinating nursing home staff against influenza may prevent deaths, use of health services, and influenza-like illness in nursing home residents.

### Use of Antivirals to Prevent and Treat Influenza in Older Adults in the Community

There are four antivirals that are approved for treating influenza: amantadine, rimantadine, zanamivir, and oseltamivir. Amantadine and rimantadine are only active against influenza A while the neuraminidase inhibitors zanamivir and oseltamivir are active against influenza A and B. These agents are 70% to 90% effective for prophylaxis in preventing influenza and when used as treatment reduce clinical severity when given within 48 hours of symptom onset. Amantadine and rimantadine are not recommended when circulating strains with resistance have been detected, and in 2005, the Centers for Disease Control (CDC) noted that the majority of H3N2 in-

fluenza strains had become resistant to those agents. Also, the utility of amantadine is reduced in the elderly given the potential for central nervous system side effects. In contrast, zanamivir and oseltamivir are associated with few adverse effects. However, the feasibility of using these agents for treatment is reduced since the majority of patients in the community present over 48 hours following symptom onset.

### Indirect Benefit of Immunization in Children to Protect Older Adults

There is good observational data to suggest that children play an important role in the spread of influenza in the community. For example, data from a 3-year longitudinal surveillance study of children and adults in New York State demonstrated that children were about twice as likely to acquire and shed influenza as compared to adults. In a longitudinal study conducted in Seattle from 1968 to 1974, elementary and junior high school students had the highest rates of influenza during epidemics, reaching 54%. In the Tecumseh, Michigan studies from 1976 to 1981, over one-third of children between the ages of 5 and 14 years had influenza virus isolated from specimens, the highest rate was among persons with febrile respiratory illness. Serological data revealed similar results, from 1977 to 1978, children in 5 to 9, 10 to 14, and 15 to 19 age groups had approximately a 30% infection rate with H3N2. This was over twice the rate seen in adults. There were similar infection rates with influenza B in children aged 5 to 14 years, rates 14-fold higher than those in adults older than 20 years of age.

Given that school-aged children appear to play an important role in introducing and transmitting influenza into households, and hence into the community, immunizing these children may interrupt spread to elderly persons who are at high risk for complications. In the Tecumseh studies, Monto and colleagues demonstrated that selectively immunizing 86% of children in this 7500-person community with inactivated influenza vaccine reduced influenza in adults by a third when compared to an adjacent community where children were not immunized. More evidence for the potential benefit of immunizing children with inactivated vaccine has been derived from an analysis of the effect of influenza vaccination in Japan. Japan began a program of immunizing school-aged children in 1962 and continued this policy until 1994. The effect of this policy was to dramatically reduce excess mortality rates to values similar to those in the United States. The fact that there was a rapid increase in excess deaths after 1994, the year in which mass immunization formally ended, supports the conclusion that the effects observed in earlier years were because of vaccine-induced herd immunity, although it is possible that social factors may have amplified the effects of this program. The authors explain their findings by hypothesizing that the high levels of vaccination in school children protected transmission of influenza to their grandparents. There have been several more recent observational studies where children have been immunized showing a reduced attack rate of influenza in adults. However, randomized clinical trial evidence of immunizing children to prevent influenza in older adults is limited.

## RESPIRATORY SYNCYTIAL VIRUS

RSV has been long recognized as the major cause of bronchiolitis in children. Since the 1970s, there have been numerous reports

about the burden of RSV in the elderly, particularly those residing in nursing homes. Although there is relatively less data about RSV in the elderly compared to influenza, it is now recognized as an important contributor to morbidity in both community-dwelling elderly as well as in residents of long-term care facilities. This section will describe the epidemiology of RSV in both settings including clinical, diagnostic, and management issues.

## Characteristics of Respiratory Syncytial Virus

RSV is an enveloped RNA virus that can be classified into two major groups, A and B, based on antigenic and genetic properties. An important feature of RSV is that reinfections occur frequently throughout life and into older age. Because RSV infection does not produce robust immunity, developing a vaccine has been a major challenge.

## General Epidemiology

Like influenza, RSV circulates during winter months in temperate climates. Epidemics last for roughly 4 to 5 months beginning in the August and lasting until early spring. Often clinical cases precede influenza epidemics. In contrast to influenza, the distribution of cases of RSV over time is fairly constant. The incubation period of RSV is 3 to 5 days. The majority of those who are infected show respiratory symptoms. In contrast to infants who shed higher titres ( $10^{5-6}$  plaque forming units/mL of secretion) for longer time periods (10–14 days), adults tend to shed lower titres of the virus  $10^{2-3}$  plaque forming units/mL of secretion for 3 to 6 days. RSV is spread primarily by large droplets and fomites.

## Community-Dwelling Elderly and Respiratory Syncytial Virus

The best data about RSV in elderly persons living in the community is derived from a cohort study conducted in Rochester, New York, from 1999 to 2003. This cohort was comprised of 608 healthy persons aged 65 years and older. Forty-six (8%) of the 608 participants developed RSV, compared to 56 (10%) of high risk elderly participants (defined as having congestive heart failure or chronic pulmonary disease). The impact of RSV infection was important in both the healthy elderly group and in the high risk group: 17% and 23%, respectively, in these groups made physician office visits. Morbidity was greater in the high-risk group, where 16% required hospitalization. The study was also useful because it allowed for a comparison to influenza: 42% of healthy elderly participants and 60% of high-risk participants required office visits for influenza, rates statistically significant higher than for RSV. A limitation of these comparisons is that other characteristics were not adjusted for.

## Epidemiology of Respiratory Syncytial Virus in Long-term Care Facilities

Respiratory syncytial virus attack rates during nursing home outbreaks have been reported to be variable, ranging from 2% to 90%. However, most involved relatively small numbers of residents and included the use of diagnostic assays with varying levels of sensitivity. In one prospective study conducted in Rochester, where a sensitive enzyme immunoassay was used, the overall attack rate was 7% and the virus was identified as a cause of 27% of illness. One retrospective cohort study estimated the burden of illness in 81,000

nursing homes in Tennessee by linking cardiopulmonary hospitalization, medical utilization, and death to viral activity in the general community. According to these data, RSV accounted for 15 hospitalizations and 17 deaths per 1000 residents. However, these data are limited by the fact that the diagnosis of RSV was not confirmed at the individual level.

## Clinical Features of Respiratory Syncytial Virus in the Elderly

It is important to note that the clinical features of RSV cannot be distinguished from those of other viruses, such as influenza, with the exception that fever is less pronounced than for influenza. The nonspecific nature of the clinical presentation indicates the need for diagnostic testing. Signs and symptoms include rhinorrhea, nasal congestion, sore throat, cough, and dyspnea.

## Diagnosis

This can be done by viral culture, antigen detection in respiratory secretions, nucleic acid amplification, or serology. For diagnosis in real time, only the first three tests are appropriate. It is important to note that viral culture is only 50% sensitive. Similarly, detection of RSV antigens using immunofluorescence are insensitive in older adults. In contrast, reverse transcriptase-polymerase chain reaction (RT-PCR) is relatively sensitive and specific (73% and 90%, respectively).

## Therapy

Care is mainly supportive in the older adult with RSV infection, including rehydration if required, oxygen, and antipyretics. The only licensed antiviral with activity versus RSV is ribavirin. Unfortunately, there is sparse data on which to base treatment recommendations in adults. A practical consideration is that the administration of this aerosolized drug to older adults using face masks maybe difficult.

## Prevention

Transmission of RSV is believed to be caused by large droplet and fomites. Strategies such as increasing hand hygiene, particularly in nursing homes, may help to reduce spread. At the present time, there are no licensed RSV vaccines.

 exercise rehabilitation in, for intermittent claudication, 970–971  
 pathophysiology of, 968

- presentation of, 968–969
  - prevention of, 872
  - surgery for, 868
- Vascular malformations, intracranial
  - hemorrhage from, 794–795
- Vascular resistance, peripheral, 700, 976
- Vascular tests, noninvasive, 969
- Vasculature. *See also* Cardiovascular; specific vessels
  - arterial stiffening in, 900
  - in large arteries, 785
  - pulmonary, 887
  - structural and functional changes in, 404–408
- Vasculitis, drug-induced, 1467–1468
- Vasodilators, for heart failure, 787
- Vasopressin stimulation, 1050
- Vasopressin system, 1049–1050
- Vasopressin, basal plasma levels of, 1050
- Vasovagal syncope, 700–702, 955
  - evaluation of, 701
  - management of, 701–702
  - pathophysiology of, 700–701
  - presentation of, 701
- Vegetables, in cancer prevention, 1150
- Venlafaxine, for depression, 769
- Venous malformations, 794
- Venous stasis, in thrombotic disorders, 1244
- Venous thromboembolism (VTE), 1243–1252
  - diagnosis of, 1245–1249
  - prophylaxis for, long-term, 1250
  - renal vein thrombosis, 1249
  - risk factors for, 1244
  - superior vena cava syndrome, 1248
  - treatment of, 1249–1252
- Ventilation, mechanical, 175–177, 175f, 176t
  - noninvasive positive pressure, for chronic obstructive pulmonary disease, 530
- Ventricular arrhythmias
  - management of, 481–487
    - cardiac pacemaker therapy in
      - indications for, 952–953, 953t
      - indications for, standard, 952–953
      - indications for, with AV block, 953
      - indications for, with sinus node dysfunction, 954
    - ICD therapy in, 960
    - with ventricular ectopy, 951
    - with ventricular tachycardia and sudden cardiac death, 960–961
- Ventricular ectopy, 951, 996
- Ventricular tachycardia, management of, 960
- Ventricular vascular coupling, 885, 904
- Verbal abuse, 731, 732t. *See also* Mistreatment, elder
- Verbal fluency, 753, 754, 759t, 760
- Vertebral basilar arterial system, 781f
- Vertebral compression fracture, 1472, 1472t. *See also* Back pain
- Vertigo, 684–685, 687
- Vestibular disorders, dizziness from, 1544–1545
  - benign paroxysmal positional vertigo, 684–685
  - Ménière's disease, 684
- Vestibular disorders, dizziness from, 684
  - acoustic neuroma, 685
  - recurrent vestibulopathy, 685
- Vestibular rehabilitation, for dizziness, 690
- Vestibulocochlear system disorders
  - dizziness from, 687
- Vestibuloocular reflex, 688
- Vestibulopathy, recurrent, 685
- Veteran's Administration, 1170
- Viral encephalitis, 155, 492t
- Vision assessment, functional, 517
- Vision rehabilitation plan, 517–518
- Visual acuity, loss of, 512
- Visual field, attentional, 512–513
- Visual impairment, 513–515
  - age-related causes of, 513
    - cataract, 513–514
  - adaptation to vision loss in, 522
  - age-related causes of, 1225–1226, 1225t
    - diabetic retinopathy, 513
    - glaucoma, 514
    - macular degeneration, 513
  - assessment of, 100, 1227–1229
    - case history interview in, 515–516
    - clinical low-vision evaluation in, 516–517
  - environments for, 1232–1234, 1232t
    - alternative strategies in, 521–522
    - color in, 521
    - organizational strategies in, 521
  - family and social support in, 522
  - management of, 1229–1232
    - instruction & practice using remaining vision and low-vision devices in, 518
    - low-vision devices in, 518–519
    - instruction in use of, 519–520
    - reading with, 520
  - rehabilitation in
    - geriatrician role in, 515
    - low vision, funding for, 522–523
    - vision rehabilitation plan in, 517–518
  - psychosocial considerations in, 522
- Visuospatial skills, 753
  - assessment of, 157, 159
- Vital capacity, 229
- Vital organs, in aging, 373, 425
- Vitamin A
  - dietary requirements for, 449t
- Vitamin B<sub>1</sub>, dietary requirements for, 449t
- Vitamin B<sub>12</sub> deficiency of
  - causes of, 450t
  - evaluation and treatment of, 450t, 451t
  - macrocytic anemia from, 450
- Vitamin B<sub>2</sub>, dietary requirements for, 449t
- Vitamin B<sub>6</sub>, dietary requirements for, 449t
- Vitamin C, 452, 643
  - deficiency, 451–452
  - dietary requirements for, 449t
- Vitamin D
  - deficiency, 451–452
  - dietary requirements for, 449t

Vitamin E, 643, 743, 1014, 1508  
 dietary requirements for, 449t  
 in prostate cancer prevention, 1150–1151

Vitamin K  
 deficiency of, 1256, 1264t  
 dietary requirements for, 449t

Vitamin(s)  
 calcium and vitamin D, 1430–1431  
 folate (folic acid), 1459  
 recommended intakes of, 449  
 supplementation of, 449–450  
 vitamin B<sub>12</sub>, 450, 1256, 1431

VO<sub>2</sub> max, 1381–1391  
 changes in, 1381–1382  
 endurance exercise capacity and, 1381–1382  
 endurance exercise training on, 1383  
 peripheral components of, 1382

Von Willebrand's disease, 1259, 1262

Vulva, 585–587
