Contents

Section I Physiology of Aging

1. Invited Commentary	3
Jesse Roth	
2. Cell and Molecular Aging	5
Priyamvada Rai and Bruce R. Troen	
3. Cancer, Carcinogenesis, and Aging	39
Lodovico Balducci	
4. Effects of Aging on Immune Function	49
Raymond P. Stowe and James S. Goodwin	
5. Hematological Changes, Anemia, and Bleeding in Older Persons	69
Bruce O. Hough and Gurkamal S. Chatta	
6. Invited Commentary	83
Stanley J. Dudrick	
7. Nutrition	87
Sandhya A. Lagoo-Deenadayalan and Danny O. Jacobs	
8. Wound Healing in the Elderly	107
Guy P. Marti, Lixin Liu, Xianjie Zhang, Dongmei Xing, Denise C. King, Angela R. Kohli, Maura Reinblatt, William B. Greenough, and John W. Harmon	
9. Frailty and Surgery in the Elderly	129
Babak J. Orandi, Jordan M. Winter, Dorry L. Segev, and Martin A. Makary	

Section II Social/Societal Issues

10. Invited Commentary	137
Michael E. Zenilman	
11. The Demography of Aging and Disability	139
Samir K. Sinha and Colleen Christmas	
12. Providing Surgical Care to an Aging Population: Implications for the Surgical Workforce	153
David A. Etzioni and Clifford Y. Ko	

13. Defining Quality of Care in Geriatric Surgery	171
Marcia L. McGory, Hiroko Kunitake, and Clifford Y. Ko	
14. Ethics in Clinical Practice	179
Margaret Drickamer	
15. Teaching Geriatrics to Surgeons	189
Hugh L. Willcox III, Darin L. Passer, and Richard M. Bell	
16. Palliative Care and Decision Making at the End of Life	197
Melissa F. Perkal	
17. Surgery in Centenarians	211
Mark R. Katlic	
18. The Effect of Advancing Age on Physician Performance	223
Jennifer F. Waljee and Lazar J. Greenfield	
 Section III Perioperative Issues	
19. Invited Commentary	233
Ben Eiseman	
20. Principles of Geriatric Surgery	235
Mark R. Katlic	
21. Geriatric Models of Care	253
Elizabeth A. Capezuti, Marie Boltz, and Hongsoo Kim	
22. Preoperative Evaluation of the Older Surgical Patient	267
Lisa M. Walke and Ronnie A. Rosenthal	
23. Invited Commentary	289
Jerry G. Reves	
24. Physiologic Response to Anesthesia in the Elderly	291
Aaron N. LacKamp and Frederick E. Sieber	
25. Choosing the Best Anesthetic Regimen	305
Sheila R. Barnett	
26. Acute Postoperative Pain Management in Elderly Patients	321
Jack M. Berger	
27. Drug Usage in Surgical Patients: Preventing Medication-Related Problems	343
Richard A. Marottoli, Sean M. Jeffery, and Roshini C. Pinto-Powell	
28. Invited Commentary	359
Donald D. Trunkey	
29. Common Perioperative Complications in Older Patients	361
Sandhya A. Lagoo-Deenadayalan, Mark A. Newell, and Walter E. Pofahl	

30. Management and Outcomes of Intensive Care in the Geriatric Surgical Patient	377
Gary T. Marshall and Scott R. Gunn	
31. Care of the Injured Elderly	391
Jay Menaker and Thomas M. Scalea	
32. Maximizing Postoperative Functional Recovery	411
Leo M. Cooney	
 Section IV Endocrine System/Breast	
33. Invited Commentary	419
Samuel A. Wells	
34. Surgical Disorders of the Thyroid in the Elderly	421
Leslie S. Wu, Julie Ann Sosa, and Robert Udelsman	
35. Parathyroid Disease in the Elderly	439
Leslie S. Wu, Sanziana A. Roman, and Robert Udelsman	
36. Adrenal Tumors in Older Persons	455
Tobias Carling and Robert Udelsman	
37. Benign Breast Disease in Elderly Women and Men	469
Kay O. Lovig and Barbara A. Ward	
38. Breast Cancer in Elderly Women	479
Monica Morrow and Lisa S. Wiechmann	
39. Diabetes in the Elderly	493
Klara Rosenquist and Kitt F. Petersen	
 Section V Oral Cavity, Eyes, Ears, Nose and Throat	
40. Invited Commentary	499
Frank E. Lucente	
41. Changes in the Oral Cavity with Age	501
Susan Pugliese and Ajay R. Kashi	
42. Geriatric Ophthalmology	513
Andrew G. Lee and Hilary A. Beaver	
43. Anatomic and Physiologic Changes in the Ears, Nose, and Throat	525
Ara A. Chalian and Sarah H. Kagan	
44. Geriatric Dysphagia	539
Neil N. Chheda, Gregory N. Postma, and Michael M. Johns	
45. Head and Neck Cancer in the Elderly	553
Babak Givi and Ashok R. Shaha	

Section VI Respiratory System

46. **Invited Commentary** 591
Earle W. Wilkins Jr.
47. **Physiologic Changes in Respiratory Function** 595
Edward J. Campbell
48. **Pulmonary Surgery for Malignant Disease in the Elderly** 605
Sarah E. Billmeier and Michael T. Jaklitsch

Section VII Cardiovascular System

49. **Invited Commentary** 619
Timothy J. Gardner
50. **Physiologic Changes in Cardiac Function with Aging** 621
Wilbert S. Aronow and William H. Frishman
51. **Risk Factors for Atherosclerosis in the Elderly** 635
Wilbert S. Aronow and William H. Frishman
52. **Cardiac Surgery in the Elderly** 649
Margarita T. Camacho and Pooja R. Raval
53. **Invited Commentary** 661
Frank J. Veith
54. **Surgical Treatment of Vascular Occlusive Disease** 663
Amanda Feigel and Alan Dardik
55. **Natural History and Treatment of Extracranial Cerebrovascular Disease in the Elderly** 673
George H. Meier and Carlos Rosales
56. **Natural History and Treatment of Aneurysms** 689
Michael Wilderman and Gregorio A. Sicard

Section VIII Gastrointestinal System

57. **Invited Commentary** 709
Courtney M. Townsend Jr.
58. **Age-Related Changes in the Gastrointestinal Tract** 711
Nefertiti A. Brown, Joshua L. Levine, and Michael E. Zenilman
59. **Benign Esophageal Diseases in the Elderly** 729
Prathima Kanumuri and Neal E. Seymour
60. **Esophageal Cancer in the Elderly** 747
Philip A. Rascoe, John C. Kucharzuk, and Larry R. Kaiser
61. **Benign Diseases of Stomach and Duodenum** 763
Daniel Borja-Cacho and Selwyn M. Vickers

62. Gastric Cancer in the Elderly	781
Daniel Albo, Daniel A. Anaya, and David H. Berger	
63. Small Bowel Obstruction in the Elderly	793
Kelley A. Sookraj and Wilbur B. Bowne	
64. Lower Gastrointestinal Bleeding in the Elderly	807
Sylvia S. Kim and Michael E. Zenilman	
65. Ischemic Disorders of the Large and Small Bowel	819
Jack R. Oak and Gregorio A. Sicard	
66. Surgery for Inflammatory Bowel Disease in the Elderly	837
Stefan D. Holubar and Bruce G. Wolff	
67. Diverticulitis and Appendicitis in the Elderly	857
Scott C. Thornton	
68. Benign Colorectal Disease	877
Elisa H. Birnbaum	
69. Neoplastic Diseases of the Colon and Rectum	889
Aundrea L. Oliver, Stanley W. Ashley, and Elizabeth Breen	
70. Abdominal Wall Hernia in the Elderly	907
Catherine Straub and Leigh Neumayer	

Section IX Hepatobiliary System

71. Invited Commentary	929
Seymour I. Schwartz	
72. Hepatobiliary and Pancreatic Function: Physiologic Changes	931
Vadim Sherman and F. Charles Brunnicardi	
73. Benign Disease of the Gallbladder and Pancreas	945
Jennifer A. Wargo and Kim U. Kahng	
74. Malignant Diseases of the Gallbladder and Bile Ducts	967
Steven A. Ahrendt and Thomas H. Magnuson	
75. Benign and Malignant Neoplasms of the Exocrine Pancreas	985
Kathryn M. Dalbec and Keith D. Lillimoe	
76. Benign and Malignant Tumors of the Liver	1007
Anita Kit Wan Chiu and Yuman Fong	

Section X Urogenital System

77. Invited Commentary	1023
George W. Drach	
78. Change in Renal Function, Fluids, and Electrolytes	1025
Juan F. Macías-Núñez and Manuel Martínez-Maldonado	

79. Urinary Incontinence in the Elderly	1039
Pat O'Donnell	
80. Neoplasms of the Kidney and Bladder	1049
Edward M. Uchio, Juan S. Calderon, and Jonathan J. Hwang	
81. Benign and Malignant Diseases of the Prostate	1069
John A. Taylor III and Peter C. Albertsen	
82. Benign Gynecologic Disorders in the Older Women	1083
Kimberly A. Gerten, W. Jerod Greer, C. Bryce Bowling, Thomas Wheeler II, and Holly E. Richter	
83. Gynecologic Malignancies in the Elderly	1101
Dan-Arin Silasi, Peter E. Schwartz, and Thomas J. Rutherford	

Section XI Nervous System

84. Invited Commentary	1119
Dennis Spencer	
85. Effects of Aging on the Nervous System	1121
Howard A. Crystal, Pedro J. Torrico, Shefali Gandhi, and Paul J. Maccabee	
86. Geriatric Neurosurgical Emergencies	1135
Toral R. Patel and Joseph T. King Jr.	
87. Benign and Malignant Tumors of the Brain	1151
Andrew D. Norden and Elizabeth B. Claus	
88. Spinal Disorders and Nerve Compression Syndromes	1165
Arash Yaghoobian and John M. Olsewski	

Section XII Musculoskeletal System and Soft Tissue

89. Invited Commentary	1197
Roby C. Thompson Jr.	
90. Age-Related Changes in Bone and Soft Tissue	1201
David Rispler and Susan M. Day	
91. Common Benign and Malignant Skin Lesions	1221
Marcus A. McFerren and David J. Leffell	
92. Surgical Management of Soft Tissue Sarcoma in the Geriatric Population	1245
Charlotte E. Ariyan and Murray F. Brennan	
93. Pressure Sores in the Elderly	1257
Alexander Y. Lin and Mary H. McGrath	
94. Orthopaedic Trauma in the Elderly	1273
William Min, Kenneth A. Egol, and Joseph D. Zuckerman	

95. Treatment of Degenerative Joint Diseases	1293
Philip J. Glassner, James Slover, and Joseph D. Zuckerman	
Section XIII Transplantation	
96. Invited Commentary	1319
Khalid M.H. Butt	
97. Elderly Donors in Transplantation	1321
Manuel Mendizabal, John W. Hsu, and Abraham Shaked	
98. Elderly Transplant Recipients	1335
Aaron M. Winnick, Ilhan Karabicak, and Dale A. Distant	
Index	1351

Contributors

Steven A. Ahrendt, MD

Associate Professor of Surgery, Department of Surgery, University of Pittsburgh, UPMC Cancer Center, Pittsburgh, PA, USA

Peter C. Albertsen, MD

Professor, Department of Surgery, Division of Urology, University of Connecticut Health Center, Farmington, CT, USA

Daniel Albo, MD, PhD

Department of Surgery, Baylor College of Medicine, Michael E. DeBakey Veterans Affairs Medical Center, Houston, TX, USA

Daniel A. Anaya, MD

Assistant Professor of Surgery, Michael E. DeBakey Department of Surgery, Baylor College of Medicine, Houston, TX, USA

Charlotte E. Ariyan, MD, PhD

Assistant Attending, Department of Surgery, Memorial Sloan-Kettering Cancer Center, New York, NY, USA

Wilbert S. Aronow, MD, FACC, FAHA

Cardiology Division, New York Medical College, Macy Pavilion, Valhalla, NY, USA

Stanley W. Ashley, MD

Frank Sawyer Professor and Vice Chair of Surgery, Department of Surgery, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

Lodovico Balducci, MD

Chief, Senior Adult Oncology Program, H. Lee Moffitt Cancer Center and Research Institute, Tampa, FL, USA

Asha G. Bale, MD

Assistant Professor of Surgery, Department of Surgery, New Jersey Medical School/ University Hospital, Newark, NJ, USA

Sheila R. Barnett, MD

Department of Anesthesiology, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA, USA

Hilary A. Beaver, MD

Associate Professor, Department of Ophthalmology, University of Iowa, Iowa City, IA, USA

Richard M. Bell, MD, FACS

Professor and Chairman, Department of Surgery, University of South Carolina School of Medicine, Columbia, SC, USA

David H. Berger, MD, MHCM

Professor and Vice Chair, Chief Division of General Surgery and Surgical Oncology;
Operative Care Line Executive, Michael E. DeBakey Department of Surgery,
Baylor College of Medicine, Houston, TX, USA; Michael E. DeBakey Veterans Affairs
Medical Center, Houston, TX, USA

Jack M. Berger, MS, MD, PhD

Professor of Clinical Anesthesiology, Department of Anesthesiology,
Keck School of Medicine, University of Southern California, LAC + USC Medical Center,
Los Angeles, CA, USA

Sarah E. Billmeier, MD

Resident, General Surgery, Brigham and Women's Hospital, Boston, MA, USA

Elisa H. Birnbaum, MD

Professor of Surgery, Department of Surgery, Barnes Jewish Hospital,
Washington University School of Medicine, St. Louis, MO, USA

Marie Boltz, PhD, RN

Assistant Professor, Hartford Institute for Geriatric Nursing,
New York University College of Nursing, New York, NY, USA

Daniel Borja-Cacho, MD

Hepatobiliary Fellow, Department of Surgery, University of Minnesota, Minneapolis,
MN, USA

C. Bryce Bowling, MD

Instructor/Fellow, Division of Women's Pelvic Medicine and Reconstructive Surgery,
Department of Obstetrics and Gynecology, University of Alabama at Birmingham
Medical Center, Birmingham, AL, USA

Wilbur B. Bowne, MD

Department of Surgery, SUNY Downstate Medical Center, Brooklyn, NY, USA

Elizabeth Breen, MD

Department of Surgery, Brigham and Women's Hospital, Harvard Medical School,
Boston, MA, USA

Murray F. Brennan, MD

Benno C. Schmidt Chair in Clinical Oncology, Department of Surgery,
Memorial Sloan-Kettering Cancer Center, New York, NY, USA

Nefertiti A. Brown, MD

Department of Surgery, SUNY Downstate Medical Center,
Brooklyn, NY, USA

F. Charles Brunnicardi, MD

Professor and Chairman, Michael E. DeBakey Department of Surgery,
Baylor College of Medicine, Houston, TX, USA

Khalid M.H. Butt, MD, FRCS(Eng), FACS

Department of Surgery – Transplant Section, Westchester Medical Center,
Valhalla, NY, USA

Juan S. Calderon, MD

Department of Urology, VA Connecticut Healthcare System, West Haven, CT, USA

Margarita T. Camacho, MD

Surgical Director, Cardiac Transplantation and Mechanical Heart Program, Department
of Cardiothoracic Surgery, Newark Beth Israel Medical Center, Newark, NJ, USA

Edward J. Campbell, MD

Department of Internal Medicine, University of Utah Health Sciences Center, Salt Lake City, UT, USA

Elizabeth A. Capezuti, PhD, RN, FAAN

Hartford Institute for Geriatric Nursing, NYU College of Nursing, New York, NY, USA

Tobias Carling, MD, PhD

Associate Professor of Surgery, Department of Surgery, Yale University School of Medicine, New Haven, CT, USA

Ara A. Chalian, MD

Department of Otorhinolaryngology: Head and Neck Surgery, Hospital of the University of Pennsylvania, Philadelphia, PA, USA

Gurkamal S. Chatta, MD

Associate Professor of Medicine, Division of Hematology-Oncology; Chief, Division of Hematology-Oncology, Department of Medicine, University of Pittsburgh Medical Center, Pittsburgh, PA, USA; Veterans Administration Public Health System, Pittsburgh, PA, USA

Neil N. Chheda, MD

Assistant Professor, Department of Otolaryngology, University of Florida, Gainesville, FL, USA

Anita Kit Wan Chiu, MD

Resident, Department of General Surgery, SUNY Downstate Medical Center, Brooklyn, NY, USA

Colleen Christmas, MD

Program Director, Johns Hopkins Bayview Medical Center, Baltimore, MD, USA

Elizabeth B. Claus, MD, PhD

Attending Neurosurgeon, Department of Neurosurgery, Brigham and Women's Hospital, Boston, MA, USA

Leo M. Cooney, Jr. MD

Yale-New Haven Hospital, New Haven, CT, USA

Howard A. Crystal, MD

Professor of Neurology, Department of Neurology, SUNY Downstate Medical Center, Brooklyn, NY, USA

Kathryn M. Dalbec, MD

Department of Surgery, Indiana University Hospital, Indianapolis, IN, USA

Alan Dardik, MD, PhD

Associate Professor of Surgery, Department of Surgery, Yale University School of Medicine, New Haven, CT, USA

Susan M. Day, MD

Orthopaedic Surgeon; Clinical Instructor, Department of Surgery, Michigan State University College of Human Medicine, Grand Rapids, MI, USA

Edwin A. Deitch, MD

Professor and Chairman, Department of Surgery, New Jersey Medical School/University Hospital, Newark, NJ, USA

Dale A. Distant, MD

Professor of Clinical Surgery, Department of Transplant Surgery, SUNY Downstate Medical Center, Brooklyn, NY, USA

George W. Drach, MD, FACS

Professor Emeritus of Urology in Surgery, Department of Surgery/Urology, Hospital of the University of Pennsylvania, Philadelphia, PA, USA

Margaret Drickamer, MD

Professor of Medicine, Department of Medicine (Geriatrics), Yale University School of Medicine, New Haven, CT, USA

Stanley J. Dudrick, MD

Professor of Surgery, Department of Surgery, Yale University School of Medicine, Saint Mary's Hospital/Yale Affiliate, Waterbury, CT, USA

Kenneth A. Egol, MD

Associate Professor, Vice Chairman and Chief of Trauma, Department of Orthopaedic Surgery, New York University Hospital for Joint Diseases, New York, NY, USA

Ben Eiseman, MD, MSc, FACS

Department of Surgery, Denver Veterans Affairs Hospital, University Hospital, Denver, CO, USA

David A. Etzioni, MD, MSHS

Department of Surgery, Mayo Clinic Arizona, Mayo Clinic College of Medicine, Phoenix, AZ, USA

Amanda Feigel, MD

Department of Surgery, Yale University School of Medicine, New Haven, CT, USA

Yuman Fong, MD

Murray F. Brennan Chair in Surgery, Department of Surgery, Memorial Sloan Kettering Cancer Center, New York, NY, USA

William H. Frishman, MD, MACP

Rosenthal Professor & Chairman Cardiology Division, New York Medical College, Macy Pavilion, Valhalla, NY, USA

Shefali Gandhi, DO, MPH

Clinical Neurophysiology Fellow, Department of Neurology, SUNY Downstate Medical Center, Brooklyn, NY, USA

Timothy J. Gardner, MD

Center for Heart & Vascular Health, Christiana Health Care System, Newark, DE, USA

Kimberly A. Gerten, MD

Instructor/Fellow, Division of Women's Pelvic Medicine and Reconstructive Surgery, Department of Obstetrics and Gynecology, University of Alabama at Birmingham Medical Center, Birmingham, AL, USA

Babak Givi, MD

Head & Neck Surgery Fellow, Head & Neck Surgery Section, Department of Surgery, Memorial Sloan Kettering Cancer Center, New York, NY, USA

Philip J. Glassner, MD

Resident, Department of Orthopaedic Surgery, NYU Hospital for Joint Diseases, New York, NY, USA

James S. Goodwin, MD

Mitchell Distinguished Chair in Geriatric Medicine, University of Texas Medical Branch, Sealy Center on Aging, Galveston, TX, USA

Lazar J. Greenfield, MD

Professor of Surgery and Chair Emeritus, Department of Surgery, University of Michigan, Ann Arbor, MI, USA

William B. Greenough, MD

Professor, Division of Geriatric Medicine, Johns Hopkins Bayview Medical Center, Baltimore, MD, USA

W. Jerod Greer, MD

Instructor/Fellow, Division of Women's Pelvic Medicine and Reconstructive Surgery, Department of Obstetrics and Gynecology, University of Alabama at Birmingham Medical Center, Birmingham, AL, USA

Scott R. Gunn, MD

Associate Professor of Critical Care Medicine and Emergency Medicine, Department of Critical Care Medicine, University of Pittsburgh Medical Center, Pittsburgh, PA, USA

John W. Harmon, MD, FACS

Professor of Surgery, Department of Surgery, Johns Hopkins Bayview Medical Center, Baltimore, MD, USA

Stefan D. Holubar, MD

Colon and Rectal Surgery Fellow, Division of Colon and Rectal Surgery, Dartmouth Medical School, Dartmouth-Hitchcock Medical Center, Lebanon, NH, USA

Bruce O. Hough, MD

Fellow, Division of Hematology/Oncology, University of Pittsburgh Medical Center, Pittsburgh, PA, USA

John W. Hsu, MD

Transplant Surgery Fellow, Division of Surgery, University of Pennsylvania Transplant Institute, Hospital of the University of Pennsylvania, Philadelphia, PA, USA

Jonathan J. Hwang, MD

Associate Professor, Department of Urology, Georgetown University School of Medicine, Washington Hospital Cancer/Georgetown University Hospital, Washington, DC, USA

Danny O. Jacobs, MD, MPH

David C. Sabiston, Jr. Professor and Chairman, Surgeon-in-Chief, Department of Surgery, Duke University Hospital, Durham, NC, USA

Michael T. Jaklitsch, MD

Associate Professor of Surgery, Department of Thoracic Surgery, Brigham and Women's Hospital, Boston, MA, USA

Sean M. Jeffery, PharmD

Associate Clinical Professor; Adjunct Assistant Professor, University of Connecticut School of Pharmacy, Storrs, CT, USA; Yale University School of Medicine, VA Connecticut Healthcare System, West Haven, CT, USA

Michael M. Johns, III MD

Director – Emory Voice Center; Assistant Professor, Department of Otolaryngology, Emory University School of Medicine, Emory University Hospital, Atlanta, GA, USA

Sarah H. Kagan, PhD, RN

School of Nursing, University of Pennsylvania, Philadelphia, PA, USA

Kim U. Kahng, MD

Associate Director, Women's Health Education Program, Department of Medicine, Drexel University College of Medicine, Philadelphia, PA, USA

Larry R. Kaiser, MD

President, Alkek-Williams Distinguished Physician Endowed Chair; Professor of Cardiothoracic Surgery, University of Texas Health Science Center at Houston, Houston, TX, USA

Prathima Kanumuri, MD

Department of Surgery, Baystate Medical Center, Springfield, MA, USA

Ilhan Karabicak, MD

Fellow, Department of Transplant Surgery, SUNY Downstate Medical Center, Brooklyn, NY, USA

Ajay R. Kashi, DDS, MS

PhD Candidate, Department of Orthopaedic Surgery and Rehabilitation Medicine, State University of New York Downstate Medical Center, Brooklyn, NY, USA

Mark R. Katlic, MD, MMM, FACS

Division of Thoracic Surgery, Director, Regional Ambulatory Campus Geisinger Wyoming Valley Medical Center, Wilkes-Barre, PA, USA

Hongsoo Kim, PhD, MPH

Assistant Professor, Department of Health Policy and Management, Graduate School of Public Health, Seoul National University, Seoul, South Korea

Sylvia S. Kim, MD

Assistant Professor of Surgery, Department of Colorectal and General Surgery, SUNY Downstate Medical Center, Brooklyn, NY, USA

Denise C. King, RN, BSN, WCC

Wound Program Manager, Department of Wound Management, Johns Hopkins Bayview Care Center, Baltimore, MD, USA

Joseph T. King Jr., MD, MSCE

Chief of Neurosurgery, VA Connecticut Healthcare System Chair, VA Neurosurgery Surgical Advisory Board; Associate Professor of Neurosurgery, Director of Outcomes Research, Department of Neurosurgery, Yale University School of Medicine, West Haven, CT, USA

Clifford Y. Ko, MD, MS, MSHS, FACS

Professor of Surgery and Health Services, Robert and Kelly Chair in Surgical Outcomes, Department of Surgery, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Angela R. Kohli, BSN, WOCN, CWCN

Ambulatory Services Manager, Johns Hopkins Wound Healing Center/Dermatology, Johns Hopkins Bayview Medical Center, Baltimore, MD, USA

John C. Kucharczuk, MD

Assistant Professor of Surgery, Department of Thoracic Surgery, University of Pennsylvania, Philadelphia, PA, USA

Hiroko Kunitake, MD

Surgical Resident, Department of Surgery, Massachusetts General Hospital, Boston, MA, USA

Aaron N. LaKamp, MD

Clinical Associate, Department of Anesthesiology and Critical Care Medicine, Johns Hopkins Bayview Medical Center, Baltimore, MD, USA

Sandhya A. Lagoo-Deenadayalan, MD, PhD

Assistant Professor of Surgery, Department of Surgery, Duke University Hospital, Durham, NC, USA

Andrew G. Lee, MD

Professor of Ophthalmology, Neurology and Neurosurgery, Department of Ophthalmology, University of Iowa Hospitals and Clinics, Iowa City, IA, USA

David J. Leffell, MD

David Paige Smith Professor of Dermatology & Surgery, Yale New Haven Hospital, Department of Dermatology, Yale University School of Medicine, New Haven, CT, USA

Joshua L. Levine, MD

Director of Surgical Services, Department of Plastic and Reconstructive Surgery, New York Eye and Ear Infirmary, New York, NY, USA

Keith D. Lillimoe, MD

Jay L. Grosfeld Professor and Chairman, Department of Surgery, Indiana University School of Medicine, Indianapolis, IN, USA

Alexander Y. Lin, MD

Former Chief Resident, UCSF Plastic Surgery, University of California San Francisco, San Francisco, CA, USA; Assistant Professor of Surgery, Division of Plastic Surgery, Saint Louis University Director, St. Louis Cleft-Craniofacial Center, Cardinal Glennon Children's Medical Center at SLU, St. Louis, MO, USA

Lixin Liu, PhD

Postdoctoral Fellow, Department of Surgery, Johns Hopkins Bayside Medical Center, Baltimore, MD, USA

Kay O. Lovig, MD

Department of Internal Medicine, Greenwich Hospital, Greenwich, CT, USA

Frank E. Lucente, MD

Vice-Dean for Graduate Medical Education; Professor, Department of Otolaryngology, Downstate Medical Center, State University of New York, Brooklyn, NY, USA

Paul J. Maccabee, MD

Professor of Neurology, Department of Neurology, State University Hospital of Brooklyn, Brooklyn, NY, USA

Juan F. Macías-Núñez, MD, PhD

Titular Professor of Medicine, Department of Nephrology, Chief Section of Nephrology, University Hospital, Salamanca, Spain

Thomas H. Magnuson, MD

John's Hopkins Bayview Medical Center, Baltimore, MD, USA

Martin A. Makary, MD

The Mark Ravitch Chair, General Surgery, Associate Professor of Health Policy, Department of Surgery, Johns Hopkins Hospital, Baltimore, MD, USA

Richard A. Marottoli, MD, MPH

Associate Professor of Medicine, Department of Internal Medicine (Geriatrics)
Yale University School of Medicine, VA Connecticut Healthcare System,
New Haven, CT, USA

Gary T. Marshall, MD

Assistant Professor of Surgery, Department of Trauma Surgery, University of Pittsburgh
Medical Center, Pittsburgh, PA, USA

Guy P. Marti, MD

Department of Surgery, Johns Hopkins Bayview Medical Center, Baltimore, MD, USA

Manuel Martínez-Maldonado, MD

Executive Vice President for Research, University of Louisville; Professor of Medicine,
Professor of Pharmacology and Toxicology, University of Louisville Medical School,
Louisville, KY, USA

Marcus A. McFerren, MD, PhD

Resident Physician, Yale New Haven Hospital, Department of Dermatology,
Yale University School of Medicine, New Haven, CT, USA

Marcia L. McGory, MD

Resident Surgeon, Department of Surgery, David Geffen School of Medicine at the
University of California, Los Angeles, CA, USA

Mary H. McGrath, MD, MPH, FACS

Assistant Professor of Surgery, Division of Plastic Surgery,
University of California San Francisco, San Francisco, CA, USA

George H. Meier, MD

Professor and Chief, Department of Vascular Surgery, University Hospital of Cincinnati,
Cincinnati, OH, USA

Jay Menaker, MD

Assistant Professor, Department of Surgery, University of Maryland Medical Center,
R. Adams Cowley Shock Trauma Center, Baltimore, MD, USA

Manuel Mendizabal, MD

Staff Hepatologist, Division of Hepatology and Liver Transplantation, Austral University
Hospital Pilar, Buenos Aires, Argentina

William Min, MD, MS, MBA

Resident, Department of Orthopaedic Surgery, NYU Hospital for Joint Diseases,
New York, NY, USA

Monica Morrow, MD

Breast Service, Department of Surgery, Memorial Sloan-Kettering Cancer Center,
New York, NY, USA

Leigh Neumayer, MD, MS

Professor of Surgery, Department of Surgery, University of Utah and Huntsman
Cancer Hospital, Salt Lake City, UT, USA

Mark A. Newell, MD

Assistant Professor, Department of Surgery, Brody School of Medicine, East Carolina
University, Pitt County Memorial Hospital, Greenville, NC, USA

Andrew D. Norden, MD

Department of Neurology, Center for Neuro-Oncology, Dana-Farber Cancer Institute,
Brigham and Women's Hospital, Harvard Medical School,
Boston, MA, USA

Jack R. Oak, MD

Vascular Surgery Fellow, Department of Vascular Surgery, Barnes-Jewish Hospital, University of Washington School of Medicine, St. Louis, MO, USA

Pat O'Donnell, MD

Department of Surgery, University of Arkansas for Medical Sciences, Little Rock, AR, USA

Aundrea L. Oliver, MD

Resident, Department of Surgery, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

John M. Olsewski, MD, FACS

Associate Professor of Orthopaedic Surgery, Department of Orthopaedic Surgery, Albert Einstein College of Medicine, Bronx, NY, USA

Babak J. Orandi, MC, MSc

Halsted Surgery Resident, Department of Surgery, Johns Hopkins Hospital, Baltimore, MD, USA

Darin L. Passer, MD

General Surgery Resident, Department of Surgery, University of South Carolina, Palmetto Health Richland, Columbia, SC, USA

Toral R. Patel, MD

Neurosurgery Resident, Yale-New Haven Hospital, Yale University School of Medicine, New Haven, CT, USA

Melissa F. Perkal, MD

Chapter 1

Invited Commentary

Jesse Roth

Get in league with the future.

Horace Greeley

The Future

By reading this piece, you are identifying yourself as a part of the vanguard in geriatric surgery. Textbooks of surgery and textbooks of geriatrics cover geriatric surgery very sparingly. You have chosen to tackle a textbook on geriatric surgery.

Demographics and Dollars

The elderly are the fastest growing segment of the population, with the so-called old-old in the lead. The elderly are highly overrepresented in the hospital population and in the medical expenses column. The application more widely of basic well-established principles of care for the elderly will almost certainly reduce the number of elderly in the hospital and increase the return on money spent. Most important, we can expect better outcomes for the elderly patients, especially for those who were hospitalized. Hospitalization and surgery are each serious threats for the elderly patient.

Geriatrics Is a Frontier

“Go West, young man,” [1] was an exhortation to move from the built up to the new, the frontier, the so-called cutting edge. Geriatrics as a branch of medicine is young and is having a

growth spurt. The subspecialties in medicine are increasing their attention to issues related to care for the elderly. In geriatric surgery, the frontiers are open.

History provides us with some models. Harvey Cushing was one of the twentieth century’s giants, a pioneer. In the early years of the twentieth century, with great daring and deep thought, he took principles of general surgery and very meticulously applied them to the brain. In addition to his skills in the operating theater, he gave his patients extraordinarily attentive care, before surgery as well as after. Indeed, infection rates on his patients in the pre-antibiotic area, would win a commendation medal today. Today we revere him as the father of neurosurgery [2].

Pediatrics emerged from adult medicine at about the same time [3]. Now pediatrics has a complete array of sub-specialists covering all aspects of care for the young. When I was a medical student 50 years ago, pediatric surgery was just coming into its own. Now it is a well-established subspecialty.

Quest for Excellence

As the age of the patient increases, the gap grows that separates the *good physician* from the *excellent physician*. A similar gap shows itself as the age of the child decreases. The premature baby and the frail elderly share many features. One very big difference – pediatrics, pediatric surgery, pediatric nursing, neonatology, pediatric gastroenterology, pediatric endocrinology, and their cousins are well-developed areas of expertise with highly trained practitioners. Their counterparts in the care of the elderly are fewer and are less deeply trained. It is much more difficult for physicians involved in the care of an elderly patient to get expert help than it is for the doctor caring for a child. Worse yet, the adult physicians (and other medical providers) who are inadequately trained in geriatric care are often unaware of their deficiencies.

e-mail: jesserothmd@hotmail.com

Fifty years ago, all of us were deficient as well as unaware of our deficiencies in care of the elderly. I have clear memories of a man in his eighties cared for by me and by a surgeon. The surgery was successful but the patient had a series of complications and died. Today, I can think of many useful interventions that were unknown and unused by us in those days.

The Challenge

The elderly patient is intrinsically more complex and challenging than the equally ill youngster. The young patient typically has one disease – complications and medications are few. The older patient classically has multiple conditions and a long list of medications, co-conspirators that blur the diagnosis and complicate the therapy. Laboratory values in young patients have established norms developed in young people. Normal ranges for the elderly are much less reliable, often guesses, appropriated with little testing from a much younger age group. Family responsibility for the young patient has a well-defined societal pattern whereas family links to the elderly patient are very variable and may require high level diplomacy. Yet, optimal outcomes for the young patient and for the old often require skillful and energetic family involvement.

Medical decisions with an elderly patient require professional skills at their best. The physician may start with an evidence-based algorithm conceived on experience with younger patients but the plan needs to be custom made for the particular patient at hand. In addition to deciding which tests and which surgery should be done, an important part of the care is deciding which tests and which surgery should not be performed. Even when a patient fulfills all the criteria for surgery, good judgment may modify or veto that decision for an elderly patient.

Medical Care from Here to the Future

Someday, care for the elderly will be totally in the hands of skilled caregivers who are highly trained in geriatrics, as exists now in pediatrics. Today, individual caregivers must gain multiple skills in many aspects of caring for the elderly. There are unique opportunities at your medical center to be among the pioneers who are importing best geriatric practices into surgery. In addition, you need to search for and

recruit as advisors the minority of health care deliverers in your community who are skilled in caring for the geriatric patient.

Learning, teaching, and research opportunities will abound.

Scientific Advances in Geriatrics

The opening chapters of this book tackle several important scientific areas related to aging and the elderly patient. I recall meetings in geriatrics 20 years ago when the papers dealing with lab studies on aging fit a single track for 1 day. Now multiple tracks on multiple days are needed. The scientific basis of bone health, muscle wasting, and longevity are each a rich lode of discovery. The coming age of science in geriatrics is best epitomized by studies of cell aging that led to the 2009 Nobel Prize for pioneer work on telomeres.

The Road Ahead for the Physician

Intense focus in a well-circumscribed area can add great value to the physician's effort. These efforts often translate into shorter less expensive stays in the hospital, a language understood by administrators. At a time when burnout is increasingly widespread among physicians, these efforts can also be very rewarding to the professional soul.

Treatment for burnout has a poor prognosis. Prevention is more likely to succeed. Given the large loan balances and uncertain retirement programs that burden young physicians, the journey ahead may be unexpectedly long. Passionate commitment to a segment of one's professional life may be the key to a long happy satisfying medical career at this difficult time. Care for the elderly is energized by a pioneer spirit that makes it especially attractive for a long career.

Introduction

Discussions of aging invariably begin by establishing a satisfactory definition for the term *aging* and the related word *senescence*. Although the term *aging* is commonly used to refer to postmaturational processes that lead to diminished homeostasis and increased organismic vulnerability, the more correct term for this is *senescence* (derived from the Latin word “senescere,” meaning to grow old or to diminish), which explicitly refers to the process of growing old and sustaining related deterioration. *Aging* on the other hand can refer to any time-related process. We will use *senescence* to refer to cellular phenomena and *aging* to refer to changes, as organisms grow old.

Gerontologists often categorize the process of aging into normal, usual, or successful aging. *Normal* aging involves inexorable and universal physiological changes, whereas *usual* aging includes age-related diseases. For example, menopause and the decline in renal function represent aspects of normal aging. In contrast, coronary artery disease is an example of usual aging and is not found in all older persons. *Successful* aging encompasses the concept of growing older without significant impairment of physiological, cognitive,

and social function. This approach to aging enables the utilization of a conceptual framework that identifies intrinsic (developmental-genetic) versus extrinsic (stochastic) causes. However, accumulating evidence increasingly stresses the importance of both. Indeed, the altered homeostasis in older organisms is likely the result of a genetic program that determines the response to exogenous influences and thereby increases the predisposition to illness and death.

Life Span and Life Expectancy

The average/median life span (also known as life expectancy) is represented by the age at which 50% of a given population survives, and maximum life span potential (MLSP) represents the longest-lived member(s) of the population or species. The average life span of humans has increased dramatically over time, yet the MLSP has remained approximately constant (Fig. 2.1) [1]. For 99% of our existence as a species, the average life expectancy for human was very short compared to the present. During the Bronze Age (circa 3,000 B.C.), the average life expectancy was 18 years due to disease and accidents. Average life expectancy in 275 B.C. was still only 26 years. By 1900, improved sanitation helped to improve the average life expectancy at birth for humans to 47 years, but infectious disease was still a major killer. As of 2005, better diet, health care, and reduced infant mortality had resulted in an average life expectancy of 77.8 years [2]. The increase in the average life expectancy has resulted in a compression of morbidity (a squaring

FIGURE 2.1 Percent survival curve for humans at different times in history with varying environments, nutrition, and medical care. The 50% survival values have improved, but maximum life-span potential has remained the same (From Troen BR (2003) *The biology of Aging*. Mt Sinai J Med 70(1):3–22. Reprinted with permission of John Wiley & Sons, Inc.).

of the mortality curve) towards the end of the life span (Fig. 2.1). Of note, the longest-lived human for whom documentation exists was Jeanne Calment, who died at the age of 122 in August 1997. The longest-lived male was Christian Mortensen, who died in 1998 at the age of 115. As causes of early mortality have been eliminated through public-health measures and improved medical care, more individuals have approached the maximum life span. Between 1960 and 2000, the population of those aged 85 years and over grew 356%, whereas the elderly population in general rose 111%, and the entire U.S. population grew only 57% [3].

A number of physiological functions begin a progressive decline from the fourth decade onward, including the cardiovascular, pulmonary, renal, and immune systems. In women, this correlates with a decline in reproductive capacity. Interestingly, one study has shown that women who are fertile in their forties are nearly four times as likely to survive to the age of 100 than women who are not [4], suggesting that reproductive fitness later in life may be an indicator of longevity. The age of menopause has also been linked to life span. Controlling for socioeconomic factors, women who undergo menopause before the age of 40 are twice as likely to die before those who experience menopause after the age of 50 [5, 6]. These findings hold true even when a history of estrogen replacement therapy is taken into account, suggesting that reduced estrogen alone is not responsible for the ostensible reduction in life span. Another study found that while late reproduction correlated with increased longevity in postreproductive Sami women, maternal age at first birth and total fecundity did not appear to impact female longevity [7]. In males, although spermatogenesis per se does not show a significant age-related decline, testosterone levels fall with advancing age, and a few studies have linked reduced bioavailability of testosterone to age-related functional

degeneration [8, 9]. Therefore, it would appear that there is a link between reproductive health, aging, and life span (see the disposable soma theory discussed below).

MLSP appears to be species-specific, implying a significant genetic component to the rate of aging. For example, humans have an MLSP 25- to 30-fold higher than mice. Some biodemographic estimates predict that elimination of most of the major killers such as cancer, cardiovascular disease, and diabetes would add no more than 10 years to the average life expectancy, but would not affect MLSP [10, 11]. This implies an upper limit to the MLSP. Some models suggest that genes operate by raising or lowering the relative risk of death by making cancer, coronary disease, or Alzheimer's disease more likely, rather than by fixing the life span. One mathematical model predicts that if participants in the Framingham Heart Study had been able to maintain the levels of 11 different risk factors similar to those of a typical 30 year old, the men and women would have survived to an average age of 99.9 and 97.0 years, respectively [10].

There are three known regimens that can extend life span. The first two involve lowering ambient temperature and reducing exercise and are effective in poikilotherms (cold-blooded species). A 10°C drop or the elimination of a housefly's capacity to fly extends the maximum life span approximately 250% [12]. Both of these manipulations decrease the metabolic rate and are accompanied by decreases in free radical generation and oxidative damage to protein and DNA.

The third intervention is caloric restriction, which can extend life span in yeast, worms, flies, grasshoppers, spiders, water fleas, hamsters, mice, rats, and dogs [13]. Dietary restriction without malnutrition can increase both the average and maximum life spans of mice and rats by more than 50% [14, 15]. Although calories are severely restricted (up to 40%), essential nutrients such as vitamins and minerals are maintained at levels equivalent to those found in ad libitum diets. The diet-restricted animals also exhibit a delay in the onset of physiological and pathological changes with aging [16]. These include hormone and lipid levels, female reproduction, immune function, nephropathy, cardiomyopathy, osteodystrophy, and malignancies. Size, weight, fat percentage, and some organ weights are markedly less in calorically restricted animals [17]. The specific metabolic rate, the amount of oxygen consumed per gram of tissue, decreased in rats subjected to caloric restriction [18, 19]. However, in one study, long-term food restriction did not alter the metabolic rate [20]. This finding suggests that the specific metabolic rate may not be a critical determinant of longevity. To date, life span extension in mammals by dietary restriction has been most convincingly demonstrated in rodents. However, dietary restriction in primates [21–24] and in humans [25, 26] does appear to improve a number of metabolic and cardiovascular disease risk parameters.

Characteristics of Aging

There is evidence supporting at least five common characteristics of aging in mammals (Table 2.1):

1. **Increased mortality with age after maturation:** In the early nineteenth century, Gompertz first described the exponential increase in mortality with aging due to various causes, a phenomenon that still pertains today [27]. In 2005, the death rate for all causes at the age of 25–34 was 104.4/100,000 and at the age of 35–44 was 193.3/100,000. Death rates at the age of 65–74, 75–84, and 85 and over were 2,137.1/100,000, 5,260.0/100,000, and 13,798.6/100,000 respectively: a greater than 130-fold increase from young adults to the oldest group [28]. Indeed, the pattern of age-related survival is similar across species, including invertebrates and single-cell organisms (Fig. 2.2).
2. **Changes in biochemical composition in tissues with age:** There are notable age-related decreases in lean body mass and total bone mass in humans [29, 30]. Although subcutaneous fat is either unchanged or declining, total fat remains the same [29]. Consequently, the percentage of adipose tissue increases with age. At the cellular level,
3. **Progressive decrease in physiological capacity with age:** Many physiologic changes have been documented in both cross-sectional and longitudinal studies. Examples include declines in glomerular filtration rate, maximal heart rate, and vital capacity [40]. These decreases occur linearly from about the age of 30; however, the rate of physiological decline is quite heterogeneous from organ to organ and individual to individual [41, 42].
4. **Reduced ability to respond adaptively to environmental stimuli with age:** A fundamental feature of senescence is the diminished ability to maintain homeostasis [43]. This is manifested, not primarily by changes in resting or basal parameters, but in the altered response to an external stimulus such as exercise or fasting. The loss of “reserve”

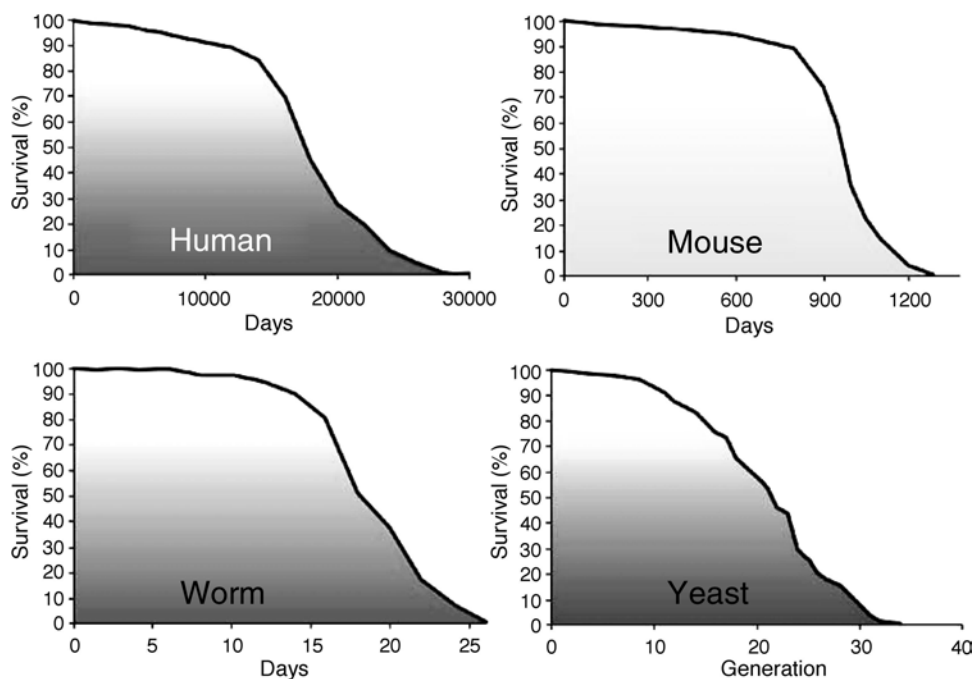

FIGURE 2.2 Viability curves from different model organisms have a similar characteristic shape. Representative mortality data are shown for *Homo sapiens*, *Mus musculus*, *Caenorhabditis elegans*, and *Saccharomyces cerevisiae* (From Troen BR (2003) *The biology of Aging*. Mt Sinai J Med 70(1):3–22. Reprinted with permission of John Wiley & Sons, Inc.).

can result in blunted maximum responses as well as in delays in reaching a peak level and in returning to basal levels. For example, the induction of hepatic tyrosine aminotransferase activity by fasting is both attenuated and delayed in old rodents [43]. The immune response also appears to be impaired in older individuals, leading to reduced ability to fight infections, less protection from vaccinations, higher incidences of autoimmunity, and impaired antigen affinity and class-switching by lymphocytes (reviewed by Dorshkind et al. [44]).

5. *Increased susceptibility and vulnerability to disease:* The incidence and mortality rates for many diseases increase with age and parallel the exponential increase in mortality with age [45]. For the five leading causes of death for people over 65 years of age, the relative increase in death rates compared to people aged between 25 and 44 is: heart disease – 92-fold, cancer – 43-fold, stroke – >100-fold, chronic lung disease – >100-fold, and pneumonia and influenza – 89-fold [46]. The basis for these dramatic rises in mortality is incompletely understood but presumably involves changes in the function of many types of cells that lead to tissue/organ dysfunction and systemic illness. Interestingly, a retrospective study of centenarians demonstrated that they live 90–95% of their lives in very good health and with a high level of functional independence [47]. The centenarians do suffer a 30–50% annual mortality at the end of their lives, but this represents a marked compression of morbidity towards the end of life and is close to the idealized survival curve in Figs. 2.1 and 2.2.

Mechanisms/Theories of Aging

In an effort to adequately explain the phenotype of aged organisms, many speculations about the cause(s) of aging have been proposed. However, what is known about the fundamental molecular mechanisms involved in aging remains controversial and largely unproven. A major reason for this is the obvious complexity of the problem. Aging changes are manifested from the molecular to the organismal level; environmental factors affect experimental observations; secondary effects complicate elucidation of primary mechanisms; there exist a dearth of easily measurable “biomarkers” that are consistent over different tissues and species. No one unifying theory may exist since the mechanisms of aging could be quite distinct in different organisms, tissues, and cells, although there appear to be certain mechanisms, such as DNA damage, that are broadly conserved despite differences in specific response.

Theories of aging have historically been divided into two general categories: developmental-genetic and stochastic (Table 2.2). The term “developmental-genetic” implies a more active genetic control of aging than likely exists. In

TABLE 2.2 Theories of aging

<i>Developmental/genetic</i>
Antagonistic pleiotropy theory
Longevity-associated genes
Disposable soma theory
<i>Stochastic</i>
Free radical/oxidative stress
Mitochondrial dysfunction theory
DNA damage theory of aging

addition, as described below, these categories are not mutually exclusive, particularly when considering the free radical/mitochondrial DNA theory of aging. Indeed, there is likely a spectrum from birth to senescence that reflects a decreasing influence of active genetic influences and an increasing effect of stochastic events. This would parallel the shift in importance in general versus species-specific genes.

Developmental/Genetic Theories

A general framework for a plausible theory of aging begins with attempting to understand the evolutionary basis of senescence. Developmental-genetic theories consider the process of aging to be part of the genetically programmed and controlled continuum of development and maturation. Although this is an attractive notion, the diverse expression of aging effects is in sharp contrast to the tightly controlled and very precise processes of development. Also, evolution selects for the optimization of reproduction; the effects of genes expressed in later life probably do not play a large role in the evolution of a species. This class of theories is supported by the observation that the maximum life span is highly species-specific. As noted above, the maximum life span for humans is 30 times that of mice. In addition, studies comparing the longevity of monozygotic and dizygotic twins and nontwin siblings have shown a remarkable similarity between monozygotic twins that is not seen in the other two groups.

However, it is also likely that the interplay of genetic responses to extrinsic stresses may modulate the extent of aging. An interesting example of this theory comes from a study by Niedernhofer et al. who demonstrated that aging mice as well as normal adult mice treated with mitomycin C to elevate DNA damage levels showed a shift in gene expression that was very similar to that observed in a mouse model of XPF-ERCC deficiency, a novel genetic disorder associated with accelerated aging [48]. The alterations in the transcriptome reflected enhanced antioxidant and anabolic pathways and reduced insulin growth factor (IGF-1) signaling (a known longevity assurance mechanism), suggesting a systemic shift of the somatotrophic axis from growth to maintenance under genotoxic stress. Thus, in the model of

XFE/ERCC^{-/-} progeroid syndrome, the phenotypic outcomes depend not just on DNA damaging stimuli, which likely cause a functional decline, but also on the genetic adaptive response to the damage mediated by the IGF metabolic pathway [48].

Antagonistic Pleiotropy

Evolutionary pressures select for a minimum successful life: this includes the ability to reach reproductive age, procreate, and then care for offspring until weaned (so that they, in turn, will achieve reproductive age and continue the cycle) [49, 50]. Within this context, it is likely that the postreproductive/parental physiology of an organism is an epigenetic and pleiotropic manifestation of the optimization for early fitness. Kirkwood proposes that three categories of genes may be involved in senescence [51]: (1) those that regulate somatic maintenance and repair, (2) negatively pleiotropic genes that enhance early survival but are disadvantageous later in life (antagonistic pleiotropy), and (3) harmful late-acting mutations upon which little evolutionary selection is exerted. The presence of these genes may represent a spectrum from general to species-specific. Genes involved in cell maintenance and repair are likely to be present in all (or most) organisms, since such essential processes are similar across species. Late-acting mutations are probably species-specific because they are likely to be individualistic and random. Nonmaintenance pleiotropic genes could be universally found within a population or species, but may not be shared between species. An example of antagonistic pleiotropy would be the high expression of testosterone in a male gorilla that could lead to increased aggression and strength that would allow the male to become dominant and mate more frequently, but may eventually lead to a shortened life span due to increased atherosclerosis. Recent studies at the molecular genetic level have suggested that cellular senescence may be antagonistically pleiotropic because it prevents tumorigenesis but also contributes to organismal aging (see below).

Longevity Genes

There is ample evidence in multiple species that MLSP is under genetic control, though the degree of heritability is likely to be less than 35% [52]. Despite this apparently low figure, genetic mutations can significantly modify senescence. In yeast, a number of genes affect both the average and maximum life span [53]. The products of these genes act in diverse ways, including modulating stress response, sensing nutritional status, increasing metabolic capacity, and silencing genes that promote aging. In the nematode (*C. elegans*), mutants with increased life span have revealed various genes

that appear to play a role [54]: *age-1* – altered aging rate, *daf-2* and *daf-23* – activation of a delay in development, *spe-26* – reduced fertility, and *clk-1* – altered biological clock. These genes alter stress resistance (particularly in response to ultraviolet light), development, signal transduction, and metabolic activity. The *daf-2* gene appears to encode an insulin receptor family member [55]. Mutations in *daf-2* can double the life span but require the *daf-16* gene [56]. A mutation in the *daf-16* gene suppresses the UV resistance and increased longevity of the other gene mutants, suggesting that it acts at a critical point downstream of the other genes [54]. The *daf-16* gene is a member of the hepatocyte nuclear factor-3/forkhead family of transcriptional regulators involved in a variety of signal transduction pathways, including insulin signaling [57]. A notable connection between single gene effects upon aging in yeast and higher eukaryotes was revealed by the finding that overexpression of the SIR2 gene and its homolog Sirt1 (sirtuin 1) extend life span in yeast and nematodes, respectively [58]. Sir2 (silent information regulator) is an NAD⁺-dependent histone deacetylase that silences transcription and stabilizes repetitive DNA in yeast. Aging and DNA damage induce Sir protein complexes to relocalize to sites of genomic instability, resulting in desilencing of genes. Sirtuin genes can function as antiaging genes in yeast, worms, and flies [59]. There are seven mammalian sirtuin genes whose protein products function as histone deacetylases (SIRT1,2,3,5,6,7) and/or ADP-ribosyltransferases (SIRT4,6). SIR2 and its homologs appear to exert their effects by linking metabolism to aging and also enhancing mitochondrial biogenesis and efficiency [59, 60] (see below). SIRT1 modulates the activity of multiple critical transcriptional regulators of metabolism, including FOXO1, FOXO3a, PPAR α , PPAR γ , and PGC-1 α , which in turn impacts fatty acid oxidation, gluconeogenesis and glycolysis, oxidative capacity, fat mobilization and adipogenesis, and insulin secretion.

A line of *Drosophila melanogaster* has been identified that exhibits an approximately 35% increase in average life span and enhanced resistance to various forms of stress, including starvation, high temperature, and dietary paraquat, a free-radical generator [61]. The mutation responsible, dubbed methuselah, appears to reside within a single gene that is homologous to GTP-binding transmembrane domain receptors. Another single-gene mutation leads to almost a doubling of the average adult *Drosophila* life span without a decline in fertility or physical activity [62]. This gene, named Indy (for I'm not dead yet), is homologous to a mammalian sodium dicarboxylate cotransporter, which is a membrane protein that transports Krebs's cycle intermediates. The investigators speculate that the mutation in the Indy gene may create a metabolic state that mimics caloric restriction. Previous studies have demonstrated that one group of long-lived flies is more resistant to oxidative stress [63], whereas another group exhibits resistance to starvation and desiccation [64].

Genetic analysis of longevity in mammals has not been as revealing. However, immune loci in mice and humans have been implicated in long-lived subjects [53]. In addition, a mutation in the gene encoding the signaling molecule p66(shc), which significantly enhances the resistance to oxidative stress, increases the mean life span of mice by 30% [65]. The Snell dwarf mouse contains a single-gene mutation that alters pituitary development and prevents the production of growth hormone, thyrotropin, and prolactin [66]. The dwarf mouse also exhibits an extended life span of 25–50% but is much smaller than normal mice. In contrast, the mice with the mutant p66 develop normally and are not significantly smaller than wild-type mice (see Table 2.3).

There does appear to be a genetic component to longevity in humans. A number of mitochondrial DNA polymorphisms and variants are associated with life span (reviewed by De Benedictis et al. [67] and by Salvioli et al. [68]). The J haplogroup was found in a significantly greater percentage of male centenarians in northern Italy than in younger subjects. Interestingly, this same mitochondrial haplotype is overrepresented in a number of complex diseases [69], raising the possibility of an antagonistically pleiotropic gene or genes that exert deleterious effects in younger patients, but lead to better health at later ages (successful aging). To complicate matters further, mitochondrial DNA polymorphisms are present in different frequencies in various aged populations from Italy, Ireland, and Japan [70].

Single-nucleotide polymorphisms in nuclear chromosomal DNA that appear to be linked to either increases or decreases in life span have been identified in a variety of populations (reviewed by Capri et al. [71] and by Glatt et al. [72]). An interesting pattern is emerging that strongly suggests that polymorphisms in genes implicated in metabolic signaling, inflammation, and stress response pathways play a role in aging and longevity. Metabolic genes implicated include the cholesterol ester transport protein [73], Foxo3A [74, 75], Foxo1A [76], SIRT3 [77, 78], the IGF1 receptor [79], and the insulin-degrading enzyme [80]. Inflammatory genes implicated include IL-6 [81, 82], IL-2 [83], CRP [84, 85], and TNF [86]. A number of genes from both of the previous categories fall into the stress response domain. It is important to stress that many gene association studies uncover modest relationships that may pertain to specific population groups. Individual genes may contribute in only small ways to aging or longevity, and it is highly likely that multigenic impacts and interactions play more significant roles in modulating longevity within the context of environmental stresses and lifestyle behaviors. Furthermore, there is intriguing evidence that a number of gene variants may play a more important role in increasing the human “health span,” rather than extending actual life span [72].

Interestingly, the human epsilon 4 allele of apolipoprotein E (ApoE), which is associated with increased coronary

disease and Alzheimer’s disease, is inversely correlated with longevity [87]. In contrast, the epsilon 2 allele of ApoE and an angiotensin-converting enzyme (ACE) allele are found more frequently in French centenarians [87], although the ApoE2 allele is associated with type III and IV hyperlipidemia, and the ACE allele predisposes to coronary disease. These findings further suggest that genes can exert pleiotropic age-dependent effects upon longevity. Further support for a genetic contribution to human longevity is provided by data demonstrating that siblings and parents of centenarians live longer [88]. In addition, centenarian offspring are significantly less likely to experience myocardial infarction, stroke, and diabetes and to die than offspring of noncentenarians [89]. Linkage analysis implicates the presence of a gene or genes on chromosome 4 that are associated with exceptional longevity [88]. Perls et al. note that a high percentage of centenarians had children while in their 40s (well before assisted reproduction). They, therefore, postulate that an evolutionary force to prolong the period of childbearing would lead to the selection of longevity-enabling genes. Collectively, these studies also raise the question whether some genes affect susceptibility to disease rather than alter intrinsic aging.

In contrast to studies that uncover alterations in the expression of single genes during aging, Weindruch and Prolla and their colleagues have investigated the broad program of changes in gene expression that occur during aging and caloric restriction in mice and in monkeys [90–93]. A common theme is that aging induces a differential gene expression pattern in muscle and brain, consistent with inflammatory and oxidative stress and reduced expression of metabolic and biosynthetic genes. In muscle and brain from mice, caloric restriction either completely or partially prevented the age-related changes in gene expression. Interestingly, caloric restriction did not ameliorate the aging-induced alteration in the program of gene expression seen in muscle from aging monkeys. So, even though the age-related changes in gene expression may be similar across species, the response to caloric restriction may not.

Disposable Soma Theory

The disposable soma theory [94] postulates that indefinite maintenance of somatic cells and tissues is not favored by natural selection, which instead allots available energy and resources towards the reproductive health of the organism in the early years of life. The basic prediction of this theory is that while immortal germline cells are faithfully maintained, the reduced investment in somatic cells causes deterioration and accumulation of unrepaired damage. Thus, the primary genetic control of longevity operates through ability to modulate the investment in basic cellular maintenance systems in

TABLE 2.3 Genetic mouse models of life-span extension

Model	Improvement in aging phenotype	Life-span extension	Model of aging examined	Genetics	References
Catalase overexpression	Increase in median and maximum life span, delayed onset of cardiac pathology and cataracts, reduced oxidative damage, slightly reduced splenomegaly and splenic lymphoid neoplasia, reduced mitochondrial deletions in skeletal muscle	Life span extended by ~5 months	Free radical theory of aging	Targeted overexpression of human catalase (an antioxidant enzyme which detoxifies hydrogen peroxide)	[135]
Thioredoxin (TRX) overexpression	Increased life span, resistance to oxidative stress, higher splenic telomerase activity, higher resistance to UV damage	35% life-span extension	Free radical theory of aging	Transgenic mice generated via pronuclei microinjection of recombinant TRX, an enzyme involved in redox homeostasis and antioxidant defense	[136]
SuperARF/p53 overexpression	Delayed aging, increased cancer resistance, decreased oxidative damage, increased antioxidant expression	16% increase in median life span	DNA damage/free radical theory	Introduction of a single extra gene-dose each of ARF/INK4a/INK4b and p53 via bacterial artificial chromosome-mediated genomic DNA transgenesis	[380]
clk1 ^{-/-}	Extended life span, reduced levels of ROS and oxidative damage in hepatocytes and ES cells from clk-deficient mice	15–30% life span extension with respect to wild-type littermates	Stochastic/free radical theory of aging	Homozygous inactivation of the mouse ortholog of the <i>C. elegans</i> gene, clk1 (an enzyme required for ubiquitome biosynthesis)	[402]
IGFR1 ^{+/-}	Increased life span, without accompanying dwarfism, reduced metabolic signaling or fertility, derived fibroblasts show reduced sensitivity to oxidants	26% mean life span extension	Genetic/developmental/free radical theory of aging	Inactivation of the insulin growth factor receptor 1 (IGFR1) gene by Cre-mediated recombination	[403]
Fat-specific insulin receptor knockout (FIRKO) mice (CR model)	Increased life span, protected against age-related obesity and glucose intolerance, lowered insulin levels	~18% increase in mean life span	Genetic/developmental	Cre-recombinase-mediated deletion of exon 4 of the insulin receptor, leading to loss of insulin signaling in adipose tissue	[404]
Heterozygotic reduction of IGF1 signaling in the brain	Increased mean life span, smaller adult size, low growth hormone (GH) levels	~2 month increase in mean life span, no change in maximal life span	Genetic/developmental/neuroendocrine theory of aging	Conditional mutagenesis to generate brain-specific IGF-1 receptor heterozygous knockout mice	[104]
uPA overexpression	Increased life span, reduced body weight, reduced food consumption and blood sugar levels	~20% increase in life span	Genetic/developmental	Chimeric uPA overexpression	[405]
p66shc ^{-/-}	Increased life span, resistance to superoxide radical-mediated damage, increased cellular resistance to apoptosis and to p53/p21 pathway induction	30% increase in life span	Stochastic/free radical theory of aging	Targeted mutation of p66shc gene (a cytoplasmic signal transducer in the mitogenic Ras pathway)	[65]
CCAAT/enhancer binding protein (C/EBP) β	Increased life span, reduced lipid accumulation in white adipose tissue, higher mitochondrial biogenesis and energy expenditure	20% increase in life span	Mitochondrial/free radical theory of aging	Knock-in replacement of the C/EBP α gene with the C/EBP β gene to generate β/β mice	[406]

(continued)

TABLE 2.3 (continued)

Model	Improvement in aging phenotype	Life-span extension	Model of aging examined	Genetics	References
Adenyl cyclase (type 5) knockout	Increased mean and median life span, increased antioxidant enzyme defense, reduced susceptibility to osteoporosis and fracture, protection against cardiomyopathy	~30% increase in median life span	Genetic/developmental/free radical theory aging	Deletion knockout of the AC5 gene, which catalyses formation of the signaling molecule, cAMP, from ATP	[407]
Ames dwarf mouse (Prop-1)	Increased life span, reduced size, delayed puberty and sterility in females, lower body temperature, reduced insulin levels and circulating glucose, reduced age-related adiposity, increased antioxidant activity and reduced oxidative damage	35–70% increase in life span, depending on sex and diet	Genetic/developmental	Recessive mutation in the Prop-1 (Prophet of Pit1) gene which encodes a homeobox transcription factor involved in hormonal regulation	[408]
Snell dwarf mouse (Pit ^{1dw})	Increased life span, reduced size, reduction in age-related immune dysfunction, delayed fertility, improved joint and cartilage health	~40% increase in life span	Genetic/developmental	Two noncomplementing point mutations in Pit-1, pituitary-specific transcription factor-1	[409]
Laron mouse (GHR/BP)	Increased life span, reduced size, reduced insulin signaling	~45% increase in life span	Genetic/developmental	Homozygous knockout of the growth hormone receptor	[410]
<i>Little</i> mouse (GHRHR)	Increased life span, small size, stunted growth, normal fertility, reduced insulin signaling	25% increase in mean life span, 15% increase in maximum life span relative to wild-type or heterozygous littermates	Genetic/developmental	Single nucleotide substitution (Asp60Gly) in the growth hormone releasing factor receptor	[408]

relation to the level of environment hazard. Accordingly, one claim of this theory would be that there is a tradeoff between fertility and longevity, with long-lived populations exhibiting reduced fertility. One study that assessed correlations between the number of children and age of members of British aristocratic families noted that the longest-lived members had the fewest children [95]; however, the oldest women studied had a mean age of 68 years. As noted above, middle-aged women who give birth tend to live longer. These two disparate observations do not necessarily need to be contradictory in the context of the disposable soma theory, as longer-lived individuals may possess a genetic advantage that allows the tradeoffs between longevity and reproductive ability to take place later in life.

Two other theories of longevity which may be broadly classed under the disposable soma theory of aging are the neuroendocrine theory and the immunologic theory of aging, both of which suggest aging is a result of declining somatic function. The neuroendocrine theory proposes that functional decrements in neurons and their associated hormones are central to the aging process [96]. An important version of this theory holds that the hypothalamic–pituitary–adrenal (HPA) axis is the master regulator of aging in the organism. Because the neuroendocrine system regulates early development, growth, puberty, control of the reproductive system, metabolism, and many other aspects of normal physiology, functional changes in this system could exert effects throughout the organism. The decline in female reproductive capacity is an obvious neuroendocrine age-related change. Mounting evidence suggests both the ovary and the brain play key roles in the menopause (rather than the previously held view of ovarian exhaustion) [97]. The neuroendocrine theory of aging is supported by experiments that show that hypophysectomy, followed by the replacement of known hormones, maintains (and may extend) life span in rodents [98]. In addition, reductions in brain dopaminergic neurotransmission are more prominent in a shorter-lived rat strain [99]. Levodopa, a dopaminergic drug can prolong the mean life span in mice [100]. Treatment of rats with deprenyl facilitates the activity of the nigrostriatal dopaminergic neurons and protects these neurons from their age-related decay [101], and deprenyl increases both the average and maximum life span [102, 103]. Many human studies demonstrate gradually decreasing levels of peripheral hormones accompanied by normal levels of trophic hormones [96]. This suggests either increased response to the peripheral hormones by the HPA axis or inappropriately low expression of the stimulating hormone. However, many organisms with aging phenotypes similar to those of higher vertebrates lack complex neuroendocrine systems. The changes that occur in the neuroendocrine system may be due to fundamental age-related changes in all cells and are therefore secondary manifestations of the aging phenotype.

However, the neuroendocrine theory received some validation via a study of aging phenotypes in a mouse model of reduced neuronal growth signaling. Partial inactivation of the IGF-1R receptor in the murine embryonic brain inhibits growth hormone and IGF signaling, leading to smaller size and an increased mean life span, apparently due to inhibition of the somatotrophic axis (see Table 2.3 [104]).

The immunologic theory of aging is based upon two main observations: (1) the functional capacity of the immune system declines with age, as evidenced by a decreased response of T cells to mitogens and reduced resistance to infectious disease and (2) autoimmune phenomena increase with age, such as an increase in serum autoantibodies [105]. There is a shift to increasing proportions of memory T cells, accompanied by enhanced expression of the multidrug resistance p-glycoprotein [106]. Humoral (B cell mediated) immunity also declines with age, as evidenced by decreased antibody production and a disproportionate loss in the ability to make high-affinity IgG, IgA antibodies. In addition, differences in the MLSP of different strains of mice have been related to specific alleles in the major histocompatibility gene complex [107]. The genes in this region also contribute to the regulation of mixed-function oxidases (P-450 system), DNA repair, and free radical scavenging enzymes. Caruso et al. suggest that mouse and human histocompatibility genes may be associated with longevity via different mechanisms: in mice via susceptibility to lymphomas and in humans via infectious disease susceptibility [108]. There is also evidence that cytokine gene polymorphisms may interact with histocompatibility genes to influence longevity [108]. Although the immune system obviously plays a central role in health maintenance and survival through the life span, similar criticism can be directed at the immunologic theory as at the neuroendocrine theory. Complex immune systems are not present in organisms that share aspects of aging with higher organisms. In addition, the inability to distinguish between fundamental changes occurring in many types of cells and tissues, not just those of the immune system, and the secondary effects mediated by the aging-altered immune system make interpretation of the theory difficult. Proposed mechanistic studies of the immune theory include producing transgenic mice carrying the histocompatibility complex from a longer-lived rodent species to determine effects on disease incidence and life span.

The discovery of caloric restriction as a means to extend organismal life span (at least in lower organisms and rodents) calls the disposable soma theory into question because it would predict reduced rather than increased life span in the face of limiting nutrient resources and consequently energy. Indeed, early studies of rodents fed on restricted diets reported a delay in the onset of puberty and lower reproductive capacity [109, 110]. A survey of the reproductive profiles of long-lived mice, including naturally long-lived

variants such as the Snell dwarf mouse as well as transgenic models such as FIRKO mice (see Table 2.3) also suggests that, as a general rule, mice with longer life span show reduced fecundity (reviewed by Partridge et al. [111]). However, another study utilizing moderate caloric restriction (60% of normal dietary intake) of adult rodents discovered that CR conferred both increased fecundity in mice as well as increased survival of their pups [112], suggesting that an optimal balance in maintaining the reproductive axis without compromising the somatic axis may be achieved via nutritional interventions (see below).

Stochastic Theories

Free Radical/Oxidative Stress

Denham Harman proposed one of the oldest and most enduring theories of aging over 50 years ago when he postulated that most aging changes are due to molecular damage caused by free radicals [113, 114], which are incompletely reduced, highly reactive intermediates of oxygen. The term “free radical” is misleading because one of these intermediates is hydrogen peroxide, which contains no unpaired electrons and is therefore not a radical. The more accurate nomenclature for these intermediates is reactive oxygen species or ROS, and for the purposes of discussion herein and in the context of aging theories, we use the term free radical interchangeably with ROS, which likely is what Harman intended when he named his theory of aging.

Aerobic metabolism generates the superoxide radical ($O_2^{\bullet-}$), which is metabolized by superoxide dismutases to form hydrogen peroxide (H_2O_2) and oxygen [115]. Hydrogen peroxide can go on to form the extremely reactive hydroxyl radical (OH^{\bullet}). These oxygen-derived species can react with macromolecules in a self-perpetuating manner; they create free radicals out of subsequently attacked molecules, which in turn create free radicals out of other molecules thereby amplifying the effect of the initial free radical attack [12]. ROS appear to play a role in regulating differential gene expression, cell replication, differentiation, and apoptotic cell death (in part by acting as second messengers in signal transduction pathways) [116–118]. In addition, nonradical prooxidants, for instance metals such as iron and copper that catalyze formation of the hydroxyl radical, as well as high concentrations of certain antioxidants can together generate a retrograde redox regenerative cycle, leading to homeostatic imbalance and oxidative stress (reviewed by Valko et al. [119]).

In lower organisms, the role of antioxidants on life-span extension is also complex. Increasing expression of the mitochondrial Mn-superoxide dismutase (aka SOD2) in flies has yielded conflicting results, with one study reporting

approximately 15% extension in mean and maximum life span without changes in oxygen consumption [120] and another reporting no significant effect on life span [121]. However, SOD2 reduction in flies reduces life span and mimics aging-related defects; progressive reduction in SOD2 activity correlates with further shortening of life span [122]. This dose-dependent effect of SOD2 on life span is consistent with overexpression of SOD2 in flies [120].

Overexpression of Cu, Zn-superoxide dismutase (aka SOD1), the cytosolic superoxide dismutase, has been reported to extend life span in flies by around 40–50% [123, 124]; however, the significance of these results to the oxidative stress theory of aging are undercut by the facts that the majority of life extension was seen in the shortest-lived flies or by overexpressing SOD1 in tissues where there was a clear deficiency of the enzyme. In ant colonies, where large differences exist in life span between queens and workers, SOD1 activity correlates mostly negatively with life span with the shorter-lived males having higher SOD1 expression and activity compared to the long-lived queens [125]. Overexpression of catalase alone in transgenic flies also does not extend life span [126]. Some transgenic flies with increased expression of both Cu, Zn-superoxide dismutase and catalase, which act in tandem to remove superoxide and hydrogen peroxide, respectively, exhibit up to a one-third extension of average and maximum life span [126]. In addition, they exhibit increased resistance to oxidative damage and an increase in the metabolic potential (total amount of oxygen consumed during adult life per unit body weight). However, combinatorial overexpression of the major antioxidants, SOD1, SOD2, catalase, and thioredoxin reductase in relatively long-lived flies did not appear to enhance longevity [127]. It has also been shown that overexpressing glutathione reductase extends the life span of transgenic flies kept under hyperoxic or oxidant-treated conditions, but not under ambient conditions [128].

In *C. elegans*, a model system in which a number of long-lived mutants have been identified, the role of oxidants and antioxidants is similarly complicated. Although nutrient-sensing pathways appear to be a dominant mechanism of life-span determination in *C. elegans*, a causal role for oxidative stress in their aging still has neither been validated nor disproved. In long-lived worms that overexpress *daf-2*, ROS production was higher than in wild-type worms throughout the life span, but protein carbonylation was reduced [129]. The observed reduction in damage in the face of elevated ROS levels has been ascribed to compensatory protective effects due to enhanced enzymatic antioxidant activity from SOD proteins and glutathione-s-transferases [129–131]. However, treatment of wild-type *C. elegans* strains with SOD and catalase mimetics failed to extend life span despite increasing antioxidant activity [132]. Yet, the role of oxygen tension nevertheless appears to have an effect on life span and oxidative damage because worms kept at 1% oxygen

have lower carbonyl levels and show approximately 24% increase in life span relative to counterparts kept at ambient oxygen [133].

Production of ROS in the heart, kidney, and liver of a group of mammals was found to be inversely proportional to the maximum life span, although the activities of individual antioxidant enzymes were not consistently related to maximum life span [134]. However, catalase overexpression targeted to the mitochondria does increase life span and improve functional health of the mice as they age [135]. Transgenic mice that overexpress thioredoxin, another antioxidant protein, also exhibit about a 30% improvement in mean life span [136]. A series of studies has demonstrated that oxidative stress resistance of dermal fibroblasts correlates with the longevity of the species [137–139].

The studies discussed above illustrate the complexity behind the free radical theory of aging. Antioxidants, in general, only appear to have a significant effect on life-span extension if their levels/function are limiting or under conditions of stress. Thus, overexpression of enzymes that are already present at robust levels are not likely to have an effect on life span simply because increasing expression does not enhance catalytic efficiency of these enzymes, which are already operating at near optimal rates. Furthermore, given the importance of antioxidant enzymes to survival of aerobically respiring organisms, there is a certain amount of redundancy between different antioxidants, and different tissues require their individual actions to different extents. This heterogeneity and overlap of function may also be obscuring the effects of altering antioxidant levels in animal models of life-span extension. Thus, rather than overexpressing antioxidants alone, a more viable strategy of life-span extension perhaps needs to center on reducing production of ROS by modulating mitochondrial function or the prooxidant factors, which contribute to the deleterious effects of oxygen radicals.

Mitochondrial Dysfunction Theory of Aging

The mitochondrial DNA/oxidative stress hypothesis represents a synthesis of several theories and therefore comprises elements of both stochastic and developmental-genetic mechanisms of aging (see below). It is proposed that ROS contribute significantly to the somatic accumulation of mitochondrial DNA mutations, leading to the gradual loss of bioenergetic capacity and eventually resulting in aging and cell death [140–142]. Ozawa has dubbed this the “redox mechanism of mitochondrial aging” [143]. Mitochondrial DNA (mtDNA) undergoes a progressive age-related increase in oxygen free radical damage in skeletal muscle [144–146], the diaphragm [147, 148], cardiac muscle [149–152], and the brain [153, 154]. This exponential increase in damage

correlates with the increase in both point and deletional somatic mtDNA mutations seen with age. Interestingly, extrapolation of the curve to the point where 100% of cardiac mtDNA exhibits deletion mutations gives an age of 129 [143].

Mitochondrial DNA is maternally transmitted, continues to replicate throughout the life span of an organism in both proliferating and postmitotic (nonproliferating) cells and is subject to a much higher mutation rate than nuclear DNA. This is due, in large part, to inefficient repair mechanisms and its proximity to the mitochondrial membrane where reactive oxygen species are generated. Defects in mitochondrial respiration with age are found not only in normal tissues [155] but also in diseases that are increasingly manifested with age such as Parkinson’s disease [156, 157], Alzheimer’s disease [158, 159], Huntington’s Chorea [160], and other movement disorders [161]. Diseases for which mtDNA mutations have been found include Alzheimer’s [162, 163], Parkinson’s [153, 163–166], and a large number of skeletal and cardiac myopathies [147, 167–171]. Apoptosis has also been associated with mtDNA fragmentation [172]. As noted above, mitochondrial haplotype J is associated with human longevity. However, the role of inherited and somatic mutations in mitochondrial DNA during human aging is clearly complex, and additional studies are required to gain further insight (reviewed by Salvioli et al. [68].)

The idea of mitochondrial involvement in aging postulates that accumulation of mtDNA damage leads to defective mitochondrial respiration, which in turn enhances oxygen free radical formation, leading to additional mtDNA damage. However, the reality appears not to be quite so simple. A mouse model has been developed to address the issue whether phenotypic aging of tissues depends on mitochondrial DNA mutations. These mice express an error-prone version of the major mitochondrial DNA polymerase, pol-gamma, generated by mutating the proofreading domain of the enzyme. The mutant mice show fairly uniform accumulation of both deletions and point mutations in the mitochondrial genomes of different tissues and an accelerated aging phenotype [173]. The observations from the mutant pol-gamma mouse model mirror previous findings regarding the role of mitochondrial mutations in aging. On the surface, these observations fit well with the free radical/oxidative stress theory of aging, since mutations in mitochondrial genes coding for respiratory chain enzymes could in principle result in leakier electron transfer, thus leading to increased accumulation of ROS. However, this does not appear to be the case in mouse embryonic fibroblasts derived from the mutant mice that, despite impaired respiration, show neither augmentation of ROS production nor sensitivity to oxidative stress-mediated cell death [174]. Lack of change in protein carbonylation levels is presented to support the idea that these mice suffer no elevation in oxidative stress, although

these lesions may not be appropriate as the sole marker of cellular oxidative damage as they are detected only if they are present in a degradation-resistant state [175]. Furthermore, since mitochondrial deletions in the pol-gamma mutant mice lead to linearized mitochondrial genomes, another possibility is that the premature aging phenotype observed in these mice is the result of a DNA damage response (DDR) (see below) rather than accruing directly due to mitochondrial dysfunction. Nevertheless, the pol-gamma mice provide an elegant and useful system in which to further explore the role of mitochondrial mutations and ROS in engendering the aging phenotype.

In humans, specific mutations, while increasing with age, seldom account for more than several percent of the total mtDNA. However, some studies suggest that the total percentage of mtDNA affected by mutations is much greater, as much as 85%, and increases with age [143]. In addition, caloric restriction in mice retards the age-associated accumulation of mtDNA mutations [176]. Agents that bypass blocks in the respiratory chain such as coenzyme Q10, tocopherol, nicotinamide, and ascorbic acid would be predicted to ameliorate some of the effects of mitochondrial disease and aging. Withdrawal of coenzyme Q from the diet of nematodes extends the life span by approximately 60% [177]. Caloric restriction, which can extend life span, reduces oxidative damage in primates [178]. There are epidemiologic studies that appear to implicate dietary antioxidants in the reduction of vascular dementia, cardiovascular disease, and cancer in humans [179]. However, results to date, in treatment of patients with myopathies, have been variably or only anecdotally successful [143]. This suggests that a complex interaction exists between prooxidant and antioxidant forces in the cell and that regulation of the balance between the two may be the critical determinant in mitochondrial, and subsequently, cellular and tissue integrity during aging.

An increasing number of studies have implicated mitochondrial biogenesis and efficiency as playing significant roles to enhance cellular fitness and organismal longevity [180]. Maintenance of energy production and prevention and/or amelioration of oxidative stress by mitochondria are key to healthy aging. As previously discussed, caloric restriction is the most reliable intervention to extend life span in a number of species, including mammals such as rodents, dogs, and rhesus monkeys [13]. Multiple signals modulate PGC1 α activity and subsequent mitochondrial production and efficiency, such as AMP kinase, sirtuins, and nitric oxide, all of which can be increased by caloric restriction [180]. Furthermore, caloric restriction increases mitochondrial biogenesis in healthy humans [181]. However, perhaps the best intervention to enhance mitochondrial production and function is exercise, which can at least partly normalize age-related mitochondrial dysfunction [182] and can significantly reverse age-related transcriptional alterations [183].

DNA Damage Theory of Aging: Somatic Mutation, DNA Repair, Error Catastrophe

Stochastic theories propose that aging is caused by random damage to vital molecules. The damage eventually accumulates to a level that results in the physiological decline associated with aging. The most prominent example is the somatic mutation theory of aging, which states that genetic damage from background radiation produces mutations that lead to functional failure and, ultimately, death [184, 185]. Exposure to ionizing radiation does shorten life span [186, 187]. However, analysis of survival curves of radiation-treated rodent populations reveals an increase in the initial mortality rate without an effect on the subsequent rate of aging [188]. The life-span shortening is probably due to increased cancer and glomerulosclerosis rather than accelerated aging per se [189].

The DNA repair theory is a more specific example of the somatic mutation theory. Impairment of genomic maintenance has been strongly implicated as a major causal factor in the aging process [190]. Defects in DNA repair mechanisms form the basis of a majority of human progeroid syndromes (see below). The ability to repair ultraviolet radiation-induced DNA damage in cell cultures derived from species with a variety of different life spans is directly correlated with the MLSP [191]. Unfortunately, there is not enough experimental support to conclude that these differences between species are a causative factor in aging. Although the prevailing belief has been that overall DNA repair capacity does not appear to change with age, several studies now indicate that repair of oxidative DNA damage lesions via base excision repair (BER) becomes more inefficient in aged mice [192, 193]. Caloric restriction can restore the age-related decline in BER [194]. Repair of DNA double-strand breaks (DSBs) is also compromised in replicatively senescent human fibroblasts [195] and in fibroblasts and lymphocytes taken from older humans [196].

Additionally, the site-specific repair of select regions of DNA appears to be important in several types of terminally differentiated cells [197]. Biochemically, oxidative DNA damage has been shown to affect specific DNA sequences more than others, with the most affected sequences corresponding to conserved motifs in transcriptional elements involved in the regulation of stress-response genes [198]. Studies in cultured human neurons show that promoters of genes involved in memory, stress protection, and neuronal survival sustain selective oxidative stress-mediated DNA damage and exhibit reduced BER [199]. Transcriptional profiling of the human frontal brain cortex reveals that the genes under the control of these promoter elements also show the most reduced function after the age of 40. Thus, DNA damage to specific areas of the neuronal genome appears to contribute to age-related cognitive decline. Future studies will need to focus upon repair rates of specific genes rather than indirect general measurements.

The error-catastrophe theory also centers on the role of DNA integrity in the aging process and proposes that random errors in synthesis eventually occur in proteins that synthesize DNA or other “template” molecules [200]. Generally, errors occurring in proteins are lost by natural turnover and simply replaced with error-free molecules. Error-containing molecules involved in the protein-synthesizing machinery, however, would introduce errors into the molecules that they produce. This could result in an amplification such that the subsequent rapid accumulation of error-containing molecules results in an “error catastrophe” that would be incompatible with normal function and life. Although there are numerous reports of altered proteins in aging, no direct evidence of age-dependent protein mis-synthesis has yet been reported. The altered proteins that do occur in aging cells and tissues are, instead, due to posttranslational modifications such as oxidation and glycation [201, 202]. The increases in altered proteins appear to be due to decreased clearance in older cells [203].

Models of Aging

Accelerated Aging Syndromes in Humans

Although no disease exists that is an exact phenocopy of normal aging, several human genetic diseases, including Hutchinson–Guilford syndrome (the “classic” early-onset progeria seen in children), Werner’s syndrome (“adult” progeria), Cockayne’s Syndrome or NFE Syndrome (another childhood-onset progeroid disease), and Down’s syndrome exhibit features of accelerated aging.

Hutchinson–Guilford progeroid syndrome (HGPS) is an extremely rare autosomal recessive disease in which aging characteristics begin to develop within several years of birth [204]. These include wrinkled skin, stooped posture, early hair loss, and growth retardation. HGPS patients suffer from advanced atherosclerosis, and myocardial infarction is the usual cause of death by the age of 30. However, unlike Werner’s Syndrome patients (see below), these patients do not typically suffer from cataracts, glucose intolerance, and skin ulcers. HGPS is a laminopathy resulting from a single-nucleotide substitution (1824 C>T) in the lamin A gene, which encodes two components of the nuclear envelope, lamins A and C (reviewed by Meshorer and Gruenbaum [205]). The mutation leads to activation of a cryptic splice site and production of a truncated version of the precursor protein, prelamin A, denoted progerin or LAΔ50 [206, 207], which then leads to formation of abnormal nuclear lamina and delayed nuclear reassembly, as well as DNA damage and chromosomal abnormalities [208–212].

Werner’s syndrome (WS) is an autosomally recessive inherited disease [204]. Patients prematurely develop arteriosclerosis, glucose intolerance, osteoporosis, early graying, loss of hair, skin atrophy, and hypogonadism (reviewed by Muftuoglu [213]). However, patients do not typically suffer from Alzheimer’s disease or hypertension. WS patients have an increased predisposition to cancer with a higher than usual incidence of sarcomatous (mesenchymal) tumors and develop cataracts in the posterior surface of the lens, not in the nucleus as is usually seen in older people. In addition, they develop laryngeal atrophy and ulcerations on the arm and legs. Most patients die before the age of 50, usually of myocardial infarction or cancer [214, 215]. The gene responsible for WS has been localized to chromosome 8 [216] and appears to be a helicase [217], an enzyme involved in unwinding DNA. DNA helicases play a critical role in DNA replication and repair. Cells from WS patients display chromosomal instability, shortened telomeres, elevated rates of gene mutation, and nonhomologous recombination (reviewed by Brosh and Bohr [218]). Furthermore, WS is characterized by hypersensitivity to the chemical carcinogen, 4-NQO [219, 220], cross-linking agents [221], and the topoisomerase inhibitor, camptothecin [222, 223], suggesting impairment of DNA repair mechanisms.

Cockayne’s syndrome (CS) is a congenital autosomal recessive disorder characterized by stunted growth, extreme sensitivity to sunlight, retinopathy, deafness, nervous system abnormalities, and premature aging (reviewed by Stevnsner et al. [224]). This is a progressive disease that becomes apparent after 1 year of age and leads to mortality by 12 years of age. There are rare variants, one of which manifests at birth and another which presents milder symptoms and appears in late childhood. CS results from mutations in the transcription-coupled repair (TCR) and global genomic (GG) repair proteins, ERCC6 and ERCC8, also known as Cockayne’s Syndrome B (CSB) and Cockayne’s Syndrome A (CSA), respectively. The CSA protein is a 396-amino acid protein with no known enzymatic activity [225] and is part of a multicomponent ubiquitin ligase complex that also includes the DNA damage binding protein DDB1 [226]. Not much is known about its specific role in producing the CS phenotype. CSB consists of 1,493 amino acids and is a member of the SWI2/SNF2 family of DNA-dependent ATPases [227]. Although there is no phenotypic difference in disease whether it arises from mutations in CSA or mutations in CSB, approximately 80% of CS cases have mutated CSB. Neither the site nor the specific nature of CSB mutations appears to correlate with severity of the disease, and in one patient, complete loss of the CSB gene product led to photosensitivity, but not CS [228], suggesting that there may be an environmental or epigenetic component to the disease. Surprisingly, unlike Werner’s syndrome and other DNA repair defect diseases, Cockayne’s syndrome patients do not have a significantly

higher incidence of cancer unless they also suffer xeroderma pigmentosum (XP), which is linked to a strong predisposition to skin cancer.

People with Down's syndrome have trisomy or a translocation involving chromosome 21 [204, 229]. They suffer from the early onset of vascular disease, glucose intolerance, hair loss, degenerative bone and joint disease, and increased cancer. The life span is apparently 50–70 years (not as short as previously believed, since earlier mortality may have represented neglect of these individuals). Dementia occurs earlier and more often in patients with Down's syndrome than in the general population. Patients develop neuropathological changes similar to the changes seen in dementia of Alzheimer's type, including amyloid deposition and neurofibrillary tangles. This may be related to the presence of the β -amyloid gene on chromosome 21.

Although not strictly classified as progeroid syndromes, two diseases that bear mention are Fanconi anemia (FA) and dyskeratosis congenita (DC). Fanconi anemia is a rare autosomal recessive blood disorder, associated with multiple clinical symptoms [230]. Classified as a developmental rather than progeroid disorder, FA is nevertheless characterized by several aspects of premature aging syndromes, including childhood-onset bone marrow failure, susceptibility to squamous cell carcinomas, and congenital deformities. Furthermore, FA patients exhibit growth hormone and thyroid hormone deficiencies, glucose intolerance, and premature infertility. There are 13 FANC genes in which biallelic mutations lead to FA (reviewed by Neveling et al. [231]). Their protein products can aggregate into different core protein complexes in the nucleus; one of the complexes acts as a ubiquitin ligase to modify another FANC complex, thereby facilitating its recruitment to chromatin foci in conjunction with the BRCA1, BRCA 2, and Rad51 DNA repair proteins. Not surprisingly, FA cells exhibit chromosomal instability and are highly susceptible to several forms of DNA damage, particularly interstrand cross-links (ICL), therefore displaying acute sensitivity to cisplatin, mitomycin, and nitrogen mustard.

More significantly, cells derived from FA patients are uniquely sensitive to ambient air and show a definitive effect of oxygen concentration on formation of chromosomal aberrations [232]. Repeated hypoxia–reoxygenation cycles have been shown to induce premature senescence of bone marrow cells in a murine model of FA [233]. Together, these observations suggest that the dramatic bone marrow dysfunction and chromosomal aberrations observed in FA likely stem from ROS-mediated DNA damage to hematopoietic cells. Additionally, there is evidence that multimerization of FANC proteins and formation of nuclear complex 1 may be redox-dependent [234], suggesting that the observed sensitivity to DNA damage may be compounded by an inability of mutated FANC proteins to facilitate recognition and repair of DNA damage. Thus, with its progeroid features and the

mechanistic convergence of oxidative stress and DNA damage in its etiology, FA appears to be the only human model for the stochastic theories of aging.

Dyskeratosis congenita is a rare syndrome associated with severe bone marrow failure around the age of 30 years [235]. In addition, DC patients suffer from aging-associated pathologies such as increased risk of cardiopulmonary failure and malignancy, early graying of hair, changes in skin pigmentation, brittle nails, and immune system failure which manifests itself as mucosal leukoplakia. DC is also characterized by chromosomal instability and telomere shortening at the cellular level [236]. The X-linked version of DC results from mutations in the dyskerin gene *DKC1* that appear to impair its association with TERC, the RNA component of telomerase, whereas the autosomal form arises from mutations in the TERC gene itself [237]. Additionally, DC patients exhibit a uniform reduction in TERC itself. Thus, DC is unique in being the only human syndrome with progeroid features associated with telomere dysfunction, long considered a major causative biomarker of aging (see below).

Consistent with the classic theories of aging, the human progeroid syndromes discussed above suggest that the critical determinants of aging are likely to be oxidative stress levels, accumulation of DNA damage/chromosomal instability, and nonfunctional or reduced DNA repair mechanisms. These three features have formed the basis of a number of animal and cellular models of aging, which are discussed below and which recapitulate the phenomenon of aging to varying degrees.

Mouse Models of Aging

The major murine models of aging are summarized in Table 2.4. These encompass defects in a fairly comprehensive cross-section of biological processes implicated in aging including DNA damage/repair, metabolic, and developmental processes. Some of these models display the gamut of aging-related morphology and pathologies besides the obligatory reduction in mean and/or maximal life span. For instance, the *klotho* mouse suffers from a defect in a single gene that codes for a membrane protein and exhibits a plethora of marked age-related phenotypes that are also seen in humans. These include reduced life span, decreased activity, premature thymic involution, skin atrophy, arteriosclerosis, osteoporosis, emphysema, and lipodystrophy. There are a number of strains of senescence-accelerated mice (SAM) that exhibit a variable aging phenotype consistent with multigenic effects. Despite the fact that none of the mouse models displays all of the phenotypes associated with human aging, they are likely to be valuable tools in permitting delineation of some of the molecular mechanisms of aging. Significantly, some of the mouse models display a more

TABLE 2.4 Mouse models of aging

Model	Similarities to human aging	Life span and onset of aging	Differences from human aging	Genetics	References
Mutant p53 (p53 m/+)	Reduced life span, osteoporosis, lordokyphosis, organ degeneration, reduced wound healing, reduced subcutaneous adipose tissue, reduced ability to regrow hair	Median life span: 96 weeks Onset of aging: >48 weeks	Resistance to late-onset spontaneous tumorigenesis, normal blood chemistry, no alopecia or graying hair	Deletion mutation in the first six exons that express a truncated RNA for the carboxy terminal of p53	[299]
p63-deficient (-/-, -/+)	Reduced life span, lordokyphosis, alopecia, weight loss, cellular senescence markers in vivo and in primary keratinocytes	Median life span: 95 weeks	Other aging phenotypes (i.e., bone density, muscle, subcutaneous fat) not examined/reported	Conditional disruption of p63 in an inducible and tissue-specific manner (using a flox/Cre system)	[392]
XPF/ERCC1-/-	Reduced life span, neurodegenerative symptoms, liver, skin and renal dysfunction, sarcopenia, kyphosis, premature senescence and sensitivity to oxidative insults in derived fibroblasts	Life span: ~4 weeks Normal embryonic and initial postnatal development followed by dramatic reduction in growth in the second week	No reported enhancement in susceptibility to cancer	Insertional inactivation of ERCC-1 by gene targeting	[48]
Mutant pol-gamma	Reduced life span, weight loss, reduced subcutaneous fat, alopecia, anemia, kyphosis, osteoporosis, reduced fertility	Life span: <61 weeks Onset of aging: ~25 weeks	Susceptibility to cancer not discussed, no observed increase in oxidative stress	Homozygous knock-in mice with a proof reading-deficient version of DNA polymerase gamma (the catalytic subunit of the mitochondrial polymerase)	[173]
SIRT6-/-	Significantly reduced life span, lymphopenia, reduced subcutaneous fat, lordokyphosis, osteopenia, reduced liver function and serum glucose	Life span: ~4 weeks Onset of aging: ~3 weeks	Other aging phenotypes not discussed	Targeted deletion of SIRT6, a nuclear, chromatin-associated histone-deacetylase	[393]
Klf-/-	Shortened life span, infertility, growth retardation, decreased spontaneous activity, premature thymic involution, ectopic calcification, skin atrophy, arteriosclerosis, osteoporosis, pulmonary emphysema, lipodystrophy	Average life span: ~9 weeks Onset of aging: ~4 weeks	Phenotypes not observed: neoplasms, cataracts, diabetes mellitus, brain atrophy	Loss of function mutations in the klotho gene (a single-pass membrane protein with homology to beta-glucosidase)	[394]
Senescence-accelerated mouse (SAM)	Amyloidosis, neoplasms, hyperinflation of the lung, hearing impairment, osteoporosis, defects in learning and memory, cataracts, brain atrophy	Average life span: ~10 months Onset of aging: <8 months	Aging phenotypes are distributed among various SAMP strains	Not determined	[395]
WRN-/-	Premature loss of proliferative capacity in fibroblasts, sensitivity to topoisomerase inhibitors	Not reported	Mutant mice are apparently normal	Targeted disruption of the Werner syndrome gene (RecQ-like DNA helicase)	[396]
CSA-/- CSB-/-	Growth retardation, neurological defects	Almost normal life span	Other age-related phenotypes are not observed/examined	Targeted disruption of the Cockayne syndrome group A (CSA) or group B (CSB) gene (DNA helicase)	[397]
Atm-/-	Growth retardation, neurological dysfunction, infertility, malignant thymic lymphoma, sensitivity to X-ray irradiation	Develop thymic lymphoma before 4.5 months of age	Other age-related phenotypes are not observed or not examined	Targeted disruption of the ATM gene (a nuclear protein with PI-3-kinase-like domain)	[398]

(continued)

TABLE 2.4 (continued)

Model	Similarities to human aging	Life span and onset of aging	Differences from human aging	Genetics	References
<i>Atr</i> ^{-/-}	Premature aging phenotype in adult mice relative to controls, including severe greying hair and alopecia, kyphosis, osteoporosis, organ fibrosis and thymic involution	No reported reduction in life span. Onset of aging phenotypes within 3 months after <i>ATR</i> inactivation in 8–12 week old mice. Severe stem cell attrition and loss of tissue homeostasis in a number of organs	Other age-related phenotypes are not reported	Cre-mediated deletion of <i>ATR</i> gene using a Cre-ERT2 transgenic mouse line	[399]
<i>TERC</i> ^{-/-}	Infertility, graying of the hair, alopecia, skin lesions, impaired stress response, impaired proliferation of hematopoietic cells, neoplasms, delayed wound healing	Average life span: 18 months in the sixth generation	Aging phenotypes appear only in late-generation telomerase-deficient mice with extremely shortened telomeres. Phenotypes not observed: arteriosclerosis, osteoporosis, cataracts, diabetes mellitus, etc Enhanced aging seen with <i>WRN</i> ^{-/-} , <i>POT1</i> ^{-/-} and <i>iATM</i> ^{-/-} double mutants	Targeted disruption of the gene for the telomerase RNA component	[339]
Over-expression of growth hormone	Scoliosis, weight loss, decline or reproductive capacity, insulin resistance, astrogliosis in the brain, glomerulonephritis, glomerulosclerosis, reduced replicative potential of fibroblasts	Life span: <50% of controls Onset of symptoms: 6–8 months of age	Growth hormone levels decline with age in humans and in experimental animals	Over-expression of rat, bovine, ovine or human growth hormone under the control of the metallothionein or phosphoenolpyruvate carboxykinase promoters	[400]
<i>LMNA</i> ^{L530P/L530P} (HGPS model)	Shortened life span, osteoporosis and bone malformation, reduced hair follicle density, poor muscle development, loss of subcutaneous fat, reduced life span and nuclear abnormality in derived fibroblasts	Life span: 4–5 weeks	Normal cholesterol/lipid levels, no obvious vascular defects, no reported predisposition to cancer	Knock-in of mutant Lamin A gene containing a leucine to proline substitution at residue 50	[401]

striking aging phenotype in conjunction with defects in other systems, for instance the mice jointly deficient in TERC and ATM or TERC and WRN [238, 239] experience accelerated premature aging relative to mice deficient in TERC alone.

Given the importance of the free radical/oxidative stress theory of aging (see above), a definitive mouse model for oxidative stress in aging is lacking, although several of the systems listed in Table 2.4 include elements of oxidative stress such as elevated oxidative DNA lesions, defects associated with ROS signaling (such as insulin resistance), and inflammation-related disorders. SOD1^{-/-} mice show slightly reduced life span (~21 months relative to 28 months in the wild-type mice), elevated levels of 8-oxoguanine, a major oxidized DNA lesion, increased incidence of liver carcinogenesis [240], and increased retinal dysfunction [241]. SOD2^{-/-} mice do not show a life span defect but do have increased age-related incidences of lymphomas and cardiac defects [242]. Mice deficient in catalase [243] and glutathione peroxidase [244] also appear to have a normal life span, with the former exhibiting tissue-specific sensitivity to hyperoxic insults and the latter showing some mild redox imbalance in platelets. The same is true for the mice in which SOD2 and glutathione peroxidase is jointly abrogated [245]. However, these results do not disprove the oxidative stress theory of aging but rather provide a caveat that laboratory mouse models, being protected from disease and fluctuations in living conditions and nutrition, perhaps do not accurately reflect the requirement for protection against oxidative stress that may alter life span. It is telling that despite a lack of longevity enhancement, many of the above model systems show a clear effect of altered redox status on stress resistance of the organism, which ultimately is a key benchmark in defining functional characteristics of the aging process. Given the importance of DNA damage and the pleiotropic effects of ROS in signaling pathways, perhaps a clearer picture of the role of oxidative stress will emerge by generating and studying mouse models deficient in antioxidant defenses as well as DNA repair/signaling mechanisms.

Cellular Senescence as a Model for Aging

The complexity of studying aging in organisms has led to the use of well-defined cell culture systems as models for cellular aging or senescence. Hayflick and Moorhead [246] pioneered the model of replicative senescence and identified normal human diploid fibroblasts in culture as an experimental system for aging by observing an initial period of rapid and vigorous proliferation, invariably followed by a decline in growth rate and proliferative activity, finally leading to cessation of proliferation. This model proposed that aging is a cellular as well as an organismal phenomenon and that the loss of functional capacity of the individual reflected

the summation of the loss of critical functional capacities of individual cells. It is important to note that populations of senescent cells do not necessarily die and that, in fact, a number of senescent cell types (although not all) are thought to be resistant to apoptosis mediated by caspase 3 and inhibited by bcl-2 [247–249]. In culture, they can be maintained for years in a postmitotic (nonproliferating) state with regular changes of culture medium [250–252].

Although a majority of studies on cellular senescence have been conducted on skin and fetal lung fibroblasts, limited *in vitro* life span has been reported for glial cells [253], keratinocytes [254], vascular smooth muscle cells [255], lens cells [256], endothelial cells [257], lymphocytes [258], and human breast epithelial cells (HMECs) [259, 260]. *In vivo*, serial transplants of normal somatic tissues, such as skin and breast, from old donor mice to young genetically identical recipients show a decline in proliferative activity and eventual failure of the graft [261]. Similarly, skin from old donors retained an increased susceptibility to carcinogens whether transplanted to young or old recipients [262].

Do changes in cells in culture parallel changes in cells from aging organisms? The replicative life span of fibroblasts in culture is inversely related to the maximum life span of several diverse vertebrate species [263]. Studies suggest that the replicative life span of cells in culture is inversely related to the age of the donor in both humans and rodents [264–266]. This *in vivo*–*in vitro* relationship also holds for several different cell types, including skin fibroblasts [267], hepatocytes [268], keratinocytes [269], arterial smooth muscle cells [255], and T lymphocytes [270]. However, in these cross-sectional studies, there is a great deal of variability, and the correlation coefficient, though statistically significant, is low. Cells cultured from healthy individuals do not appear to exhibit a consistent age-related proliferative capacity [271]. Cells from people with Werner's syndrome do senesce more rapidly in culture than age-matched controls; however, a consistently similar relationship does not hold for cells from people with Hutchinson–Guilford syndrome [204]. Thus, under some circumstances, the proliferative characteristics of cells during aging *in vivo* are maintained in culture. There are several studies that point to an accumulation of senescent cells *in vivo* with advancing age of both humans and primates [35, 270, 272, 273].

The number of population doublings achieved before reaching a replicative limit is intrinsic to different cell types [246]. Even more significantly, cells rederived from animals that are the result of reproductive cloning via nuclear transfer show the same replicative proliferative capacity and rate of telomere shortening as the donor cells [274], suggesting an inherent mechanism of cellular life-span determination that is conserved even during the genetic reprogramming that occurs after nuclear transfer. The number of times the cells divide is more important in determining proliferative life

span than the actual time the cells spend in culture [275]. Cells continuously passaged in culture until the end of their proliferative life span achieve approximately the same number of population doublings (PDLs) as cells that are held in a stationary phase for an extended period (months) and then recultured until senescence. Therefore, under a given set of culture conditions, cells seem to possess an intrinsic mechanism that “counts” the number of divisions and not the time that passes.

However, suboptimal culture conditions or environmental stresses can adversely affect cellular replicative life span, leading to accelerated loss of proliferative capacity that is referred to as premature senescence or stress-induced premature senescence (SIPS) [276–278]. A number of acute exogenous stresses can lead to premature senescence, including, but not limited to oxygen radical producers, radiation, chemotherapeutic drugs, and high oxygen tension culture. Additionally, creation of endogenous DNA damage due to failure of repair mechanisms and elevated ROS stemming from mitochondrial dysfunction or oncogene activation can also lead to rapid induction of a permanent proliferative arrest.

In morphological and biochemical respects, SIPS is almost identical to replicative senescence, leading to the idea that all exhaustion of replicative capacity may be a form of stress-induced proliferative arrest. In accordance with this idea, one pervasive common denominator between replicative and SIPS appears to be induction of a DDR ([279] and reviewed in [280]). In fact, a persistent DDR and elevated intracellular ROS production appear to play a critical role not only in the induction of the senescent phenotype but also in its maintenance [279, 281].

Products of the retinoblastoma (Rb) and p53 tumor suppressor genes have been identified as the major molecular pathways implicated in cellular senescence [282, 283]. The Rb gene product is not phosphorylated in senescent cells [284]. Simian virus 40 large T antigen, which is bound by the p53 and Rb gene products, can facilitate escape from senescence [285]. T-antigen deletion mutants that lack either Rb- or p53-binding domains are unable to mediate escape from senescence [286]. Furthermore, treatment with antisense oligonucleotides to the Rb and p53 tumor suppressor genes can extend the in vitro life span of human fibroblasts [287]. The p21 CIP1/WAF1 [288–290] and p16 INK4a [291–293] inhibitors of cyclin kinases (and therefore cell cycle progression) are overexpressed in senescent cells. The p21 protein appears to act by forming complexes with members of the family of E2F transcription factors in senescent cells (Rb/CDK2/cyclin E or with the Rb-related p107/CDK2/cyclin D), downregulating transcriptional activity, and thereby inhibiting progression through the cell cycle [288]. Targeted disruption of the p21 gene delays the onset of senescence in fibroblasts derived from human lung [294]. However, adrenocortical cells express high levels of p21 throughout their in vitro life span,

up to and including senescence [295]. Skin fibroblasts from patients with Li–Fraumeni syndrome are heterozygous for p53. These cells in culture lose the remaining p53 allele and are subsequently unable to express p21 but still undergo in vitro aging [296], suggesting that p53 and p21 are not required for senescence. In senescent cells, p16 complexes to and inhibits both the CDK4 and CDK6 cell cycle kinases [291]. Induction of expression of p16 by demethylation-dependent pathways or of p21 by demethylation-independent pathways can induce senescence in immortal fibroblasts that do not express p53 [297]. Of genes whose expression is required for G1/S cell cycle progression, senescent fibroblasts express no cdk2 and cyclin A and reduced amounts of the G1 cyclins, C, D1, and E, compared to young cells [298]. The expression of early G1 markers, but not late G1 markers, indicates that senescent cells may be blocked at a point in late G1 [299].

The p53/p21 and the p16/Rb pathways are not induced to equivalent extents during cell senescence and do not contribute equally to the senescent phenotype; the dominating pathway depends both on cell type and the nature of senescence-inducing stress. In general, the p53 pathway is activated in response to genotoxic stress, DNA damage, and telomere dysfunction, whereas the p16 arm of tumor suppression is engaged under conditions of oncogenic and other stresses. Skin fibroblasts typically enter senescence via the p53 pathway and have low levels of p16 even as they approach cellular senescence; in these cells, inhibition of the p53 pathway is sufficient to reverse the senescent phenotype [300]. Lung fibroblasts, on the other hand, tend to show elevated levels of both tumor suppressor proteins in a senescing population as a whole, although individual cells may show one pathway is more dominant than the other (reviewed by Itahana et al. [301]). Even so, a mosaicism has been reported in senescent cultures whereby both p53- and p16-mediated senescence programs are activated either in parallel or even jointly in individual cells [302].

The *ras* oncogene product can induce senescence that is accompanied by accumulation of p53 and p16 [303]. This occurs only in nonimmortalized cells and may reflect a tumor-suppressive response of the cell to a transforming stimulus, as discussed below. However, it has been reported that the RAS oncoprotein can only induce senescence in cells that have already upregulated levels of p16 [304]. Induction of a DDR and senescence by increasing oxidized nucleotides and accompanying genomic DNA damage in human skin fibroblasts also leads to upregulated levels of both p53 and p16, but the senescence response can be rescued by abrogation of the p53 (but not the p16) pathway [305]. In human mammary epithelial cells, there appear to be two different barriers to proliferation. After the initial four to five population doublings, these cells enter an early senescent-like arrest termed M0 that is mediated by p16, but a number of cells in

a population are able to escape this proliferative barrier and continue to divide before reaching a p53-mediated senescence termed M1 [306]. In keratinocytes, abrogation of both p16 and p53 is needed to extend life span, but these cells still undergo senescence unless immortalized by introduction of hTERT. However, expression of hTERT alone does not immortalize these cells if one of the senescent pathways is still functional [307]. Together, these observations emphasize the presence of complex and incompletely understood overlapping networks regulating cell cycle progression and proliferation. Depending upon the balance of positive and negative influences, cell proliferation can continue or senescence may ensue.

Although many biochemical, metabolic, and phenotypic differences have been reported between senescent cells and their early passage counterparts, several characteristics appear to be shared across a majority of cells that have entered senescence and can therefore be accurately referred to as markers of senescence. These include a lack of proliferation and response to proliferative stimuli, absence of DNA replication, a marked morphological change involving a flattened appearance, accumulation of stress fibers and vacuoles as well as nuclear abnormalities, upregulation of p53 and/or p16 proteins, and beta-galactosidase activity detected at an acidic pH [308]. Senescent cells also exhibit autofluorescent globules of oxidized cellular proteins denoted as lipofuscin [309]. Additionally, heterochromatic nuclear DNA foci called SAHFs (senescence associated heterochromatic foci) have been observed in cell types in which Rb/p16 signaling is the dominant molecular mechanism of senescence [310]. These foci consist of a transcription-silencing variant macroH2A and various heterochromatic proteins and are believed to be formed by the action of chromatin regulator proteins, HIRA and ASF1a. They can be readily detected by their punctate appearance during DAPI staining of cell nuclei. Formation of DNA double-strand break (DSB) foci via activation of the ATM/ATR pathway has also been reported as a senescence marker, both in senescent cells as well as aging mice and primates [36, 37, 279, 302].

The senescence-associated (SA) beta-galactosidase activity, which is detected at pH 6.0, is commonly used in studies that assess induction of senescence both in cells and tissues [272]. Despite its common usage, conflicting data exists regarding the status of SA beta-gal activity as a specific marker for senescence. For instance, *in situ* expression of beta-galactosidase exists in confluent quiescent presenescent cells [311] and in cells undergoing crisis [312] or terminal differentiation [313]. The origin of SA beta-galactosidase activity appears to result from increases in lysosomal mass during the cellular aging process [314] or under cellular stresses that can induce senescence [311, 315]. Fibroblasts from patients with the lysosomal disorder GM1-gangliosidosis (in which lysosomal beta-galactosidase is defective) do not

show SA beta-galactosidase activity [316]. Furthermore, beta-galactosidase activity at low pH is also observed in nonsenescent cells with high lysosomal content such as vascular smooth muscle cells and endothelial cells [314, 317]. Thus, it would appear that SA beta-galactosidase activity is not a direct measure of senescence but a reflection of the lysosomal alterations that commonly occur as a consequence of senescence. Nevertheless, in general, for most cell types, beta-galactosidase activity is still a reliable if nonspecific marker, although it is advisable to look for beta-galactosidase positivity in conjunction with the other markers of senescence.

The three markers most commonly used to assess senescence *in vivo* are lack of proliferation (measured by Ki67 staining), SA beta-galactosidase activity, and levels of p16 protein. In particular, p16 protein is likely to be a good marker for *in vivo* aging as well because it has been reported to be strongly upregulated (sevenfold to eightfold) in aging human skin and in islet cells from aged humans [273, 318] and in a number of tissues from aged rats and mice [319]. Additionally, a DNA microarray screen of oncogene-induced senescence *in vitro* identified three *de novo* markers of senescence which were validated *in vivo*, namely, p15INK4b, Dec1, and DcR2 [320].

Telomere length is another commonly used marker of senescence. The phenomenon of telomere shortening with aging represents a potential “clock” or counting mechanism for cellular lifespan [321]. Telomeres are structures at the end of chromosomes that prevent degradation and fusion with other chromosome ends [322]. The average length of the terminal restriction fragment of chromosomes decreases with both *in vitro* and *in vivo* aging of fibroblasts and peripheral blood lymphocytes [321, 323–327]. Indeed, telomere length in lymphocytes progressively declines as a function of donor age from newborn to great-grandparents in their eighties [328]. Immortalized and transformed cells and germline cells express telomerase, which prevents shortening of the telomeres [329, 330]. However, some immortal cells exist without detectable telomerase [331], whereas stem cells and some normal somatic cells express telomerase, yet continue to experience telomeric shortening [332–334]. Telomere length has been correlated with better health in centenarians [335]. Interestingly, telomere length also appears to be related to physical activity [336]; however, no correlation was found between telomere length and frailty in an elderly cohort [337].

Shortened telomeres are associated with the progeroid pathology of dyskeratosis congenita and Werner’s syndrome (see earlier discussion; reviewed by Hofer et al. [338]) and also appear to lead to a form of premature aging in *in vivo* mouse models [339]. Mice lacking the RNA component of hTERT, TERC, do not show significant aging defects until the sixth generation [339]. Transgenic mice that overexpress

TERT exhibit increased tissue regeneration and a modest increase in maximal life span; however, these benefits are offset by the increased incidences of tumorigenesis suffered by these mice. Experimental nonenzymatic elongation of telomeres extends the life span of cells [340]. Furthermore, reactivation of telomerase, via the introduction of the telomerase reverse transcriptase unit into normal human cells, increased telomere length and extends the life span of a number of different cell types without inducing morphological or pretransformative abnormalities [341].

Furthermore, despite a clear ability to inhibit replicative senescence in a number of different cell types, telomerase cannot prevent or rescue many forms of SIPS, which are sometimes referred to as telomere-independent forms of senescence [342, 343]. However, it is not clear if telomeres are indeed not affected or whether telomerase is unable to heal certain types of damage to telomeres. Interestingly, while telomerase can readily immortalize adult lung fibroblasts under ambient culture conditions, fetal lung fibroblasts can only be immortalized under 3% oxygen and by addition of a number of chemical antioxidants to the culture medium [344], suggesting either that the integrity of the telomerase complex or its function may be affected by oxidative stress or that oxidative damage to telomeres may alter telomeric structure in a way that inhibits recognition/healing by telomerase.

Telomeric shortening has been attributed to inefficient repair of DNA single-strand breaks, which are hallmark lesions of oxidative damage [345]. Improvement of mitochondrial function, the major determinant of cellular ROS production, also slows down telomere shortening [346]. Although irrefutable *in vivo* proof for a causal role for oxidative stress in generating senescence-inducing telomere dysfunction is still lacking, telomeres appear to be excellent candidates for the missing link between DNA damage and oxidative stress that will allow us to achieve a complete understanding of the mechanism behind the internal “clock” that governs cellular life span.

Using the markers of senescence discussed above, senescent cells have been detected in tissues from aged rodents, primates, and humans [35, 36, 272, 273, 319]. Nevertheless, the question remains whether the *in vivo* presence of senescent cells in renewable tissue is coupled to any loss of organismal function. Presumably, such cells do not need to divide *in vivo* to the point of replicative exhaustion because they can be replenished by tissue progenitor cell populations. Thus, the role of cellular senescence in organismal aging, over and beyond its role as a tumor suppressor mechanism, may have greater functional relevance in stem cell populations than in more differentiated cells. The self-renewal and differentiation of stem cells is critical for the maintenance of tissue function, repair, and homeostasis. Hematopoietic stem cells (HSC) from older mice, which have deficiencies in self-renewal, repopulating, and homing mechanisms, accumulate

high levels of p16 that impair their ability to undergo serial transplantation; HSCs displayed improved function and stress resistance in the absence of p16 [347]. There is also evidence to suggest that self-renewal ability of the lymphohematopoietic stem cell system correlates with life span as a whole in mice ([348] and reviewed by Geiger and Van Zant [349]). Increasing p16 levels are also linked to decreased regenerative potential in pancreatic islet cells [318] and reduced proliferation of progenitor populations in the mouse forebrain [350].

Aging and Cancer

The idea that aging acts as a deterrent to tumorigenic transformation is one of the bases of the antagonistic pleiotropy theory of aging (discussed above). Within this context, traits that enhance the fitness of a younger organism (cellular senescence prevents cancer) may exert adverse effects later in life (increased predisposition to senescence leads to tissue aging and overall dysfunction). At a cellular level, senescence and tumorigenesis appear to be two sides of the same coin. Spontaneous transformation of normal primary human cells is an extremely rare event. Indeed, in the absence of telomerase activity or abrogation of the tumor suppressor pathways via viral oncoproteins, onset of senescence is an inevitable outcome of culturing primary cells, which must necessarily overcome this antiproliferative barrier before undergoing tumorigenic transformation. Cells that are immortalized via introduction of the catalytic subunit of telomerase, hTERT, and/or viral oncoproteins such as SV40 large T antigen or human papilloma virus proteins E6/E7, which block the p53 and p16 pathways, can continue to proliferate indefinitely [351], (reviewed by Vaziri and Benchimol [352]). These cells exhibit changes in morphology and growth rate and can be readily transformed by introduction of oncogenes [351, 353–355]. In contrast, introduction of activated oncogenes leads to premature senescence in primary cells [303, 356], again emphasizing the role of senescence in preventing tumorigenic transformation.

Significantly, senescent cells have been detected in tissue surrounding primary tumors, as well as in regions of nontumorigenic growths such as melanocytic nevi [357] and benign prostate hyperplasias [358, 359]. Similar results were observed with mice containing a conditionally expressed KRAS-V12 allele. Senescence markers were observed with far greater frequency in premalignant adenomas than in adenocarcinomas, which rarely exhibited senescence [320]. Together, these observations strongly suggest that senescence induction is a cellular response to hyperproliferative stimuli and that tumorigenic lesions are outgrowths of cells that have sustained further mutations/adaptations, thereby

allowing this tumor-suppressive block to be circumvented. This theory is further substantiated by the finding that DNA damage and senescent markers are sharply increased in pre-neoplastic and early neoplastic tissue, but are not observed in late-stage tumors [356, 360]. Additionally, mouse models of oncogene activation exhibit *in vivo* induction of DNA damage-mediated senescence in response to the hypermitogenic signaling associated with oncogene stress [361, 362]. Similarly, short dysfunctional telomeres are able to induce a senescent response in pretumorigenic cells in Emu-myc transgenic mice (a model for Burkitt's lymphoma) crossed with TERC-null mice [363]. Interestingly, the tumor suppressor function of shortened telomeres can be rescued by abrogating p53, but not by expression of the antiapoptotic protein, bcl-2. In mouse models of inducible p53, restoring p53 expression in murine liver carcinomas leads to induction of senescence (rather than apoptosis) in the entire tumor and to its clearance by activation of an innate immune response [364]. Similarly, intact p53 and p16 senescence pathways are required for c-Myc inactivation-induced regression of lymphomas [365]. These results not only point to the importance of cell senescence as a major antitumorigenic barrier but also suggest that, at least in certain types of tumors, it may be a more dominant barrier than cell death.

Besides the obvious conclusion that in order to progress, tumors need to overcome senescence, these observations underscore another fact. Stimuli or stresses that lead to the induction of senescence in a majority of cells may also select for cells that are either inherently resistant to or are no longer responsive to such stresses. When p53 function is restored in established lymphoma cells, they experience rapid clearance; however, most of the treated animals eventually relapse due to the emergence of tumors with inactivated ARF or p53 [366]. In animal models of lung hyperplasia that experience sustained DNA damage signaling and genomic instability, progression to full-blown carcinoma is strongly associated with an increasing trend of p53 inactivation, suggesting that cells which have lost p53 function are strongly selected for in an environment where a functional DNA damage-induced tumor suppressor response is ongoing [367]. The notion of such stress-resistant cell populations is congruent with the emerging idea of tumor-initiating or cancer "stem cells" (reviewed by Eyler and Rich [368]). Investigations as to the behavior of such cells towards genotoxic stress or oncogene activation and changes in their population with advancing age should prove both interesting and instructive.

In addition to cell-autonomous means of senescence induction, stressed or senescent cells release growth-inhibitory soluble factors that may serve to engender or enforce the senescent phenotype in neighboring cells. These include upregulation of the secreted insulin-like growth factor IGFBP7 in response to oncogenic BRAF signaling [369], elevated expression of CXCR2 and cognate ligands leading

to p53 induction and senescence [370], and oncogene-induced senescence mediated by the concerted action of C/EBP transcription factors and the cytokines IL-6 and IL-8 [371]. Recently, a broader senescence-associated secretory phenotype (SASP) in response to genotoxic stress has been identified and includes IL-6, IL-8 and insulin-like growth factor proteins (although not IGFBP7) [372]. The SASP is found to be amplified by loss of p53, by introduction of oncogenic RAS, and, *in vivo*, by chemotherapeutic treatment of prostate tumors. Further study of the role of these factors in inhibiting outgrowths of resistant cells is required to understand the full extent of their tumor-suppressive function.

Consequently, these studies provide increasingly convincing evidence for a tumor suppressor function of *in vivo* cell senescence. However, the argument for whether organismal senescence is a tumor suppressor response is less clear. On the surface, a paradoxical observation in this context is that older organisms are more susceptible to cancer, not less so. Interestingly, studies of *in vivo* senescence in mouse models of tumorigenesis suggest that the link between cellular senescence and transformation mimic the observed link between organismal aging and cancer in that senescence precedes the onset of tumorigenesis. This can be interpreted in two ways – either that the process of aging/senescence creates conditions for tumorigenic transformation or the conditions that lead to aging or senescence can engender tumorigenesis in the absence of senescence induction. At an organismal level, the former hypothesis has been popular given that from 2001 to 2005, 55.2% of all cancers were diagnosed in people over the age of 65, suggesting cancer is a disease of the elderly [373]. Furthermore, the incidence rate of invasive cancers is almost tenfold greater in those over 65 years of age. However, at a cellular level, the latter theory is more strongly supported because the markers of senescence are most strongly upregulated in preneoplastic and early neoplastic tissue rather than in late-stage tumors (see above). However, even in a cellular context, there is evidence that once senescent cells are established, they can nevertheless encourage an environment that promotes carcinogenesis. To this end, it has been reported that senescent cells can foster the growth of premalignant and malignant epithelial cells in culture and the tumorigenesis of these cells in mice [374, 375] and that a genotoxic damage-invoked SASP in premalignant epithelial cells induced a potentially highly invasive and malignant mesenchymal phenotype in these cells [372].

These observations suggest that the role of senescence and indeed aging as an antitumor measure may be more complicated than initially believed. Just as activation of tumor suppressor pathways represents an example of antagonistic pleiotropy, the process of senescence itself may also become deleterious in later life, turning from a predominantly tumor suppressor mechanism, activated in response to isolated stresses that threaten immediate survival of the

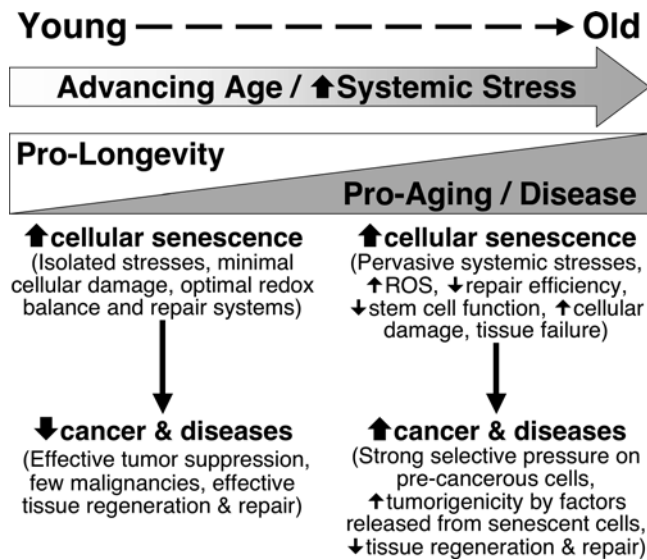

FIGURE 2.3 The cellular senescence paradox. In a background of low general damage and optimal stress responses, the process of cellular senescence can act as a prolongevity mechanism, activated in response to isolated stresses that threaten immediate survival of the young organism. However, in the context of mounting systemic stresses, cellular senescence may become deleterious in later life, turning from a predominantly tumor suppressor mechanism to a pervasive and ultimately degenerative response, paradoxically contributing to increased malignancies by allowing for selection and propagation of malignant cells that are able to evade of the senescence response.

young organism, to a pervasive and ultimately degenerative response to mounting systemic stresses (Fig. 2.3). Perhaps cancer is an aging-associated disease, not just because the stresses that induce aging also select from transformation-prone cells, but because the senescent tissue itself may be promoting tumorigenic growth in such cells.

From the mutant p53-expressing mouse model (see Table 2.4), the discouraging conclusion appeared to be that life span must be sacrificed to evade tumorigenesis [299, 376]. However, the above-mentioned models were the result of a genetic method that essentially led to elevated levels of p53 by eliminating its negative regulation by Mdm2. A more recent model of enhanced p53 function suggests that there need not be an inevitable tradeoff between increased cancer resistance and reduced life span. Transgenic mice that carry a genetic element containing the intact p53 gene [377] or the ARF gene [378], leaving these genes under normal physiologic regulation, or mice with moderately reduced Mdm2 activity [379] appear to benefit from the increased cancer protection accorded by elevated p53/ARF expression but without experiencing a concomitant reduction in life span. Even more significantly, using the same genetic technique, transgenic mice with combined enhanced p53 and ARF function have been generated that exhibit both an increased cancer resistance relative to the single gene-dose transgenic mice and also a 16% increase in median life span and improved stress

resistance (see Table 2.3, [380]). These results provide the first indication of an exciting new paradigm, namely, that longevity-assurance mechanisms (such as optimal levels of p53 function) exist that may cooperate with cancer protection mechanisms. Furthermore, similar to the two-hit hypothesis of tumorigenesis, the remarkable antiaging benefits that appear to accrue from enhancing both p53 and ARF functions suggest that perhaps the onset of aging is also triggered by coordinated dysfunction/dysregulation in more than one pathway. Thus, the genetic and stochastic components of aging may be explained by inherited deficiency in one or both of these pathways resulting in variable response to environmental stresses depending on the existing p53/ARF function.

Aging, Nutrition and Metabolism: A Modern-Day Elixir of Life?

Nearly every culture and civilization has its own mythic search for the elixir of life, from the desperate pursuit of immortality by Gilgamesh in ancient Babylon and by the Chinese emperor Qin Shi Huang before 200 B.C. to the European alchemists' attempts at creating the longevity-conferring philosopher's stone and the Spanish conquistador Ponce de Leon's quest for the fountain of youth. With an improved understanding of the molecular and biochemical pathways behind the aging process and the advent of nutraceuticals, there has been resurgence in the interest to generate scientifically validated interventions that can extend life span while minimizing the systemic disadvantages of aging.

Mouse models of life-span extension can be broadly categorized as either embodying alterations in metabolic/nutrient responsive-pathways or in mitochondrial/oxygen responsive pathways (Table 2.3). Most of these transgenic animal models exhibit a 15–30% life-span extension, with varied improvements in functional aging, such as low damage levels, increased tissue function and stress resistance at later stages of life, and reduced incidences of cancer. However, few of these models have more than a modest impact on MLSP, and almost none show the broad gamut of improved physiologic function that would translate to significant improvement in human quality-of-life aging issues. A valid criticism leveled at murine models of aging is that most of these organisms are studied under laboratory-controlled conditions that are unlikely to mimic the environmental vagaries that affect true aging [381]. Therefore, while these model systems offer mechanistic insights into the processes that may impact aging, the actual effects of these processes need to be assessed in human beings in a systematic and noninvasive manner.

The confluence of oxygen metabolism and nutritional signaling on life span observed in animal models ranging from

C. elegans to rodents suggests that dietary modifications are the most likely candidate for yielding maximal dividends when it comes to extending longevity and maintaining good health later in life. The ability to modulate diet is relatively simple, and accordingly, caloric restriction (CR) studies are at the forefront of life-span extension strategies. Caloric restriction in rhesus monkeys leads to reductions in body temperature and energy expenditure, consistent with changes seen in rodent studies in which aging is retarded by dietary restriction [21, 22]. Calorie restriction also increases high-density lipoprotein [23] and retards the postmaturational decline in serum dehydroepiandrosterone sulfate in the rhesus monkeys [382]. Levels of the aging biomarker, p16INK4a, are reduced in tissue from aging rodents fed a calorically restricted diet [319].

The Comprehensive Assessment of the Long-Term Effects of Reducing Intake of Energy (CALERIE) study is a randomized clinical trial to assess whether CR improves aging biomarkers in humans. After an initial 6-months of CR in 48 healthy men and women in their 40s and 50s, the study found an improvement in two biomarkers of longevity, namely, reduction in fasting insulin levels and body temperatures in groups that underwent dietary restriction [25]. Other CALERIE studies have found that CR improves liver [383] and cardiovascular health [26] and increases muscle mitochondrial biogenesis and decreases oxygen consumption [181].

Population-based characterizations of aging have also identified diet and nutrition as likely major contributors to longevity. Long-lived human populations tend to share a few features in common, among them diets enriched in low-fat proteins such as fish and in fruits or beverages high in polyphenols and low in sugar and processed carbohydrates, often referred to as the Mediterranean Diet [384]. Consumption of red wine is also believed to be conducive to a healthy life span. In Sardinia and the south-western regions of France, longevity of the local population has been correlated with the high vasoactive polyphenol contents of the locally produced red wine [385].

Polyphenols such as quercetin, epigallocatechin gallate (EGCG), and resveratrol (3,5,4'-trihydroxystilbene) are naturally occurring protective compounds found in dark-green vegetables, fruits, green tea, dark chocolate, and red wine currently being included in a number of studies of aging and aging-related pathologies such as cancer and diabetes. Indeed, resveratrol is notable for its ability to activate sirtuins and to increase maximum life span in lower organisms, such as yeast, worms, and flies [386]. Resveratrol treatment improves the exercise capacity, insulin sensitivity, mitochondrial biogenesis, and survival of mice on a high fat, high calorie diet [387]. Resveratrol can prevent diet-induced obesity concurrently with improved mitochondrial production, insulin sensitivity, and exercise endurance by

activating SIRT1 and PGC1 α [388]. Resveratrol treatment of mice can also delay age-related changes in physical performance, bone mineral density, inflammation, and the vasculature [389] and concomitantly induces transcriptional profiles in a variety of tissues similar to those seen with dietary restriction [389, 390]. Consequently, there has been much interest in resveratrol as a supplement to enhance health and increase life span in humans. However, resveratrol does not appear to extend the maximum life span of mice, but can increase the mean life span of mice with cardiovascular- and obesity-related pathology who would otherwise die earlier.

Although nutritional interventions may be able to significantly impact aging, it is likely that the genetic background of the individual will determine just how effective any particular modification is likely to be. Both calorically restricted and long-lived mice share common longevity assurance mechanisms when compared to progeroid mice, although the efficacy of such mechanisms varies widely in the two sets of mice [391].

Conclusions

Despite the near-universal phenomenon of aging in living organisms, there is an extraordinarily varied phenotype that accompanies aging in specific individuals. Furthermore, it appears that evolutionary pressures have led to the development of a remarkable homeostatic complexity to the underlying mechanisms that cause us to grow old. The three quotations at the beginning of this chapter aptly represent these processes. Butch Cassidy recognized the inexorable forces that cause us to age. The concept of antagonistic pleiotropy is reflected in the other two insights. It seems that we clearly pay a price to maintain a high level of reproductive fitness – there is no free lunch. However, the ironic, yet ultimately satisfying, paradox may be that the only way that we can actually live as long as we do is, in fact, to grow old.

Chapter 3

Cancer, Carcinogenesis, and Aging

Lodovico Balducci

Cancer is mainly a disease of aging. At present 50% of all cancers occur in the 12% of the population aged 65 and older [1]. By the year 2030, individuals over 65 years will represent 20% of the population of the United States and account for 70% of all cancers [1, 2]. The management of cancer in the older age group is going to become the most common practice of oncology.

The interactions of cancer and age are multiple and complex. They include carcinogenesis, tumor biology, as well as cancer prevention and treatment. We will explore these interactions after reviewing the extent of the problem.

Epidemiology of Cancer in the Aged

The incidence and prevalence of most cancers increase with age (Fig. 3.1). The association of cancer and age elicits a number of important questions: Is there a linear association between age and the incidence of cancer? Is the patient going to die or suffer from cancer? Does the presentation of cancer differ in older and in younger individuals? What are the consequences of cancer and its treatment for the older person? Epidemiology may provide important insights into these questions.

The Age Window

The incidence of most cancers increases steeply between ages 55 and 80, plateaus between 80 and 85, and declines thereafter. The prevalence of cancer, even occult cancer discovered only at autopsy, is negligible after age 95 [3]. This observation suggests a number of explanations including the possibility that the so-called longevity genes confer a protection against cancer or alternatively that an increasingly catabolic status prevents cancer growth after age 95.

Variations in the Incidence of Different Cancers in Older Individuals

Whereas the incidence of most cancers increases with age, the pattern of increase varies from one neoplasm to another. For example, the incidence of melanoma peaks at the age of 55 in men and plateaus thereafter; the incidence of breast cancer plateaus around the age of 80, whereas the incidences of cancer of the prostate and of the large bowel seem to increase without plateau even beyond the age of 80 [2]. These different incidence patterns suggest that a lesser number of carcinogenic stages are involved in the cancers whose incidence peaks earlier and also that some tissues, including the prostate and the colonic mucosa, become more susceptible to environmental carcinogens as the patient ages.

The case of lung cancer is of particular interest. In the last 20 years, the median age of lung cancer has changed from age 55 to age 71 [4]; the incidence of the disease has decreased for those younger than 50 years but has increased for individuals aged 65 and older, and the incidence of lung cancer in ex-smokers or non-smokers has increased. The likely explanation involves a decreased rate of cardiovascular deaths after smoking cessations, the development of a less aggressive type of lung cancer in ex-smokers, and a persistent susceptibility of the bronchial mucosa to environmental carcinogens in ex-smokers or non-smokers exposed to passive smoke. This hypothesis is supported in part by the change in lung cancer histology that includes higher incidence of adenocarcinoma and lower incidence of the most aggressive histologies, such as small cell and squamous cell.

Cancer Epidemics

Between 1950 and 1970, the incidence of non-Hodgkin lymphoma has increased by 80% among individuals aged 60 and over, and the incidence of malignant brain tumors (anaplastic carcinoma and glioblastoma multiforme) has increased sevenfold in those aged 70 and over [4]. These findings

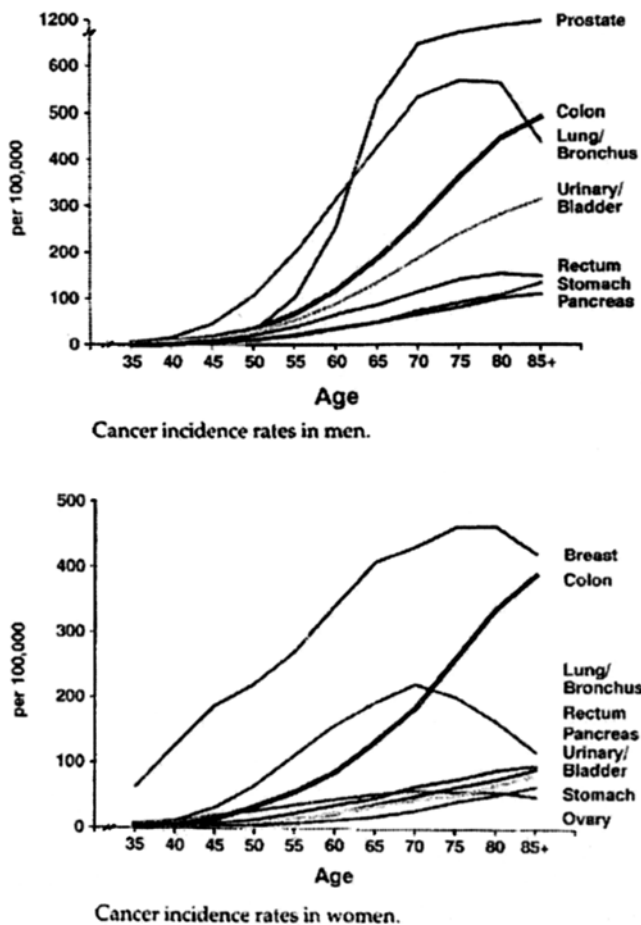

FIGURE 3.1 The incidence of cancer increases with age (from Yancik [2]. Reprinted with permission of John Wiley & Sons, Inc.).

suggest one of two possibilities. The first is that the improved life expectancy of the population has allowed the survival of individuals predisposed to develop these neoplasias. The second is that older individuals are natural monitoring systems for new environmental carcinogens. In other words, when exposed to new environmental carcinogens, older people are likely to develop cancer earlier than younger people. An epidemic of cancer in older individuals may herald an epidemic of cancer in the general population at a later time.

Who Are the Elderly with Cancer?

In studying the National Cancer Institute's Surveillance Epidemiology and End Results (SEER) data, Diab et al. determined that breast cancer did not shorten the survival of women aged 75–80 and was associated with an increased survival when it was diagnosed at the age of 80 and over [5]. These findings suggest that cancer is a prevalent disease among healthy elderly people. This suggestion is supported by the findings of Repetto et al. [6], indicating that older individuals with cancer were more likely than individuals of

similar age without cancer to be independent and to have fewer comorbid conditions. The low prevalence of cancer among long term nursing home residents also supports this suggestion [7]. Obviously, cancer is a cause of mortality for older individuals and the prevention and treatment of cancer in the elderly can prolong life and preserve function.

Presentation of Cancer in the Older Person

A number of studies in the 1980s, on the basis of statewide tumor registries, indicated that some cancers present at a more advanced stage in older individuals [8]. These included cancer of the breast, of the colon, and of the bladder, whereas lung cancer was diagnosed at an early stage in older individuals. More recent studies of the issue are wanted. The increased use of early detection might have increased the diagnosis of breast and colon cancer. At least three explanations may account for the presentation of some cancer at a more advanced stage: increased aggressiveness of cancer with age (unlikely), lesser use of cancer screening and early detection by older individuals, and delayed recognition of cancer symptoms. It is well known that older individuals may harbor many comorbid conditions at the same time. Comorbidity may delay the diagnosis of cancer because early cancer symptoms may be mistakenly ascribed to preexisting conditions.

Multiple Malignancies

Approximately 20% of individuals aged 70 and over with cancer may carry a diagnosis of two or more malignancies [9]. It is not clear whether multiple malignancies may be attributed to increased susceptibility to cancer. In some cases, the use of diagnostic tests for monitoring the first malignancies may precipitate the diagnosis of a second one. For example, the association of non-Hodgkin's lymphoma and renal cell carcinoma may be explained through this mechanism. The frequent scanning of the abdomen to monitor the lymphoma may lead to early diagnosis of kidney cancer. In other cases, the treatment of a previous cancer may be responsible for the second one: for example adjuvant chemotherapy of breast cancer may increase the incidence of myelodysplasia and acute myelogenous leukemia in women aged 65 and older [10–13]. In the majority of cases, the association appears simply casual and because of the fact that age is a risk factor for multiple cancers.

Cancer Behavior and Age

Some cancers become more aggressive and others more indolent with age. For example, breast cancer in older women is

more likely to metastasize to bone and skin rather than to the viscera and the brain [14]. Likewise, older studies showed that the metastases from non-small cell lung cancer had a longer doubling time in older individuals [14]. Conversely, age is a poor prognostic factor for acute leukemia, lymphomas, and ovarian cancer. The potential mechanisms of these differences will be discussed in the biology of aging and cancer.

Consequences of Cancer and Its Treatment in the Older Person

Cancer has become the most common cause of death up to age 85 since 2000 [15]. Surprisingly, in the same period of time, the overall cancer-related mortality has decreased, but not as rapidly as mortality from cardiovascular disease.

A number of recent studies have also shown that age is a risk factor for the development of acute myelogenous leukemia [10–13] and of late congestive heart failure after chemotherapy [16–18]. A recent study based on the SEER data also suggested an association between chemotherapy and dementia [19]. Prolonged castration with LH-RH analogs for prostate cancer has been associated with increased incidence of osteoporosis and bone fractures and possibly also with increased incidence of diabetes and coronary artery disease [20, 21].

Are cancer and its treatment causes of disability? The answer to this important question is still wanted. Older studies suggested an inverse relationship between incidence and prevalence of disability and cancer, probably related to the fact that cancer was associated with an early death which prevented the emergence of chronic disabling conditions [22]. This situation might have changed, however, with the emergence of more effective cancer treatment that results in prolonged survival from many malignancies.

In conclusion, the epidemiology of cancer and age provides important information that allows the formulation of appropriate clinical and research questions (Table 3.1).

TABLE 3.1 The lessons from epidemiology

1. Cancer has become the main cause of mortality in the older aged person: it is likely, but yet unproven that cancer is a major cause of disability
2. Cancer affects predominantly older individuals in good health, for whom cancer is a cause of morbidity and mortality. Effective prevention and treatment of cancer may prolong the life and preserve the function of older individuals
3. Cancer may be diagnosed at a later time in older than in younger individuals, as a result of decreased use of cancer screening and neglect of the initial symptoms of cancer
4. Multiple malignancies are found in as many as 20% of cancer patients aged 70 and older. In the majority of cases, the association appears casual; in some cases it may be related to treatment of a previous cancer
5. The prognoses of some cancers change with age. The underlying biology of these changes is described in the section of cancer biology and aging

Biologic Interactions of Cancer and Age

Aging and Carcinogenesis

The association of cancer and age may be explained by three non-mutually exclusive mechanisms: duration of carcinogenesis, increased susceptibility of aging tissues to environmental carcinogens, and environmental changes that favor the development of cancer.

As carcinogenesis is a time-taking process, it is reasonable to expect that cancer will become more common with advanced age. Again, the example of lung cancer is compelling. Smoking cessation has been associated with a spate of lung cancer in older ex-smokers [4]. Apparently, smoking cessation resulted in reduced mortality from cardiovascular complications of smoking, and this allowed ex-smokers to live long enough to develop cancer.

The application of the same dose of a carcinogen to the skin of younger and older mice causes more cancers in the older than in the younger animal, suggesting that the older skin is in a condition of advanced carcinogenesis and consequently more susceptible to “late stage carcinogens.” The lymphatic system, the liver, and the central nervous system of older animals also display increased susceptibility to environmental carcinogens [23].

For obvious reasons, these experiments cannot be performed in humans. Epidemiological observations suggest however that this may be the case in older humans as well. As already discussed in the epidemiology section, the incidence of prostate cancer, colonic cancer, and non-melanomatous skin cancer increases geometrically with age, and this finding suggests accelerated carcinogenesis. Likewise, one possible mechanism for the increased incidence of lymphoma and malignant brain tumors in older individuals includes enhanced susceptibility of the aged to environmental carcinogens [4]. In addition, age is a risk factor for acute myelogenous leukemia and myelodysplasia following adjuvant chemotherapy of breast cancer [11–13].

The contribution of the body environment to carcinogenesis is less clear. Chronic inflammation may cause the formation of carcinogens from the adipose tissue [24–26]. Adiponectin, a hormone produced by the adipose tissues, appears to stimulate the growth of colonic cancer in predisposed individuals [27]. Proliferative senescence of the stromal cells may facilitate tumor growth and metastases and possibly may influence carcinogenesis [28, 29]. Of special interest is the fact that the small molecules thalidomide and lenalidomide are able to reconstitute a normal hemopoiesis in some patients with myelodysplasia and to abrogate, for some time at least, the neoplastic clone involving the 5q-mutations [30]. As these agents act mainly at the level of the marrow microenvironment, their effectiveness suggests that the stroma has a role in carcinogenesis.

Aging and Tumor Growth

If one thinks of cancer as a plant, the growth of the plant depends on the seed (the tumor cell) and the soil (the tumor host). The importance of the tumor host was illustrated by a now classical experiment by Ershler et al. [31] These investigators injected the same doses of Lewis Lung Carcinoma and B16 melanoma into both older and younger mice [31]. The younger animals died earlier and with many more lung metastases than the older ones. As the seed in this case was exactly the same, only the diversity of the tumor bearers could explain the different outcome.

Age related differences in the neoplastic cells are well known. In older individuals, acute myelogenous leukemia (AML) presents a number of negative prognostic and predictive factors, including mutations in *flt-3*, wild type nucleophosmin, and multidrug-resistant 1 (MDR-1) [32]. In addition, AML in older individuals appears to be a disease of the pluripotent stem cells, which renders its eradication all but impossible. Breast cancer presents a more favorable proteomic and genomic profile in older than in younger patients. It has been known for a long time that the prevalence of hormone receptor positive breast cancer was higher among older women, whereas the prevalence of HER-2 positive or triple negative breast cancers was more common among the younger ones. More recently, a study from Duke University showed that a cluster of 24 genes purporting a particularly bad prognosis was more common in breast cancers occurring in women aged 35 and younger [33]. In breast cancer, the characteristics of the tumor bearer may also lead to a more indolent disease in older women. These include endocrine senescence and possibly immune senescence. Through mechanisms that have not been completely clarified, immune senescence may also be a favorable prognostic factor in the case of breast cancer [34].

Age is a poor prognostic factor in both follicular and large cell lymphoma. In the case of large-cell lymphoma, the prevalence of unfavorable genomic abnormalities does not seem to change with age, so that the seed does not seem different with age [35]. Increased concentration of IL6 in the circulation may explain in part the poorer prognosis in older individuals, because IL-6 is a lymphocytic growth factor. A recent study showed that the stromal pattern (stromal II), rich in new vessels, heralds a poor prognosis [36]. It is not clear whether this pattern becomes more common with age.

In conclusion, aging is associated with a different behavior and prognosis in a number of common neoplasms. These changes may be explained by fairly well defined genomic and proteomic changes in the tumor cell (seed effect) and less well defined but equally well established changes in the tumor host (soil effect). The exploration of soil effects in tumor growth appears as a promising research area in geriatric oncology.

Aging and Cancer Prevention

Aging has contrasting effects on cancer prevention [22]. On one side, the increasing prevalence of cancer in the older person makes the aged an ideal target of cancer prevention; on the other side, reduced life-expectancy, increased risk of treatment complications, and the less aggressive course of some tumors, such as breast cancer, may lessen the benefits of prevention in older individuals. We'll briefly describe two common forms of cancer prevention: chemoprevention and early detection.

Chemoprevention

Chemoprevention involves offsetting carcinogenesis with chemical substances. Older individuals appear as ideal targets for chemoprevention because of their condition of advanced tissue carcinogenesis and increased susceptibility to late stage carcinogens. A number of chemopreventative agents are available (Table 3.2), but none of them has widespread clinical use. The selective estrogen receptor modulators (SERM) tamoxifen and raloxifen prevent the occurrence of hormone-receptor positive breast cancer, but neither has been associated with a decreased risk of breast cancer mortality [37]. Both may exacerbate menopausal symptoms such as hot flashes and vaginal dryness and may cause deep vein thrombosis (more common in women 70 years and older who are overweight). Unlike tamoxifen, raloxifen does not cause endometrial cancer. Both substances prevent osteoporosis. Given the lack of demonstrable survival advantage and the substantial compromise of quality of life, the majority of practitioners do not recommend this form of cancer prevention.

Finasteride reduces the incidence of prostate cancer but it may increase the risk of aggressive prostate cancer [38]. Until this issue is properly addressed, the value of finasteride as a chemopreventative agent remains dubious. Furthermore, the treatment may cause gynecomastia and decreased libido. An ongoing trial explores the chemoprevention of prostate cancer with a dual 5alpha reductase inhibitor, dutasteride [39].

Retinoids may reduce the risk of smoking-related cancer of the upper digestive tract and airways, but the high incidence of serious complications prevents the general use of these agents [40].

TABLE 3.2 Chemopreventative substances

Selective estrogen receptors modulators (SERMs)	Breast cancer
Retinoids	Upper airways
Finasteride	Prostate
Non-steroidals (NAS)	Large bowel
Statins	Multiple cancers

A number of retrospective studies support a reduction in the incidence of colorectal cancer with aspirin and other non-steroidal agents [41]. A small prospective study showed that Vioxx, no longer clinically available, reduced the number and the size of colonic polyps in patients with familial colonic polyposis. The clinical applications of these findings are problematic; in the absence of prospective studies, the dose and the treatment duration are unknown. The cancer-preventing ability of statins is controversial [42].

In conclusion, some human cancers may be prevented with chemoprevention, but the benefits of this cancer-preventing strategy are marginal at best.

Screening and Early Detection of Cancer

Early detection of cancer by screening asymptomatic individuals at risk has reduced cancer-related mortality from breast cancer among women aged 50–65, the mortality from cervical cancer for sexually active women, and the colon cancer-related mortality for people aged 50–80 [22]. The benefits of early detection may decline with age, given the patient's limited life expectancy and increased susceptibility to treatment complications. Is screening beneficial in older individuals? Data from randomized controlled studies are nonexistent and probably will never be obtained. Given the rapid development of new diagnostic techniques, randomized studies would become obsolete by the time they have been terminated. Retrospective analysis based on SEER data suggests that mammographic screening for breast cancer may be beneficial up to the age of 85, even in women with moderate degrees of comorbidity [43, 44]. Some form of screening for colorectal cancer appears reasonable in individuals with a life expectancy of 5 years and longer. Indiscriminate screening in older individuals is not advisable as it may have more complications than benefits [45]. In this respect, it is useful to remember that the United State Preventive Service Task Force (USPSTF) recently issued a recommendation against screening men aged 75 and older for prostate cancer because the risk of complications from unnecessary treatment appears to overwhelm the potential benefits of early detection [46].

Aging and Cancer Treatment

It has already been highlighted that aging involves a reduced life expectancy and reduced tolerance of stress, including cancer and cancer treatment. The risk/benefit ratio of preventive and therapeutic interventions may become smaller with age. The risk of therapeutic complications may mandate the enactment of measures that may ameliorate these complications, such as the administration of myelopoietic growth factors following

cytotoxic chemotherapy or adjustment of the doses of chemotherapy to the glomerular filtration rate (GFR) [47].

In addition to prolongation of survival and preservation of quality of life, preservation of function is another major goal of cancer treatment in older individuals (which is often referred to as “active life expectancy”) [48]. Functional dependence purports a decline in a person's life expectancy and quality of life, and substantially increases costs of management of the older aged person. Cancer treatment in older persons should therefore be undertaken with these considerations in mind.

Assessing the Geriatric Patient for Cancer Treatment

Clearly, elderly cancer patients may benefit from an array of treatment modalities. The practitioner is often faced with the vexing decision of whether to recommend a toxic treatment to patients with compromised functional status. While aging is universal, the rate of aging is highly individualized. For the purpose of clinical decisions, it is thus important to estimate each person's physiologic age rather than relying on chronological age alone. As the prevalence of age-related changes increases rapidly after the age of 70, it appears reasonable to estimate the physiologic age of individuals aged 70 and older [49–51]. In this estimate, it is important to remember that social support is instrumental to overcome some age-related limitations in a person's activities. For example, a reliable home caregiver may provide adequate access to care to a person unable to use transportation and to mitigate the complications of treatment.

The time honored methods to assess the physiologic age of an individual is a comprehensive geriatric assessment (CGA) that includes ability to perform activities of daily living and instrumental activities of daily living, comorbidity, presence of geriatric syndromes, nutrition, and social support [47, 52, 53]. Activities of daily living (ADL) include transferring, continence, feeding, grooming, dressing, and ability to use the bathroom alone. Instrumental activities of daily living (IADL) include use of transportation, ability to take medications, to provide to one's nutrition, to go shopping, using the telephone, and to manage one's finances. The geriatric syndromes are conditions that become more common with aging, although they are not specific of age, and include dementia, severe depression, delirium triggered by diseases and drugs that do not affect the central nervous system, spontaneous bone fractures, falls, dizziness, failure to thrive, and neglect and abuse.

The CGA provides an estimate of life expectancy on the basis of age, function, and co-morbidity. Using the CGA, 4 year mortality of patients of different ages (Fig. 3.2) can also

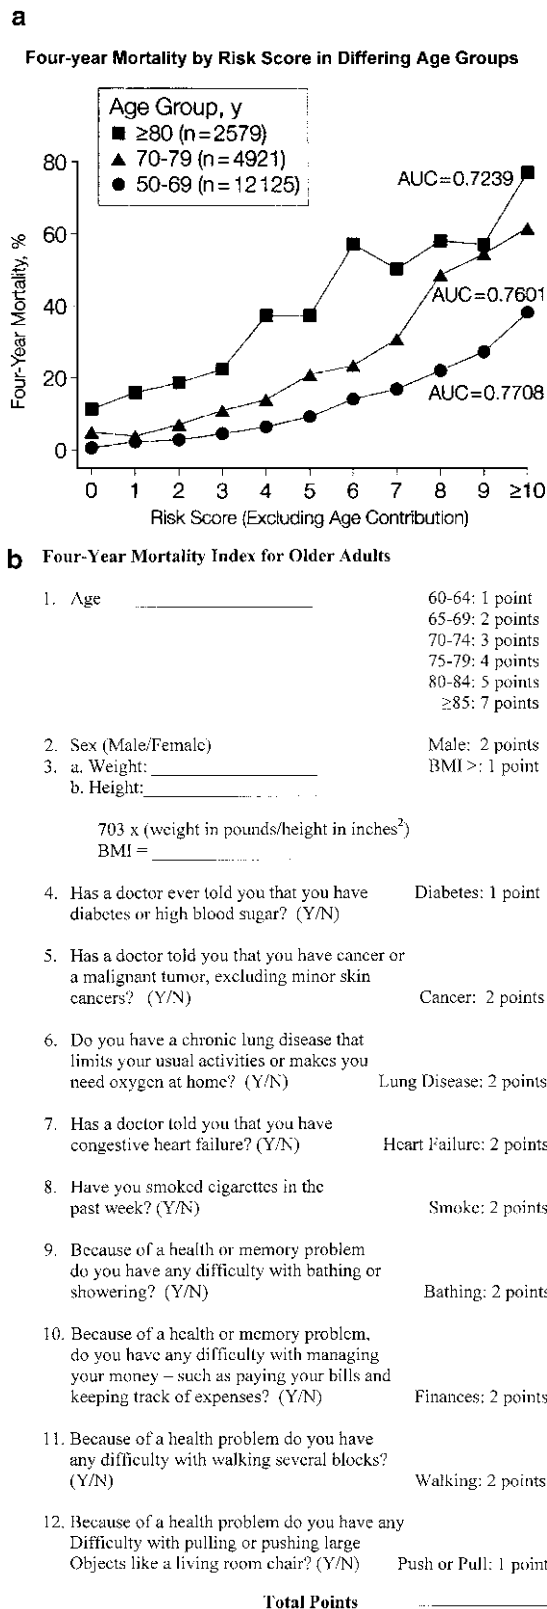

FIGURE 3.2 (a) The relationship between age, geriatric assessment, and 4-year mortality in a home dwelling population. (b) Mortality index: each element of the geriatric assessment receives a score. The total score provides an estimate of the 4-year mortality for individuals of different ages (from Lee et al. [49] Copyright © 2006 American Medical Association. All rights reserved).

be estimated [49]. The CGA also provides information on treatment tolerance on the basis of function and co-morbidity, as well as of family support and cognition (information of how treatment and cancer affect quality of life). According to recent studies, the CGA may also provide an estimate of the risk of chemotherapy-related complications [54]. An ongoing study, the Chemotherapy Risk Assessment Score in High Age Patients (CRASH) is aimed to assess the contribution of the various components of the CGA to an individual's risk of myelotoxicity and other complications.

The CGA also provides a profile of potentially reversible conditions, such as malnutrition, limited mobility, inadequate social support, and unrecognized geriatric syndromes, which may compromise treatment outcome.

Perhaps most importantly, the CGA translates the diversity of the elderly population into objective categories that may be used when planning clinical trials of cancer treatment in old persons.

Systemic Therapy

Hormonal Therapy

The major forms of hormonal cancer treatment are listed in Table 3.3. In the management of breast cancer, both adjuvant and metastatic, the aromatase inhibitors have proven more active than the SERMs and are now the management of choice. The main complications of these agents include severe arthralgias and osteoporosis [55]. The SERMs tamoxifen and toremifene may delay osteoporosis, but do cause endometrial cancer and deep vein thrombosis and the risk of these complications increases with age and in the presence of obesity. They may still represent valid options for the occasional patient for whom arthralgia causes severe impairment of movements. The role of the pure estrogen antagonist, Faslodex®, is not clear at present. This agent does not cause endometrial cancer and deep vein thrombosis. Progestin, estrogen in high doses,

TABLE 3.3 Common hormonal treatment of cancer

Tumor	Cancer
Breast	Aromatase inhibitors
	Selective Estrogen Receptor Modulators (SERMs)
	Pure estrogen antagonists (Faslodex)
	Progestins
	Estrogen in high doses
Prostate	Androgen
	Orchiectomy
	Estrogen
	LH-RH analogs
	Ketoconazole
	Abiraterone

and androgen are rarely used, although they may still have a role, especially in patients without visceral disease who have experienced a prolonged response to hormonal treatment.

Castration, surgical or chemical (LH-RH analogs, estrogen, ketoconazol, abiraterone), is the treatment of choice for metastatic prostate cancer and for locally advanced prostate cancer in combination with radiation therapy. The benefits of treating patients experiencing a chemical recurrence (elevated PSA) after prostatectomy or radiation have not been established, although this approach has become a common practice. Prolonged castration with LH-RH may cause increased risk of bone fractures, diabetes, and coronary artery disease [20, 21]. Intermittent medical castration may be as effective as continuous castration, and is associated with fewer complications [56]. Estrogens are now seldom used, because of the risk of deep vein thrombosis, but they had significant benefits over LH-RH analogs, including preservation of libido, as well as prevention of osteoporosis and hot flashes.

Ketoconazol blocks steroidogenesis throughout the body. Without a supplement of corticosteroids, it would cause renal insufficiency. It may also cause hepatitis. It is generally used after disease progression with LH-RH analogs. Abiraterone, currently in clinical trials, has two advantages over current treatment [57]. Unlike ketoconazol, it selectively blocks the production of sexual steroids in the testicles and the adrenal. Also, it seems to prevent steroidogenesis within the neoplastic tissue which is a major cause of resistance to current hormonal treatment. Androgen antagonists are mainly used in combination with castration; as single agents, they are less effective than castration. As single agents, they may represent the treatment of choice for patients who do not want to lose their libido.

Cytotoxic Chemotherapy

Cytotoxic chemotherapy is still the mainstay systemic cancer treatment. Individuals over the age of 70 appear to benefit from cytotoxic chemotherapy in terms of cure, survival prolongation, and palliation. It is important to recognize, however, that the information related to patients aged 80 and older is very limited [58].

A number of complications of chemotherapy become more common with aging (Table 3.4). This is due in part to age-related alterations in pharmacokinetics and in part to decreased functional reserve of normal tissues. The most common pharmacokinetic change is reduction in GFR. Other changes of interest that are more difficult to assess include decreased intestinal absorption and hepatic metabolism, and decreased volume of distribution of hydrosoluble agents.

Myelotoxicity and febrile neutropenia may be prevented in more than 50% of older individuals with prophylactic myelopoietic growth factors (filgrastim, pegfilgrastim, and lenograstim). Prevention of malnutrition and anemia may also ameliorate the complications of chemotherapy to some extent.

TABLE 3.4 Age and complications of chemotherapy

A. Acute complications

Neutropenia and neutropenic infections
Mucositis
Cardiomyopathy
Neuropathy

B. Chronic complications

Myelodysplasia (MDS) and Acute Myelogenous Leukemia (AML)
Chronic cardiomyopathy and congestive heart failure
Neuropathy
Dementia

Cardiotoxicity may be prevented by avoidance of cardiotoxic anthracyclines, by combining anthracyclines with dexrazoxane, a drug that chelates the iron in the heart sarcomeres and prevents the release of free radicals responsible for the cardiac damage, or by substituting doxorubicin with pegylated liposomal doxorubicin that causes minimal cardiac damage. The use of anthracyclines has decreased dramatically in recent years and is largely restricted to the management of lymphomas and leukemias.

Mucositis is mainly a complication of methotrexate and intravenous fluorinated pyrimidines. There is no proven antidote to mucositis, but the utilization of the oral prodrug of fluorouracil, capecitabine, in lieu of intravenous fluorouracil may minimize this complication.

Peripheral neuropathy is a complication of alkaloids, platinum derivatives, and tubulin modulators (taxanes and epothilones), and may restrict considerably the independence of older individuals. The only prevention is early detection and dose-reduction. The substitution of cisplatin with carboplatin and of paclitaxel with docetaxel may minimize the risk of peripheral neuropathy.

The long term complications of chemotherapy in older individuals have been described only in the last 5 years [10–13, 16–19]. Age is a risk factor for anthracyclines induced myelodysplasia and acute leukemia. The reduced role of these drugs in the adjuvant treatment of breast cancer will minimize the risk of this complication; likewise, age is a risk factor for a chronic cardiomyopathy, incidence of which increased over the years since the chemotherapy was terminated, and has been described in patients treated for breast cancer, lymphoma, and small cell cancer of the lung. According to a SEER study, the incidence of dementia increases progressively in breast cancer patients treated with chemotherapy beginning 3 years from the termination of the treatment [19].

Unfortunately, there is no information concerning the most undesirable chronic complications of chemotherapy in older individuals, loss of independent living, and decreased active life-expectancy. Prospective studies of survivors are necessary to establish the risk and the prevention of this complication.

The NCCN has issued a number of guidelines for the safe management of older individuals with chemotherapy (Table 3.5) [47].

TABLE 3.5 NCCN guidelines for the management of older patients with chemotherapy

1. A geriatric assessment is necessary in all individuals aged 70 and older with cancer. This may provide an estimation of life expectancy and tolerance of treatment, and it may unearth conditions such as comorbidity or inadequate social support that may interfere with treatment
2. All patients aged 65 and older receiving moderately toxic chemotherapy should receive prophylactic filgrastim or peg-filgrastim
3. Hemoglobin should be maintained around 12 g/dl
4. In patients aged 65 and over, the dose of chemotherapy should be adjusted to the GFR
5. When possible the less toxic forms of chemotherapy should be utilized including capecitabine, pegylated liposomal doxorubicin, gemcitabine, vinorelbine, weekly taxanes, and pemetrexed

Targeted Therapy

An exhaustive review of the subject is beyond the scope of this chapter. We'll describe here commonly used products relevant to the management of older patients [59].

Imatinib is the quintessential form of targeted therapy. This small molecule is an inhibitor of the cytoplasmic tyrosine kinase, and has prolonged the survival of patients with chronic myelogenous leukemia, who now rarely need bone marrow transplantation. It is also effective against the tyrosine kinase encoded by c-Kit and for this reason, it is effective in gastro-intestinal stromal tumors (GIST). Complications are rare and reversible, and include myelosuppression and fluid retention.

Rituximab is a monoclonal antibody with CD20 specificity that has improved the survival in virtually all B-cell malignancies. Besides rare allergic reactions, the incidence of complications is minimal, although it has been reported that long term use may lead to demyelinating disorders.

Alentuzumab is also a monoclonal antibody with CD52 specificity that is very effective in some of the most therapy-refractory B-cell malignancies such as chronic lymphocytic leukemia with 17p (-) mutation. This agent has considerable myelotoxicity and should be used with prophylactic antimicrobial coverage.

Trastuzumab has revolutionized the history of the 25% of breast cancers that over-express HER2neu. It is a monoclonal antibody with specificity for Epidermal growth factor 2 (EGFR2). In combination with chemotherapy in the adjuvant setting, it almost doubles the number of patients who are free of disease 5 years from mastectomy. Trastuzumab causes myocardial freezing by interfering with myocardial trophism. Age is a risk factor for this complication that is generally reversible upon discontinuance of the treatment.

Bevacizumab is a monoclonal antibody directed against the endothelial growth factor, which inhibits tumor angiogenesis and decreases intratumoral pressure, thus allowing better chemotherapy diffusion. As a single agent, bevacizumab is

active only in renal cell carcinoma, but it enhances the effects of chemotherapy in cancer of the colon, of the lung, and of the breast. Bevacizumab is associated with hypertension, bleeding, and deep vein thrombosis. It should not be used within 4 weeks of surgery, because it interferes with healing. Rarely, after abdominal surgery, bevacizumab has caused visceral perforation. All complications of bevacizumab are more common in the aged.

Receptor bound tyrosine kinase is critical to the signal transduction. This enzyme is the target of a number of agents, both monoclonal antibodies and small molecules. A common complication of all these agents is a maculopapular rash, that is more common and severe in the elderly, in whom necrolytic epidermolysis occasionally may be fatal.

Conclusions

Age is a risk factor for cancer because carcinogenesis is a lengthy process, older tissues are more susceptible to environmental carcinogens, and changes in the body environment favor cancer growth. Changes in cancer behavior are seen in some common malignancies. These are partly because of a change in the neoplastic cell and of changes in the tumor host. Although the elderly appear as ideal targets for chemoprevention, the benefits of this form of prevention have not been conclusively demonstrated. Screening and early detection of breast and colon cancer may be beneficial in older individuals with a life expectancy of at least 5 years. Systemic cancer treatment is effective in older patients. Although the complications become more common with age, most of the time they may be minimized with appropriate interventions.

Chapter 4

Effects of Aging on Immune Function

Raymond P. Stowe and James S. Goodwin

Physiologic changes with age – immune system

Parameter	Change with age	Functional impact of change
T-cells		
Memory T cells	Increase	Increased susceptibility to acute viral infections; increased latent herpesvirus reactivation along with clonally expanded CD8 ⁺ T-cells
Thymus gland	Decrease (involuting)	
Naïve T cells	Decrease	
DTH	Decrease	
IL-2 production	Decrease	
Proliferation	Decrease	
Cytotoxicity	Decrease	
B-cells		
Number	Decreased	Increased autoantibodies; decreased antibody production following vaccination
High-affinity antibodies	Decreased	
Non-specific antibodies	Increased	
Inflammation		
Increased morbidity and mortality; may play a role in age-related diseases (Alzheimer's, Parkinson's, osteoporosis, atherosclerosis, and type-2 diabetes)		
Low-grade inflammation		
Circulating IL-6	Increased	
Circulating TNF- α	Increased	
CRP	Increased	

In this chapter we describe changes in the immune system that are thought to be related to age per se. We subsequently review the clinical implications of these changes, including the effects of surgical trauma on immune function (see the physiology table at beginning of chapter). We then discuss how stress modifies many of these changes. We also describe recent information on persistent infections, in particular latent viral infections and how they may be partly responsible for shaping the aging immune system. We conclude with a discussion of some of the latest research on ways to restore or stimulate immune function in the elderly.

Changes in Immune Cell Function with Age

T Lymphocytes

Quantitative changes in T cell populations in aging humans and experimental animals include declines in “virgin” (reactive) T cells and increases in “memory” (primed) T cells [1–5]. It is not clear which subpopulations account for the accumulation of memory cells. Some studies have described increases in the population of CD4⁺ T-helper memory cells [6] and others reported increases in CD8⁺ T suppressor memory cells as well [1]. Although the number of naive T cells declines in old animals, they appear to produce larger amounts of interleukin-2 (IL-2) than naive cells from young animals [7]. Memory T cells normally produce IL-2; and although aged animals have larger proportions of memory

cells, many studies have described decreased IL-2 production by aged memory lymphocytes. This paradox of low production of IL-2 despite increased proportions of IL-2-producing cells may be related to a lack of other regulatory cytokine signals, such as IL-4 [8].

A decrease in the proliferative response of lymphocytes to specific antigens or nonspecific mitogens was one of the earliest age-related changes in immune function to be reported [9–12]. Decreased responsiveness to mitogens is due to a number of variables, including reduced numbers of mitogen-responsive cells and decreased vigor of the proliferative response [10]. A smaller percentage of T splenocytes from old mice respond to mitogenic stimulation by entering active phases of cell replication, a defect noted with CD4⁺ T-helper cells and to a lesser extent with CD8⁺ T suppressor/cytotoxic cells [13]. Some studies suggest that the type of stimulus may affect the degree of decreased proliferation of lymphocytes from old animals [14]. T-helper cells from old mice generate fewer cytotoxic effector cells involved in delayed hypersensitivity skin reactions [15].

The ability of T cells to support antibody production changes with increasing age. Lymphocytes from old subjects display increased helper activity *in vitro* for nonspecific antibody production [16, 17], and they proliferate more to nonspecific stimulation [14]. Studies comparing suppressor cells from young and old mice have shown that cells from aged animals have more difficulty in recognizing and exerting suppressive effects against specific antigens from self and other old animals [17–20]. The increased incidence of autoantibodies seen during aging (antibodies directed against parts of the self) may be related to a failure of tonic inhibition by suppressor T cells [21] and has been correlated with the decreased proliferation of T cells to mitogen [22] (i.e., the lower the proliferation of T cells to mitogens, the higher was the level of autoantibodies).

One mechanism that is believed to contribute to the decline in T cell immunity is involution of the thymus, which precedes the age-related decline in T cell function and decreased thymic hormone levels (Fig. 4.1). Thymic function gradually starts declining from the first year of life [23, 24]. The thymic epithelial space, in which thymopoiesis occurs, shrinks to less than 10% of the total thymus tissue by age 70. Despite the reduction in functional thymic area, the aging thymus still demonstrates T-cell output although at a lesser rate [25]. The continual presence of T-cell receptor excision circle-positive T-cells, which represent recent thymic emigrants, were found in the peripheral blood of elderly adults [26]. Thymic atrophy has been speculated to be the result of aging of the T-cell progenitor population [27], loss of self-peptide expressing thymic epithelium [28], defects in TCR β gene rearrangement [29], and aging of the thymic microenvironment with loss of trophic cytokines such as IL-7 [30].

Another mechanism contributing to T cell immunosenescence is “replicative senescence” [31]. Senescent T cells

in vitro exhibit a loss of CD28, a costimulatory molecule critical to the outcome of antigen recognition and signal transduction induced by the T-cell receptor [32]. Similarly, during aging, there is a progressive accumulation of memory CD8 T cells that are CD28-negative, with some elderly adults having more than 50% of their total CD8 T cells being CD28-negative [33, 34]. Notably, CD28 is involved in a number of critical T-cell functions such as lipid raft formation, IL-2 gene transcription, apoptosis, stabilization of cytokine mRNA, and cell adhesion [35–37].

Another observation of CD28-negative T cells is their inability to proliferate, even when using phorbol esters to bypass cell-surface receptors and directly signal proliferation [38]. Extensive research on a variety of cell types have attributed this to the irreversible nature of the proliferative block, which is linked to the upregulation of cell-cycle inhibitors and p53 checkpoints [39]. Once generated, these T cells do not disappear, but show increased expression of bcl2 and are resistant to apoptosis *ex vivo* [40]. Moreover, increased CD8⁺CD28⁻ T cells are often present as a result of oligoclonal expansions that may reduce the overall spectrum of antigenic specificities within the T cell pool [31, 41].

A clinically important implication of large expansions of antigen-specific CD8 T cells in the elderly is that they appear to function as suppressor T cells and affect a number of immune parameters. Poor antibody responses to influenza vaccination in the elderly were significantly correlated with high proportions of CD8⁺CD28⁻ T cells [42, 43]. High levels of CD8⁺CD28⁻ T cells also correlate with greater disease severity in patients with ankylosing spondylitis [44]. CD8⁺CD28⁻ T cells have been implicated as the critical subset in allogeneic organ transplant tolerance, whereby donor-specific CD8⁺CD28⁻ T cells can be found in peripheral blood of stable transplant recipients but not in patients with acute rejection [45]. Notably, CD8⁺CD28⁻ T cells have been shown to induce antigen-presenting cells to become tolerogenic to helper T cells with cognate antigen specificity [45]. Importantly, increased numbers of CD8⁺CD28⁻ T cells (along with low CD4 and poor proliferative responses) were found to predict higher 2-year mortality in a Swedish longitudinal study [46].

B Lymphocytes

Age-related quantitative changes in B cells have become apparent more recently than those described in T cells. The absolute number of B cells does not appear to change appreciably with age [47]. Studies in aged mice have shown a decrease in bone marrow B-cell precursors [48–50] and structural changes in B-cell membranes [51]. B cells from old individuals proliferate less efficiently in response to mitogen stimulation, similar to what has been described for T cells [21]. Also similar to T cells [52], activation of PKC

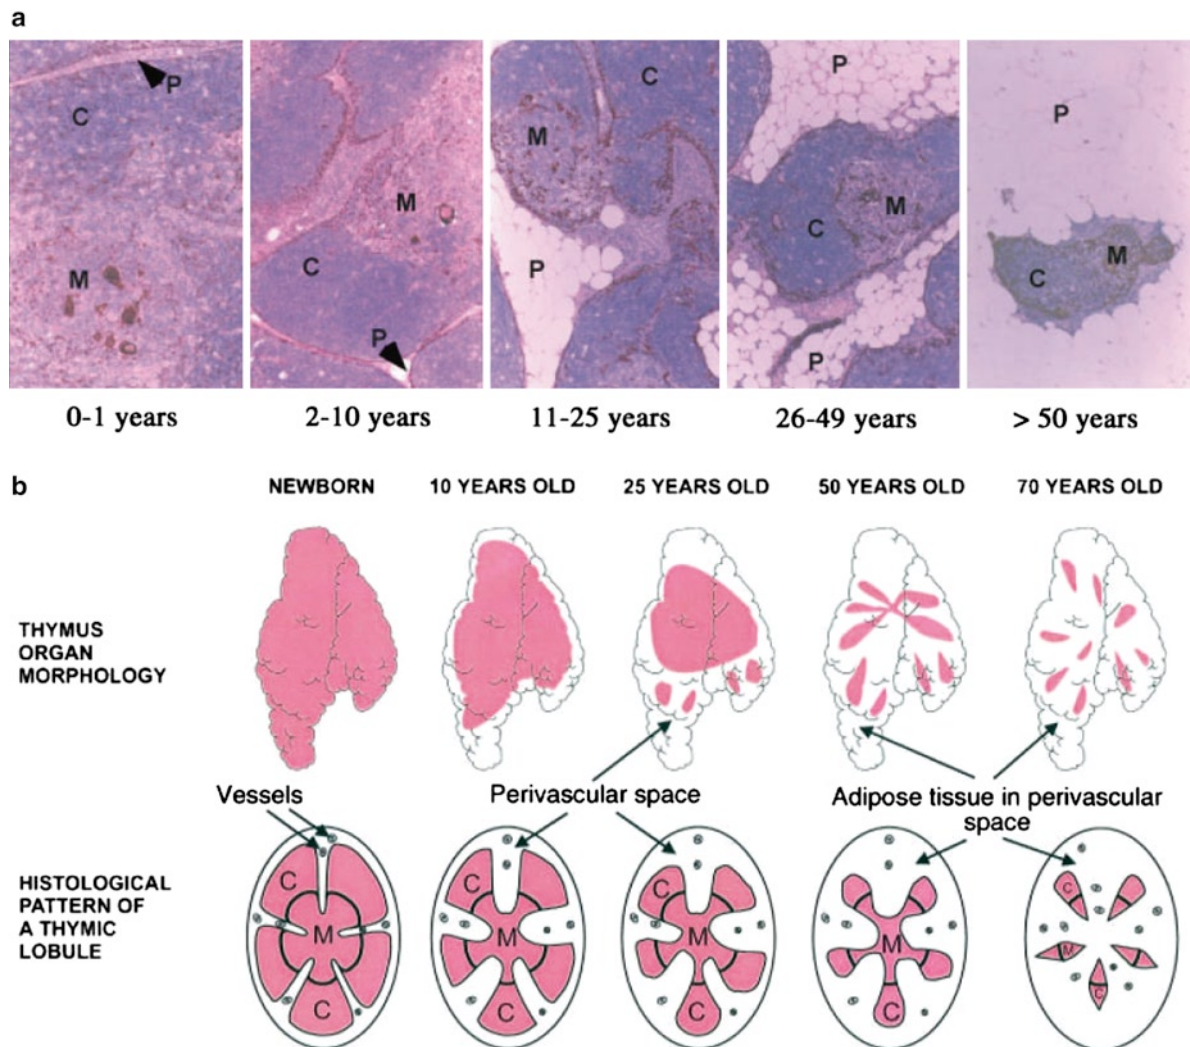

FIGURE 4.1 The human thymus across the lifespan. (a) Representative views of human thymus morphology throughout aging. and protein tyrosine kinases is reduced in B cells from old humans [53]. The expression of PKC was not reduced in B cells in this study [54].

The generation of antibody responses by B cells does change with age [55], although much of it is related to changes in T cell function. The distinction between antibody responses to T cell-dependent and T cell-independent antigens is made on the basis of whether there is an absolute requirement for T cell help in the antibody response. The decrease in T cell-dependent antibody responses is obvious in experimental animals, with 80% fewer antibody-forming cells in older animals [2]. The accumulation of anti-idiotypes (antibodies directed against other antibodies) with increasing age may interfere with the production of specific antibody [56].

The ability to respond to specific antigenic challenge with specific antibody production decreases with age [55].

This phenomenon has been described in studies of both primary and secondary antibody responses. When subjects of different ages were immunized with the primary antigen flagellin, similar levels of anti-flagellin antibody were found in both old and young subjects, but the older subjects were unable to maintain the response [57]. In contrast, De Greef et al. immunized old and young subjects with the primary antigen *Helix pomatia* hemocyanin. Compared to young subjects, old subjects had similar numbers of antibody-producing cells after in vitro stimulation with the antigen [58].

Although most investigators agree that changes in antibody production with age are primarily the result of declines in T lymphocyte function, there is also evidence for a decline in intrinsic B cell function. Some studies suggest a diminished ability of purified human B cells to respond to purified T-helper cells, or to T cell-derived helper factors [59, 60].

Studies with murine cells have shown that certain subsets of B cells from old animals function at a much lower level than the same cells from young mice, whereas other subsets produce comparable levels of antibody [61]. Cerny et al. found that the antiphosphorylcholine antibody produced by aged mice did not protect animals against lethal doses of *Streptococcus pneumoniae*, although old animals produced levels of antibody comparable to those in young animals [62]. The genes encoding the variable heavy portions of the antibody molecule were different in the old mice. The resulting antibody had lower affinity for the bacterial antigen and conferred less protection [62, 63].

Macrophage Function

Macrophage function during aging is particularly relevant to the theme of this book, suggesting that “old” macrophages are comparable to “young” macrophages in terms of producing similar levels of cytokines. Differences in function appeared to be modulated through changes in T and B cell responses to the cytokines [64, 65]. Studies of human monocytes have shown decreased secretion of IL-1 with mitogen stimulation [66]. Bone marrow stem cells from senescence-accelerated mice are defective in their ability to generate granulocyte/macrophage precursor cells [67]. In vivo function of macrophages illustrated by cutaneous wound healing in mice, showed that wounds in aged control animals took twice as long to heal as in young ones [68]. When peritoneal macrophages from animals of different ages were added to wounds on old mice, healing was accelerated regardless of the age of the source animal, although, macrophages from young mice accelerated the healing process to the greatest degree [68].

Studies of macrophage function in aged mice and humans suggest defects in macrophage–T cell interactions. Antigen-sensitized macrophages from old mice stimulated significantly lower levels of T cell proliferation than sensitized macrophages from young mice [14]. Dendritic cells are tissue-fixed macrophages that stimulate formation of germinal centers in lymph follicles where B cell memory develops; they thus play an important role in the secondary immune response. Szakal et al. described serious age-related compromise in this pathway [69]. When macrophages were replaced with other sources for activation (e.g., IL-2, or an activator such as phorbol-12-myristate-13-acetate), T cells from old adults displayed enhanced responses [70]. Macrophages from young adults were able to restore old T cell responses to the level seen in young adults in 70% of the subjects studied. Because the “old” macrophages effectively supported “young” T cells, the authors postulated that the defect resulted from impaired macrophage–T cell communication [70].

In other studies, monocytes from old adults displayed less cytotoxicity against certain tumor cell lines, decreased production of reactive oxygen intermediates (H_2O_2 and NO_2), and lower IL-1 secretion than monocytes from young adults [66, 71].

Natural Killer Cells

Natural killer (NK) cells are cytotoxic cells with the ability to lyse targets without the need for antigenic sensitization, a characteristic that distinguishes them functionally from cytotoxic T cells. Lymphokine-activated killer (LAK) cells, thought to be highly activated NK cells, are able to lyse certain cell lines that are resistant to NK cells. NK cells from mice display a declining ability to lyse spleen cells with increasing age [72, 73]. Most studies using old human subjects have shown little or no change in NK cell cytotoxic ability [74]. There do appear to be differential requirements for maximal activation of NK cells by interferon- α ($IFN\alpha$). Young NK cells show maximal responses when stimulated with low concentrations of $IFN\alpha$ [75]. The activity of LAK cells from old humans appears to be reduced compared to that of LAK cells from young humans [74, 75].

Changes in Production and Response to Regulatory Factors

Prostaglandins

Prostaglandin E_2 (PGE_2), a metabolite of cell membrane arachidonic acid, is a feedback inhibitor of T cell proliferation in humans [76]. T cells from adults over 70 years of age are a magnitude more sensitive to inhibition by PGE_2 than those from adults less than 40 years of age [9, 77]. Thus PGE_2 may interfere with expansion of antigen-specific T-helper cell clones. T cells from aged mice are not only more sensitive to inhibition by PGE_2 , their splenocytes appear to produce more PGE_2 than splenocytes from young mice [78]. Meydani et al. have continued to provide evidence that macrophage production of excess PGE_2 is a significant mechanism in the suppression of T cell proliferation and IL-2 production in old mice [79].

Delfraissey et al. found that PGE_2 suppressed the primary antibody response to trinitrophenylated polyacrylamide beads by lymphocytes from old adults [65]. Removing the monocytes that were the source of PGE_2 production or adding drugs that blocked production of PGE_2 , partially reversed

the depressed response [9, 65]. Using a different system of lipopolysaccharide-stimulated versus unstimulated lymphocytes, other investigators have not found increased PGE₂ production in old versus young donors [80]. Polyclonal antibody production was not suppressed by PGE₁ when added to lymphocytes from donors of any age [80].

The increased sensitivity to PGE₂ with age does not appear to be part of a general increase in sensitivity to all immunomodulators. Lymphocytes from subjects over 70 years of age are less sensitive to inhibition by substances such as histamine and hydrocortisone [77].

Interleukins

Interleukins-1 and -2 play a primary role in activation, recruitment, and proliferation of T lymphocytes. Activated T cells then go on to produce a variety of growth and differentiation factors. T-helper (Th) cells can be classified based on the profile of the cytokines they produce and by distinct surface receptors. Th1 cells elaborate IFN- γ , IL-2, IL-12, and tumor necrosis factor- β (TNF- β), leading to the induction of cytotoxic T cells and cellular immunity; Th2 cells elaborate IL-4, IL-5, IL-6, IL-10, and IL-13, which ultimately results in antibody production [81, 82].

A decreased response to IL-2 has been studied extensively as a potential mechanism underlying the age-related defect in cellular immunity. Work from various investigators has demonstrated decreased production of IL-2 after mitogen stimulation, decreased density of IL-2 receptor expression, and decreased proliferation of T cells in response to IL-2 [83–88]. The picture is complicated by variable sensitivity to IL-2 depending on the activation signal [3, 89]. Human memory T cells generally produce low levels of IL-2 when stimulated by mitogen, in contrast to high IL-2 production by young memory T cells [8]. However, production of IL-2 by old cells was greater when a different stimulus was employed [8]. Studies from Nagelkerken's group found no differences in T cell proliferation or IL-2 production when memory T cells from old and young humans were stimulated with a variety of activation signals [3]. CD4⁺ T cells from old mice accumulate similar levels of IL-2 transcripts, though secretion of IL-2 is lower than that seen in cells from young mice [90].

Increasing evidence has been accumulating that there are age-related declines in lymphocyte production and response to cytokines other than IL-2 [2, 91]. Monocytes from aged humans produce levels of IL-1 precursor comparable to monocytes from young humans, although they secrete less IL-1 [67]. Lymphocytes from old individuals produce higher levels of IL-1, IL-2, and TNF- α than those from healthy young individuals in mixed lymphocyte culture [92].

Li and Miller found a threefold decline in IL-4 production with age when activated murine T cells were immobilized with antibody to the T cell receptor, CD3, and cultured with anti-CD3 and IL-2 [93]. Memory T cells from old donors displayed a sixfold deficit in IL-4 production compared to cells from young donors [93]. In a similar system, CD4⁺ T cells from young mice were more sensitive to stimulation with exogenous IL-4, producing much higher levels of IL-2 than old CD4⁺ T cells [8]. Blocking endogenous IL-4 boosted "old" lymphocyte production of specific anti-influenza IgM and IgG1 to levels seen in young animals during a primary antibody response [94]. A similar effect was achieved by blocking endogenous IFN- γ and IL-10 [94]. We have shown that lymphocytes from old adults produce less IL-4 when stimulated with specific antigen than lymphocytes from young adults [95]. When IL-4 is added early during the course of stimulation, old lymphocytes are less inhibited to produce specific antibodies [95], similar to findings described earlier in mice [8].

Other investigators have found no differences between lymphocytes from old and young adults in terms of their ability to produce IL-4 or IL-6 when stimulated with the mitogen phytohemagglutinin [96]. In this system, lymphocytes from old adults produced significantly less IFN- γ [96]. With variation in the activating signals, old human T cells produce larger amounts of IL-4 and IFN- γ [3, 97].

Proinflammatory Cytokines

Aging is associated with elevated levels of circulating inflammatory cytokines such as TNF- α , IL-6, IL-1ra, and the acute phase protein CRP [98–100]. The plasma levels of TNF- α were positively correlated with IL-6, sTNF-RII, and CRP in 126 centenarians indicating an interrelated activation of the entire inflammatory cascade [101]. However, the increased proinflammatory cytokines in healthy elderly adults is not very marked and far from levels observed during acute infection. Thus, aging is associated with chronic low-grade inflammation.

In agreement with low-grade inflammation in aging, aged T cells produce much higher levels of the proinflammatory cytokines TNF- α and IL-6 [102]. Increased production of TNF- α by unstimulated mononuclear cells has been shown [103]. Increased production of IL-6 and IL-1ra by unstimulated mononuclear cells was demonstrated, but no difference was found in levels of TNF- α and IL-1 β [104]. However, cells in tissues other than peripheral blood may also contribute to the increased levels of circulating proinflammatory cytokines such as endothelial cells, adipose cells, and macrophage-derived cells in CNS and peripheral tissues.

Clinical Implications of Age-Related Immune Changes

All-Cause Mortality

We have described a variety of immunologic changes with aging. What are the implications of these changes for the occurrence of disease and maintenance of health in older adults? There is little direct causal evidence linking specific changes in immunity to specific clinical diseases or mortality. Most authorities simply assume that a decline in immune function is deleterious, or use theoretic arguments to support this belief. The question of whether decreased immune responses contribute to morbidity and mortality in elderly persons has been addressed mostly by cross-sectional studies looking for associations between a particular abnormal immune response and general health status [105]. For example, the Baltimore Longitudinal Aging Study found that declines in absolute lymphocyte counts predicted mortality after 3 years in aging men [106]. Ferguson et al. found that the presence of two or more suppressed immune parameters predicted poor 2-year survival in a group of adults over the age of 80 [46].

The response to delayed-type hypersensitivity skin tests has been associated with mortality in a number of studies. Delayed-type hypersensitivity skin testing is thought to be the *in vivo* correlate of *in vitro* mitogen-stimulated proliferation. Elderly subjects who respond poorly or not at all to a battery of antigens placed intradermally (anergy), have an increased risk of mortality compared to elderly subjects who respond well to one or more antigens [12, 107]. We found a twofold higher mortality rate and incidence of pneumonia during 10 years of follow-up in the one-third of healthy elderly individuals who were anergic at initial testing [107, 108].

We and others have examined mitogen-stimulated lymphocyte proliferation in community-dwelling adults over age 65 years [46, 105, 108, 109]. One study found that 18% of adults seen in an outpatient geriatric clinic had lymphocytes that did not respond to any of the three mitogens [109]. These nonresponders had a 26% mortality rate at 3-year follow-up versus 13% mortality in those whose lymphocytes proliferated to at least one mitogen. The increase in all-cause mortality remained significant after controlling medication use, an indirect indicator of health status. Our own studies showed slightly higher all-cause mortality in old adults with low proliferative responses to the mitogen phytohemagglutinin [105].

Response to Immunization and Infections

Adults over the age of 65 experience greater morbidity and mortality in association with common infections, providing a basis for targeting this population with preventive immunization.

Unfortunately, elderly people respond less well to preventive immunizations against common infections compared with young individuals because of the waning of immunity. Epidemiologic evidence suggests that despite decreased efficacy in the elderly, immunizations do reduce morbidity and mortality. The next section focuses on influenza, pneumococcal pneumonia, tetanus, tuberculosis, and herpes zoster, because information is available on disease epidemiology and aging immune responses specific to these entities.

Influenza

Influenza is a common viral respiratory illness that becomes clinically important when complicated by bacterial pneumonia, or when it occurs in debilitated or elderly patients (reviewed by Burns et al.) [110]. Individuals who suffer from one or more chronic, systemic illnesses (e.g., chronic obstructive pulmonary disease, diabetes, chronic renal insufficiency) experience a 40- to 150-fold increase in the basal incidence rate for influenzal pneumonia of four cases per 100,000 persons per year. More than 80% of deaths related to influenza epidemics occur in the elderly [111], and the risk of developing influenzal pneumonia or superimposed bacterial pneumonia increases with increasing age. Individuals living in long-term care facilities are at particularly high risk of morbidity and mortality.

After vaccination with influenza, old mice display impaired cytotoxic T cell function and ineffective antibody generation against the virus [112]. When an intranasal viral load is administered after vaccination, old animals are more likely to develop influenzal pneumonia than young animals [112]. Studies in humans have described impaired production of anti-influenza antibodies and impaired influenza-specific cytotoxic activity in old adults compared to that in young adults [113]. Some of the mechanisms mediating this response include reduced IL-2 production and T cell activation *in vivo* and *in vitro* [85]. NK cell cytotoxicity is unchanged in old adults after vaccination against influenza, in contrast to increased NK cell activity in young adults [114]. Elderly individuals who do display a significant response to influenza vaccine have increased numbers of T cells capable of responding to the specific viral stimulus, whereas nonresponders have low numbers of such cells [115]. After immunization, IgG and IgG1 antibody production and agglutinating ability were decreased in the elderly compared to that in young subjects [116]. The investigators were able to restore the responses of the elderly subjects to the levels seen in young subjects by doubling the dose of vaccine [116].

Although influenza vaccination is less effective in the higher risk population of old adults, the incidence and severity of influenza infections is clearly reduced by annual usage of the standard preparation [117]. The vaccine confers the highest degree of protection when the epidemic strains are similar to those in the vaccine [118]. Even when the antigenic

determinants of the wild virus have drifted over the course of a year, vaccine utilization can still have a substantial impact on morbidity and mortality [117].

Pneumococcal Pneumonia

An increased incidence of morbidity and mortality due to pneumonia has been recognized in the elderly for years [110]. Hospitalization necessitated by a diagnosis of pneumonia is most often caused by bacteria, primarily (about two-thirds of cases) *S. pneumoniae*. High mortality rates result from the increased incidence of bacteremia and meningitis seen in old adults. Similar to influenza, patients with one or more chronic systemic diseases are at increased risk of complications and mortality from pneumococcal infection.

Most of the information on the immunologic response to pneumococcal vaccination derives from murine studies. After vaccination with phosphocholine, old mice produced levels of antibody similar to those in young mice, but with a molecular shift in the antibody repertoire [62]. The antibody produced by old animals has a lower affinity for its target and is less effective in preventing infection [62]. In old mice, many of the antibodies produced after pneumococcal vaccination cross-react with self-antigens [62]. In humans, serum antibody levels fade more rapidly in old individuals, prompting recommendations to re-vaccinate after 6 years in elderly patients [119]. The vaccine has been estimated to be about 70% effective for reducing morbidity and mortality in the elderly [120].

Tuberculosis and Intracellular Infections

For more than 20 years the risk of active tuberculosis in the Western world is increasingly confined to two populations: those with immunocompromising diseases (e.g., AIDS) and the very elderly [121, 122]. Animal studies show that old mice display increased susceptibility to infection with *Mycobacterium tuberculosis* [123]. The infection containment rate in old mice is similar to that in young animals; but once pulmonary infection is established, there is increased hematogenous spread to other organs [123]. Old animals display decreased CD4⁺ T cell function, significantly lower levels of IL-12 in the lung [123], and delayed emergence of protective, IFN- γ -secreting CD4⁺ T cells [124]. The protective cells from old animals were slower to express surface adhesion markers necessary for migration across endothelial linings to sites of active infection [124]. The increased spread of disease in old animals may also be related to alterations in other cytokine levels [123]. Orme has shown that CD4⁺ cells from young mice protect old mice from infection, suggesting that old macrophages function adequately and the major defect lies in the T cell population [123, 124].

Herpes Zoster

There is a clear positive correlation between age and the incidence of herpes zoster, with an annual incidence rate of 400 cases per 100,000 adults over age 75 [125]. Other surveys suggest an even higher overall incidence [126]. The varicella-zoster virus (VZV) is harbored in dorsal root ganglia for many decades following childhood illness; and when it is reactivated it causes a cutaneous, varicella-type vesicular eruption involving the dermatome of the involved dorsal root ganglion.

Cellular immunity, measured by cutaneous delayed hypersensitivity to varicella zoster, wanes with increasing age, although other factors may be involved in controlling viral latency [127]. Cutaneous zoster is often an indication of immune-compromised status in young persons and those with early recurrence [126], but is not associated with occult malignancy in old adults [128].

Stress, Immunity, and Aging (Table 4.1)

Physical Stress

A number of studies have described the effects of physical stress on the immune system, although most have not analyzed outcomes by age. Time-limited physical stress, such as hypoxia, head-up tilt challenge (approximating conditions of acute hemorrhage), hyperthermia, and exercise, tend to enhance measures of immunity on a transient basis (e.g., increased lymphocyte numbers and increased NK cell activity) [129]. Physical stress associated with tissue injury (e.g., trauma, burns, surgery) is generally characterized by suppressed immune function. CD4⁺

TABLE 4.1 Immunologic changes during stress

Type of stress	Parameter	Functional impact of change
Physical (e.g., surgical, trauma, burns)	↓ T-cell number and function	↑ Post-op infections
	↓ NK cell number and function	Delayed wound healing
	↓ PMN function	
	↑ Inflammatory cytokines	
Psychological (e.g., academic exams, major life events, caregiving, spaceflight)	↓ T-cell function	↑ Herpesvirus reactivation
	↓ NK cell function	Delayed wound healing
	↓ Th1 cytokines (e.g., IL-2)	↓ Vaccine responses
	↑ Th2 cytokines (e.g., IL-10)	

and CD8⁺ cells have been reported to decrease in number [130–132], and T cell activation is decreased [133]. Mitogen-induced lymphocyte proliferation is decreased after surgery and trauma [134–136], and anergy is increased [137]. The presence of anergy has been associated with an increased incidence of postoperative infections [137]. Neutrophil function is adversely affected by surgery, with decreased chemotaxis [137, 138], decreased intracellular killing [139], and disruption of superoxide release [138, 139].

One of the most consistently demonstrated findings is decreased cytotoxicity of NK cells [129, 130, 140–142]. In murine studies, decreased NK activity following surgery is associated with increased tumor metastases [143]. Levels of IL-2, mRNA for IL-2, IFN IL-10, and IL-12 are decreased [131, 135, 137, 144], whereas IL-4 and IL-6 levels are generally increased [131, 133, 136, 137, 144], although some investigators have reported decreased IL-6 [133, 145]. Of clinical relevance are observations that the degree of immune suppression correlates positively with the duration of surgery and volume of blood loss [137, 139].

The mechanisms underlying immune suppression with physical stress are slowly becoming elucidated. Tissue damage results in release of inflammatory substances, including TNF, IL-1, and IL-2 [146–148]. Hypothalamic production of corticotropin-releasing hormone (CRF) and arginine vasopressin (AVP) is stimulated by the locally produced cytokines and by afferent nerve signals from the site of injury. CRF and AVP stimulate pituitary adrenocorticotrophic hormone (ACTH) release and subsequent adrenal glucocorticoids, the latter two of which are also directly stimulated by the cytokines from the site of injury [149, 150]. Activation of the hypothalamic–pituitary–adrenal (HPA) axis stimulates transformation of uncommitted Th cells to Th2 cells and inhibits transformation to Th1 cells [151]. The cellular immune responses are thus suppressed partly due to a lack of Th1 cells. The cytokines secreted by the Th2 cells (e.g., IL-1, IL-6, TNF- α) further stimulate the HPA axis and glucocorticoid production [152] and subsequently cause immune suppression [153, 154]. Given the extensive age-related changes in immunity, it is not surprising that old age in surgical patients has been associated with increased postoperative immune suppression and septic complications [139]. It is interesting to speculate that postsurgical immune suppression might be less pronounced in the elderly than expected because of decreased sensitivity to glucocorticoids [76], as mentioned previously.

Psychological Stress

In addition to physical stress from trauma or surgery, psychological stress can have a significant impact on immune system function. Complex and direct links have been described between the immune system and the perceptual

capabilities of the central nervous system. Ader and Cohen demonstrated that it was even possible to condition specific immune responses with sensory cues [47]. In a series of taste-aversion learning experiments in rats, saccharin water was initially administered to the animals along with a dose of cyclophosphamide. The rats were subsequently injected with sheep red blood cells with or without readministration of the saccharin solution. Animals who received the saccharin along with the injection had profound suppression of the hemagglutinin response to sheep red blood cells [47].

Carefully controlled experiments with rodents and primates have demonstrated the neurohumorally mediated effects of stress on the immune system [155, 156]. Similar findings are seen in cross-sectional studies with humans, though it is impossible to achieve the same degree of control as in the animal studies. Clusters of illness, from the common cold to cancer, have been reported to occur around the time of major life changes [157]. Strong negative correlations have been seen between loneliness and the proliferative response of lymphocytes to mitogens, NK cell activity, and DNA splicing and repair [157, 158]. We found that healthy old adults with a strong social support system had greater total lymphocyte counts and a stronger mitogen-induced proliferation of lymphocytes than those without a close confidant [159].

Studies of individuals in “naturally occurring” stressful situations have also demonstrated links to suppressed immune function and illness. Mitogen-induced lymphocyte proliferation is suppressed after bereavement [160] and with depression [161]. The stress of taking final examinations has been correlated with recurrence of cold sores, rises in serum antibody titers against herpes simplex type I virus [162], and decreased proliferation of memory T cells [163]. Caregiving for a demented spouse is associated with a poor response to influenza vaccination [164]. Lymphocytes from the caregivers produced less IL-1 β and IL-2 when stimulated with influenza virus *in vitro* compared to age-matched, non-care-giving controls [164]. Caregivers displayed slower wound healing after skin biopsy than did matched controls [165].

Spaceflight

Many studies have reported similarities between spaceflight and aging. The average age of NASA astronauts is early to mid 40s [166–169]. In 1998, however, former Senator John Glenn flew on STS-95 at the age of 77 as a payload specialist (PS2). This afforded a unique opportunity to compare the effects of stress and microgravity in an aged individual to those of six younger astronauts under identical spaceflight conditions. After the 9-day mission, blood and urine samples were collected and neuroendocrine and immune responses were compared to those before flight. As shown in Fig. 4.2, variable levels of plasma and urinary cortisol were observed

FIGURE 4.2 Postflight change in plasma cortisol (PCort), ACTH, urinary cortisol (UCort) and urinary epinephrine (UEPI). *Filled circles* indicate values for PS2. *Open circles* indicate individual values for the remaining six STS-95 crewmembers. Data are expressed as the percent change at landing as compared to L-10 values.

after spaceflight for all seven crew members. However, PS2 had the greatest increase in both plasma and urinary cortisol. Little change was found in ACTH for the younger astronauts, but once again a significant increase was found in PS2. Postflight levels of urinary epinephrine were mostly increased for the seven astronauts. Again, the aged astronaut had one of the highest epinephrine levels.

Given prior studies of psychological and physical stress on circulating leukocytes and lymphocytes, it would be expected that spaceflight would also result in significant changes in these white blood cell populations. As expected, significant increases in neutrophils were found postflight for all seven astronauts [170]. Excluding PS2 from data analysis, there was a significant increase in circulating B-cells (Fig. 4.3). A non-significant decrease was found in NK cells at landing, while significant increases were found in CD3⁺ T-cells and CD4⁺ T-cells. Notably, the magnitude ($\geq 20\%$ difference) and the direction of the shift in lymphocyte subsets for PS2 was opposite from that of the other six crew members. Given the recent explosion in commercial spaceflight and associated opportunities for adults (both young and old) to fly in space, this will be an important area of future research.

Reactivation of Latent Herpesviruses: A Potential Role in Shaping the Aged Immune System

Herpesviruses commonly establish latent infections in the majority of adults. The best known members of this family

FIGURE 4.3 Postflight change in circulating lymphocytes. *Filled circles* indicate values for PS2. *Open circles* indicate individual values for the remaining six STS-95 crewmembers. Data are expressed as the percent change at landing as compared to L-10 values.

include herpes simplex virus (HSV), VZV, cytomegalovirus (CMV), and Epstein-Barr virus (EBV). Herpesviruses are medically important viruses; HSV-1 infects 70–80% of all adults and is classically associated with oropharyngeal lesions such as cold sores, pharyngitis, and tonsillitis [171]. EBV infects over 85% of the adult population and is the causative agent of infectious mononucleosis, Burkitt's lymphoma, undifferentiated nasopharyngeal carcinoma, and diffuse polyclonal B-cell lymphoma [172]. Most CMV infections in adults are asymptomatic, but may result in an infectious mononucleosis-like syndrome, central nervous system infections, and febrile illnesses [173]. Notably, CMV infections can be severe in immunocompromised individuals such as AIDS and post transplant patients [174]. VZV causes chicken pox on primary infection and remains latent thereafter; VZV may reactivate resulting in episodes of zoster or “shingles” [175].

Recent work on has focused on herpesviruses, in particular CMV. Numbers of CD8⁺CD28⁻ T cells have been found to positively correlate with CMV seropositivity independent of age [176]. This correlation was also found in the OCTO study [177] as well as the subsequent NONA study [178].

The recent development of MHC tetramers, which allows direct detection of T cells carrying receptors for single peptide epitopes [179], has yielded new information on the way that CMV shapes the immune system. Using tetramers, numerous studies have demonstrated detectable levels of CMV-specific CD8⁺ T cells present in both healthy and diseased individuals [180–184]. Notably, studies of CMV tetramer-positive cells

have demonstrated the following: (a) CMV tetramer-positive cells are mainly pp65-specific, owing to the fact that pp65 is the most abundant structural protein throughout CMV infection and it is regarded as the dominant antigen recognized by CD8 T cells [185, 186]; (b) the frequency of pp65 tetramer-positive cells can reach 25–50% in healthy individuals and are often present as oligoclonal expansions as determined by TCR-V β analysis [181, 187–189]; (c) CMV-specific T cells increase in direct proportion with age [189, 190]; and (d) pp65-positive cells are CD28-CD57⁺ indicating a fully differentiated effector T cell [178, 181, 187, 188, 191].

Importantly, high levels of CMV pp65-specific T cells may downregulate immune responses to other herpesviruses. Recently, Khan and coworkers [192] who found that CMV infection in the elderly impaired the CD8 T cell immunity against EBV, another important member of the herpesvirus family that is known to cause numerous diseases including carcinomas and lymphomas. The authors found aged related increases in the number of EBV-specific T-cells. However, the frequency of EBV-specific CD8⁺ T cells never exceeded 3% in CMV seropositive individuals, whereas in CMV seronegative individuals it was as high as 14%. Additionally, they also found that the proportion of functional EBV-specific CD8⁺ T cells was significantly lower than for CMV-specific CD8⁺ T cells. This study confirmed an earlier report that also demonstrated reduced IFN- γ production by EBV-specific CD8⁺ T cells in the elderly [193]. Subsequently, Vescovini and coworkers [194] showed that several elderly subjects had a predominance of CD8⁺ T cells specific for EBV latent epitopes rather than lytic epitopes typically found in younger subjects. Collectively, these observations suggest a lack of immune control over EBV in the elderly.

It was not known until recently whether the clonally expanded herpesvirus-specific T-cells represented increased viral reactivation or simply reflected an accumulation over time. We showed for the first time direct evidence of increased viral reactivation in the elderly which included increased antiviral antibodies and increased viral load (EBV) in peripheral blood B-cells [195]. In addition, we found plasma viremia (EBV DNA), which was supported by a program of viral gene transcription (e.g., LMP-1, gp350) similar to that found in patients with infectious mononucleosis. CMV DNA was not found in peripheral blood mononuclear cells; however, we did frequently detect CMV DNA in urine. These results were accompanied by clonal expansions of CD8⁺ and CD4⁺ T-cells directed against EBV (Fig. 4.4) and CMV (Fig. 4.5).

Notably, recent reports have suggested a link between herpesviruses and inflammation. Elevated levels of CMV antibodies have been associated with increased IL-6 and TNF- α levels in older adults [196–198]. The EBV-encoded dUTPase has also been shown to upregulate TNF- α , IL-1 β , and IL-6 [199, 200]. EBV and CMV infection also result in a clonal expansion of virus-specific CD8⁺ T-cells [181, 187,

192, 195, 201]. Thus, activation or an increase in the numbers of virus-specific CD8⁺ T-cells, as well as direct interaction with viral antigens, may result in increased levels of circulating inflammatory cytokines. Consistent with this notion, we found increased urinary IL-6 levels in elderly subjects with plasma viremia as compared to those without viremia (Fig. 4.6, unpublished data).

The increased levels of proinflammatory cytokines associated with herpesvirus infection may have important health consequences. CMV, and more recently, EBV have been implicated in the development of coronary artery disease [202, 203]. Strandberg and coworkers [204] found that HSV and CMV were associated with cognitive impairment in elderly adults with cardiovascular disease. A subsequent study identified CMV as a predictor of cognitive impairment even after controlling for numerous covariates including age, education, and health conditions [205]. In perhaps the most striking study, Wikby et al. [197] found that the immune risk phenotype, characterized in part by co-infection with EBV and CMV, was significantly associated with cognitive impairment; the individuals with cognitive impairment were all deceased at follow-up, which was attributed to allostatic overload due in part to multiple herpesvirus infections. Future studies are needed to investigate the role of herpesvirus reactivation in healthy aging.

Reversal of Age-Related Declines in Immune Function

When considering physiologic changes of aging it is important to keep in mind that the changes described do not appear to be synchronized with each other [2, 206]. Defects occur to varying degrees in different systems within a given individual, and immune modulatory substances may affect some systems and not others. It is increasingly clear that there are complex interactions between the nervous, endocrine, and immune systems, although no “global” mechanism has been found that might be the common underlying cause of immune senescence [207]. We conclude with a brief discussion of potential ways to stimulate a failing immune system in elderly persons and review a number of investigations reporting attenuation or reversal of surgically induced immune suppression in animals and humans.

One of the most obvious organ changes that occur with aging is involution of the thymus, loss of thymic hormones, and a subsequent decline in T cell function [208]. In humans and experimental animals, involution begins during adolescence; and the lymphatic mass, particularly in the cortical area, decreases with age [209]. These observations stimulated a number of experiments attempting to enhance lymphocyte function by reestablishing “young” levels of thymic hormone. Exposing lymphocytes of old individuals to thymic hormones *in vivo* or *in vitro*, or transplanting young thymic tissue into

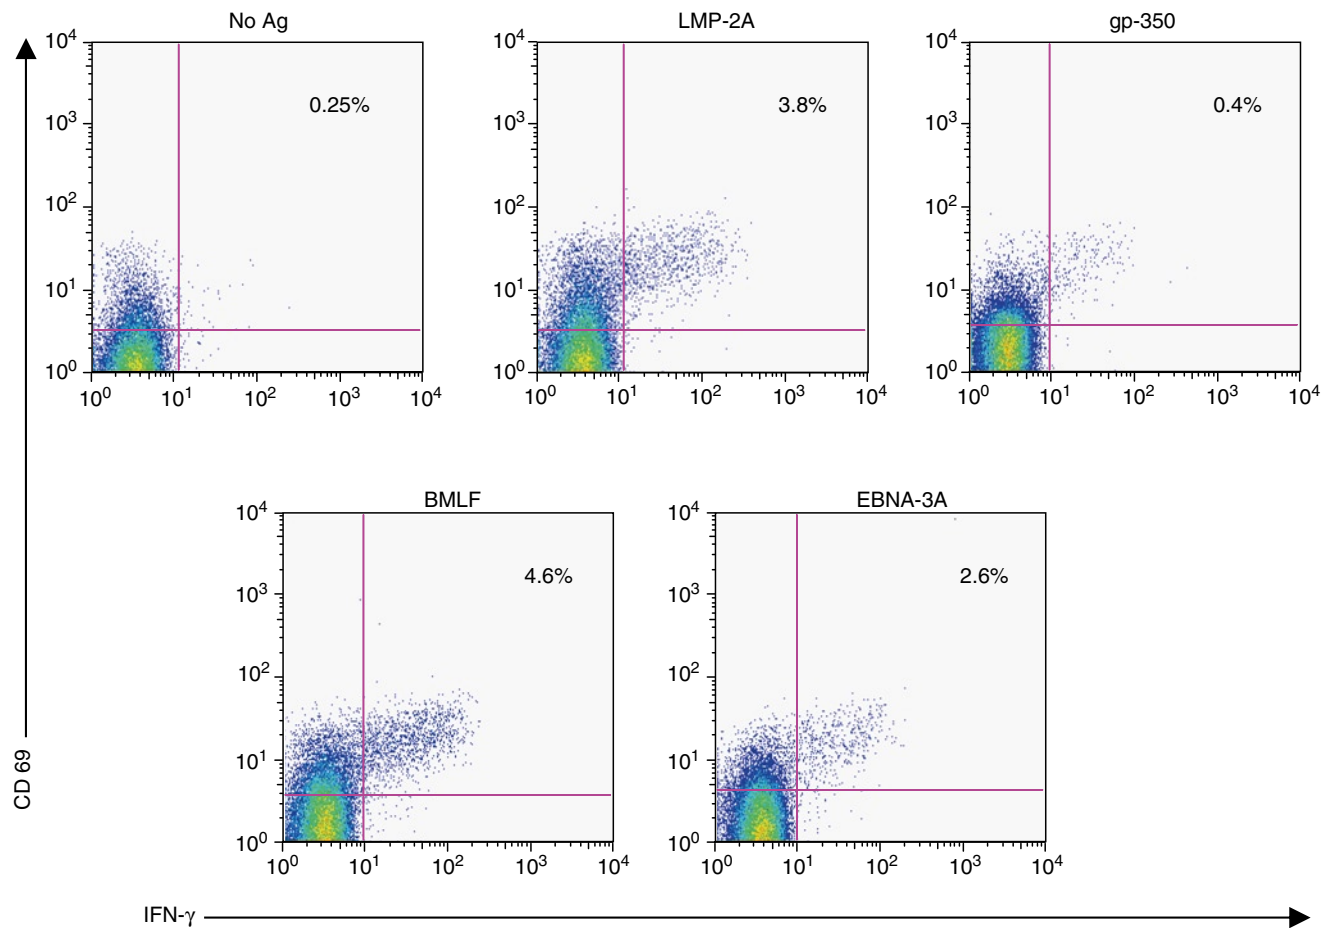

FIGURE 4.4 Frequency of EBV-specific CD8 T cells in healthy elderly subjects. Fifty thousand cells were included in each analysis. The frequency of CD8⁺ T cells shown indicate the percentage of CD69

and IFN- γ -positive cells after pulsing with A*0201-restricted peptides to EBV lytic (gp-350; BMLF) and latent proteins (LMP-2A; EBNA-3A).

FIGURE 4.5 Frequency of CMV-specific CD4 and CD8 T cells in healthy elderly subjects. The frequency of CMV-specific CD4⁺ or CD8⁺ T cells shown indicate the percentage of CD69 and IFN- γ -positive cells after incubating with lysates from CMV-infected fibroblasts (CMV lysate) or A*0201-restricted peptides to CMV (pp65), respectively.

FIGURE 4.6 Levels of urinary IL-6 in: young versus elderly subjects, and elderly subjects with viremia versus non-viremic subjects.

old animals has resulted in at least partial restoration of immunity on a temporary basis [210–216]. IL-7 therapy alone in old mice can rejuvenate the thymus, but never to the point of the thymic size and output observed in young mice [217, 218]. Although production of IL-7 by thymic epithelial cells and dendritic cells clearly plays a role in murine thymocyte proliferation, attempts to show an age-related change in IL-7 in human studies have failed [219]. Other growth factors have been studied including IL-12, which appears to slow down thymic involution [220], while keratinocyte growth factor may provide critical survival signals for the thymic epithelium [221].

Other hormonal substances being studied for their potential to reverse age-related declines in immunity include melatonin, growth hormone, and adrenal androgens. The pineal hormone melatonin has free-radical-scavenging properties, and its production declines with age [222]. When melatonin has been administered to individuals with a variety of cancers, improved measures of immunity after surgery have been observed (increased number of lymphocytes, T cells, and Th cells) [223] as have partial tumor regression and enhanced 1-year survival of patients with metastatic solid tumors [224]. When melatonin is injected into old mice, it enhances antibody production and increases Th cell activity and IL-2 production [225].

Growth hormone (GH) and its precursor insulin-like growth factor-I (IGF-I) have immune-enhancing effects,

including stimulation of phagocyte activity and cytokine production, both of which may help protect against bacterial infection [226]. Elderly patients with GH deficiency have low NK cell activity, but it can be at least partially restored in vitro by exposing NK cells to IGFI [227]. However, healthy old women who were not GH-deficient did not display changes in immune parameters after receiving 6 months of daily supplements [228]. VaraThorbeck et al. gave hypocaloric parenteral nutrition with or without growth hormone supplements to patients undergoing the stress of open cholecystectomy [229]. Those receiving GH had improved responses to delayed hypersensitivity skin testing, a lower incidence of wound infection, and shorter duration of hospital stay than the nonsupplemented group [229, 230]. In a series of experiments by Hinton et al., rats were given total parenteral nutrition with or without IGF-I and were subjected to the stress of a surgical incision or treatment with the synthetic glucocorticoid dexamethasone [231]. IGF-I treatment was associated with restoration of splenic B cell numbers in surgically stressed animals and increased mitogen-stimulated thymocyte proliferation and lymphocyte-produced IL-6 in the dexamethasone-stressed animals [231].

The adrenal androgen dehydroepiandrosterone (DHEA) has been evaluated as a potential immune stimulant because it antagonizes the actions of cortisol, stimulating increased production of IL-2 and IFN- γ [153]. In vivo administration also augments antibody production by upregulating T cell subsets that are associated with increased antibody production [232]. When aged mice are primed with DHEA, the response to hepatitis B surface antigen vaccination and influenza vaccination is enhanced [233, 234], and the animals are more resistant to infection with influenza [234]. Old humans who received oral DHEA supplements before receiving influenza vaccine displayed a fourfold increase in hemagglutinin inhibition titers compared to elderly individuals who did not take supplements [235].

A few studies in mice have explored the effect of administering cytokines to animals after surgical or burn trauma. In one study, administration of the recombinant cytokine IL-1 α 20 h after surgery showed restoration of suppressed NK and LAK cell activity [236]. In another study, mice with 20% burn injuries were treated in vivo with IL-12, which increased splenocyte production of IFN and significantly decreased mortality [144].

The 1990s saw a rapid accumulation of studies investigating links between nutrition and immune function (reviewed by Chandra [237] and Burns and Goodwin) [238]. Work on the effects of nutritional deprivation showed that starvation of experimental animals at young ages results in preservation of normal immune function into old age [238]. It is now known that caloric restriction rather than starvation can achieve the same results [239, 240]. The possibility that lesser amounts of caloric restriction supplemented with

essential nutrients might have similar beneficial effects in humans is being formally tested in primate models [241].

In contrast to findings in the experimental setting, nutritional deficiencies in the clinical setting are generally associated with poor immune responses [237]. In both nutritionally deficient and healthy elderly adults caloric, vitamin, and trace element supplementation has been associated with enhanced immune responses, better responses to vaccines, and fewer days of infectious illness [242, 243]. NK cell activity correlates negatively to the level of polyunsaturated fatty acids in the diet, but there was no effect on NK activity in men who ingested high levels of polyunsaturated fatty acids for 5 weeks [244]. Nutritional supplements given by the enteral or parenteral route have been associated with improved surgical outcomes, but the effects on immune function are not well characterized. Rats receiving total parenteral nutrition display deficits in gut immunity and lymphocyte proliferation [245–249]. In humans, most studies have focused on the role of lipid additives in depressing immune function [247, 249–253]. In contrast to the immune suppression associated with surgery, patients with closed head trauma who receive early parenteral nutrition have preserved or increased CD4⁺ cell counts and improved lymphocyte proliferation to mitogen stimulation [254].

Antioxidants such as vitamins C (ascorbic acid) and E (tocopherol) have been studied intensively as potential “anti-aging” treatments [255, 256]. When healthy elderly subjects were supplemented with 400–800 IU of vitamin E, delayed-type hypersensitivity skin testing and in vitro lymphocyte production of IL-2 increased [257, 258]. Vitamin E may cause these effects via inhibition of PGE₂ or other suppressive factors [255] (see below). In vitro exposure of T cells from mice to another antioxidant, glutathione, enhanced T cell proliferation at all ages owing to at least in part to blockade of eicosanoid production [259]. A placebo-controlled, double-blind trial of vitamin E and β-carotene supplementation in healthy old adults was associated with marked increases in various parameters of immunity, 50% fewer days with infection, and 40% fewer days taking antibiotics during the 1-year trial [242]. Although there is concern over the findings of a higher incidence of lung cancer in heavy smokers, taking β-carotene [260, 261], supplementation with vitamin E was not associated with an increased incidence of lung cancer [260].

Administering drugs or vaccines that in one way or another stimulate immune function are other potential ways of preventing age-related declines in immunity. Nonsteroidal antiinflammatory drugs (NSAIDs) inhibit cyclooxygenase and reduce production of PGE₂, thus stimulating immune responses in vitro and in vivo [76]. For example, an early case report of two anergic patients with an acquired immunodeficiency state showed restoration of the response to delayed-type hypersensitivity skin testing after treatment with indomethacin [262]. The proportion of adults over age

75, displaying a fourfold rise in anti-A/Beijing antibody after influenza immunization was significantly increased by aspirin supplementation [263]. The use of NSAIDs might be especially relevant to elderly persons because their T cells are more sensitive to inhibition by PGE₂ [9].

Cyclooxygenase inhibitors might also reduce the excess autoantibody production that occurs with age [264] and stimulate primary antibody responses to new antigens [22]. Unfortunately, the use of NSAIDs is not without risk, and older adults are at greater risk for experiencing the potential adverse effects of medications.

Suppression of immunity due to psychological stress has been reversed with psychological interventions. Simple relaxation exercises and writing about traumatic events enhanced the measured immune response compared to that in control subjects [265, 266]. The duration of these effects and the mechanisms that underlie them are not fully understood.

Chapter 5

Hematological Changes, Anemia, and Bleeding in Older Persons

Bruce O. Hough and Gurkamal S. Chatta

Hematological changes, anemia, and bleeding in older persons

Change observed	Key points	Clinical implications
Anemia	Anemia is the most common hematologic abnormality observed in the elderly Age per se is not associated with a change in baseline blood counts	Look for underlying cause, in particular occult gastrointestinal bleed and/or neoplasm
Propensity for bleeding	Bleeding disorders are more common in the elderly	Clotting factor and blood product support prior to and after surgery
Thrombophilia	Hypercoagulable states are more common in the elderly	Appropriate prophylaxis prior to and after surgery
Reduced hematopoietic reserve	Hematopoietic reserve diminishes with advancing age – Rate of restoration of hemoglobin levels after blood loss may be decreased – Granulocyte responses to stress may be decreased	Blood product support and growth factor support as indicated
Primary marrow disorders	Marrow disorders like myelodysplasia (MDS) and clonal hematological diseases like acute myeloid leukemia (AML), polycythemia vera (PV), essential thrombocythemia (ET), and idiopathic myelofibrosis (IMF) have a predilection for the elderly	Appropriate diagnosis and treatment

Introduction

Age-related changes in the human hematopoietic system are subtle, are often difficult to separate from coexistent comorbidities, and are of clinical import under conditions that stress hematopoiesis. Anemia is the most common age-related hematologic abnormality, and in the elderly surgical patient, proper management of disorders of hemostasis and thrombosis is particularly important. These are covered in detail in the chapter that follows. Marrow disorders such as myelodysplasia (MDS), acute myeloid leukemia (AML), monoclonal gammopathies (MG), polycythemia vera (PV), essential thrombocythemia (ET), and idiopathic myelofibrosis (IMF), all of which have a predilection for the elderly, are also discussed.

Hematopoiesis [1]

The hematopoietic system derives from a small pool of hematopoietic stem cells (HSCs), which can either self-renew or differentiate along specific lineages to form mature leukocytes, erythrocytes, or platelets. HSCs differentiate into mature cells through an intermediate set of committed progenitors and precursors, each with decreasing self-renewal potential and increasing lineage commitment. Hematopoiesis is tightly regulated by a complex series of interactions between HSCs, their stromal microenvironment, and diffusible regulatory molecules, the hematopoietic growth factors (HGFs) that effect cellular proliferation. The orderly development of the hematopoietic system in vivo and the maintenance of homeostasis require that a strict balance be maintained between self-renewal, differentiation, maturation, and cell loss. A major question with regard to the aging hematopoietic system is whether or not the pluripotent hematopoietic stem cell has a finite replicative capacity. Currently, it is thought that although

finite, the life span of HSCs is thought to be well in excess of the potential life span of a species. Accumulated DNA damage has been proposed as the principle and unifying mechanism underlying age-dependent HSC decline [2].

Evaluation of the effect of age on human hematopoiesis at the organ or cellular level demonstrates evidence of a diminished reserve capacity. Abnormalities in function, not evidenced in the basal state, become apparent in the stimulus-driven state. In addition to being lower, the aging response tends to be more variable. Given a comparable stress, hematologic abnormalities are likely to occur earlier and to be of greater severity in elderly than in younger persons. Thus, the rate of return of the hemoglobin level to normal following phlebotomy may be blunted, and the ability to mount a granulocyte response to infection may be reduced. Data from earlier studies suggest that in the setting of severe infection, older patients may have normal or suppressed granulocyte counts. However, the precise definition of “elderly” and the impact of coexistent comorbidities and concomitant medications were not accounted for in these studies [3, 4]. Based on contemporary literature, it is true that a blunted hematopoietic response to different insults may be seen in the elderly [5, 6]. However, this can be overcome by the administration of exogenous growth factors [7, 8]. Furthermore, the relative contributions of age per se and age-related comorbidities to this suboptimal response are unclear. Several elegant animal studies have shown a reduced ability of the aged hematopoietic system to respond to a sustained insult [1]. Similar studies in humans are either not feasible or have been inconclusive. It is currently believed that HSC function in humans, though finite, is well in excess of human life span. Thus, diminutions in hematopoietic reserve capacity in aging humans may only be of clinical relevance in the presence of other comorbidities (occult or latent)¹ or under conditions of extreme hematopoietic stress [1].

Thus, as we age, changes occur in multiple components of the hematologic system. In this chapter, we discuss the more commonly observed age-associated phenomena and the likely clinical consequences in the elderly surgical patient. The emphasis is on anemia and disorders of hemostasis and thrombosis.

Anemia [9, 10]

Clearly, the most common age-related hematologic abnormality, anemia, occurs in both older men and women. According to World Health Organization (WHO) criteria, anemia is diagnosed if the hemoglobin concentration (Hb) is <13 g/dL in men and <12 g/dL in women. Studies have shown a high prevalence of anemia in hospitalized older persons, patients attending geriatric clinics, and institutionalized older persons. However, if stringent criteria are employed for the

selection of apparently normal subjects, the prevalence drops. Results from the third National Health and Nutrition Examination Survey (NHANES III) in the United States indicated that the prevalence of anemia was 11% in community-dwelling men and 10.2% among women over 65 years of age. Survey findings indicated further that most anemia among the elderly were mild; only 2.8% of women and 1.6% of men had a Hb <11 g/dL. NHANES III data also indicated that about 35% of all anemia among elderly individuals in the U.S. results from nutrient deficiencies (iron, vitamin B12, and/or folate); 45% of all anemia in the elderly was attributable to chronic disease/s; and in 15–20%, despite an exhaustive workup, the anemia was unexplained. In the elderly patient, extra caution must be exercised to exclude subtle iron deficiency due to either occult gastrointestinal (GI) blood loss or a GI malignancy or both.

There are few reports on the incidence of new cases of anemia in the elderly population. In the general population, the annual incidence of anemia is estimated to be 1–2%. Compared with this, the incidence of anemia in a well-defined population of elderly (>65 years of age) Whites attending the Mayo Clinic was reported to be four- to sixfold higher [11]. In this study, in every age group over 65 years, the incidence of anemia in men was higher than that in women. This has been attributed to a reduced sensitivity of erythroid progenitors to erythropoietin (EPO), secondary to declining testosterone concentrations. In several studies, the prevalence of anemia in the population over 80 years of age is reported as being 12–16% in women and 18–22% in men. At the time of diagnosis, over 50% of the patients had mild anemia (Hb >11.0 g/dL), and only 2% had a hemoglobin concentration lower than 10 g/dL [12]. In the latter cohort, over 80% of patients had a normocytic anemia, with the etiology being multifactorial.

Significantly, despite an exhaustive workup, in 15–20% of elderly persons, the cause of the anemia remained uncertain [9]. Several theories have been put forward to explain this: reduced pluripotent HSC reserve, decreased production of HGFs, reduced sensitivity of HSCs to HGFs, marrow microenvironment abnormalities, unrecognized anemia of chronic disease, occult renal failure, and undiagnosed myelodysplasia. It is also possible that age-associated increases in levels of proinflammatory cytokines, such as interleukin-6 (IL-6), may reduce the responses of stem cells to growth factors, including EPO. Results from the InChianti study have examined levels of Hb, EPO, and inflammatory molecules (C-reactive protein [CRP], IL-6, IL-1, IL-1b, and TNF-a) in 1453 elderly individuals. In this population, the inflammatory score based on the upper tertile results of the following increased with age: CRP, >3.8 mg/L; IL-6, >1.75 pg/mL; IL-1b, >0.12 pg/mL; TNF-a, >2.52 pg/mL. There was a commensurate increase in the EPO level in individuals with a normal Hb and an inappropriately low EPO level in those with anemia [13, 14].

Presentation of Anemia

The presence of multiple pathologic conditions in older persons often makes the evaluation of anemia challenging. The possibility of a multifactorial etiology – including blood loss, malnutrition, folate deficiency, or hemolysis – should always be considered when the anemia of chronic disease or inflammation is associated with a hemoglobin level below 10 g/dL. In this circumstance, laboratory investigations commonly give equivocal results; hence, a bone marrow examination may be required. Clinical judgment is critically important in deciding how aggressive the workup for anemia ought to be.

Workup of Anemia

For practical purposes, we recommend 12 g/dL as a lower limit of normal for hemoglobin for both elderly men and women. Attempting to define the cause of anemia when the hemoglobin concentration is between 12 and 14 g/dL rarely yields a cause. Even at a level of 12 g/dL, a decision as to how aggressively should a patient with borderline low hematocrit be evaluated must rest on clinical judgment. In the surgical patient, subtle changes in hemoglobin should always prompt a thorough search for subtle GI blood loss and/or an early GI malignancy, both of which increase exponentially with increasing age. Once a decision has been made to investigate low hemoglobin in an older person, the principles involved in assessment and evaluation are very similar to those that would be used in patients of any age.

The causes of the various anemias seen in elderly persons are summarized in Table 5.1 [15]. The initial approach to the patient with anemia must include a complete history and physical examination, including a rectal exam, as well as a complete blood cell count to allow evaluation of the production rate of red blood cells. Microcytosis (mean corpuscular volume [MCV] < 84) indicates an impairment of hemoglobin synthesis, and macrocytosis (MCV > 100) may be caused by

reticulocytosis or more commonly by an abnormality in nuclear maturation. Red cell production is estimated from the reticulocyte production index. Hemolytic anemia usually has a reticulocyte index greater than 3, whereas a failure of production is indicated by a reticulocyte index of less than 2. Decreased production is caused by the hypoproliferative anemias or by ineffective erythropoiesis. An elevated lactate dehydrogenase (LDH) level and indirect hyperbilirubinemia result from the increased destruction of red cell precursors in the marrow and may be used to distinguish ineffective erythropoiesis from hypoproliferative anemia. A systematic approach to the laboratory workup of anemia is illustrated in Fig. 5.1. A significantly elevated reticulocyte count, indirect hyperbilirubinemia, and an elevated LDH level are diagnostic of hemolytic anemia. A low reticulocyte count, elevated indirect bilirubin, and an elevated LDH level suggest ineffective erythropoiesis. In older persons with ineffective erythropoiesis, macrocytosis strongly suggests vitamin B₁₂ or folate deficiency [16], and microcytosis should suggest sideroblastic anemia [17]. However, as alluded to earlier, anemia in the elderly may have complex pathophysiology. Hence, one must maintain a high index of suspicion for the existence of GI pathology, and every effort should be made to exclude GI blood loss and/or a GI neoplasm as the cause of the anemia.

The Hypoproliferative Anemias [9]

These are categorized as being due to (a) iron-deficient erythropoiesis, (b) lack of erythropoietin, or (c) stem cell dysfunction and/or aplastic anemia (Table 5.1)

Iron-Deficient Erythropoiesis

Inadequate iron supply for erythropoiesis is the commonest cause of anemia in the elderly. Absolute iron deficiency (blood loss) is the usual cause of iron-deficient erythropoiesis in younger persons. Blood-loss anemia, the anemia of inflammation or chronic disease, and the anemia associated with protein-energy malnutrition are the most prevalent anemias in older populations. Nutritional iron deficiency is very rare in the older age group, despite the prominence of other nutritional problems. When unexplained iron deficiency does occur, it is almost exclusively due to blood loss from the GI tract. Typical findings in blood-loss anemia are low serum iron, low serum ferritin, and high total iron-binding capacity (TIBC), reflecting absence of iron stores. Angiodysplasia of the large bowel and diverticular disease are common causes in the elderly but should be considered only after a neoplasm has been excluded. Rarely, iron deficiency can result from malabsorption or urinary losses of iron, which occurs in the face of intravascular hemolysis.

TABLE 5.1 Physiologic classification of anemia

Hypoproliferative	Ineffective	Hemolytic

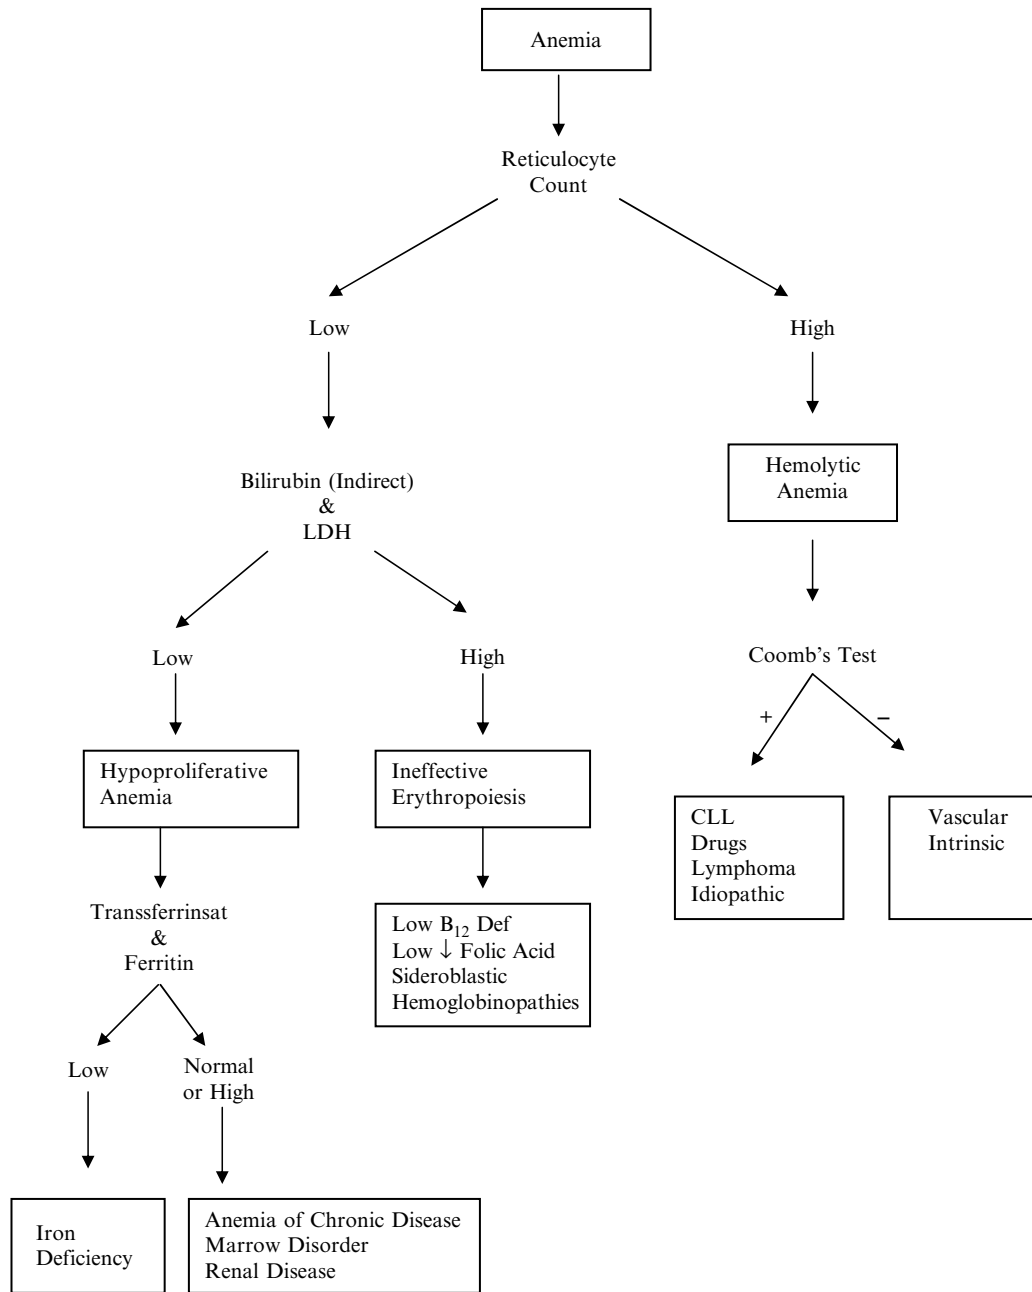

FIGURE 5.1 Workup of anemia (from Chatta et al. [1] Adapted with permission from The McGraw Hill Companies).

Iron-deficient erythropoiesis as opposed to absolute iron deficiency is much more common in the elderly. The former reflects a defective ability of the reticuloendothelial system to reutilize iron derived from senescent red cells. This is diagnosed by the presence of a decreased serum iron and a reduced transferrin saturation (serum iron divided by the TIBC, expressed as a percentage). Thus, tissue iron stores are normal or increased, resulting in a serum ferritin concentration above 50 ng/mL. In contrast, in the setting of blood-loss anemia, iron stores are absent or low, with a low serum ferritin and high TIBC.

The terms *anemia of inflammation* or *anemia of chronic disease* are often used to explain the anemia associated with iron-deficient erythropoiesis [18]. This occurs in major disease processes including cancer, collagen vascular disorders, rheumatoid arthritis, inflammatory bowel disease, and protein-energy malnutrition. However, laboratory parameters often can be equivocal, and it may be difficult to distinguish between iron deficiency and defective iron utilization. Hepcidin [18], a 25-amino-acid peptide produced in the liver, has been implicated in the pathogenesis of anemia of chronic disease. Hepcidin functions as a direct mediator of iron

homeostasis, regulating both intestinal iron absorption as well as release of macrophage iron to erythroid progenitors. Although hepcidin levels have been reported to be increased nearly 100-fold in association with anemia of chronic disease, studies on the clinical utility of hepcidin are limited by the availability of a suitable clinical assay. The possibility of a multifactorial causation, including blood loss, malnutrition, folate deficiency, or hemolysis, should always be considered when the anemia of inflammation or chronic disease is associated with a Hb < 10 g/dL.

Lack of Erythropoietin

Decreased erythropoietin (EPO) production accounts for the anemia of end-stage renal disease and is implicated in some anemias of cancer and chronic diseases [19]. Depending on symptoms, erythroid support is recommended for patients with hemoglobin concentrations <10 g/dL. EPO has been in clinical use since 1985 for patients with end-stage renal disease. EPO treatment should be instituted after excluding hemolysis and iron deficiency. Typically, the starting dose of EPO ranges from 20,000 to 40,000 units subcutaneously every week. If required, the dosage can be escalated to 60,000 units per week. Conversely, some patients require treatment only every 2–3 weeks. Hemoglobin levels should be monitored weekly, to avoid the vascular sequelae of an iatrogenic polycythemia. This is even more true in the elderly given the higher incidence of hypertension and cerebrovascular disease. A target hemoglobin level of 11 g/dL is usually safe. The 2007 revision of the National Kidney Foundations Outcomes Quality Initiative [20] has specifically recommended targeting the hemoglobin between 11 and 12 g/dL with the recommendation to stay below 13 g/dL. No distinction is made between aged and nonaged populations in their recommendations. Most patients respond within 4–6 weeks. Iron should be added to the regimen if ferritin levels fall below 50 ng/mL.

Many cancer patients have anemia independent of any myelosuppressive therapy. The anemia is characterized by an inability to use iron stores and an inadequate EPO response, indicated by inappropriately low EPO levels. In addition, a component of the erythroid suppression is mediated by cytokines such as interleukin-1, TNF- α , and transforming growth factor beta (TGF- β). Although the precise incidence of cancer-related anemia is not known, a number of studies have documented a decrease in transfusion frequency after treatment with EPO. If there is no reticulocyte response after 4–6 weeks of EPO treatment, therapy should be discontinued. Although it is difficult to prospectively identify responders, it has been reported that patients with endogenous EPO levels of <200 mU/mL are most likely to respond to treatment with EPO [21].

Stem Cell Dysfunction and/or Aplastic Anemia

Marrow failure due to interference with the proliferation of hematopoietic cells is seen in older adults. The disorder is generally associated with suppression of all marrow elements and is suggested by the presence of peripheral pancytopenia. Common causes include medications, immune damage to the stem-cell population, intrinsic marrow lesions, and marrow replacement by malignant cells or fibrous tissue. The latter is usually associated with a myelophthritic blood picture (nucleated RBCs, giant platelets, and metamyelocytes) as a reflection of the disruption of marrow stromal architecture. The presence of pancytopenia and the absence of iron-deficient erythropoiesis is an indication for bone marrow aspiration and biopsy. Occasionally, isolated suppression of erythropoiesis occurs, which is referred to as *pure red cell aplasia*. This disorder can be related to medication or caused by benign or malignant abnormalities of lymphocytes, including thymoma. These patients have isolated anemia, an increased serum iron, and an absence of erythroid precursors on bone marrow examination [22].

Ineffective Erythropoiesis [16]

Ineffective erythropoiesis and *macrocytic anemias* in the elderly person result from vitamin B₁₂ and folate deficiency. The prevalence of pernicious anemia increases with advancing age. The disorder results from malabsorption of vitamin B₁₂ as a consequence of the action of antibodies against gastric parietal cells and intrinsic factor. Atrophic gastritis and decreased secretion of intrinsic factor occur, resulting in failure of vitamin B₁₂ absorption. The presence of pancytopenia, macrocytosis, hypersegmented neutrophils in the peripheral smear, a decreased reticulocyte index, an increased LDH level, and indirect hypobilirubinemia suggests a diagnosis of megaloblastic anemia. Chronic pancreatitis and diseases of the distal ileum (blind loop syndrome) may also cause vitamin B₁₂ deficiency. Folate deficiency of sufficient severity to cause anemia in the elderly person is rare. Alcohol and various other drugs are also known to interfere with folate absorption and metabolism. Vulnerability to deficiency is significantly greater when folate requirements are increased as a result of inflammation, neoplastic disease, or hemolytic anemia.

Vitamin B₁₂, Folate, and Homocysteine [16]

In epidemiologic studies, approximately 10% of apparently healthy persons aged 70 years and over were found to have vitamin B₁₂ levels that are deficient, and 5–10% were found

to have low folate values. These low values may be clinically important, and there is evidence that even low normal vitamin B₁₂ levels may contribute to cognitive decline in older adults. Hence, vitamin B₁₂ and folate should be aggressively replaced in the elderly. Even in patients with atrophic gastritis, oral vitamin B₁₂ is generally adequate; 10% will be absorbed by mass action alone and not require the presence of intrinsic factor. Thus, a daily dose of 1 mg (1,000 mcg) of vitamin B₁₂ will replete a person with concentrations in the low-to-normal range. Parenteral replacement should be used in severe deficiencies with vitamin B₁₂, i.e., concentrations <100 pg/mL.

In older adults with low normal (≤ 350 pg/mL) B₁₂ concentrations, methylmalonic acid (MMA) concentrations may be more sensitive for excluding metabolically active B₁₂ deficiency. Renal failure can artificially increase the serum MMA concentration. In patients with low-normal B₁₂ concentrations and macrocytosis (with or without anemia), vitamin replacement should be considered, particularly if the MMA concentration is increased. Low concentrations of vitamin B₁₂ or folate are also accompanied by increased concentrations of homocysteine. In recent years, studies have focused on the role of raised homocysteine levels in coronary artery disease risk. A relationship may exist between coronary artery disease and low vitamin B₁₂ and elevated homocysteine in older persons. Levels of homocysteine can be reduced by prescribing 400 μ g of folic acid once or twice daily. Empiric prescription of vitamin B₁₂ or folate for older persons with ischemic heart disease may be reasonable.

The major causes of ineffective erythropoiesis and *microcytosis* are thalassemia and the sideroblastic anemias. Although thalassemia is generally diagnosed at an earlier age, there are reports of its initial detection in older people. Mild anemia, a disproportionately low MCV, and the absence of iron deficiency usually points to a diagnosis of thalassemia trait, a condition of little or no clinical consequence. Iron supplements have no role in the treatment of thalassemia trait; on the contrary, they can be detrimental. Acquired sideroblastic anemia, although uncommon, is primarily a disease of elderly persons [18]. It is a heterogeneous group of disorders characterized by the presence of iron deposits in the mitochondria of normoblasts. The disorder is a consequence of impaired heme synthesis. It usually reflects an intrinsic marrow lesion (idiopathic) but may be secondary to inflammation, neoplasia, or drug ingestion. The common finding is the presence of a dimorphic red cell population, in part markedly hypochromic and in part well filled with hemoglobin. The diagnosis is made by the demonstration of ringed sideroblasts in the bone marrow as well as the presence of maturation abnormalities of myeloid and erythroid precursors. A fraction of elderly patients (<5%) with sideroblastic anemia show some response to pharmacologic doses of pyridoxine (200 mg three times daily).

The *myelodysplastic syndromes (MDS)* [17, 23] are a group of stem-cell disorders characterized by disordered hematopoiesis that occur primarily in the elderly age group. Refractory anemia and refractory anemia with ringed sideroblasts account for 25–30% of the MDS syndromes. Refractory anemia commonly presents as a macrocytic anemia with marrow erythroid hyperplasia and relatively normal myeloid and megakaryocytic lineages. Cytogenetic abnormalities are relatively common in MDS, and one of particular interest in elderly patients is deletion of the long arm of chromosome 5 (5q–). The median age at presentation of the 5q– syndrome is 68 years with a female:male ratio of 7:3 [24]. The syndrome is characterized by macrocytic anemia, modest leukopenia, normal or increased platelet counts, and marrow erythroid hypoplasia or hyperplasia. Di Guglielmo's syndrome is another stem-cell disorder that is more common in older people; patients present with anemia that is characterized by megaloblastic erythroid precursors, dysplastic myeloid cells, and hyperplasia in the marrow. The disease usually evolves into an erythroleukemia, with an associated pancytopenia and the presence of nucleated red cells, and immature myeloid and megakaryocytic precursors in the circulation.

Treatment of MDS in the elderly person till now has been primarily supportive. However, recent advances in elucidating the molecular basis of MDS have identified hypermethylation of the promoter region as an important mechanism of gene silencing. Treatment with hypomethylating agents can restore gene expression and induce differentiation of hematopoietic progenitors in MDS. Thus far, 5-azacytidine and decitabine (both hypomethylating agents) have been FDA-approved for the treatment of MDS [25, 26]. Immunomodulatory agents such as lenalidomide are also currently being evaluated for high-risk MDS patients (especially those with a 5q– abnormality) [27].

Hemolytic Anemias [9]

The causes of hemolytic anemia in elderly persons are somewhat different than in younger persons. Autoimmune hemolytic anemia (AHA) is the commonest cause in the elderly age group; the diagnosis is made by the presence of a positive Coombs' test. In an elderly population, the anemia is likely to be associated with a lymphoproliferative disorder (non-Hodgkin's lymphoma or chronic lymphocytic leukemia), collagen vascular disease, or drug ingestion. Corticosteroids and splenectomy are usually effective in patients with red cell antibodies of the immunoglobulin G (IgG) type.

A disorder of some importance in older adults is microangiopathic hemolytic anemia [28], secondary to either disseminated intravascular coagulation (DIC) or occurring as a manifestation of the syndrome of thrombotic thrombocytopenic

purpura (TTP). DIC is usually associated with severe infections or disseminated neoplasm and presents not only with hemolysis but also with a consumptive coagulopathy [29]. The presence of red cell fragmentation, thrombocytopenia, a prolonged prothrombin time and prolonged partial thromboplastin time, and hemosiderinuria suggests this diagnosis. Treatment of DIC entails treating the underlying disorder, as well as blood product support (including fresh frozen plasma and cryoprecipitate as needed). TTP is characterized by the pentad of fever, intravascular hemolysis, thrombocytopenia, neurologic symptoms, and renal dysfunction [30, 31]. In contrast to DIC, in TTP, both the prothrombin time and partial thromboplastin time are normal. Early diagnosis is imperative, as TTP responds very well to treatment with plasmapheresis [29, 32].

Hemolysis is also associated with prosthetic heart valves. In different series, the incidence of hemolysis varies from 5 to 35% and is conditioned by a variety of factors, most of which relate to the type of valve implanted and to the hemodynamic conditions following implantation [33]. However, the anemia is seldom severe, and both the presence and degree of hemolysis is assessed on the basis of the level of serum lactic dehydrogenase and serum haptoglobin and the presence and amount of reticulocytes and schistocytes in the peripheral blood. Treatment of hemolysis includes the supplementation of iron and folate when their deficiency is evident. The use of β -blockers appears to decrease the severity of hemolysis, likely because of the induction of bradycardia and of their negative inotropic effects. In a recent report of 278 patients, for both mitral and aortic valves, at 12 months, mild subclinical hemolysis was identified in 26% of patients with a mechanical prosthesis and 5% with a bioprosthesis ($P < 0.001$) [33].

Hemostasis and Thrombosis

Platelet counts do not change with aging, but the concentrations of a large number of coagulation enzymes have been shown to increase with age [34]. These include factors VII, VIII, and fibrinogen. In centenarians, highly significant increases in the concentrations of these factors are noted, as are levels of factors IX, X, and thrombin–antithrombin complexes. Fibrin formation is also increased, as evidenced by higher concentrations of fibrinopeptide A. In addition, elevated levels of d-dimers suggest increased hyperfibrinolysis. Hyperhomocysteinemia, secondary to low B_{12} levels, is also more common in the elderly. Thus, aging may be accompanied by increased hypercoagulability, as supported by Silverstein's retrospective review, demonstrating an increase in the incidence of deep vein thrombosis (DVT) and pulmonary embolism (PE) in the elderly [35].

The coagulation cascade can be viewed as two intimately related processes. The *first* is the formation of the *platelet*

TABLE 5.2 Disorders of bleeding and clotting

<i>Disorders of bleeding</i>	
Acquired	Congenital
<i>Common</i>	
Drugs-iatrogenic	von Willebrand's disease
Sepsis	
DIC	
Malnutrition, vitamin K deficiency

Immobility, venous stasis	
<i>Unusual</i>	
Essential thrombocytosis	
Paroxysmal Nocturnal Hemoglobinuria	
Polycythemia Vera	

plug that occurs with vascular injury when the basement membrane is exposed to blood and platelets. Adherent platelets attract fibrinogen to bind together multiple platelets along with von Willebrand Factor (vWF) that attaches to platelet glycoprotein IIB/IIIA. This process causes *primary hemostasis*. The second simultaneous process is activation of the clotting cascade, which results in conversion of fibrinogen to fibrin by thrombin, allowing the fibrin to crosslink, thereby making the primary plug stronger. A comprehensive review of the clotting cascade is beyond the scope of this chapter, but it is well summarized in Alving and Kitchens [36]. There are multiple sites along this cascade that both drugs and disease act to either disrupt or facilitate hemostasis. We first discuss the most common causes of excessive bleeding in the elderly surgical patient and then follow with the most common causes of excessive clotting or thrombophilia. Table 5.2 lists the most common causes of bleeding and clotting in the elderly.

Bleeding Diathesis

Unexplained bruises, repeated nosebleeds, gastrointestinal losses, or excessive blood loss during surgery or following

dental extraction are common presentations. In these patients, screening platelet counts and coagulation studies should be obtained.

Platelets

Thrombocytopenia is a common cause of bleeding problems in older persons [32]. A level less than 100,000 per μL is considered significant, but bleeding usually occurs at much lower levels. Common causes include decreased production of platelets in the bone marrow, sequestration in enlarged spleens, and increased peripheral destruction. Decreased production of platelets in older persons is most commonly associated with drugs that suppress platelet production. The major cause of increased peripheral destruction is immune thrombocytopenia, secondary to either drugs or an underlying lymphoproliferative disorder [37, 38]. Tests of platelet aggregation are useful in detecting disorders of platelet function.

Treatment of thrombocytopenia depends upon the cause. For decreased production, platelet transfusion should be considered if there is significant blood loss, irrespective of the platelet count. Generally, spontaneous bleeding occurs when the count drops to 20,000 per μL or less. Immune thrombocytopenia is typically treated with a trial of corticosteroids and/or IVIG. Isolated thrombocytopenia in the elderly person should prompt a workup to exclude MDS. DIC and TTP are also important causes of thrombocytopenia in the elderly group, which ought to be recognized and treated appropriately. For most surgical procedures, the platelet count should be maintained over 75,000–100,000 per μL (see under “Blood Products and Transfusions”) [39]. Platelet function disorders, although uncommon, can cause significant bleeding and are often medication-related. Patients on treatment with either vitamin K antagonists or oral direct thrombin inhibitors are also prone to bleeding in the context of supratherapeutic dosing. The common offending agents include:

- (i) *Aspirin (ASA)*, which causes irreversible, noncompetitive inhibition of cyclooxygenase (COX), an enzyme necessary for the formation of thromboxane, a prostaglandin that activates platelets. ASA is a more potent inhibitor of COX-1 than it is of COX-2. COX-1 is the enzyme that catalyzes thromboxane, while COX-2 is the enzyme that catalyzes prostacyclin, a prostaglandin that causes platelet inhibition and vascular dilation. Given that this action is irreversible and given that platelets have a half-life of 5–7 days, aspirin should be held for 7 days prior to an intervention expected to cause bleeding. NSAIDs inhibit both COX-1 and COX-2, and given that they are competitive inhibitors, their action is shorter than that of aspirin. Additionally, the

NSAIDs do not cause the same degree of platelet inhibition as aspirin does.

- (ii) *Clopidogrel (Plavix)* is a medication used for platelet inhibition in atherosclerotic disease of the heart, brain, or peripheral arteries. It acts by inhibiting the binding of ADP to the platelet which normally results in platelet activation. This inhibition remains for the life of the platelet and thus the action of clopidogrel is irreversible [40]. Hence, in the event of bleeding, the only available treatment is platelet transfusion.
- (iii) *Vitamin K antagonists (VKA)* such as Coumadin are medications used to inhibit the production of clotting factors II, VII, IX, and X, as well as protein C and protein S. Bleeding secondary to overanticoagulation is not uncommon. Fortunately, VKAs can be reversed either immediately by giving the patient fresh frozen plasma or nonemergently by giving excess vitamin K orally or intravenously.
- (iv) *Thrombin inhibitors*: these are new medications [41] including lepirudin, argatroban, and bivalirudin which directly inhibit thrombin rather than acting through antithrombin as heparin does. They are used in patients who have been diagnosed with heparin-induced thrombocytopenia (HIT). As discussed below, HIT is paradoxical in that despite a declining platelet count, the risk for thrombosis is increased. This is due to an immune reaction resulting in platelet clumping. In these patients, it is necessary to give anticoagulants until the platelet count rises above 150,000 or longer if the patient has a resultant clot.

Hereditary Factor Deficiencies

Unprovoked bleeding may also be caused by hereditary von Willebrand’s disease, which may present initially in older persons. The disease is caused by a reduction in concentration of von Willebrand’s factor (vWF) that is accompanied by reductions in factor-VIII concentrations. vWF is essential for normal platelet function, and so bleeding occurs because of a platelet function defect. Acquired von Willebrand’s disease, although rare, is a disease of older persons. It is commonly associated with monoclonal gammopathies, lymphomas, or myeloma [42, 43]. When treatment is necessary, desmopressin acetate (DDAVP) may be used for type I vWF. Type II disease, which is characterized by normal concentration of an abnormal protein, requires individualized treatment. DDAVP is a synthetic analog of arginine vasopressin that stimulates endothelial cells to release stored vWF. Treatment is often successful, but adverse effects are common. In this instance, factor VIII concentrates that have high doses of vWF should be used [44].

Acquired Factor Deficiencies

Bleeding can also occur because of clotting factor deficiencies, which in the elderly person are usually acquired and caused by the presence of circulating clotting factor inhibitors. The most common is an acquired inhibitor to factor VIII. The onset is often sudden, titers to anti-factor VIII antibodies can be very high, and presentation is with bleeding into joints and muscle, similar to that in hemophilia A [45]. The characteristic laboratory abnormality is a prolonged PTT that does not correct with a mixing test. Treatment involves factor replacement. Depending on the severity, prednisone or cyclophosphamide may also be needed.

Deficiency of the vitamin K-dependent clotting factors tends to occur in older persons with major illnesses. Disorders of the hepatobiliary tree, antibiotics that neutralize bowel bacteria (a major source of the vitamin), malabsorption, and severe malnutrition are the causes. Even if the patient was not prescribed warfarin, inappropriate use must be considered. The deficits are readily treated with vitamin K. Liver disease must always be considered in patients who present with excessive bleeding. The prothrombin time is prolonged even in mild to moderate liver disease. The partial thromboplastin time remains normal until liver disease becomes severe. With the exception of factor VIII (which is produced by endothelial cells), liver disease causes reductions in all clotting factors. Liver disease is also associated with DIC. Fibrin degradation products are not cleared as well, and platelet function may be affected. The treatment of a bleeding diathesis in liver disease is fresh frozen plasma [44]. A bleeding disorder will be thought of only if it is appropriately included in a differential diagnosis. This particularly applies to chronic blood loss from the gastrointestinal system. In patients for whom endoscopic evaluation does not identify a cause, careful evaluation of platelets, including platelet functions and coagulation, should always be considered.

Workup of a Patient with a Bleeding Disorder

The cornerstone of the workup remains a thorough personal and family history. This helps narrow the differential into an acquired or congenital coagulopathy. In the elderly patient without a history of bleeding, a coagulopathy is likely to be acquired if hemostatic stress has been tolerated in the past. To that end, care must be taken to ask about childbirth, types of prior surgery including dental extraction, and any blood products required after any surgical procedure.

All patients with a new bleeding disorder should have a CBC and PT/PTT performed. If those tests are unrevealing, hematology consultation should be requested to evaluate for more unusual problems. If the PT or PTT is prolonged, a

mixing study should be obtained to determine if there is a factor deficiency or the presence of a circulating inhibitor. If the CBC reveals a thrombocytopenia that is a potential contributor, care must be taken with both current and recent medications to exclude an iatrogenic cause.

Thrombophilia

The risk for unprovoked venous thromboembolism increases with age [34, 46]. There is a constant balance in our body between clotting and fibrinolysis to maintain homeostasis. Aging and the diseases associated with it alter this balance through several different mechanisms. The LITE study (Longitudinal Investigation of Thromboembolism etiology) evaluated cohorts from two separate studies to determine the risk factors for thromboembolism: Atherosclerosis Risk In Communities (ARIC) study and the Cardiovascular Health Study (CHS). Analysis of those combined cohorts identified a clear increase in incidence of venous thromboembolism with age [47, 48]. A detailed discussion regarding the inherited causes of thrombophilia (including Protein C, S, and Antithrombin C deficiency) are beyond the scope of this review and may not be especially pertinent to the elderly population. However, the acquired causes of thrombophilia are pertinent and are especially helpful to determine the risk of postoperative venous thrombosis in an elderly surgical patient. Some of the common causes of acquired thrombophilia in the elderly are listed in Table 5.3.

Acquired thrombophilia may be either drug-related (estrogens, heparin, thalidomide, lenalidomide, etc.) or secondary to disease. Cancer increases the risk of thrombosis through increased production and expression of tissue factor and other procoagulable factors, which trigger the coagulation cascade. Some malignancies, such as pancreatic adenocarcinoma, ovarian cancer and glioblastoma multiforme have especially high rates of thrombosis, approaching a 5–6% incidence

TABLE 5.3 Common causes of acquired thrombophilia in the elderly

Malignancy – all, but especially ovarian, pancreatic, glioblastoma multiforme (GBM)
Immobility, venous stasis
Smoking
Thalidomide treatment for myeloma
Lupus anticoagulant
Paroxysmal nocturnal hemoglobinuria (PNH)
Lupus anticoagulant
Nephrotic syndrome with ATIII deficiency/loss
Central venous catheters
Intimal injury
Myeloproliferative disorders (CML, ET, PV, IMF)
Hormone replacement therapy (maybe)
Heparin-induced thrombophilia

among patients with metastatic disease [47]. These tumors occasionally present with thrombosis as the sentinel event in their cancer diagnosis. Moreover, once diagnosed, the several treatments for malignancy increase the risk of thrombosis. One such example is the use of thalidomide and lenalidomide (Revlimid) for the treatment of multiple myeloma [49]. Cytotoxic chemotherapy through the destruction of tumor and the resultant spillage of tissue factor into the circulation may increase the risk of thrombosis. Immobility and venous stasis further increase the risk of clot, as does venous stasis from a bulky pelvic lymphadenopathy and/or tumor.

Heparin-Induced Thrombocytopenia [50]

HIT is an immune disorder that causes platelet clumping and activation. This clumping and activation causes a reduction in the circulating platelet count while increasing the risk for both arterial and venous clotting. Patients who are on chronic heparin are the least likely to develop HIT, while those undergoing large joint repair or replacement with postoperative heparin are the most likely to develop HIT. Definitive diagnosis is challenging in that the most available test, the platelet factor 4 antibody test, has a high false positive rate. Therefore, the patient's pretest probability has to be taken into account when interpreting the test. The pretest probability is derived by evaluating four factors – *timing* of heparin (usually 5–10 days after initiation), rate and magnitude of *thrombocytopenia* (a 50% drop in platelets and a count of >20,000), *thrombosis* or skin necrosis, and lack of alternative causes of *thrombocytopenia* [51]. This 4 T's scoring system for the evaluation of HIT has recently been validated both retrospectively and prospectively (Table 5.4). If the diagnosis of HIT is likely, patients should be started on a direct thrombin inhibitor while waiting for the result of the test. If the PF4 antibody test is discordant with the clinical picture, a confirmatory test, the serotonin release assay, can be done. It has a high specificity, but a low sensitivity. Unfortunately, this test is done in only a few reference laboratories in the country and seldom impacts clinical management in real time.

TABLE 5.4 Pretest probability of HIT: the 4 T's score

Points	2	1	0
Thrombocytopenia	>50% drop; nadir >20K	30–50% drop; nadir 10–19K	<30% drop; nadir <10K
Timing of drop in platelets	5–10 Days	>10 days	<4 Days (1st exposure)
Thrombosis	Yes	Suspected	None
Other causes of low platelets	None	Possible	Definite

Source: Adapted from Pouplard et al. [51], with permission from Wiley-Blackwell

Score 0–3: <5% likelihood of HIT

Score 4–5: 10–30% likelihood of HIT

Score 6–8: 40–80% likelihood of HIT

The Lupus Anticoagulant [52, 53]

The Lupus anticoagulant (LAC) is a contradictory term in that it gives rise to a procoagulant state and can occur in patients without lupus. It is due to acquired antibodies to phospholipids that can cause an increase in laboratory parameters (PT and PTT) used for assaying time to clotting. These circulating antibodies interfere with the phospholipids reagents used in the in vitro assays, causing a prolongation of the PT and/or PTT. In contrast, “in vivo,” these antibodies have the potential of binding procoagulation factors and triggering the clotting cascade. The classic presentation is that of a patient with prolonged aPTT, either asymptomatic or in the setting of a recently diagnosed unprovoked clot. While the diagnosis of LAC in a patient with thrombosis should prompt initiation of anticoagulation, the asymptomatic presence of a LAC does not require prophylactic anticoagulation. In terms of surgical prophylaxis, patients with a clear history of a clot in the past and a positive LAC need aggressive postoperative DVT prophylaxis if they are not already on anticoagulation. Management of perioperative anticoagulation is beyond the scope of this text, but the reader is directed towards an excellent review of the recently published guidelines from the ACCP [54], summarized in Table 5.5.

Myeloproliferative Disorders [55]

The Philadelphia chromosome-negative chronic myeloproliferative disorders, namely, polycythemia vera (PV), essential thrombocythemia (ET), and idiopathic myelofibrosis (IMF), occur primarily in the elderly age group and are characterized by the involvement of a multipotent hematopoietic progenitor cell. Marrow hypercellularity, overproduction of one or more marrow lineages, thrombotic and hemorrhagic diatheses, exuberant extramedullary hematopoiesis, and a slow rate of spontaneous transformation to acute leukemia are hallmarks of these disorders. Thus, PV [56] (excess production of red cells), ET [55] (excess production of platelets), and IMF [57] (extramedullary hematopoiesis) have a long natural history, distinguishing them from chronic myeloid leukemia, the

TABLE 5.5 AACP guidelines for prevention of venous thrombosis

Type of surgery	Recommendation
Hip or knee replacement	LMWH or Arixtra starting 12–24 h after surgery, or VKA started the evening before surgery
Hip-fracture surgery	LMWH, LDUH, or VKA
Length of anticoagulant for hip or knee surgery	>10 Days up to 35 days
General surgery low risk	Early ambulation
General surgery mod-high risk	LMWH, LDUH tid, Arixtra
At risk for both bleeding/thrombosis	Mechanical thromboprophylaxis with GCS and IPC

LMWH low-molecular-weight heparin, i.e., enoxaparin (Lovenox) or dalteparin (Fragmin); *LDUH* low-dose unfractionated heparin; *VKA* vitamin K antagonist, i.e., Coumadin; *GCS* graduated compression stockings; *IPC* intermittent pneumatic compression; *ACCP* American College of Chest Physicians

Source: Data from Geerts et al. [54]

Philadelphia chromosome-positive myeloproliferative disorder, which progresses and transforms much more rapidly. The main cause of morbidity and mortality in PV and ET is thrombosis, which occurs more commonly in older patients or in those with previous vascular complications. Severe bleeding is rare and limited to patients with a very high platelet count or to those taking antiplatelet drugs. Since there is no curative therapy for PV and ET, the goals of therapy are to minimize thrombotic and bleeding risk and prevent progression to marrow fibrosis or acute leukemia, or both.

The risk of thrombotic events in PV is highest in patients aged 60 years or older and those with a prior history of thrombosis. The Italian PV study group demonstrated a 3.4% yearly risk of thrombosis following diagnosis. The recommendations for the treatment of PV are as follows: (a) phlebotomy in all patients to keep the hematocrit below 45% and (b) myelosuppressive agents in patients at high risk of thrombosis (>60 years of age) and in those with excessive phlebotomy requirements. Finally, all patients with PV should be treated with low-dose aspirin, as there is a 59% reduction in cardiovascular mortality, with a nonsignificant risk of increased bleeding. The incidence of thrombotic and hemorrhagic complications in ET ranges from 7 to 17% and 8 to 14%, respectively. Age over 60 years, a prior thrombotic event, and a long duration of thrombocytosis are the major risk factors for thrombotic events. A very high platelet count (1.5 million/cmm) is a risk factor for both thrombosis and bleeding. Consensus-based practice guidelines for ET include: (a) observation in asymptomatic low-risk patients with platelet counts below 1.5 million/cmm, (b) hydroxyurea plus aspirin in high-risk patients with a platelet count over 1.5 million/cmm. Anagrelide, a new antiplatelet agent, is also very effective at reducing high platelet counts. However, its efficacy as compared with hydroxyurea in reducing thrombotic events remains to be proven in a randomized controlled trial. An elderly patient with PV or ET should

have a hematology consultation prior to surgery. Management for the elderly surgical patient with PV or ET has to be individualized based on prior thrombosis history, current platelet count, type of surgery, risk of anticoagulation, etc.

Mechanical Causes

Central venous catheters (CVC) also increase the risk of thrombosis through several mechanisms including foreign body reaction, local stasis, and intimal injury. For patients with symptomatic clot, most clinicians treat by first removing the catheter. The current ACCP (American College of Chest Physicians) guidelines [54] recommend treating an upper extremity clot in the same manner as a lower extremity clot. Therefore, catheter removal is most often supplemented with anticoagulation. For symptomatic patients in whom the CVC is critical, catheters may be left in place and the clot treated with anticoagulants, usually delivered through the line. Since many of these cases are complex, decision making about catheter removal and anticoagulation needs to be individualized.

Two other important questions often arise when discussing central venous catheters. The first is whether patients with CVCs benefit from prophylaxis with low-dose Coumadin prior to the formation of a clot. Unfortunately, data regarding primary prevention with Coumadin is conflicting [58]. The second centers on whether patients with asymptomatic clots should be treated. Treatment of asymptomatic clots is also controversial, given the high frequency with which the ends of catheters become clogged with fibrinous debris. The ACCP [54] makes a distinction between those clots that *do not cause swelling* and those clots *that do* and recommends treating clots that cause swelling. What is less clear is what to do about large, asymptomatic clots found on routine imaging that do not cause swelling. Most clinicians would treat patients with symptomatic clot in a CVC and remove the catheter if the indication for placement has expired. However, the most common scenario is a patient who continues to require a CVC and develops a symptomatic clot.

Workup of a Patient with a Clotting Disorder

In a patient with a new unprovoked clot, attention should be given to finding an underlying cause for clotting. In the elderly patient, this is most likely to be due to an acquired cause (Table 5.2). The first course of action is to check a CBC and PT/PTT. A prolonged PTT in a patient with a recent clot is highly suggestive of the antiphospholipid syndrome (aka lupus anticoagulant). However, 40% of patients with a LAC do not have a prolonged PTT, so additional testing is required for evaluation. A high hemoglobin or platelet count in a patient

with a recent clot is suggestive of one of the myeloproliferative disorders mentioned above (PV or ET). Lastly, pancytopenia with a recent unexplained clot should prompt concern for paroxysmal nocturnal hemoglobinuria (PNH), a stem cell disorder. Ideally, testing for thrombophilias should be ordered prior to anticoagulation. If there is a concern about what tests to send, draw three blue top tubes from the patient and set aside on ice prior to initiating anticoagulation. Anticoagulation is typically initiated with a heparin, either unfractionated (intravenous) or low-molecular-weight heparin (LMWH) [59]. LMWH is easy to administer (subcutaneous), can be given in an outpatient setting, and does not require regular monitoring like heparin. However, its half-life is much longer and it cannot be reversed as easily with protamine. Therefore, the specific clinical situation will dictate which initial heparin is used to eventually bridge to Coumadin [60]. In the presence of a history of HIT, initial anticoagulation needs to be initiated with a direct thrombin inhibitor (DTI). The choice of a DTI is often dictated by the presence or absence of normal renal and liver function [41].

Blood Products and Transfusions [32, 39, 44, 61, 62]

Blood products commonly available for transfusion include packed red blood cells (pRBC), platelets, plasma, cryoprecipitate, and recombinant clotting factors. These products are made by separating single units of blood from donors. Platelets acquired from one donation are pooled into a larger unit along with 3–4 other donors. One unit of pRBCs is expected to increase the hemoglobin of a 70-kg patient by 1 g/dL. One 4–5 pack of platelets is expected to increase the platelet count of a 70-kg patient by 10×10^9 cells/L).

The indications for transfusion have changed over the last decade, bear repetition, and are summarized in Table 5.6 [61]. It has been previously felt to be advantageous for sicker patients to have a hemoglobin level closer to 10 g/dL, to allow for maximum oxygen exchange. Hebert et al. have recently compared an aggressive versus a restrictive

transfusion regimen in critically ill patients and found the restrictive strategy to be at least as effective and possibly superior with a lower hospital mortality rate among those in the restrictive group (22.2% vs. 28.1%, $P=0.05$) Therefore, most clinicians feel that in patients who are not actively bleeding, who have not received myelotoxic treatment, and who are not having active cardiac or cerebral ischemia, the transfusion threshold should be closer to or below 8 g/dl [32, 61] However, in the elderly patient with compromised cardiac function, a higher hemoglobin threshold for transfusion may be appropriate, i.e., Hb at or around 10 g/dl.

Platelet transfusions occur in two broad categories – prophylactic, to prevent spontaneous bleeding or bleeding during a procedure, and therapeutic, when a patient is actively bleeding with a low platelet count. The current consensus is that the platelet count should be over $50 \times 10^9/L$ for surgical procedures and over $100 \times 10^9/L$ for neurologic and ophthalmologic procedures. Most consensus papers adhere to these guidelines [39].

Transfusion of plasma products for prophylaxis for a procedure is another common hematologic question in the surgical setting. Thus, fresh frozen plasma (FFP) contains normal levels of all coagulation factors and is typically administered at a dose of 10–20 mL/kg (3–6 units), to correct a significant coagulopathy. Indications for the use of FFP include: (a) active bleeding/invasive procedure with PT > 3 s above normal (INR > 1.5), (b) massive transfusion and bleeding with proven coagulopathy, (c) congenital deficiency of factors II, V, X, XI, XII, or XIII, (d) emergency reversal of warfarin overdose, since immediate oral or intravenous vitamin K reversal takes 6–8 h, and (e) in the setting of plasmapheresis for TTP. The volume of one unit of plasma is approximately 220 mL. Since plasma stays in the vascular space, caution should be used in those patients prone to volume overload [44].

Other types of blood products include cryoprecipitate as well as factor replacements and most recently activated factor VII, which can be used to overcome factor VIII inhibitors found in patients with hemophilia or in the elderly. Each unit of cryoprecipitate (15–20 mL) contains (a) fibrinogen (150–250 mg), (b) vWF, factor VIII (80–100 units), (c) factor XIII, and (d) fibronectin. Typically, it is administered as a pool of 6 units. Indications for the use of cryoprecipitate include: severe DIC, congenital or acquired hypofibrinogenemia, and uremic bleeding diathesis unresponsive to DDAVP [44, 63]. It is no longer used for von Willebrand's Disease or hemophilia due to availability of factor concentrates. Evidence-based guidelines for blood product administration are reviewed in more detail in the references listed above.

In summary, aging is associated with an increasing incidence of anemia and an increasing frequency of problems associated with hemostasis and thrombosis. The latter, particularly in the perioperative setting, can be challenging and require timely hematologic consultation.

TABLE 5.6 Indications for transfusion

Transfusion type	Trigger	Grade of evidence
Anemia in the steady state	7 g/dL	RCT ^a
Plasma for coagulopathy	INR \geq 1.5	Lab/correlative
Platelets for major surgery	$50 \times 10^9/L$	Consensus
Platelet for neuro- or ophthalmologic surgery	$100 \times 10^9/L$	Consensus
Platelets for prophylaxis in AML	$10 \times 10^9/L$	RCT ^{b,c}

RCT randomized clinical trial

Chapter 6 Invited Commentary

Stanley J. Dudrick

Optimal nutritional support in the geriatric population, of which I am a grateful living member, is obviously important not only for the maintenance of optimal structure, body composition, cellular and system function, health, well-being, and life style, but also for productive longevity and vitality. Life itself, the quality of life, and living life to its full capacity are all clearly dependent upon, and related to, the quality of all aspects of nutritional support and fitness.

Nutrition support is an amalgamation of art and science, as is the rest of the broad field of medicine including geriatrics. Both had their origins in curiosity, empirical observations, ideals, concepts, philosophy, innovation, experimentation, and the application of newly accumulated and evaluated knowledge to practical use. This has been the basis for the practice of medicine for millennia, and advances have been made arithmetically and tediously for hundreds of years until the late nineteenth century and early twentieth century, when discovery, creativity, science, and technology virtually exploded, and have continued to advance logarithmically to the current day. Moreover, this rapid increase in knowledge and technology is likely to continue in the foreseeable future and has a significant influence on the application of nutritional support to the practice of geriatrics, especially geriatric surgery.

When I was a first year surgical resident in 1962 at the Hospital of the University of Pennsylvania, I experienced an epiphany from which I have not recovered nor deviated to this day. While caring for the complex, critically ill patients of my chair and mentor, Dr. Jonathan E. Rhoads, on a particularly devastating weekend, I was unable to support them adequately after technically successful major operations performed earlier that week, and despite my best efforts to provide them with the highest possible state-of-the-art care available in that venerable tertiary care academic institution at that time, three of the patients, all elderly in their seventh

and eighth decades of life, died. I was disheartened, disappointed, and discouraged by my helplessness and ineffectiveness in achieving success in our therapeutic goals, and I unabashedly expressed my frustrations to Dr. Rhoads on rounds afterward. Indeed, I informed him that this series of ultimate failures indicated to me that I was not likely to become an effective surgeon and that I was seriously considering leaving the surgical residency to train in another specialty or even a different profession. Dr. Rhoads listened patiently to my lamentations, and then gave me the most significant tutorial of my life. He explained to me that surgical operations were only one important part of patient care: that the procedures undertaken might have been maximally technically proficient, but that the patients could not withstand the sum of the series of insults imposed by the pathophysiologic condition, the major operative injury (sometimes multiple within a short time period), the general anesthetic side effects, the associated comorbidities, complications including pneumonia and sepsis, and the resultant poor nutritional and metabolic state. Indeed, he pointed out to me that the common denominator contributing to the death of these patients was clearly malnutrition, which severely compromised their ability to recover, to restore normal cellular function, and to survive, and even though the operation was a technical success, the overall functional reserve capacity of the patient was exhausted beyond the requirements essential to provide endogenous substrates to support immunocompetence, healing, and vital bodily functions. Essentially, although the patients starved to death, they manifested their malnutrition clinically and functionally by serial failure of their cellular and system functions. This concept, of which I had not previously been aware, was not only surprising, but also foreign and difficult for me to accept initially. After all, the surgical mantra at that time was, “cut well, sew well, do well.” The master had patiently and skillfully converted what started out to be quite a negative encounter to the most positive turn-around in my embryonic career. My life was forever transformed from that moment, and I have pursued the “holy grail” of providing optimal nutrition to all patients from that point forward and will likely be obsessed with attempting to perfect the technology and results until my own end.

I owe much to the many geriatric individuals I have had the privilege of having as patients throughout my career for all that they have taught me in so many ways. My experiences with them have served to forge a body of knowledge, skills, expectations, and more importantly, an attitude that if you give them the opportunity and a little help and direction, that there is virtually no limit to what they can accomplish within the realm of human possibility. Contrarily, in a manner analogous to premature infants, if you ignore their needs, are inattentive to them for too long a time, or do not provide them with the critical support they require in adequate amounts and for critical periods of time, then they are likely to slip through your fingers and be irretrievably lost. Nowhere is the old adage more relevant, "be where you are supposed to be, when you are supposed to be there, fully prepared and willing to do what you are expected to do, as well as you can do it." Without an appropriate attitude and timing, all of the skills acquired from mastery of the "six competencies" of education and training will fall short of expectations, and of the potentials both of the patient and the caregiver.

Early in my training, I met a 97-year-old woman in the emergency department with acute upper abdominal distress. She proved to have multiple gallstones in an inflamed gallbladder together with secondary pancreatitis. The medical service consulted our surgical service pro forma, indicating that this "ancient" lady had an obviously lethal situation from which she would not likely recover, and that a surgical procedure would only accelerate her demise. But they, nonetheless, consulted us out of courtesy and for reinforcement of their decision rather than for surgical intervention. However, she was an intelligent, strong, and delightful lady with a positive outlook and supportive family who all wanted our best help and services. I admitted her, resuscitated her, started her on antibiotics, initiated pulmonary toilette procedures, and confirmed the adequacy of her hematologic and biochemical indices, together with an appraisal of her renal, kidney and cardiopulmonary functions. She responded to the supportive measures much to our satisfaction, and the next day I removed her gallbladder under local anesthesia supplemented by mild analgesics and sedatives. She rebounded amazingly well and left the hospital for home in 5 days. All she needed was adequate supportive preoperative and postoperative care and the chance to show that she had the strength, will, and reserve to overcome this major threat to her life. She was "the talk of the hospital" for quite some time and a great source of satisfaction to me and the surgical service. She celebrated her 100th birthday anniversary with us a few years later to our mutual great joy.

In a cadre of 39 patients with end-stage malignancies and malnutrition secondary to their pathophysiologic processes, and compounded further by surgical procedures, chemotherapy, radiotherapy, and combinations thereof, we undertook a study of the feasibility of attempting to meet nutritional requirements by infusing moderately hypertonic (5–15%)

nutrient solutions by peripheral vein in volumes of 5 L per day while giving intravenous diuretics to help excrete the excess water administered as a vehicle for infusing the nutrients. The vast majority of these patients were in their seventh, eighth, and ninth decades of life, many of them were cathectic, and all of them were aware that they would not likely benefit from the study and perhaps might even be harmed by fluid and electrolyte aberrations, pulmonary edema, congestive heart failure, infection, thrombophlebitis, sepsis, etc. Nonetheless, this seemingly fragile, debilitated, incurable group of mostly geriatric patients demonstrated the courage, strength, determination, hope, and desire to be useful in the generation of new medical knowledge and experience, such that they participated willingly, conscientiously, and enthusiastically in this clinical experiment.

They all improved their strength, sense of well-being, ambulation, self-help, hygiene, and overall quality of hospital life to the point that several of the patients and/or their families began to express the thought that the parenteral feeding solution might be "curing" their cancers. This was most likely related to the anabolic effect of the nutrient energy substrates on their body cell mass and systems, but also in part, secondary to the fact that the health care team was much more involved with them, was keenly interested in them, spent much more time with them, and obviously cared about them. In some instances, we felt morally and ethically obligated to inform the patient and/or family sadly that the improved mental, physical, and emotional response they were witnessing was a caloric and balanced nutrient effect rather than an anticancer effect so as not to promote false hope or unfairly raise their expectations for a cancer cure. I remain grateful to this courageous, caring, unselfish group of patients and their families to this day. Furthermore, my experiences with them have convinced me of the importance of providing optimal nutrition and support to geriatric patients, even when they are likely to succumb imminently or ultimately to their underlying nonneoplastic or neoplastic pathologic disorder.

Thus, I have developed the philosophy over the years that there is more to the nutritional support of the cancer patient, especially the geriatric cancer patient, than the current science and clinical practice of medicine and surgery mandate or justify unequivocally. The emotional and psychological support of the patient and their significant others and the socially important aspects of food or nutrient intake and "breaking bread" with family and friends cannot be denied. These needs do exist, and we must address and do something about them rather than ignore them, as is all too often done. After we have exhausted all possibilities of providing reasonable, rational, or justifiable specific antineoplastic, and/or nutritional, therapy for the patient with an inexorably lethal cancer, it is of utmost importance that we never abandon the patient or the family, and at the very least, continue to support them, bond with them, relieve their guilt, and above all,

reinforce their faith in our humane and core values simply by “being there” for them and providing a feeling of comfort and hope that cannot otherwise be accomplished. The frontiers for specialized nutritional support of geriatric patients, especially geriatric cancer patients await our exploration, discovery, and judicious clinical applications.

Another illustrative vignette that I would like to share is related to the importance of will and determination on the part of seriously ill elderly patients in making difficult clinical judgment decisions. Even if we cannot cure them, and might actually accelerate their demise by our interventions, we must discuss all of the options with the patient and family and be tolerant of their right to make choices that may expose the patient to significant risks with major surgical treatment. This is especially true when taking no action will inevitably result in death. For example, at the Philadelphia VA Hospital, I had an 80-year-old patient with COPD who developed a squamous cell carcinoma in his left mainstem bronchus. His split pulmonary functions indicated that he would have marginally adequate ability to survive with only his right lung if he underwent left pneumonectomy. He was an avid Pennsylvania deer hunter who enjoyed hunting with his sons and his grandsons virtually as a family tradition. He knew from our discussions that he had a highly lethal condition, might not survive a pneumonectomy procedure, and certainly could not entertain rationally the thought that he would be capable afterward of withstanding the rigors of hunting deer in the cold winter season. However, he pleaded with me to give him a chance to have just one more deer season hunting with his boys, and I could not look into his pleading eyes and deny him his fervent wish. He tolerated the left pneumonectomy surprisingly well after having stopped smoking for a week or so, and his recovery was uncomplicated, reinforcing to me that patient goals and motivations are invaluable assets to surgeons and to surgical outcomes. Later that winter he not only hunted with his sons, but shot a deer while having to place the heavily padded butt of his rifle against his shoulder only 4 months post pneumonectomy. I shall never forget how happy he was to see me afterward and relate the details of his successful hunt in the snow to me and share pictures of the event. Subsequently, he rejoined his bowling team, and much to my delight, hunted again and bowled again the following year. He died more than 2 years later at age 82, but he did it his way, with our consideration, understanding, support, and love, all of which he and his wonderful family appreciated. Even though we have much more to learn regarding geriatric surgery, geriatric nutrition, and the complexities introduced by malignancies, we can take useful actions and accomplish satisfactory results while producing and/or awaiting new data, simply by exercising compassion, common sense, good judgment, and “giving a damn.” Those of us who have helped caring for geriatric surgical patients have learned first-hand that age of the patient is not uniformly an independent risk factor and

that physiologic changes associated with the normal aging process occur at different rates among individuals.

I have very little patience or tolerance for those of my colleagues who “write off” geriatric patients and deny them optimal care simply because they are elderly. This is the most unprofessional, disrespectful, and demeaning attitude that is anathema to me, but I am fearful that it is already creeping insidiously and increasingly into our culture and society and beginning to corrupt not only our healthcare system, but our morals, ethics, and core values. We are obligated to treat all patients, especially geriatric patients, as individuals and with respect, dignity, and compassion rather than as inanimate entry items in a computerized management algorithm.

With improved medical care delivery and effectiveness, people are living longer, and the population of patients with whom general surgeons interact is becoming progressively older at an unprecedented rate. Currently, in 2009, there are more than 38 million people in the USA who are 65 years of age or older. By the year 2030, more than 20% of the population will be over the age of 65 years, and one-half of these individuals will be admitted to a hospital during their remaining lifetime for an operative procedure. Caring for these individuals requires an awareness and understanding by the surgeons of the global changes that take place as an individual ages, as well as a clinical acumen and ability to assess accurately their relative needs, both as inpatients and as outpatients.

Issues in overall geriatric management and in geriatric surgery and nutritional support will continue to challenge us in the future and must be addressed expeditiously. The most compelling reality is that the geriatric population will continue to grow both in numbers and in longevity. This will require a major sea-change in the manner in which their health, fitness, and function will be supported, literally on an individual basis, and the means by which the fundamental social, professional, medical, ethical, financial, and other costs thereof will be embraced and met by our society.

We must develop and carry out relevant meticulously controlled study protocols specifically designed for the various cohorts of the geriatric populations to provide the data essential to understanding and solving their unique nutritional, functional, and surgical problems. We must recognize and allow for the difficulties associated with carrying out studies in aged patients with seemingly inevitable comorbidities. Moreover, we must understand that the physiologic changes that accompany the normal aging process, especially those related to nutritional needs, occur at different rates among human beings. The difference between chronologic age and physiologic age in the elderly patients must be determined clinically in a scientific manner in order to help guide prudent decision-making in their management. Although the old adage is that the chronologic age of the patient is not an independent risk factor for surgical procedures or actions, the age of the elderly patient can, indeed, become an independent risk factor

in some patients in whom a great disparity exists between their chronologic age and their physiologic age. Furthermore, establishing nutrient requirements for a heterogeneous population is not an easy task even when the group is healthy, much less when accompanied by a wide variety of health conditions, comorbidities, fitness, disabilities, nutritional status, etc.

Prior to the latter part of the twentieth century, people in the 50–65 years age range were defined as the geriatric or elderly population, and a reasonable amount of useful clinical data had been accrued to justify various aspects of their health and nutritional recommendations for management. However, it has become obvious to nutritionists, surgeons and others that it is not valid to extrapolate from the data that exist for the 50–65-year-old age group upward to the eighth, ninth, and tenth decades of life. This problem must be solved by the systematic collection of data specifically for the older groups from 65 to 100 years of age if they are to receive optimal care based on their scientifically determined requirements, potentials, and tolerances. The challenges involved will be difficult enough in determining nutrient requirements and assessing nutritional and physiological status, but will become increasingly more difficult and complex when evaluating nutritional interventions and appraising the success of other outcomes of implementing ambitious nutritional and/or surgical therapies among the patients in these deciles. The most difficult group, and those who are most vulnerable from a nutritional standpoint, are the elderly who are institutionalized, have little or no family support, have multiple health problems, have neurological challenges, cannot perform the activities of daily living competently, and require assistance not only with feeding, but also with total custodial care. The rather steady loss of lean body mass [about 1% per year, which has been documented to occur in the elderly (>50 years age)] is greatest in those who are not able or willing to ambulate or exercise, while ingesting diets adequate in protein, thus resulting in a compounding of the usual sarcopenia that occurs in such patients. Nowhere is the “chicken or egg” phenomenon more evident than in this group of elderly persons. In addition to protein deficiencies, energy, macronutrient, micronutrient, and fluid deficiencies are also relatively more common in geriatric patients than in younger adults, although their daily requirements per kilogram body weight are not dissimilar. A major problem in the elderly is the difficulty in convincing them to drink more water and fluids, thus resulting in dehydration and its untoward consequences. Examples of other nutrient aberrations that occur commonly in the elderly are calcium and vitamin D deficiencies, which can lead to significant increases in morbidity and mortality, and these essential nutrients must be provided in larger doses in the diet or as supplements. Preventive health measures regarding the intake of these important nutrients are likely to result in significant reductions in morbidity, mortality, and health care costs, which remain to be confirmed in future studies.

As the current saga regarding health care funding and regulation unfolds, and as the vested interests of the various private and governmental power groups become more “transparent,” debated, and compromised or modified, it will be particularly critical to the welfare of the geriatric population that the highest moral and ethical values be followed, that all age groups receive the respect and quality health care appropriate to their needs, and that the financial burdens be shared equitably among the citizens of this nation not only as a compassionate and caring duty, but also as a fulfillment of humane responsibility to humanity and to society.

Of paramount importance is the right of self-determination of elderly individuals and their families in the provision, modification, and cessation of all aspects of nutritional support not only from the ethical and religious points of view but from the legal mandate. A government that guarantees the rights of women to decision-making regarding their bodies and fetuses must guarantee the equivalent rights of the elderly to decision-making regarding their nutrition, surgical management, and life support. How we nourish and treat our elderly population during the next decade or two will influence greatly how we define our character as a society, culture, and nation.

I would like to close this commentary with one of my favorite anecdotal recollections from my long-time friend and fellow surgeon, Dr. David Heimbach. “It was a busy morning, about 8:30 a.m., when an elderly gentleman in his 80s, arrived to have stitches removed from his thumb. He said he was in a hurry as he had an appointment at 9 a.m. I took his vital signs and had him take a seat, knowing it would be over an hour before someone would be able to see him. I saw him looking at his watch, and decided, since I was not busy with another patient, that I would evaluate his wound. On examination, it was well healed, so I talked to one of the doctors and got the needed supplies to remove his sutures and redress his wound. While taking care of his wound, I asked him if he had another doctor’s appointment this morning as he was in such a hurry. The gentleman told me no, that he needed to get to the nursing home to eat breakfast with his wife. I inquired as to her health; he told me that she had been there for a while and that she was a victim of Alzheimer’s disease. As we talked, I asked if she would be upset if he was a bit late. He replied that she no longer knew who he was, that she had not recognized him in 5 years now. I was surprised, and asked him, “And you still go every morning, even though she doesn’t know who you are?” He smiled as he patted my hand and said, “She doesn’t know me, but I still know who she is.” I had to hold back the tears as he left; I had goose bumps on my arms, and thought, “That is the kind of love I want in my life.” True love is neither physical, nor romantic. True love is an acceptance of all that is, has been, will be, and will not be.” Such is the human condition from my perspective.

Chapter 7 Nutrition

Sandhya A. Lagoo-Deenadayalan and Danny O. Jacobs

Nutrition in the Elderly

Throughout most of adult life, our bodies maintain near-perfect metabolic balance interrupted only by disease. This equilibrium lasts a finite period – until the inevitable aging process begins. Aging is a complex phenomenon that includes molecular, cellular, physiologic, and psychological changes. Individual aging is influenced primarily by a person's genetic makeup, lifestyle, and environment. Of these factors, the first is predetermined and constant; the other two are optional, variable, and therefore modifiable. Some very old individuals can stay healthy and have a good nutritional status [1, 2], but physiologic decline and health problems are expected for most of us before death. Aging of cellular function results in a natural decline in physiologic performance and reserve capacity. Thus elderly individuals have increased susceptibility and are less resistant to illness [3].

These factors contribute to an increased prevalence of illness and increased risk for primary and secondary malnutrition. There is an estimated 5–10% prevalence of protein-calorie malnutrition among community-dwelling elderly. In the USA, approximately 85% of the noninstitutionalized elderly suffer from at least one condition that could be improved by proper nutrition [1]. Physicians often fail to recognize its presence. Malnutrition in this population may predispose the elderly to prolonged hospitalization.

Many studies have documented a high prevalence of malnutrition among the elderly residents of nursing homes. Surveys have shown incidences of malnutrition that range from 30 to 85% and increased mortality rates [4, 5]. Hypoalbuminemia is also common: a 37% incidence of this disorder was documented in a Veterans Administration nursing home. In elderly medical patients, nutritional status during acute illness is a determinant of morbidity, length of hospital stay, and mortality [1, 6]. In older surgical patients

malnutrition is associated with high morbidity and mortality, particularly when emergency surgery is necessary. In addition, malnutrition negatively affects postoperative functional recovery and rehabilitation [3]. Nutritional screening and intervention in the elderly has been proposed as a cost-effective measure [1], as approximately 30% of the health-care budget is spent on this age group.

Physical and Psychosocial Issues in Nutrition

A combination of physical, social, and psychological factors contributes to primary malnutrition in the elderly. Physical deterioration with age can influence nutritional status. As years pass, the elderly become frail, have diminished visual function, increased cognitive impairment, and gait and balance disorders that affect mobility and decrease their ability to obtain and prepare food. The US National Health and Nutrition Examination Survey (NHANES) III cohort study evaluated the hypothesis that socio-economic status is consistently and negatively associated with levels of biological risk. The nine parameters known to predict health risk are diastolic and systolic blood pressure, pulse, HDL and total cholesterol, glycosylated hemoglobin, C-reactive protein, albumin, and waist-hip ratio. Education and income effects were each independently and negatively associated with cumulative biological risks, independent of age. However, older age was associated with significantly weaker education and income gradients [7].

Adherence to lifestyle guidelines has been shown to markedly reduce mortality in middle-aged women in a study that observed them for 24 years. Guidelines addressed five lifestyle factors, namely cigarette smoking, being overweight, little to moderate exercise, light to moderate alcohol intake and low diet quality score [8].

Malnourishment is common in home-bound adults due to a variety of causes. These include various co-morbidities, medications, economic, social, religious, and psychological problems. Men are more likely to be undernourished than women and the higher the patients' body mass index, the

Durham, NC, USA
e-mail: lagoo002@mc.duke.edu

greater the odds of under eating, defined as not consuming enough calories to maintain their current body weight [9].

Dental diseases are common in the elderly. There is a direct relationship between poor dentition and difficulty ingesting certain food items, such as meat and hard foods such as nuts, raw vegetables in salads, and multigrain bread or rolls. This may result in changes in choice and the quality of food intake. Taste and smell are also affected. A progressive loss of taste buds occurs, predominantly affecting the anterior tongue. This region has taste buds that detect sweet and salt. Because the remaining buds detecting bitter and sour are relatively increased with aging, elderly people have a greater sensitivity to these tastes. This could explain their preference for high sugar foods. The elderly need a greater concentration change to perceive a difference in intensity. They also have a reduction in taste intensity (hypogeusia) and an increase in taste distortion (dysgeusia). These conditions can be exacerbated by medications and concurrent disease states [10, 11]. Use of food flavors (roast beef, ham, natural bacon, maple, and cheese) has been found to increase intake and nutritional status in elderly institutionalized patients.

The presence of multiple diseases can also affect nutritional status. Disorders that interfere with eating include neurological diseases, such as Parkinson's disease, cerebrovascular disease, chronic obstructive pulmonary disease, congestive heart failure, and chronic renal insufficiency. Some of these diseases require dietary restrictions that affect the palatability or variety of the food offered. Swallowing disorders are not uncommon in the elderly, and nutritional disorders are frequently associated with dysphagia in institutionalized persons (refer to Chap. 43 on swallowing disorders).

Disturbances of mood and affect are common in the elderly. Anorexia is a common symptom during depression, and these depressed patients often become malnourished. The prevalence of malnutrition among older patients hospitalized for depression can be as high as 20–35% [5]. One of the most difficult situations in geriatric medicine is to determine if the refusal of food is due to a curable depression or is the will of a mentally healthy individual. In particular, the death of a spouse can dramatically influence appetite and food intake. Depressed patients may put less effort into caring for themselves and may lose the symbolism of warmth and sharing associated with eating. The anorexia of aging is neither depression nor willfulness yet it is also a major cause of poor nutrition (see below).

Cognitive impairment such as dementia may also significantly decrease nutrient intake. To study this, a prospective study of 349 patients with a mean age of 85.2 years admitted to a Geriatric Rehabilitation center was carried out. Patients included those with no dementia, mild cognitive dysfunction or dementia. Although there was no significant difference in co-morbidities between older demented vs. nondemented

patients, there was a considerable deterioration in nutritional and functional status in the patients with dementia [12]. Routine nutritional assessments, functional assessment and review of medications should therefore be performed more often in patients with dementia so that appropriate interventions can be instituted.

Approximately 30% of elderly Americans live alone, and 25% of free-living elderly need assistance with activities of daily living. Social isolation can lead to problems of obtaining and preparing food. Timing of meals in hospitals and nursing homes may be disadvantageous, as meals may be separated by short periods of time. Appetite may be poor for each meal when they are offered too close together. Food presentation is key for patients to accept the meals offered. Food intake can increase by 25% if the environment is changed to a familiar one (home cooked meals, family and friends visiting during meal times, favorite music). Pureed food is not readily accepted, so imaginative ways of presenting such meals should be tried [13].

Age-Related Changes in Body Composition

Lean Body Mass

Presently, the most widely used body composition model is a two-compartment model in which the body is divided into lean body mass and fat. Aging is accompanied by a net loss of lean body mass. As a consequence, the elderly becomes debilitated and lose an important portion of their tissue amino acid and energy reserves. The lean body mass declines by approximately 6.3% every 10 years. Thus it decreases by an average of 0.45 kg/year after age 60. By age 70 muscle mass may be 20% less than that in young adults. This loss occurs disproportionately more from skeletal muscle than from viscera. Studies have suggested that changes in growth hormone metabolism may mediate age-related changes in body composition. People deficient in growth hormone have a decrease in lean body mass similar to that experienced by the healthy elderly [14, 15]. In addition, treatment with growth hormone or insulin-like growth factor-I (IGF-I) increases lean body mass, nitrogen retention, and muscle strength in the elderly [16]. Androgens have also been proposed to play a role in the body composition changes of aging. Plasma levels of testosterone may decrease with aging, and testosterone supplementation in aging individuals may increase their lean body mass.

Serum total testosterone and the calculated free testosterone correlate well with each other and are superior in defining a group of elderly men with suspected androgen deficiency. In contrast, free testosterone measured by direct

RIA reflects gonadal function poorly. Repetitive use of total testosterone is therefore recommended when screening for androgen deficiency in elderly men [17]. A study investigating the association between various testosterone measures and clinical and biochemical parameters of the aging male was undertaken. The parameters included serum levels of sex hormone-binding globulin, estradiol, and lipid profile after an overnight fast; questionnaires assessing clinical symptoms, erectile function and mood; bone mineral density and body composition. Testosterone values did not correlate with clinical signs and symptoms of hypogonadism. It is therefore critical that symptoms of the aging male be considered multifactorial and not be indiscriminately assigned to the age-associated decrease in testosterone levels [18].

Age-associated decline in growth hormone and androgen secretion contributes to the alterations in body composition and organ function seen during the normal aging process. Despite all these changes, the elderly may continue to function adequately but may have decreased capacity to adapt and to mobilize endogenous protein stores during the catabolic stress imposed by infection or trauma.

Body Fat

The proportion of body fat increases with age and is redistributed from subcutaneous to intramuscular sites. Body fat increases at a rate of 0.4–1.5% per year, beginning at around age 30. As with lean body mass, growth hormone and androgen administration appear to minimize alterations in body fat. The impact of testosterone supplementation on body fat is less dramatic. Testosterone appears to decrease the uptake of triglycerides and increase triglyceride turnover while reducing lipoprotein lipase activity. Furthermore, growth hormone and androgens may act together in the regulation of fat metabolism during adult life.

Energy Requirements

The total energy expenditure (TEE) can be divided into three parts: resting energy expenditure (REE, the energy expended at rest after overnight fasting), thermic effect of feeding (TEF, the increase in energy expenditure above baseline due to the consumption and processing of food), and energy expenditure for physical activity and arousal (EEPAA). Daily energy expenditure declines progressively throughout adult life. REE is approximately 15% lower (7.35 vs. 6.20 mega Joules (MJ)/day) in elderly subjects than that in the young. Changes in REE and EEPAA, which account for most of the energy consumed during daily activity, account for most

(73%) of the decline in TEE observed in elderly individuals [19]. Interestingly, body weight, rather than fat-free mass, appears to best predict the REE (Fig. 7.1). Aging is also associated with a significant decrease in energy expenditure per unit of fat-free mass and body weight. Changes in muscle mass affect energy consumption and utilization. Creatinine excretion, which is an index of muscle mass and is closely related to the basal metabolic rate, decreases with aging; thus the reduction in energy expenditure is in large part due to a decrease in lean body mass (fat-free mass) and to a more sedentary life style. These changes are reflected in a decreased total energy requirement in men from 2,700 kcal/day at age 30 to 2,100 kcal/day by age 80 [20]. These observations suggest that preservation of muscle mass and prevention of muscle atrophy could help prevent the decrease in metabolic rate associated with advancing age [21].

FIGURE 7.1 Resting energy expenditure in relation to fat-free mass and body weight in young men (filled circles) and elderly men (open circles) (from Roberts et al. [18], with permission).

Nutritional Assessment

Nutritional assessment is a key aspect of elderly patient care. With so many physiologic changes due to aging that heighten the susceptibility to disease, the importance of proper nutrition grows. It is a challenge, however, to identify elderly persons who would benefit from dietary intervention. Not every elderly patient needs to undergo a cascade of anthropometric, dietary, and laboratory tests to assess their nutritional status in the perioperative period. Simplified nutritional assessment can be done quickly (see Chap. 22) and will provide the caregivers with the appropriate perspective to plan for perioperative nutritional needs. This knowledge can drastically influence therapy and outcome. Key elements of a full nutritional assessment are defined below.

History and Physical Examination

A detailed social, nutritional, and medical history is an essential first step in assessing the nutritional status of the elderly. Particular attention should be paid to the presence of chronic diseases. Cancer by itself impairs nutritional status. Other diseases such as chronic obstructive pulmonary disease and congestive heart failure may make feeding difficult. Neurological illnesses that interfere with the eating process place patients at particular risk. Swallowing function and absorptive capacity should be specifically assessed. Disturbances of mood and affect (e.g., depression) are not uncommon and should be considered during the evaluation.

A social history is equally important. The degree of independence can influence the capacity to purchase and prepare food. Information about who lives with the patient, cooking facilities, and income is also needed. Particular attention should be paid to patients who live in nursing homes and institutions. The physical and cognitive conditions of these patients and the eating environment and food presentation may be unsuitable, placing them at risk of undernourishment. Elderly patients commonly take multiple medications. These drugs should be listed, as should alcohol use; and possible drug–nutrient interactions must be considered. Drugs that may interfere with nutrition are listed in Table 7.1.

The physical examination should always include body weight and height. Oral health, dentition, and swallowing capability should be assessed. Because dehydration may present subtly and atypically in the elderly, hydration status must be carefully evaluated. Orthostatic hypotension or tachycardia may indicate dehydration. Physical signs of malnutrition include muscle wasting and dermatitis associated with deficiency syndromes as well as perioral stomatitis and hair loss due to zinc deficiency. Cognitive impairments could

TABLE 7.1 Drug therapy that interferes with nutritional support

Drug therapy	Subject of interference or effect
Drugs that interfere with nutrient assimilation	
AlOH and MgOH	Phosphorus
H ₂ antagonists	Vitamin B ₁₂
Cholesterol-binding agents	Fat-soluble vitamins, folate
Phenytoin	Vitamins D and K, folate
Drugs interfering with nutrient delivery	
Sucralfate	Forms clogs in the feeding tube
Digoxin, phenytoin, theophylline, potassium chloride	Diarrhea due to hyperosmolarity
Nutrients affecting drug therapy	
Calcium	Phenytoin absorption
Vitamin K	Anticoagulants

indicate a deficiency of vitamin B₁₂, which should always be considered in the elderly if mentation is affected. The presence of decubitus ulcers is a common sign of malnutrition in institutionalized elderly and can indicate protein or vitamin C deficiency.

Nutrition Screening Initiative

Evaluation of nutritional status is an especially important aspect of the surgical evaluation. Many attempts have been made to standardize nutritional risk assessment in the elderly. Screening tools are shown in Table 7.2. The Malnutrition Universal Screening Tool (MUST) classifies malnutrition risk as low, medium, or high based on body mass index, unintentional weight loss, and acute illness. This test is for community-based ambulatory populations but also has high validity in a hospital setting [22]. Another test, the Mini Nutritional Assessment (MNA) has been developed to evaluate the risk of malnutrition in the elderly in home-care programs, nursing homes, or hospitals [23]. The factors included in the evaluation are shown in Table 7.3. The MNA-SF (Mini Nutritional Assessment – Short Form) was developed and validated to allow a two-step screening process. The MNA-SF and MNA are both sensitive, specific, and accurately identify nutrition at risk. The MNA detects risk of malnutrition before severe change in weight or serum protein. In hospital settings,

Question	Ratings	Score
Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties?	0=Severe loss of appetite 1=Moderate loss of appetite 2=No loss of appetite	
Weight loss during the last 3 months?	0=Weight loss greater than 3 kg 1=Does not know 2=Weight loss between 1 and 3 kg 3=No weight loss	
Mobility?	0=Bed or chair bound 1=Able to get out of bed/chair but does not go out 2=Goes out	
Has the patient suffered psychological stress or acute disease during the past 3 months?	0=Yes 1=No	
Neuropsychological problems?	0=Severe dementia or depression 1=Mild dementia 2=No psychological problems	
Body mass index (BMI)=weight(kg)/height(m ²)	0=BMI less than 19 1=BMI 19 to less than 21 2=BMI 21 to less than 23 3=BMI 23 or greater	
Maximum screening score: Total score of 12 or more: not at risk for malnutrition; no need to complete the remainder of MNA		
Total score less than 12: may be at risk for malnutrition; complete the full MNA assessment		
<i>Additional questions for full MNA (12 questions)</i>		
Lives independently (not in a nursing home or hospital)?	0=No; 1=Yes	
Takes more than 3 prescription drugs per day?	0=Yes; 1=No	
Pressure sores or skin ulcers?	0=Yes; 1=No	
How many full meals does the patient eat daily?	0=1 meal; 1=2 meals; 2=3 meals	
At least 1 serving of dairy products per day? Yes or No	0=If 0 or 1 Yes answers	
2 or more servings of legumes or eggs per week? Yes or No	0.5=If 2 Yes	
Meat, fish, or poultry every day? Yes or No	1.0=If 3 Yes	
Consumes 2 or more servings of fruits or vegetables per day?	0=No; 1=Yes	
How much fluid is consumed per day?	0=Less than 3 cups 0.5=3–5 cups 1.0=More than 5 cups	
Mode of feeding?	0=unable to eat without assistance 1=Self-fed with some difficulty 2=Self-fed without any problem	
Self view of nutritional status?	0=View self as malnourished 1=Uncertain of nutritional state 2=Views self without nutritional problems	
In comparison with other people of the same age, how do they consider their health status?	0=Not as good 0.5=Does not know 1.0=As good 2.0=Better	
Mid-arm circumference (MAC) in cm?	0=MAC less than 21 0.5=MAC 21 or 22 1.0=MAC 22 or greater	
Calf circumference in cm?	0=CC<31; 1=CC>31	
Maximum full assessment score=16	Total score ≥23.5 – normal nutrition, no further action required	
Combine screening + full assessment scores = maximum of 30	Total score ≤23.5 – risk of malnutrition Total score ≤17 – protein and calorie	

a low MNA score is associated with increased mortality, prolonged length of stay, and a greater likelihood of discharge to a nursing home [24]. Other screening tools include nutri-

tional risk index (NRI), nutritional risk screening tool 2002 (NRS-2002) and subjective global assessment (SGA) (Table 7.2). NRS-2002 has been shown to have higher sensi-

tivity and specificity than the MUST and NRI. In general, nutritional status and risk can be assessed by SGA, NRS-2002, and MUST in patients at hospital admission [25].

Anthropometrics

Anthropometric measurements are a convenient tool for evaluating nutritional status. They are inexpensive, safe, and easily performed in any outpatient clinic or surgery ward. They do have some drawbacks. First, anthropometric data are affected by age and severity of illness more than any other index of nutritional status [26]. Second, they are subject to individual variation depending on who monitors the measurements. Third, they must be compared to normal standards; and in the case of the elderly, there are few normative anthropometric data. Change of a specific parameter over time is generally more important than comparing it to standards. Various tables of weight per height that include elderly populations have been suggested by various investigators [27, 28], and a more valid ideal weight can be assigned using these age-specific tables. Weight loss of 5% over 4 weeks or 10% over 3 months is a sensitive indicator of malnutrition.

If the patient is not able to stand upright, height can be calculated from knee-height measurements using a normogram or the following height formulas [29].

$$\begin{aligned} \text{Stature for men} &= (2.02 \times \text{kneeheight}) \\ &\quad - (0.04 \times \text{age}) + 64.19 \end{aligned}$$

$$\begin{aligned} \text{Stature for women} &= (1.83 \times \text{knee height}) \\ &\quad - (0.24 \times \text{age}) + 84.88 \end{aligned}$$

Calculation of ideal body weight provides a valid weight reference for the individual. Percent of ideal weight is calculated as follows:

$$\text{Actual weight} / \text{ideal weight} \times 100$$

An ideal body weight of less than 90% is an indicator of malnutrition. Weight/height ratios can be expressed as the body mass index (BMI) – weight in kilograms/height in square meters. A normogram for body mass index is shown in Fig. 7.2. The Euronut–Seneca survey, which studied apparently healthy elderly individuals aged 70–75 years, found a mean BMI that ranged from 24.4 to 30.3 in men and from 23.9 to 30.5 for women. Results of the Third National Health and Nutrition Examination Surveys (NHANES III) include BMI data from men and women over 60 years of age in 10-year increments [30]. BMI,

however, correlates more strongly with body fat than with lean body mass and may not be a sensitive index of muscle or body protein stores, except in the presence of emaciation.

Other anthropometric measures can determine body fat and lean body mass. Body fat can be assessed by measuring the triceps and subscapular skinfold thickness, and at other sites [31]. Lean body mass can be estimated in women and men by measuring the mid-arm muscle circumference and by the creatinine height index. Equations that use these indexes have been developed to relate anthropometric measurements to body composition [32]. In 1989 Frisanchio reported standards for the elderly 64–74 years of age [33], the anthropometric data for European elderly over 90 years old were completed later [34].

Biochemical Markers

Use of serum laboratory values is an integral part of nutritional assessment in the adult population, although aging itself can affect test results. The most commonly used parameter, albumin, has been reported to be modified in the elderly. Albumin concentration decreases 3–9% each decade after age 70 in the community-dwelling elderly [35, 36].

In these individuals, the albumin loss is close to 0.8 g/l per decade [35], and in institutionalized individuals, the albumin has been observed to decrease by 1.3 g/l per decade. Of course, relative hypoalbuminemia may indicate poor nutritional status. Serum albumin is positively correlated with muscle mass in the elderly, and the relation may reflect shared changes with age in protein synthesis [37]. This decrease may be attributed to the decrease in skeletal muscle mass. Because of the minimal decline in albumin levels with age, hypoalbuminemia should not be ascribed solely to aging, and other causes should be considered [1]. Albumin is an important predictor of length of hospitalization, morbidity, and mortality among elderly people [37]. Severe hypoalbuminemia (<20 g/l) strongly predicts 90-day mortality and extended hospitalization in the elderly. It requires focused clinical attention regardless of the elderly patient's admitting diagnosis [38]. In the VA National Surgical Quality Improvement Program (a prospective analysis of surgical risk factors), low serum albumin was the single factor most predictive of poor postoperative outcome [39].

Because of their shorter half-lives compared to that of albumin, prealbumin, transferrin, and retinal-binding protein are better markers for acute changes in nutritional status. The serum concentration of these proteins, especially prealbumin, are better maintained in the geriatric population [39].

Level II Screen

Complete the following screen by interviewing the patient directly and/or by referring to the patient chart. If you do not routinely perform all of the described tests or ask all of the listed questions, please consider including them but do not be concerned if the entire screen is not completed. Please try to conduct a minimal screen on as many older patients as possible, and please try to collect serial measurements, which are extremely valuable in monitoring nutritional status. Please refer to the manual for additional information.

Anthropometrics

Measure height to the nearest inch and weight to the nearest pound. Record the values below and mark them on the Body Mass Index (BMI) scale to the right. Then use a straight edge (paper, ruler) to connect the two points and circle the spot where this straight line crosses the center line (body mass index). Record the number below; healthy older adults should have a BMI between 22 and 27; check the appropriate box to flag an abnormally high or low value.

Height (in): _____
 Weight (lbs): _____
 Body Mass Index
 (weight/height²): _____

Please place a check by any statement regarding BMI and recent weight loss that is true for the patient.

- Body mass index <22
- Body mass index >27
- Has lost or gained 10 pounds (or more) of body weight in the past 6 months

Record the measurement of mid-arm circumference to the nearest 0.1 centimeter and of triceps skinfold to the nearest 2 millimeters.

Mid-Arm Circumference (cm): _____
 Triceps Skinfold (mm): _____
 Mid-Arm Muscle Circumference (cm): _____

Refer to the table and check any abnormal values:

- Mid-arm muscle circumference <10th percentile

- Triceps skinfold <10th percentile
- Triceps skinfold >95th percentile

Note: mid-arm circumference (cm) - {0.314 x triceps skinfold (mm)} = mid-arm muscle circumference (cm)

For the remaining sections, please place a check by any statements that are true for the patient.

Laboratory Data

- Serum albumin below 3.5 g/dl
- Serum cholesterol below 160 mg/dl
- Serum cholesterol above 240 mg/dl

Drug Use

- Three or more prescription drugs, OTC medications, and/or vitamin/mineral supplements daily

LEVEL II SCREEN

Name: _____

Date: _____

FIGURE 7.2 Normogram for body mass index (from the Nutrition Screening Initiative, a project of the American Academy of Family Physicians, the American Dietetic Association, and the National

Council on the Aging, with permission. Funded in part by a grant from Ross Products Division, Abbott Laboratories).

Serum prealbumin protein appears to be a more sensitive marker of protein malnutrition than transferrin, although its use as a predictor of clinical outcome has yet to be determined [39, 40].

Iron stores (ferritin) usually increase with aging, which can cause circulating transferrin levels to diminish. Other conditions that may decrease transferrin levels include the anemia associated with chronic disease, acute inflammation,

Clinical Features

Presence of (check each that apply):

- Problems with mouth, teeth, or gums
- Difficulty chewing
- Difficulty swallowing
- Angular stomatitis
- Glossitis
- History of bone pain
- History of bone fractures
- Skin changes (dry, loose, nonspecific lesions, edema)

Eating Habits

- Does not have enough food to eat each day
- Usually eats alone
- Does not eat anything on one or more days each month
- Has poor appetite
- Is on a special diet
- Eats vegetables two or fewer times daily
- Eats milk or milk products once or not at all daily
- Eats fruit or drinks fruit juice once or not at all daily
- Eats breads, cereals, pasta, rice, or other grains five or fewer times daily
- Has more than one alcoholic drink per day (if woman); more than two drinks per day (if man)

Living Environment

- Lives on an income of less than \$6000 per year (per individual in the household)
- Lives alone
- Is housebound
- Is concerned about home security

- Lives in a home with inadequate heating or cooling
- Does not have a stove and/or refrigerator
- Is unable or prefers not to spend money on food (<\$25-30 per person spent on food each week)

Functional Status

Usually or always needs assistance with (check each that apply):

- Bathing
- Dressing
- Grooming
- Toileting
- Eating
- Walking or moving about
- Traveling (outside the home)
- Preparing food
- Shopping for food or other necessities

Mental/Cognitive Status

- Clinical evidence of impairment, e.g. Folstein < 26
- Clinical evidence of depressive illness, e.g. Beck Depression Inventory > 15, Geriatric Depression Scale > 5

Patients in whom you have identified one or more major indicator (see pg 2) of poor nutritional status require immediate medical attention; if minor indicators are found, ensure that they are known to a health professional or to the patient's own physician. Patients who display risk factors (see pg 2) of poor nutritional status should be referred to the appropriate health care or social service professional (dietitian, nurse, dentist, case manager, etc.).

FIGURE 7.2 (continued)

and chronic infection. High transferrin levels may be found with iron deficiency.

Plasma IGF-I concentration is considered a valuable index of PEM in young and middle-aged adults. As mentioned previously, because IGF-I levels decrease with age, it may not be valid to extrapolate these results to the elderly. However, changes in IGF-I strongly predict the

likelihood of life-threatening complications in the elderly [41]. Furthermore, in one study IGF-I was well correlated with markers of nutritional status, including (1) serum albumin, transferrin, and cholesterol; (2) triceps skinfold thickness; and (3) percentage of ideal body weight. These changes may reflect the detrimental effects of low IGF-I concentrations. Despite these findings, the validity of

IGF-I as a nutritional marker in the elderly still must be determined.

Various signaling pathways are influenced by reactive oxygen species. The glutathione precursor cysteine has been shown to decrease insulin responsiveness in the fasted state. Supplementation with cysteine in clinical trials leads to improvement of various conditions that deteriorate with aging. These include skeletal muscle function, immune functions and plasma albumin levels. It also causes a decrease in body fat/lean body mass ratio. These data suggest that aging may also be associated with a deficiency in cysteine [42].

Immune Markers

Total lymphocyte count is a nonspecific indicator of protein-energy malnutrition (PEM). An absolute lymphocyte count of less than $1,500/\text{mm}^3$ indicates malnutrition if other causes of lymphopenia can be excluded. The lymphocyte count appears to decrease in the elderly, although it remains above $1,500/\text{mm}^3$ [43].

Delayed hypersensitivity skin testing is a parameter used to assess relative immune competence. An anergic response has been linked to both increasing age and malnutrition. As yet it is unclear whether PEM-Associated changes in immune competence can be distinguished from those due to aging alone. In general, anergy is a poor predictor of malnutrition in the elderly and may be less reliable than in younger patients.

Functional Assessment

Functional assessment of the elderly helps detect physical and cognitive alterations that may increase the risk of malnutrition. Nutritional well-being is related to the ability of elders to perform the activities of daily life. The BMI, used as a standard measure of overall nutrition, is related to the functional capabilities of community-dwelling elderly. Elderly individuals with a low BMI are at greater risk for functional impairment [44]. Among other methods for evaluating capacity, direct measurements of neuromuscular performance, including motor strength, vibratory sense, gait and balance, and gait speed, are strongly related to disability [45]. In addition, many evaluation scales for cognitive and physical assessment that vary in simplicity have been developed [46]. These include the Activities of Daily Living (ADL) and Instrumental Activities of Daily Living (IADLs). ADL include bathing, dressing, toileting, transfer in and out of bed/chair, bowel and bladder continence, and the ability to feed oneself. Instrumental activities of daily living include the ability to use the telephone, shop-

ping, food preparation, laundry, transportation, responsibility for medications, and ability to handle finances. Poor performance scores on these tests should be carefully evaluated because deficits may result from malnutrition or may render the patient susceptible to malnutrition. Depressive symptoms and cognitive impairment are independent predictors of decline in functional status and increased dependence in activities of daily living [47]. These, in turn, can lead to inadequate food intake and malnutrition.

Nutritional Requirements of the Elderly

Energy requirements in the elderly decrease because of a reduction in muscle mass and a reduction in physical activity. Subjects over the age of 70 consume about a third less calories than their younger counterparts. Without adequate supplementation, this results in a reduction of all nutrients. Unfortunately, the requirements for these nutrients does not decrease. Nutrient dense foods can decrease mortality and decrease LOS in hospitals [48]. The modified MyPyramid (Fig. 7.3) was developed by researchers at Tufts University

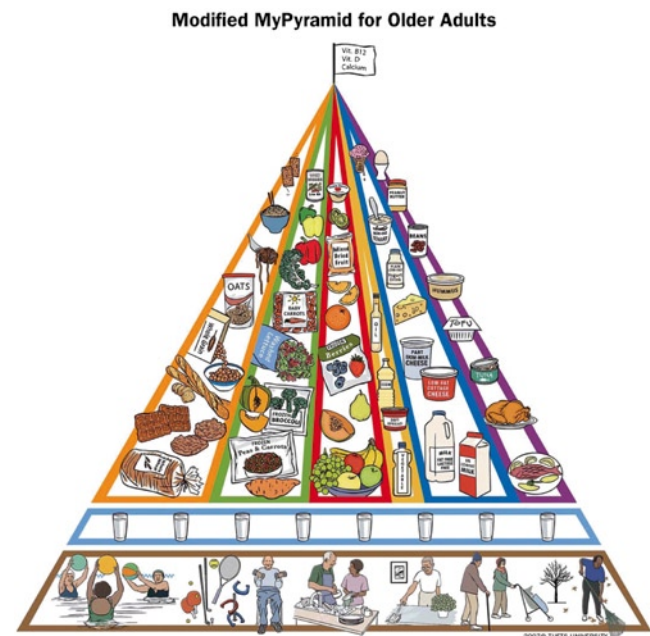

FIGURE 7.3 The major features of the modified MyPyramid for Older Adults graphic that are different from MyPyramid are the expanded presentation of food icons throughout the pyramid highlighting good choices within each category, a foundation depicting a row of water glasses and physical activities emphasizing the increased importance of both fluid intake and regular physical activity in older adults, and a flag on the top to suggest that some older adults, due to biological changes, may need supplemental vitamins B-12 and D, and calcium (reprinted from Lichtenstein A (2008) Modified pyramid of older adults. *J Nutr* 138(1):5–11, with permission from the American Society for Nutrition).

in Boston and emphasizes the importance of nutrient and fiber-rich foods and provides guidance about alternate food forms and the importance of regular exercise and adequate fluid intake [49]. The pyramid is most useful when used in combination with the US Department of Agriculture’s general MyPyramid food guide.

Fluid Requirements

Dehydration is one of the main discharge diagnoses in patients over age 65 [50]. Inadequate intake is one of the most common reasons for water and electrolyte disorders in this age group. Possible explanations include a decrease in the thirst sensation with increasing age. Age-related decreases in vasopressin secretion and an alteration in the opioid system may also impair fluid regulation [51]. Renal function decreases with age, as does the kidney’s capacity to adapt to changes in hydration status and electrolyte intake, thereby interfering with regulatory mechanisms. Stress and infection are often associated with decreased fluid intake and hydration. Fluid losses may be further increased by fever, vomiting, diarrhea, fistulas, and open surgical wounds, and they should be accounted for. In addition, fluid intake may be restricted owing to chronic renal insufficiency or congestive heart failure. The above factors predispose the elderly patient to hydration and fluid overload. Thus a more gradual approach to fluid delivery is appropriate. Dehydration may lead to confusion, resulting in decreased fluid intake. Patients and their families should be informed about the importance of adequate fluid intake and the need for monitoring intake and output during stressful periods.

Various formulas can be used to predict baseline fluid requirements, although some formulas do not account for obesity and low body weight and may give unrealistic estimates [52]. The following formula is appropriate for establishing fluid recommendations, as it adjusts for height and weight: 100 ml fluid/kg for the first 10 kg of body weight, 50 ml/kg for the next 10 kg of body weight, and 15 ml/kg for the remaining kilograms of body weight. A goal of at least 1,500–2,000 ml fluid is recommended. Given the reduced volume of formula required to meet the decreasing energy needs of the elderly, patients receiving the tube feeding may need additional fluid to maintain adequate hydration [1].

Energy Requirements

Several formulas are available to estimate energy requirements of the elderly. The Harris and Benedict equations (HBEs), which take into consideration sex, age, height, and

weight, can be used to estimate the resting energy expenditure (REE).

$$\text{Men} = 66.47 + [13.75 \times W(\text{kg})] + [5.0 \times H(\text{cm})] - [6.76 \times A(\text{years})]$$

$$\text{Women} = 66.51 + [9.6 \times W(\text{kg})] + [1.85 \times H(\text{cm})] - [4.68 \times A(\text{years})]$$

W is the weight, *H* is the height, and *A* is the age. The REE obtained is expressed in kilocalories per day. Unfortunately, the HBEs are performed poorly in some instances, and they can underestimate the actual REE in malnourished and critically ill patients [53]. The same is true in undernourished nursing home residents [54]. In these instances, direct measurement of REE is more appropriate. REE can also be predicted without height with only a minor loss of accuracy [1].

$$\text{Men} = 13.5(W) + 487$$

$$\text{Women} = 19.5(W) + 596$$

A correlation factor should be added to the REE depending on the degree of metabolic stress of the patient (Table 7.4).

Currently, recommendations for energy requirements in the elderly are based on assumed levels of physical activity relative to the basal metabolic rate (BMR). However, substantial error is found when total energy expenditure is derived from measurements or predictions of BMR [55]. Furthermore, current recommended daily allowances (RDAs) may significantly underestimate the energy requirements for physical activity in healthy elderly persons. Accurate estimation of energy needs is important for delivering adequate nutritional care and preventing disability. Human aging has been associated with reduced ability to regulate energy balance. This might explain the vulnerability of older persons to unexplained weight gain and weight loss [56]. Thus in some older individuals, successful weight maintenance may require increased control over food intake and energy requirements.

TABLE 7.4 Adjustment factors for resting energy expenditure

Correction factor	Stress
1.0–1.1	Postoperative
1.1–1.3	Multiple fractures
1.2–1.5	Weight gain/replenishment
1.3–1.6	Severe infection/bullet wounds
1.6	Sepsis
1.5–2.1	Third-degree burns
1.2	Confined to bed
1.3	Out of bed
1.5	Active

Source: Data from Nelson and Franzi [13]

Protein Requirements

Although the recommended daily allowance for protein is 0.8 mg/kg/day, recent studies have shown that the protein requirement in the elderly should be as much as 1.5 g/kg/day, i.e., 15–20% of total caloric intake [57]. This may increase muscle mass and function leading to greater activity. This is particularly important in patients with co-morbidities such as diabetes, low-grade inflammation, etc. that cause anorexia. A 24-h urine urea nitrogen (UUN) can determine the amount of total nitrogen excreted and can be used to estimate protein requirements, though it is rarely used in clinical practice. Rather, nitrogen losses are more commonly estimated or extrapolated. The following formula accounts for insensible and fecal losses and can be used to estimate total nitrogen loss.

$$\begin{aligned} \text{Total nitrogen loss} &= 24 \text{ h UNN (g / day)} \\ &+ (0.20 \times 24 \text{ UNN}) + 2 \text{ g / day} \end{aligned}$$

$$\begin{aligned} \text{Nitrogen (N) balance} &= \text{N intake} \\ &- [\text{urine N} + \text{stool N} + \text{insensible} \\ &\quad \text{N losses}] \end{aligned}$$

Generally a positive nitrogen balance of 4–6 g is necessary for anabolism. During the metabolic response to trauma, proteins are broken down to amino acids and are used for hepatic gluconeogenesis. The decrease in lean body mass that occurs with aging reduces tissue protein reserve and may diminish the body's capacity to resynthesize proteins. However, excluding burn patients, it seems prudent that during periods of stress such as infection, surgical trauma, or cancer, the daily protein intake should be increased to 1.5 g/kg/day [7].

Vitamin Requirements

As we have discussed, it is a combination of physical, social, and psychological factors that make the elderly population particularly susceptible to malnutrition. Aging alone might be accompanied by a decrease in some vitamin levels. These modifications may lead to an increased risk of vitamin deficiencies and disease. In the following sections, we review the most important vitamins and the role their supplementation may play in the nutritional status of aged individuals.

Vitamin A

Special consideration should be given to vitamin A supplementation in elderly subjects. In contrast to other vitamin levels, serum concentrations of vitamin A are usually within

the normal range in the elderly. The liver has a great capacity to store vitamin A, and hepatocellular levels of vitamin A are maintained through life. In addition, older individuals have an increased capacity to absorb vitamin A, and they have decreased renal excretion. Thus, over supplementation could predispose the elderly to vitamin A toxicity [58]. Increased vitamin A intake by the elderly can raise serum retinyl ester concentrations, which are an index of vitamin A overload. Elderly subjects with elevated fasting plasma retinyl esters were shown to have elevated liver function tests, indicative of liver damage. In view of the above findings, the current RDA for vitamin A of 5,000 IU for men and 4,000 IU for women may be too high for the elderly and should probably be reduced.

Vitamin B₆

Vitamin B₆ appears to play an important role in the regulation of homocysteine metabolism. Vitamin B₆ plasma concentrations inversely correlate with homocysteine concentrations, and elevated levels of homocysteine are associated with the development of occlusive vascular disease [59]. In addition, plasma pyridoxal-5'-phosphate (the coenzyme of vitamin B₆) concentrations have been linked to stenosis [60]. At this time, it cannot be concluded that lowering plasma homocysteine by increasing vitamin intake reduces the risk of vascular disease. It is not uncommon to encounter low vitamin B₆ plasma levels among the elderly, so it is probable that vitamin B₆ requirements are insufficient [60, 61]. Considering the above findings, a vitamin B₆ intake of 1.9–2.0 mg/day is adequate.

Vitamin B₁₂

Serum vitamin B₁₂ levels decline with advancing age. Prevalence of vitamin B₁₂ deficiency varies among countries, from none in the United Kingdom up to 7.3% in the rest of Europe [62]. In the USA, the prevalence of vitamin B₁₂ deficiency was shown to be more than 12% in a large sample of free-living elderly. By measuring serum homocysteine, a vitamin B₁₂ metabolite, many elderly people with normal serum vitamin concentrations were found to be metabolically deficient in cobalamin [63]. The reasons for the high prevalence of vitamin B₁₂ deficiency is probably a major etiologic factor. The vitamin B₁₂ level may also be affected by the high prevalence of atrophic gastritis (a partial decrease in fundic glands and of parietal cell mass) in the elderly population. There is a significant association between age and the prevalence of atrophic gastritis, which is as high as 24% after age 50 and 37% after age 80 [64]. In addition, gastric and intestinal bacterial overgrowth may contribute to vitamin B₁₂ malabsorption.

In view of these findings, the current RDA may underestimate the need for vitamin B₁₂ in the elderly. Low B12 concentrations were less prevalent among persons consuming B12-containing supplements. Biochemical B12 deficiency has been found to be higher in adults over 50 years of age. Current recommended daily allowance for B12 of 2.4 µg may be insufficient for those aged >50 years [65]. Clinically, the hematological changes typical of megaloblastic anemia can be absent in most subjects with evidence of deficiency.

Neuropsychiatric symptoms of vitamin B₁₂ deficiency may be present even with normal serum levels of vitamin B₁₂. Any elderly patient who is, or is suspected to be, vitamin B₁₂-deficient, based on the neurologic symptoms of vitamin B₁₂ deficiency, should receive a course of parenteral vitamin B₁₂ to replete stores [1]. Once the etiology of the deficiency is determined, appropriate maintenance therapy can be initiated.

Calcium and Vitamin D

With aging, serum vitamin D levels decline as a result of less-efficient synthesis of vitamin D by the skin, less-efficient intestinal absorption, and possibly reduced sun exposure and intake of vitamin D [66]. Sun exposure is essential for maintaining vitamin D levels and institutionalized elderly who do not receive enough sun are at particular risk of vitamin D deficiency. [67] Note that exposure of skin to sunlight that has passed through windowpane glass or Plexiglas does not produce cholecalciferol [68]. Sunscreen use and dark skin pigmentation can also substantially influence cutaneous production of vitamin D. Latitude influences the amount of vitamin D as well. In northern latitudes and during winter, ultraviolet B rays do not reach the earth's surface. People in these regions are entirely dependent on dietary sources of vitamin D during this season. In the USA, the major dietary source of vitamin D is milk. Elderly individuals with lactose intolerance may avoid milk products that contain vitamin D and may be dependent on endogenous synthesis of this vitamin.

Intestinal calcium absorption is independently reduced with age and after menopause as estrogen levels decrease [69]. This might be due to age-related changes in the metabolism of vitamin D. Although antifracture efficacy is of primary interest, change in bone mineral density (BMD) is widely used in clinical trials because it is a strong predictor of fracture risk; with its use, a far smaller number of patients are required for a study [68]. Data have shown that calcium supplements significantly reduce bone mineral loss and increased bone density. In addition, calcium combined with vitamin D supplements have reduced hip and other nonvertebral fracture rates in nursing home residents [70]. However, vitamin D supplements alone do not decrease the incidence of hip fractures, which suggest that only the combination of calcium and vitamin D is beneficial [71]. *The current vitamin D RDA*

of 200 IU may not be sufficient to minimize bone loss. An intake of 400–800 IU/day appears to be needed for healthy postmenopausal women [1, 62, 72]. A randomized placebo-controlled double blind study in patients greater than or equal to 64 years of age revealed that in greater than 97.5% of these individuals, the requirement for vitamin D is met by intake between 7.9 and 42.8 µg/day of Vitamin D. Factors influencing this requirement include summer sun exposure at an adequacy of 25(OH)D [73]. Calcium intakes of 1,000 mg/day for postmenopausal women taking estrogen and 1,500 mg/day for women not taking estrogen are now considered optimal by many [54, 61, 68]. Calcium intake should not exceed 2,400 mg/day, because of the risk of nephrolithiasis [1].

Nutritional Problems in the Elderly

Obesity

Obesity is a major problem worldwide. In the USA, 74% of men and 66% of women aged 60 and older in are overweight or obese based on body mass index. A recent study showed that increased body mass index did not correlate with increased mortality in the elderly. Instead, it was the waist circumference that served as a more significant marker of increased mortality in the elderly [74]. It is therefore felt that both body mass index and waist circumference should be taken into account when evaluating obesity in the elderly. Obesity has also been shown to relate to functional disability in the elderly. In women, waist circumference has been found to be a better predictor of functional disability than BMI [75]. Obesity may exacerbate cardiovascular disease through several mechanisms including systemic inflammation, hypercoagulopathy and activation of the renin-angiotensin mechanisms [76].

Anorexia of Aging

Anorexia commonly occurs with aging. The decrease in appetite can be due to a decrease in basal metabolic rate, most likely secondary to a decrease in lean body mass and to a more sedentary lifestyle. Drugs can also cause anorexia as well as interfere with the intake, absorption, and metabolism of nutrients. Because of their use of multiple medications, the elderly are at increased risk of drug interactions, which may interfere with nutrient assimilation. Decreased food intake is more common in men than in women [4]. It is also seen in healthy elderly individuals. Psychosocial factors, such as depression and isolation also influence food intake.

The physiological decrease in food intake in the elderly is termed anorexia of aging and can be attributed to several factors. Among these are an increase in peripheral satiating systems, decreased compliance of the fundus of the stomach, an increase in basal levels of cholecystokinin and in secretion of cholecystokinin in response to intraduodenal fat. Decrease in testosterone in males results in increased levels of leptin and this in turn may accentuate anorexia.

Cachexia

Cachexia may result from an adaptation to an underlying illness such as cancer. A diagnosis of cachexia is made when there is a weight loss of at least 5% in a period of 12 months accompanied by three of the five following factors: decreased muscle strength, fatigue, anorexia, low fat-free mass index and abnormal biochemistry such as increased CRP or IL-6, anemia or low serum albumin. These factors help to distinguish cachexia from anorexia alone. Cachexia can result from problems with oral intake due to mucositis, or due to gastrointestinal concerns such as nausea and vomiting, bowel obstruction due to tumor burden, or delayed gastric emptying. Increased levels of TNF- α and IL-1 can cause cachexia, nausea, and vomiting. Central nervous system mediated effects result from pain and altered sense of smell and taste. Treatment options are limited. The use of androgens, selective androgen receptor modulators, antimyostatin drugs, growth hormone, insulin-like growth factor, and ghrelin have yet to show significant efficacy [77]. Megestrol acetate has been shown to improve appetite and decrease nausea in some cases, by causing a reduction of IL-1, IL-6, and TNF- α [78]. Data is still sparse for geriatric recommendations with nutritional repletion using Omega-3 fatty acids, co-essential/essential aminoacids.

Sarcopenia

Decreased food intake coupled with decreased activity leads to decreased muscle mass, which is termed sarcopenia. Cytokines play a role in both anorexia and sarcopenia. Chronic inflammatory conditions lead to an increase in cytokines such as IL-1 β , IL-6, and TNF- α . Several cytokines belong to the same family as leptin and exert their effects by stimulating the leptin receptor. IL-1 causes a decrease in luteinizing hormone, resulting in decreased testosterone levels and worsening anorexia and sarcopenia. Recently, a specific dietary approach has been found to prevent or slow down muscle loss with ageing. Rather than suggesting a large global increase in protein intake, it has been

found that ingestion of a sufficient amount of protein with each meal is more beneficial. Dietary plans that include 25–30 g of protein with each meal can maximize muscle protein synthesis [79].

Unintentional Weight Loss

Unintentional weight loss is a common problem in elderly patients and should be recognized and evaluated without undue delay. Several studies have shown that weight loss of 4–5% of body weight or more within 1 year or 10% over 5–10 years is associated with increased morbidity and mortality [80]. Low BMI (body mass index of less than 18.5) is an indication of protein-calorie malnutrition [81]. In nursing home residents 65 years of age or older, low BMI has a negative impact on the quality of life [82].

Although a quarter of these patients may not have any identifiable cause to explain the weight loss, the etiology can be detected in others by specific symptom-related investigation. Common causes of unintentional weight loss include malignant diseases (16–36%), psychiatric disorder (9–42%), gastrointestinal disease (6–19%), hyperthyroidism (4–11%), nutritional disorders or alcoholism (4–8%), and respiratory disease (6%) or renal disease (4%) [83] (Table 7.5). A thorough history and physical examination and the mini-nutritional assessment are used to assess unintentional weight loss. Attention should also be paid to medications that cause anorexia, dry mouth, nausea or vomiting, and dysphagia. Psychological and psychosocial causes should be identified and addressed. Nonpharmacological interventions include minimizing dietary restrictions [84] adding favorite foods to the diet, adding nutritional supplements, and involving nutritional programs such as meals on wheels. Pharmacological therapies are used to either stimulate appetite or cause weight gain. These include megestrol, acetate, ornithine, oxoglutarate, recombinant human growth hormone and dronabinol.

TABLE 7.5 Meals on wheels mnemonic for weight loss in older adults

Medications
Emotions – depression
Alcoholism
Late life paranoia
Swallowing problems
Oral factors
Nosocomial infections
Wandering
Hyperthyroidism, hypercalcemia, hypoadrenalism
Enteral
Eating problems
Low salt, low cholesterol diets
Stones

They are associated with multiple side effects and there are no prospective randomized trials that justify their use in elderly patients.

Frailty

Both undernutrition and obesity should be viewed as indicators of frailty in the older adult. The definition proposed by Fried [85] includes the presence of three or more of the following factors: unintentional weight loss, self-reported exhaustion, weakness, slow gait speed, and low physical activity. Severity and duration of weight loss and enquiry into activities of daily living (ADL) such as cooking and meal preparation are important. Frail older people may show low leptin levels and increased levels of IL-6 and C-reactive protein [86]. Other markers include 25-hydroxyvitamin D, IGF-1, and D-Dimer, suggesting a state that is pro-inflammatory [87].

Anemia

It has been shown that there is a significant association between anemia and malnutrition in the elderly. A third of anemia cases can be attributed to deficiency of nutritional factors such as iron, vitamin B12, and folic acid [88]. A cross-sectional study of 60 elderly hospitalized patients showed a 36.7% incidence of anemia. In this study, mid-arm muscle circumference (MAMC), albumin, and prealbumin correlated with hemoglobin in the bivariate analysis. MAMC and albumin were found to be significant predictors of hemoglobin in patients without inflammation (estimated by erythrocyte sedimentation rate) and prealbumin was found to be a predictor of hemoglobin in patients with inflammation [89].

Calorie Restriction

Changes with age include a gradual build up of degradative agents such as reactive oxygen and nitrogen species. Gene stability and function at fat-soluble and water-soluble sites within the mitochondria are affected by these reactive species [90]. The only intervention that has been shown to alter this phenomenon is calorie reduction. Restriction of total caloric intake has been shown to delay the rate of primary aging in many species such as worms, flies, and mice [91] although the mechanism responsible for this is not clear. Candidate mechanisms of calorie restriction in these species include decreased oxidative damage due to a reduction of reactive oxygen species generation and increased removal, altered neuroendocrine function and decreased incidence of

chronic diseases such as obesity, diabetes and cardiovascular diseases [92].

In overweight nonobese humans, caloric restriction improves whole body metabolic efficiency and lowers markers of oxidative stress [93]. Studies in mice and rats have shown that caloric restriction leads to a delay in immunosenescence – the expected decline in humoral and cell-mediated immune function associated with aging. The phenomenon may account for the delay in the development of certain neoplasms in these animals. Caloric restriction has also been shown to decrease the oxidative damage to proteins, lipids, and DNA resulting in decreased production of free oxygen radicals. Surrogate measures show that calorie restriction in humans reduces the risk factor for atherosclerosis and diabetes [94]. These include a very low level of inflammation as evidenced by low circulatory levels of c-reactive protein and TNF α , serum triiodothyronine levels at the low end of the normal range, and a more elastic “younger” left ventricle (LV), as evaluated by echo-Doppler measures of LV stiffness.

Nutritional Supplementation

Acute Care

Nutritional support in elderly patients is particularly important during admission for acute illness. Attention should be focused on the initial medical or surgical management of the acute problem. Strategies to counteract decreased consumption, poor appetite, and chewing problems are particularly critical in the elderly [95].

Enteral Nutrition

Physicians should be careful with orders that prohibit or limit oral intake. Such orders should be temporary in nature, with specific plans for nutritional supplementation in the event that the oral intake has to be withheld longer than anticipated. Fast-track rehabilitation may be possible in elderly patients following laparoscopic or open colonic surgery. In a small nonrandomized study, early enteral feeding and mobilization coupled with pain relief and management of postoperative nausea and vomiting (PONV) was feasible in patients over the age of 70 and resulted in improved organ function and improved outcomes [96].

There is a need to determine values or markers that can help assess prognostic factors of 6-month mortality in patients admitted in the post-acute care setting. Functional and nutritional changes following an acute health crises can help determine such outcomes [97]. The INTERACTIVE

trial combines nutrition (recommendations of nutrient dense foods, provision of recipes and referral to community meal programs and supplementation with commercial liquid diets, protein supplements or multi-vitamins where deemed necessary by a dietitian) and exercise therapy (exercise and fall prevention information) as an early intervention to address deconditioning, weight loss, and the ability to return to pre-admission status in elderly patients following proximal femur fractures. The study will be completed in September 2009, following which the results will become available [98].

Meal replacement products are often used to supplement oral intake in older adults. Liquid products, more than solid replacements, blunt the postprandial decline in hunger and therefore increase subsequent food intake in older adults [99].

Enteral nutrition is a preferred form of nutritional supplementation in the postoperative period. It helps to maintain epithelial cell structure and function and also helps in maintenance of mucosal immunity. Enteral tube feeding may be necessary in elderly patients hospitalized for an acute illness when they are unable to eat or swallow but have a functioning gut. Short-term feeding is possible through a small bore nasogastric feeding tube that does not interfere with the patient's ability to swallow. Radiographic evidence of proper placement of tubes is important before starting feeds. Full strength formulas should be used, starting at 25 ml/h and gradually increasing to reach the goal in 24–48 h.

Gastrostomy tube and jejunostomy tubes are used for long-term feeding, especially in patients who may require nutritional support for greater than 6–8 weeks. Temporary feeding tubes help maintain nutrition with the perioperative period. However, there is concern about placing feeding tubes in elderly patients who will not benefit from its intervention and whose quality of life in terminal stages of illness is adversely affected. Problems encountered include need for placement in nursing homes, lack of social interaction, need for restraints to protect the feeding tube and cellulites at the tube sites. Multidisciplinary approaches and frank discussions between the patient, the patient's family, and physicians can help with informed decision-making [100].

In patients with the prerenal disease, the BUN:plasma creatinine ratio may be greater than 20:1 due to an increased absorption of urea. BUN also increases with increased nitrogen intake. Adequate attention needs to be paid to high protein administration in elderly patients with impaired renal function [101]. These patients can retain excessive fluid resulting in peripheral edema and cardiac failure.

Fiber supplementation is important in enteral feeding. Although it does not have any effect on nutrition, it results in improved bowel function. In a study of 183 patients (mean age=82 years), randomized to enteral feeds with and without fiber, the patients who received fiber had reduced stool frequency and more solid stool [102].

Total Parenteral Nutrition

Elderly patients tolerate total parenteral nutrition (TPN) well and are not at greater risk of complications than their younger counterparts [103]. If oral feeds have to be withheld for greater than 7 days due to a nonfunctioning gut as in paralytic ileus, then TPN should be considered, through a centrally or peripherally inserted central venous catheter. There is no data showing any significant advantage of peripherally inserted central catheters over centrally inserted central venous catheters. A recent study showed that while peripherally inserted lines were not superior to centrally inserted lines, the incidence of thrombotic complications was higher in peripherally placed lines. Other studies show that peripherally placed lines have a lower cost of insertion, lower rate of infection, and lower complication rate [104].

Irrespective of the site of the intravenous catheter, parenteral nutrition can be associated with metabolic, infectious, and technical complications [105]. It should therefore be used for the shortest period possible and every attempt made to start enteral or oral feeding as soon as possible. Protein and caloric requirements can be provided and are calculated using the Harris–Benedict Equation. The goal is to achieve a positive nitrogen balance using amino acids, 10% dextrose and intralipids. Calorie requirements should be calculated carefully and patients should not be given excessive calories. Metabolic complications include hyper- or hypoglycemia, hyperlipidemia, hypercapnia, acid-base disturbances, and refeeding syndrome. Older patients are particularly susceptible to overfeeding with resultant azotemia, hypertonic dehydration, and metabolic acidosis [106].

Liver dysfunction can occur when patients are on TPN. Liver function tests are monitored on a weekly basis. In a prospective cohort study of patients in 40 Intensive Care Units, administration of TPN within the first 24 h after admission was found to have a protective effect on liver function [107]. Once the patient is able to tolerate 50% oral intake or enteral feeds, TPN can be weaned off. Percutaneous lines should be left in place until there is assurance that the patient can continue to tolerate oral intake.

Frequent accuchecks are critical to avoid hypoglycemia. Patients are usually given 10% Dextrose at 50 cc/h during the weaning period. Inability to tolerate oral intake should be an indication of failure to wean and the patient should be restarted on TPN. The importance of glycemic control in older sick surgical patients, particularly in the ICU cannot be overemphasized. Hyperglycemia (glucose > 10 mmol/l) contributes to mortality seen in critically ill ICU patients. The incidence of infectious complications also increases with hyperglycemia. Currently glucose levels between 4.5 and 6.1 mmol/l are recommended, as there is a significant risk of hypoglycemia in patients treated to tighter limits [108].

Nutritional Issues in Specific Disease States

Few changes in the gastrointestinal system occur with aging and therefore signs and symptoms should be attributed to specific disease processes. Table 7.6 summarizes age-related alterations in the GI tract. The information is helpful in the evaluation and management of understanding nutritional needs in the elderly in the perioperative period [109].

Pancreatitis

Nutrition in the setting of acute pancreatitis is a challenging problem. Most of these patient present with abdominal pain, nausea, and vomiting. A metaanalysis of 11 randomized controlled trials showed that enteral nutrition in comparison with parenteral nutrition resulted in a statistically significant (59%) decrease in infectious complications and a statistically non-significant (40%) decrease in mortality [110]. A subsequent metaanalyses evaluated the effect of timing of the commencement of feeds in patients with acute pancreatitis. When started within 48 h of admission, enteral nutrition as compared to parenteral nutrition showed a statistically significant reduction in the risk of multiple organ failure, infectious complications, and mortality. There was no decrease in multiple organ failure risk, infectious complications or mortality if initiation of enteral nutrition was delayed to greater than 48 h following admission. This shows that timing of artificial nutrition is critical in patients with pancreatitis [111].

When enteral feeding is started, it is usually through a Dophoff tube with the tip positioned as distally to the ampulla

of Vater as possible. Once the pancreatitis has resolved, low fat oral intake is encouraged.

Enterocutaneous Fistula

Maintenance of fluid and electrolyte balance is critical in the initial management of small bowel fistulas. Nutritional disturbances are present in 55–90% of patients with enterocutaneous fistulae [112]. Parenteral nutrition maybe initiated and should include trace elements and vitamins. Enteral nutrition should be administered in small bowel fistulas that are not expected to close spontaneously, in colcutaneous fistulas and when fistula output does not interfere with wound care [113]. Clear fluid up to 500 cc/day can be ingested. Enteral nutrition should consist of low residue diets [114].

Pressure Ulcers

Pressure ulcers can be a significant drain on energy reserves. Advanced stage pressure ulcers cause a catabolic and this state is influenced by the volume of the ulcers [115]. Specific instructions should be followed by the nursing staff to prevent development of pressure ulcers during hospitalizations for an acute problem. MNA is a useful screening and assessment tool in multimorbid geriatric patients with pressure ulcers [116]. Identification and management of nutritional deficiencies can decrease the risk of developing pressure ulcers.

TABLE 7.6 Gastrointestinal changes of senescence by segment

Segment of GI tract	Age-related alterations in GI tract	Diseases with nutritional consequences
Esophagus	Minor alterations in UES	Dysphagia GERD
Stomach	↓ Pepsin activity ↓ Prostaglandin synthesis ↓ Mucosal blood flow ↓ Gastric fluid secretion	Gastritis type A Gastritis type B Delayed gastric emptying Achlorhydria
Small intestine	↓ Lactase activity ↓ Intestinal blood flow ↓ Sodium/glucose co-transport	Bacterial overgrowth Lactose intolerance Inflammatory bowel disease
Colon	↓ In neuronal density ↓ Wall elasticity from collagen deposition ↓ Resting pressure of internal sphincter	Constipation Diverticulosis Angiodysplasia
Liver	↓ Liver size and blood flow ↓ Dynamic liver function	Hepatic encephalopathy cirrhosis (hepatitis C, ethanol, primary biliary cirrhosis)
Pancreas	↓ Pancreatic mass Ductular changes/fibrosis	Pancreatic cancer Chronic pancreatitis Diabetes

CASE STUDY

A 74-year-old man presented with an incarcerated ventral hernia. At exploratory laparotomy he was found to have a small bowel perforation within the hernia sac. Following small bowel resection and anastomoses, his fascial defect was too large to be repaired primarily. It was therefore repaired with a double layer of vicryl mesh and wound vacuum device. His past medical history was significant for diabetes, hypertension, and remote history of left hemicolectomy for diverticular disease.

Nutrition Assessment included weight 125 kg, height 175 cm, ideal body weight (IBW): 75 kg, percent IBW:167%, BMI=41. Duration of inadequate nutrition: 7 days. He was eating adequately until a week prior to admission. His albumin (1.9) was severely depleted but likely represented a stress response rather than long-term nutritional status. Preoperatively, it was recommended that he receive: 1,875–2,250 cal/day to maintain weight. As part of the weekly nutritional assessment, he was weighed three times a week, and visceral protein labs were checked once a week.

The patient was kept NPO following surgery. The nasogastric tube placed prior to surgery was removed on postoperative day 2; he was given clear liquids on postoperative day 3; and advanced to a regular diet on

postoperative day 5 after return of bowel function. He was subsequently discharged home on postoperative day 6.

He was readmitted 2 weeks later following increased drainage from abdominal wound and found to have an enterocutaneous fistula with an output of 1,200 cc/day. He was kept NPO and started on total parenteral nutrition (TPN) through a PICC line. Three weeks later, examination of his abdominal wound revealed small bowel mucosa at the site of the enterocutaneous fistula. At this time it was felt that the fistula would not close spontaneously and that he would need to undergo an exploratory laparotomy with small bowel resection and anastomoses. He was started on a low residue diet and weaned off his TPN. He was allowed 1,000 ml of free water per day to avoid dehydration. Calorie counts performed over a 2-day period showed an average calorie intake of 1,600 cal/day, with 80 g of protein per day. A higher protein intake of 113–135 g/day (1.3–1.5 g/kg) was advised.

At the time of his preoperative evaluation 5 months later, he weighed 125 kg.

His nutritional lab findings revealed an albumin of 3.3. He underwent a successful takedown of his enterocutaneous fistula and repair of his ventral hernia with bilateral separation of components. Five days following his surgery he was tolerating a regular diet.

Correcting zinc and calcium deficiencies and increasing the protein intake to 25% of total caloric intake increases the rate of healing of pressure ulcers.

Palliative Care

Artificial nutrition is considered medical treatment and not basic care [117]. The distinction is important because patients have a right to avail themselves of, or deny, medical treatment. Whenever possible, patient's wishes regarding enteral nutrition, parenteral nutrition, and the acceptable length of time for such intervention should be elicited. The "TLC" model of palliative care encourages a timely and team-oriented, longitudinal, collaborative, and comprehensive approach [118]. Artificial nutritional support is indicated in patients with head and neck cancers or esophageal cancer who are unable to swallow but continue to have an appetite. However, it has not been shown to improve survival

in patients with advanced cancer. Megestrol acetate can be used in these patients to stimulate appetite, as can a short course of corticosteroids. The patient's condition, prognosis, and treatment goals should be discussed with patient and family. Treatment options should include curative treatment and palliative care. Treatment withdrawal should be discussed. Specific details of comfort care afforded to terminally ill patients should be shared with patients. In a study of patients who had cancer or stroke as their terminal diagnosis, patients were offered food and assistance with feeding but without force. Fifty three percent of patients did not experience hunger; 34% initially felt hunger but this resolved. Sixty two percent of patients did not experience thirst or did so only initially [119]. When a terminally ill patient cannot make decisions, the advance directive should be consulted to obtain information regarding the patient's wishes. If this does not exist, the legal guardian or first order relative of the patient will need to make decisions based on the patient's known wishes. In unbefriended patients, the physician's judgment should be used to determine a care plan [120].

Chapter 8

Wound Healing in the Elderly

Guy P. Marti, Lixin Liu, Xianjie Zhang, Dongmei Xing, Denise C. King, Angela R. Kohli, Maura Reinblatt, William B. Greenough, and John W. Harmon

Introduction

Wound healing impairment in the elderly has been accepted as a medical reality for many years now. The most devastating wounds in the elderly include pressure ulcers, diabetic foot ulcers, venous stasis ulcers, and poorly healing surgical wounds. Recently, improved wound care products (see Table 8.1) and best practice guidelines (see Table 8.2) have helped to improve care of elderly patients with these types of wounds.

However, to date there is no compelling clinical study that proves that increased age impairs wound healing. The best evidence available is from studies, performed four decades ago which reported an increase in the incidence of wound dehiscence after laparotomy in older men [1, 2]. Likewise, the incidence of anastomotic complications was reported to increase with age [3, 4]. None of these studies is definitive owing to the variability of patient co-morbidities such as nutrition, vascular insufficiency, and the presence and severity of diabetes. Furthermore, human wounds cannot be precisely matched. These factors make it extremely difficult to carry out a conclusive clinical study. In contrast, animal studies have successfully demonstrated age related defects in wound healing.

However, these classical studies, along with fundamental histological findings and, more recently, in-depth descriptions of cellular functions and interactions remain the basis for future studies at a molecular and genetic level.

From a biological point of view, wound healing, tumor development and suppression, and aging are processes involving common mechanisms. Hayflick showed in 1961 that cultured cells in vitro had a limited lifespan, thus giving rise to the term cellular senescence [5]. New and powerful methods, which are now routinely available, have introduced the concepts of telomeric attrition and DNA damage by

oxidative stress [6]. Despite the growing body of knowledge and exciting fundamental research, cellular senescence and its mechanisms in vitro have only tenuous links with the aging of a whole organism [7]. Therefore, animal models remain our best option to study the physiology of wound healing in the elderly.

Physiology of Wound Healing

From the moment of injury, the body responds with a series of complex interactions that culminate in the restoration of integrity. Under normal conditions, healing can be divided into four specific stages: coagulation, inflammation, fibroplasia, and remodeling. Although described in a sequential fashion, healing is an active, dynamic process that proceeds through a series of mechanisms that are often redundant and simultaneous.

Coagulation

Coagulation initiates the process that leads to healing. Injury disrupts tissues and cells and induces local hemorrhage. Vasoconstriction occurs almost immediately as a response to catecholamine release to limit blood loss. Tissue destruction induces mast cells to release various vasoactive compounds including bradykinin, serotonin, and histamine, which initiate the process of diapedesis. Platelets from the hemorrhage help form the hemostatic plug by releasing clotting factors that produce fibrin and form the fibrin mesh onto which inflammatory cells migrate. Fibrin deposition is followed by fibrinolysis and the release of chemoattractive peptides, particularly fibrinopeptide E, which attracts monocytes, and fibrinopeptide B, which is angiogenic. In addition, platelet degranulation releases platelet-derived growth factor (PDGF), platelet factor IV, transforming growth factor 1 (TGF-1), and insulin-like growth factor 1 or somatomedin C (IGF-1), all of which stimulate fibroblast replication. Platelets

TABLE 8.1 Wound care products categories

Product classification	Most common brands
<i>Antimicrobial dressings</i>	
Topical wound products derived from <i>silver, iodine, and/or polyhexethylene biguanide</i>	Silver products
Available in	Acticoat absorbent dressing
Foams	*Aquacel Silver
Alginates	Contreet foam dressing
Hydrogels	Contreet Hydrocolloid
Hydrocolloids	Silva Sorb (silver hydrogel)
Barrier layers	*Silverlon
May or may not need secondary dressing	*Silver Med (silver hydrogel)
Use in draining, and non-healing wounds where protection from bacterial contamination is desired	Iodines
	*Cadexomer Iodines
	*Iodosorb Gel
	Iodoflex Pad
<i>Calcium alginate</i>	
Absorbs moderate to heavy drainage	*Aquacel is a hydrofiber, not a Ca alginate but performs in a similar fashion
Origin – brown seaweed	
Non-woven fibers	Curasorb
Ropes	Kaltostat
or pads	SeaSorb alginate
Absorbent and conforms to the shape of the wound	3M Tegagen
Absorbs up to 20 times its weight	Genteel calcium alginate
	Restore calcicare
	Sorbsan
<i>Collagens</i>	
Promotes the deposition of newly formed collagen fibers and granulation tissue in the wound bed. Stimulates new tissue development and wound debridement	Fibracol + collagen with alginate
Available in	*Promogran Matrix
Sheets	*Promogran Prisma Matrix (collagen + silver)
Pads	
Particles	
Gels	
<i>Composite dressings</i>	
Combination of two or more different products into one dressing, i.e., absorptive layer with an adhesive border for ease of application	*Alldress – low-adherent layer + absorbent pad + tape border
	Covaderm
	DermaDress
	Stratasorb
	3M Tegaderm Plus
<i>Compression</i>	
Used to manage edema, promote venous return to the heart and manage wounds caused by venous insufficiency. Multilayered. Available in individual layers or packaged as a multi-layer system	Alto press (single-layer system)
	Coban2 compression system
	DYNA-FLEX (multi-layer system)
	Profore (multi-layer system)
	Seto press (single-layer system)
	*Zinc Unna Boot + cotton padding + Flex wrap or Coban
<i>Debriding agents</i>	
Debridement of necrotic tissue and liquefaction of slough	*Accuzyme (gel Rx)
Dry eschar must be scored before applying debriding gel	Gladase (gel Rx)
Gels available by prescription only	*Mesalt
Mesalt available in:	Panafil (gel Rx)
Squares	Santyl (gel Rx)
Ribbons	

(continued)

TABLE 8.1 (continued)

Product classification	Most common brands
Foams	
Absorbs moderate to heavy drainage	Allewyn
Provide a moist environment and thermal insulation	*Biatain
Primary dressing for absorption and insulation, or secondary dressing for wounds with packing. Also effective to treat hypergranulation tissue. May be used under compression	Curafoam Hydrasorb Polyderm
Available:	PolyMem
With adhesive border	3M Tegaderm Foam
Without adhesive border	Tielle
Varied shapes and sizes	
Hydrocolloids	
Absorbs light to moderate exudates	Combiderm
Occlusive or semi occlusive dressings composed of gelatin, pectin, and carboxymethylcellulose	Comfeel Plus
Provide a moist healing environment	*DuoDerm CGF or -DuoDerm Extra Thin
Promotes granulation in clean wounds	RepliCare Hydrocolloid
Helps debride necrotic wounds autolytically	Restore
Used as primary or secondary dressing	*3M Tegisorb
Available in:	*3M Clear Acrylic Dressing – new product that performs similar to a hydrocolloid. Absorbs more than a hydrocolloid. Clear acrylic that allows visualization of the wound. May extend wear time due to visualization
Thin or thick	
Varied shaped wafers	
May or may not have transparent film border	
May be used under compression	
May be opaque or translucent	
Also available in pastes and powders	
Hydrogels	
Can absorb minimal drainage. Water or glycerin-based gels. Helps to maintain moist wound environment. Promotes granulation and epithelialization and facilitates removal of necrotic tissue or slough by autolytic debridement	Curafil Gel Curasol Gel
Available in:	*DuoDerm Gel IntraSite Gel Purilon Gel SAF-Gel TenderWet Gel Pad Curagel DermaGel Hypergel NormlGel
Amorphous gels	*Restore Hydrogel
Impregnated gauze	SoloSite Wound Gel
Sheets	3M Tegagel
Non-adherent layer	
Wound contact layers used to prevent dressing from sticking to the wound bed	*Adaptic Mepitel
May or may not be impregnated with gel, petroleum jelly, or other compounds	*Vaseline gauze *Xeroform Gauze
Also used over hydrogel to keep gel in place and prevent secondary dressing from absorbing gel	
Transparent films	
Non-absorbent	Clearsite
Adhesive, semi permeable, polyurethane membrane dressings that vary in thickness and size	Dermaview OpSite
Waterproof and impermeable to bacteria and contaminants, yet permit water vapor to cross the barrier	*3M Tegaderm
Maintain a moist healing environment, promoting granulation tissue and autolysis of necrotic tissue	
Not recommended for infected wounds	
Available in varied sizes	

When writing orders, refer to the product classification and not the brand name

TABLE 8.2 Pressure ulcer prevention best practices

Interventions	Reason
Get resident out of bed if condition allows. Residents with skin breakdown, should be up a maximum of 2 h at a time	Redistributes weight bearing sites and minimizes the risks of immobility
Teach and encourage resident to shift weight every 15 min, assisting as necessary, while up in chair	Prevents pressure points from developing and allows blood flow to return. Helps prevent pressure ulcers from developing on the lower portion of the buttocks
Assist or provide resident with devices to maintain mobility, i.e., passive ROM, splint, hand cones	Lessens resident's risk for development of a pressure ulcer or contracture
Turn and/or reposition non-ambulatory residents every 2 h minimum	Rotates the sites of pressure and allows blood flow to return to an area where blood flow had been restricted
<ul style="list-style-type: none"> • Lift resident off bed, do not drag when moving, especially heels and sacrum • Use a draw sheet to help when moving or turning resident • Place socks or heel protectors on resident • Place pajama top or elbow protectors on resident to protect elbows 	Minimizes shear and friction which can tear the skin and damage the capillaries supplying blood to the skin
Elevate heels by placing a pillow lengthwise under the residents calves	Decreases pressure on the heels and may decrease shear and friction
Place resident on pressure reducing mattress	Reduces effects of pressure
Place resident on pressure reducing cushion in chair	Reduces effects of pressure
Use maximum of two incontinent pads under resident in bed	Too many layers of linen between resident and pressure reducing mattress, will decrease the effectiveness of the mattress
Avoid incontinent pads over wheelchair cushion, use drawsheet or pillowcase for cover	Incontinent pads reduce effectiveness of pressure reduction provided by cushion
Inspect resident's skin during bath, when changing clothes, etc.	Identify any redness or skin break so that appropriate treatment or prevention measures can begin immediately
Apply lotion to bony prominences, back, and dry, flaky skin at bath time and prn	Keeps skin soft and supple
Apply moisture barrier ointment to the skin of an incontinent resident	Helps prevent incontinence from making the skin soft and prevents burning of the skin
Report frequent incontinence to ensure that appropriate methods of containment or treatment will be promptly implemented	Decreases the chance of complications from incontinence
Encourage resident to drink prescribed supplements and adequate amounts of water between and/or with meals. Report if resident refuses supplements	Helps maintain and/or improve nutritional status and hydration
Keep linen neat and wrinkle free	Helps prevent shear and friction

Prevention is part of every aspect of wound care, regardless if a wound exists or not. Many recommended practices regarding pressure ulcer prevention are nothing more than "good old common sense." Prevention requires a holistic approach from all members of the health care team

are critical in wound healing because they are the first to produce several essential cytokines thought to modulate many subsequent wound healing events [8].

Inflammation

The inflammatory stage is characterized by an increased migration of mast cells, polymorphonuclear leukocytes (PMNs), and lymphocytes into the wound. Within 24 h of injury, PMNs predominantly populate the wound area. Their role is more important for antibacterial defense than for repair. These cells are progressively replaced by macrophages, which are predominant by 48 h after injury. Macrophages stimulate replication and movement of fibroblasts and vascular endothelial cells, which in turn regulate the repair of the connective

tissue. When stimulated by injured tissue, fibrin, foreign bodies, low oxygen, and high lactate concentrations, macrophages have been shown to secrete IL-1 (Interleukine-1), IL-6, IL-8, tumor necrosis factor- α (TNF- α), transforming growth factor- β (TGF- β), IGF-1, and fibroblast growth factor-like molecules (LDGF). These factors regulate cell growth and chemotaxis of inflammatory cells, new fibroblasts, and endothelial cells. Inflammation is aggravated by the release of free radicals. The damaging effect of free radicals is enhanced by reactive hyperemia.

Fibroplasia

Fibroplasia is the stage where wound strength increases and integrity is restored. Fibroblasts originate locally, and

replication rates are proportional to oxygen availability. By 72 h fibroblasts migrate into the wound and synthesize collagen and proteoglycans. The latter are important extracellular compounds that stabilize and support cells and fibrous components of tissue. Collagen synthesis starts as early as 10 h after injury and reaches a peak between the first and second week before stabilizing. Initially, the collagen within a wound is comprised of large amounts of type III collagen but relatively little type I collagen. Collagen III provides strength during the late phase of wound healing by cross-linking. Vitamin C plays an important role in this process.

During this stage, the production of ground substance in the matrix increases, and vessels proliferate. Neovascularization occurs along the steep oxygen gradient that characterizes wounds. Regrowth of sympathetic nerve fibers is also associated with angiogenesis. Along with invading fibroblasts, fibronectin appears and promotes cell adhesion and phagocytosis, and it may be involved in matrix remodeling. Fibrinogen, laminin, and fibronectin constitute a framework from which new vessels can form and reepithelialization can occur. Reepithelialization is a complex phenomenon in which resting G_0 cells (cells in the inactive phase of mitosis) are recruited from the margins of the wound, followed by migration of epidermal cells. This process is essential for reconstitution of cutaneous barrier function [9]. It has been suggested that as the wound epithelializes, inflammation is downregulated owing to the presence of apoptotic cells at the advancing epithelial wound edge [10–12].

Remodeling

Remodeling is an extensive phase during which collagen is produced and remodeled to reach an equilibrium between collagen formation and destruction by collagenases. The type III/type I collagen ratio decreases allowing the mature type I collagen fibers to cross-link, organize, and rearrange along the tension lines of the skin. Acute and chronic inflammatory cells gradually diminish, and fibroplasia ends. Fibronectin that guided the migration of multiple cells during earlier phases is removed within a few weeks [13].

The first migration of epithelial cells has been observed 6–48 h following an injury, and epidermal proliferation reaches maximum values at 12–48 h. Neovascularization regresses, and a mature scar is formed.

Aging and Wound Healing

While clinical studies have not been able to clearly demonstrate an isolated age related defect in healing in humans, ani-

mal studies have shown this age related defect. In human studies, confounding variables of nutrition and vascular insufficiency and the difficulty in identifying sufficient numbers of identical wounds, make a definitive study impossible. On the other hand numerous animal studies demonstrate very clearly an impairment of wound healing in the elderly compared to the young.

Coagulation and Inflammation

Specific age-related alterations in both the coagulation and immune system have been shown to influence wound healing. Older patients show signs of vascular fragility or risk of hemorrhage. However, the cellular and molecular events that could support these clinical findings are unclear. Frequent comorbidities and impaired renal function are the primary reasons for hemostasis dysfunction [14–16].

Platelet and macrophage adhesion to substrates within the wound increases while macrophage function declines [17]. Old mice display a slower wound healing rate when compared to young mice [18]. Furthermore, wound healing is accelerated when macrophages from young mice are added locally to wounds of old mice. It is possible that the migratory capacity of macrophages in addition to other macrophage functions are affected by age, and the correction of such dysfunction might stimulate wound healing [19]. In accordance with the above reports, Ashcroft et al. observed a similar phenomenon. At 7 days after injury, wounds of young animals consisted of mature granulation tissue and scattered inflammatory cells, whereas the wounds of middle-aged and old mice showed persistent inflammation and immature granulation tissue [20].

Any study of macrophages is affected by their source (spleen, liver, brain, bone, mice, humans) and their state of activation and the experimental conditions (circulating macrophages, peritoneal exudates, in vivo, in vitro) leading to contradictory results in the cellular functions like chemotaxis and phagocytosis. However, there is a general consensus that macrophages are impaired by aging at a molecular level including a decrease in cytokine production and dysfunction of intracellular signaling pathways like NF-KappaB [21].

T cell-mediated immune function also deteriorates during aging. There is a loss of T cell proliferative capacity, a decline in the synthesis and release of IL-2, and a decrease in IL-2 receptor expression. A major factor responsible for the loss of T cell function is the inability of the T cell to respond to activation signals transmitted through the membrane binding of specific stimulatory signals [22]. An IL-2 deficit alone cannot explain these effects because exogenous administration of IL-2 does not completely restore the decreased T cell proliferative response of the elderly. A defect in the IL-2 receptor

expression or function may exist. In addition to IL-2, T cells have an increased ability to produce interferon- γ (IFN- γ), IL-4, IL-6, and TGF [23, 24]. Aging is associated with a decrease in cytotoxic lymphocyte activity and a reduction in lytic capacity. A significant portion of the age-related decline in CD8⁺ T cell-mediated cytotoxic activity is secondary to age-related alterations in the CD4⁺ T cell subset. The well-documented diminution in IL-2 production with age may contribute to the defect seen in the CD4⁺ cells [25].

Proliferation

Cell proliferation is affected by aging in a number of ways. Fibroblast migration in vitro is reduced, but the number of cells within an acute wound is not altered. Fibroblast proliferation declines as well. It seems that the mitogenic and stimulatory effects of growth factors, hormones, and other agents are significantly reduced during aging [26, 27]. The in vitro loss of responsiveness to specific stimulatory cytokines also occurs, with no changes in response to inhibitors [28]. In addition, fibroblast cultures from premature aging syndromes such as Werner syndrome, show a significantly reduced mitogenic response to PDGF, fibroblast growth factor (FGF), and serum [29, 30].

In addition to these intrinsic alterations, a detrimental microenvironment such as hypoxia has been demonstrated to have a dramatic effect on the migration of fibroblasts impeding even further the healing capacity of the elderly [31].

Studies show that epidermal behavior in elderly subjects differs from that of young subjects. Reepithelialization has shown to be delayed in wounds of old mice [32]. The rate of epithelialization of open wounds is slowed in elderly patients compared to that in young individuals [33, 34]. This is due, in part, to a longer migration time for the kera-

tinocytes to migrate from the basal layer to the epidermal surface [35].

Moreover, in vitro studies have revealed a decline in keratinocyte responsiveness to stimulatory cytokines, an increased response to inhibitory cytokines, and a decline in IL-1 production in elderly patients. This physiologic delay, when coupled with other factors that impair epithelial repair, may result in significant healing problems in the elderly.

Several studies have described changes in angiogenesis during aging. Elements of the microvasculature in young rats are periodic acid-Schiff (PAS)-negative and become increasingly PAS-positive beyond the halfway life-span. This observation reflects an increase in the carbohydrate content of blood vessels with aging. During acute wound repair in old animals the microvasculature is PAS-negative after injury and intensely PAS-positive after 8 weeks, reproducing the process of aging in an accelerated manner [36].

Aged endothelium may exhibit an increased adhesive response to leukocytes and TNF- α . Furthermore, IL-1 production increases and subsequently endothelial cell proliferation declines but vascular smooth muscle cell proliferation increases.

Recent work may guide the way to understanding the precise biological processes that are impaired in the elderly. Instability of hypoxia inducible factor I alpha (HIF) seems to be involved in the impairment of neovascularization and wound healing in elderly mice [37, 38]. HIF is a transcription factor that upregulates the expression of numerous angiogenic peptides including vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), Angiopoietin 1 and 2, as well as placental growth factor [38, 39]. Delivery of a constitutively stable form of HIF can improve wound healing in diabetic mice (see Fig. 8.1), and this improvement in wound healing is associated with increased angiogenesis [38]. Recently it has been shown that aged mice had significant upregulation of hydroxylases

FIGURE 8.1 Wound closure in db/db mice after electroporation-facilitated DNA transfection of CA5 (constitutively active form of HIF) versus Empty Vector (EV). (a) Open wound area (in pixels) was determined on the indicated day after wounding and transfection with gWIZ-CA5 (CA5)

or gWIZ-EV (EV). Mean \pm SEM is shown ($n=48$ for CA5; $n=20$ for EV). * $P<0.05$, ANOVA with Tukey Test. (b) Percentage of wounds achieving $\geq 95\%$ closure after transfection with CA5 versus EV is shown. * $P<0.001$, Mann-Whitney Rank Sum Test (from [38], with permission).

FIGURE 8.2 Wound healing characteristics of *db/db* mice. (a) Excisional wound closure in 2-month-old diabetic mice (*db/db*) and their heterozygous littermates (*db/+*). The bar graph shows the wound area (in pixels) measured by computer assisted planimetry on day 9 (mean \pm SEM,

$n=20$ for each group). * $P<0.01$, Student's *t* test. (b) The effect of age on wound healing in *db/db* mice. For mice of the indicated age, the bar graph shows wound area on day 9 (mean \pm SEM, $n=20$ for each group). * $P<0.01$, Student's *t* test (from [38], with permission).

which degrade HIF. The aged mice had significantly delayed wound healing (see Fig. 8.2) with reduced levels of HIF and downstream transcription products (see Fig. 8.3) as well as decreased neovascularization, compared with younger mice. Inhibitors of hydroxylation of HIF tended to improve wound healing in the older mice [37]. These studies provide an interesting insight into the biology of impaired wound healing in the elderly and suggest strategies for directly addressing the problem with targeted treatments. In addition to this recent work on the role of HIF in the impairment of wound healing in the elderly, defects in other aspects of wound healing have also been demonstrated.

Remodeling and Collagen Deposition

The structure of the extracellular matrix changes with age. Aging is associated with significantly reduced levels of wound matrix constituents, including collagen, basement membrane components, glycosaminoglycans, and fibronectin [40].

It is assumed that anastomotic strength and collagen metabolism are primarily determined by assessing collagen synthesis and content [36]. Collagen metabolism also seems to be altered by aging, with decreased production and increased degradation, although animal studies have reported conflicting findings and no general agreement has been reached [40–42]. In healthy human volunteers, intrinsic aging can be studied excluding extrinsic aging like UV light exposure. In covered skin, age will show a decrease in collagen content when, in

contrast, this content will be increased in exposed tissue. In both situations, age will constantly show a disorganization of the collagen and elastin fibers and architecture [43].

Wounds have been reported to change with age. The tensile strength of skin is positively correlated with collagen fiber diameter. During normal wound healing, the tensile strength of wounds increases with time, despite a decrease in the rate of collagen synthesis. The breaking strength of wounds in old animals has been found to be lower than that of young animals [44, 45]. This difference is believed to be due to less organized collagen fiber arrangement [46]. Tensile strength and energy absorption of abdominal incisional wounds are lower in old rats than in young rats by the fourth postoperative day. If wound strength is in fact impaired in the elderly, collagen might not be the only element involved in this phenomenon. A defect in the synthesis of noncollagenous proteins such as glycosaminoglycans, laminin, enzymes, and cytokines may affect the mechanical properties of wounds in the elderly. Imbalance between matrix metalloproteinases and their inhibitors [tissue inhibitors of metalloproteinases (TIMPs)] has been shown in humans but, to complicate things further, this phenomenon seems tissue and cell type dependent [27, 47].

Skin Stem Cells

Different types of adult stem cells have been found in the skin and are protected within a specific niche by a group of

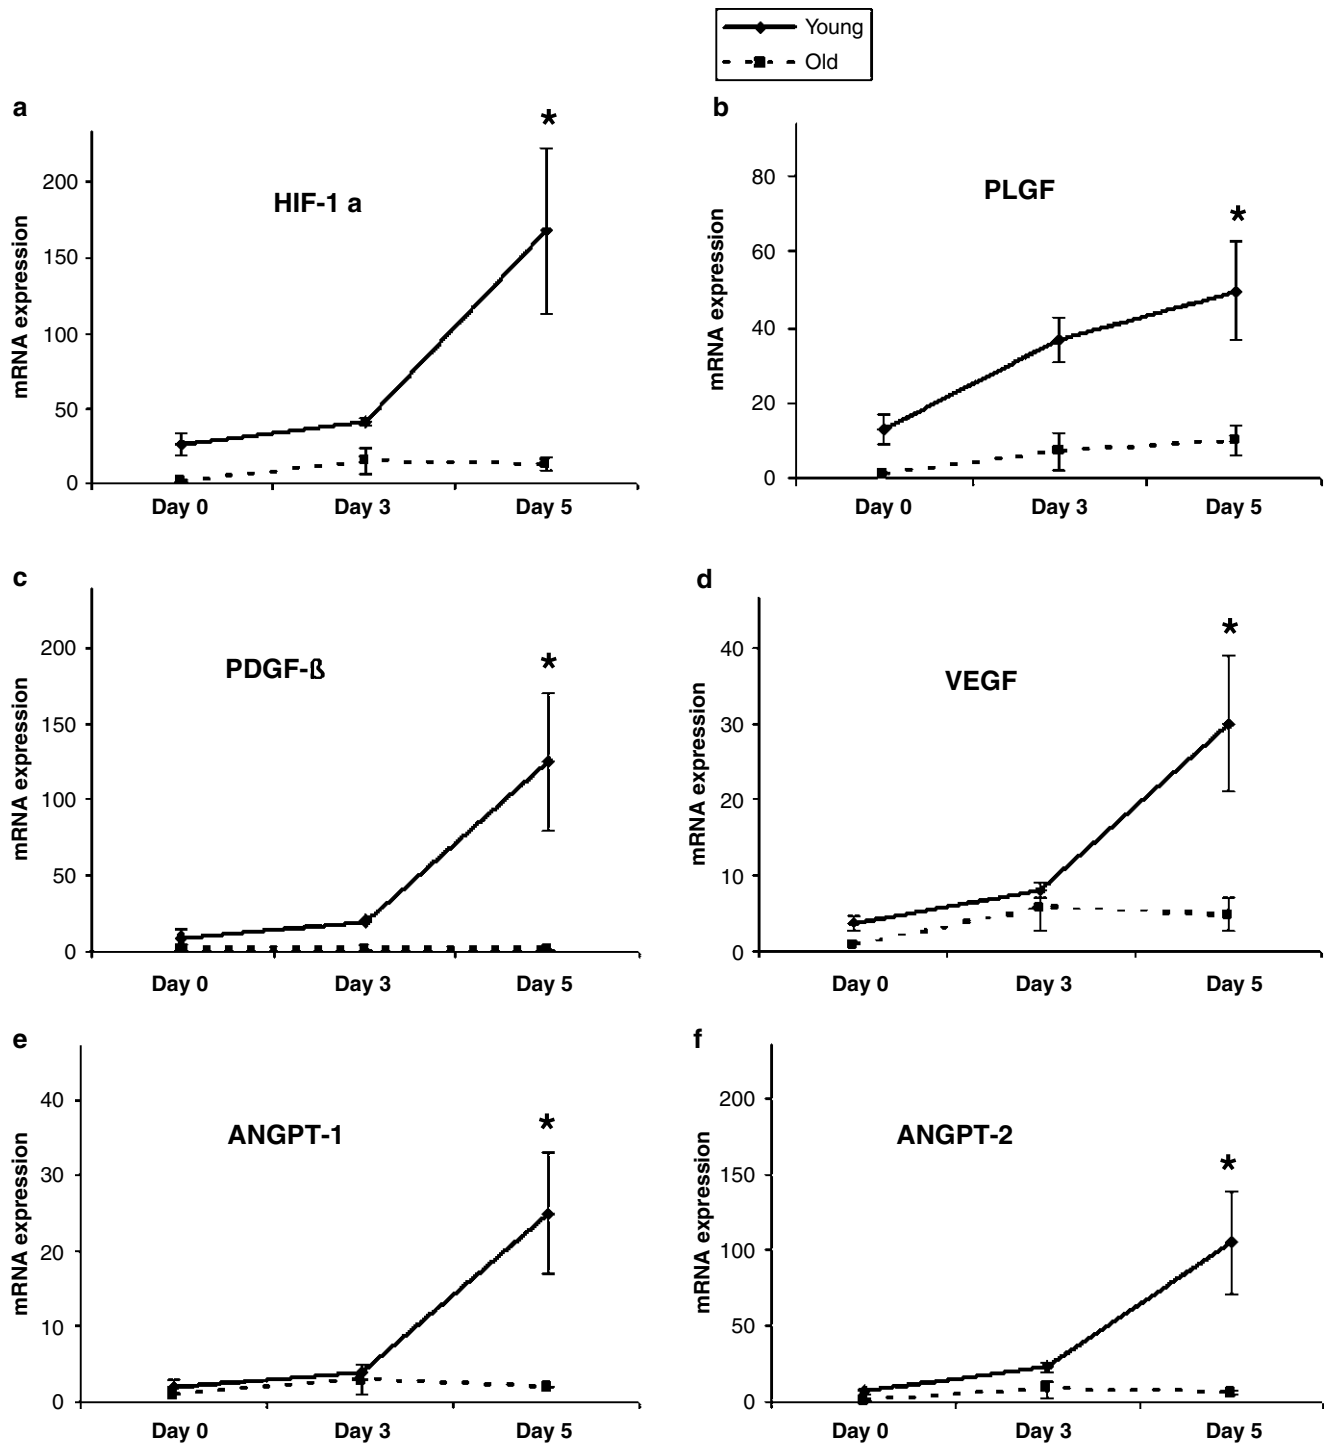

FIGURE 8.3 Expression of mRNAs for HIF-1 α (alpha) and angiogenic cytokines in wounds of 2- and 6-month-old db/db mice. Total RNA was extracted from normal skin (day 0) and wounds on day 3 and day 5 and

assayed by qRT-PCR for each mRNA. (a) HIF-1 α (alpha); (b) PLGF; (c) PDGF-B; (d) VEGF; (e) ANGPT1; (f) ANGPT2. * $P < 0.01$, ANOVA with Tukey Test, $n = 3$ for each group (from [38], with permission).

specialized niche-cells from extrinsic trauma. It has been observed that the number and self-renewal capacity of these stem cells are not affected by age, but their specific role, which is the ability to produce differentiated effector cells, declines [48].

Muscle and hepatic production of progenitor cell also decline with age. Exposure to young animals' systemic factors (serum) has increased, *in vitro*, the capacity of niche-cells from liver tissue of aged animals to proliferate and increased the gene expression of specific remodeling pathways to levels seen in younger animal tissues [49]. These findings, together with the study of dermal gene expression, suggest that epidermal stem cells are resistant to intrinsic aging, but sensitive to changes in the local environment. Recently, strong data supports the new idea of stem cells within hair follicle bundles homing into epidermal scar tissue. This finding opposes a common paradigm that hair follicles do not regenerate [50]. This whole new field in medicine holds great promise for future treatment in tissue repair and cell-based therapies.

Co-morbidities

Co-morbidities can further impair the healing process in the elderly. Often co-morbidities appear to be the primary impediment to successful wound healing. Careful clinical evaluation of the patient can reveal the presence of disease processes that require intervention.

Nutrition

Frequent minor deglutition accidents, loss of appetite, and loss of social interaction are the major causes of malnutrition in the aging population. Poor nutrition is associated with impaired wound healing [51], with decreased wound tensile strength, decreased T-cell function, decreased phagocytic activity, and decreased complement and antibody levels.

However, the nutritional status will affect the healing course differently depending on the type of wound. A wound such as a surgical incision or colonic anastomosis that heals by primary intention could heal in a malnourished patient in a reasonable time if protected from infection. On the contrary, a wound like a bed sore or a large burn that heals by secondary intention will be severely affected by a poor nutritional status and could trigger a state of catabolism [52].

Animal studies have helped us understand this relation. A commonly encountered degree of malnutrition, insufficient to affect nutritional indices used for clinical assessment, may interfere with colonic healing. Early feeding to enhance nutrition during the postoperative period may be

able to reverse this effect [53]. Daly et al. showed that rats deprived of protein for only 1 week exhibited a 17% reduction in mean bursting strength of colonic anastomoses compared to that of controls. They also observed a correlation between serum albumin and bursting strength with prolonged malnutrition [54]. These studies were later confirmed by Irving, who showed that severe protein deprivation reduced the breaking strength of abdominal wall wounds. A recent animal study from 2009 confirmed these original findings. Malnutrition impairs the healing of colonic anastomosis and a proper food intake given to malnourished rats 7 days prior to surgery will normalize the anastomosis tensile strength and its collagen contents [55].

In humans the wound healing response has been assessed by measuring the collagen content (hydroxyproline) of subcutaneously inserted Gore-Tex tubes. In this respect, a delay in the wound healing response is also seen in malnourished elderly surgical patients; but contrary to what happens in animals, it occurs even with mild degrees of protein-calorie malnutrition [56]. In addition, low serum levels of nutritional markers such as albumin and transferrin correlate with a high incidence of wound complications in elderly patients undergoing vascular operations [57].

The wound healing response, measured by hydroxyproline accumulation, is improved by intravenous nutrition in surgical patients. This improvement is seen after only 1 week of nutritional therapy and before the indices of nutritional status are significantly changed [58]. In the latest meta-analysis update from the Cochrane collaboration on nutritional supplementation for hip fracture aftercare, oral multinutrient feeds seem to reduce the risk of unfavourable outcomes, but data are insufficient to recommend nasogastric feeding, whereas protein-rich supplementation may reduce long-term complications and the number of days spent in hospital [59]. ESPEN guidelines on parenteral nutrition are in agreement with this review and conclude that a time limited parenteral support is beneficial only to severe malnourished patients and should be quickly replaced by intraoral intake [60].

Diabetes

Diabetes has been shown to impair wound healing and increase the potential for infection. Cruse and Foord demonstrated that diabetic patients have five times the risk of infection in a clean surgical wound compared to nondiabetic patients. Obesity, insulin resistance, and hyperglycemia all contribute significantly and independently to the wound impairment observed in diabetics [61, 62].

In experimental animals, insulin restores collagen synthesis and granulation tissue formation to normal levels if given during the early phases of healing [63]. However, this is not

the case in phenotypically obese mice [38, 64]. In humans with juvenile-onset diabetes, insulin treatment ensures normal wound collagen accumulation. Specific phases of wound healing involving collagen metabolism and cellular proliferation as well as chemotactic, phagocytic, and adherence properties of neutrophils have been shown to improve with insulin administration or lowering of the blood glucose level below 200 mg/dl. Careful preoperative correction of blood glucose levels can improve the outcome of wounds in diabetic patients [65].

Future approaches in diabetic wound treatments will probably take into account the critical role played by advanced glycoxidation products that seem to act negatively both on the vascular and peripheral nerve injuries sustained by diabetic patients [66].

Hypoxia and Hypoperfusion

Local tissue perfusion and oxygenation are key elements in wound healing [67]. Unfortunately, the elderly experience a progressive decline in health and are more prone to develop diseases that compromise tissue perfusion. Diabetes, arteriosclerosis, venous insufficiency, and cardiac failure are among the major diseases that can affect local oxygen delivery. It is even possible that a substantial portion of surgical patients are hypoperfused [68]. Healing of ischemic wounds in old animals is impaired by 40–65% (wound shrinkage) compared to similar wounds in young animals [69]. Tissues from older animals are less tolerant to ischemia with increasing age. Consequently, limiting ischemia time during surgical procedures in older patients is beneficial [70].

Collagen synthesis requires oxygen as a cofactor, especially during hydroxylation of proline. Oxygen tensions in surgical wounds are often below what is desirable [71]. Perfusion during the first postoperative days seems to be crucial for collagen accumulation. In fact, collagen deposition is directly proportional to wound oxygen tension and other measurements of perfusion [72]. Interestingly, moderate anemia does not influence collagen deposition. Thus replacing fluid postoperatively based on the results of tissue oxygen tension measurements rather than clinical criteria may improve the overall wound healing response [67, 73]. The use of a transcutaneous oxymeter device has proven useful in predicting a successful wound closure but no consensus has been reached in clinical practice [74].

Infections

Infection of surgical sites and healing of secondarily infected wounds, are two wound problems commonly affecting aged patients with various co-morbidities.

Surgical site infection is the most frequent nosocomial infection in hospitalized patients and will affect at least 2% of all surgical patients and up to 20% of patients undergoing some specific surgical procedures. Local wound infection represents the most frequent cause of defective wound healing. These numbers are very likely underestimated because of a lack of documentation concerning patients prematurely discharged in the context of private insurance coverage [75]. The transfer of the cost of disabilities, depression, and death due to these infections to the community is therefore very high [76].

For classification purposes, these infections have been classified according to the initial incision (superficial, deep, organ/space) and the preexisting infectious risk (clean, contaminated, dirty, infected). This classification is now essential to determine a risk index, to study various risk factors, and suggest specific practice guidelines [77] including the use of general measures, skin preparation, and surgical environment and eventually antimicrobial prophylaxis. These measures can be found in extensive reviews [78, 79].

The clinical examination is the first most important element to recognize a wound that is being challenged by a bacterial infection. The loss of bacterial balance can affect the wound superficially or within deeper tissues. The most important evidence of this imbalance is the delay in wound closure and the presence of an exudate. Odor, pain, and surrounding tissue inflammation will indicate uncontrolled infection, but these signs may be less obvious in the elderly patient [80]. Therefore, it may be necessary to study the bacterial contents of the wound.

The mere presence of organisms in a wound is less important than the level of bacterial growth. Experimental data have shown that bacterial growth of more than 100,000 organisms per gram of tissue is necessary to delay or inhibit wound healing. The bacterial growth can be measured in the clinic by performing a biopsy for culture. It is more reliable than a bacterial swab that can isolate superficial noninvasive bacteria and miss the anaerobes responsible for the infection [81].

Recently, the pathophysiology of infections associated with chronic wounds has begun to be better defined. Many more microorganism species have been identified [such as methicillin resistant *Staphylococcus aureus* (MRSA)] but most of them develop in the form of biofilms. This complex structure supports colony growth, retention of nutrients, and formation of water channels and allows cell–cell communication and even gene transfer through transduction [82]. In addition, bacterial cells in these structures are protected from antimicrobial agents and host defenses, explaining the frequent inability to eradicate them in infections. In addition, developing molecular microbiology techniques (nucleic acid amplification-PCR and metagenomic methods) have shown that chronic wounds from different

etiologies will display a different microorganism population and therefore require different treatment regimens. These molecular techniques are indeed reserved for the research community but should become a standard for resistant wounds [83].

Drugs

The major effect of steroids is to inhibit the inflammatory phase of wound healing. The stronger the anti-inflammatory effect of the steroid used, the greater is the inhibitory effect on wound healing [84, 85]. Large doses of steroids reduce collagen synthesis and wound strength. Dexamethasone increases the frequency of colonic anastomotic rupture 5 days postoperatively [86]. In addition, long-term perioperative steroids have a deleterious effect on colonic anastomoses and skin healing [87, 88]. Short-term high preoperative and postoperative steroid therapy does not decrease the strength of the anastomoses as measured by bursting pressure. Treatment with a single preoperative high dose of methylprednisolone may improve pulmonary function and reduce the inflammatory response without having a detrimental effect on collagen accumulation in the wound [89].

Cancer therapies have long been known to affect wound healing adversely. Chemotherapeutic antimetabolite drugs inhibit early cell proliferation, which is crucial to the onset of successful wound repair. Radiation therapy also has unwanted effects, as it can induce fibrosis, strictures, and ischemia in adjacent tissues. It can also generate an early decrease in seromuscular blood flow in colorectal anastomoses, although single preoperative doses may not compromise healing [90].

Other drugs may also have unexpected adverse effects on wound healing. Octreotide, a somatostatin analogue commonly used in surgical patients, has been shown to decrease wound breaking strength in experimental animals; these effects are comparable in magnitude to those caused by steroids [91].

Therapeutic Approaches

The healing impairment in aged individuals is a combination of intrinsic and extrinsic factors that act at multiple levels of the healing cascade. As a result, a multifaceted therapeutic approach is necessary. In addition, the incomplete success in translating animal research results to human clinical applications demonstrates the complexity of human biology in which, identification of relevant subtypes will be the next avenue to explore.

The correct assessment and correction of co-morbidities will be the first major step to take to achieve success. Each co-morbidity will have a specific age-related treatment to render with the relevant medical specialties.

Nutritional Support

Nutritional support will have to be adapted to the degree of malnutrition, the urgency in closing the wound, and the ability of the patient to tolerate nutritional intake. General nutritional support can be started by mouth if there is no deglutition problem, which generally manifests itself as a pulmonary infection in the elderly. Enteral nutrition is a very effective way to correct malnutrition and should not be delayed for patients with even a moderate 10% weight loss. Specific nutritional supplementation such as arginine, vitamin A, vitamin C, and zinc have been shown to be effective experimentally, but their mechanisms of action are still unclear. Again, subpopulations of patients have responded differently to specific supplements depending on their comorbidities and the type of wound.

Growth Hormone

In wound healing research studies, growth hormone (GH) has been shown to increase the strength of incisional wounds [92]. Rats treated with preoperative and postoperative GH experienced an increase in breaking strength and collagen content of colonic anastomoses. The increments in these parameters were accompanied by an increase in collagen deposition in the anastomotic segment. These effects were seen only when GH was given during the healing phase [93]. GH seems to stimulate structural organization of the anastomotic collagen fibrils into fibers [94]. In addition, GH administration significantly improves skin wound strength in malnourished rats [95].

GH appears to exert its favorable effect in part by stimulating IGF-1 synthesis; in turn, IGF-1 mediates the anabolic effects of GH. IGF-1 is released early during wound healing by the lysis of platelet alpha granules and later by fibroblasts. This molecule stimulates fibroblast and endothelial cell proliferation as well as collagen synthesis [96]. IGF-1 appears to be critical for effective wound healing.

Rats depleted of IGF-1 experience a 50% decrease in wound protein, DNA, hydroxyproline, and macrophage concentrations. Moreover, infusion of IGF-1 into the wounds restores these variables [97]. Similar to GH, IGF-1 increases wound breaking strength in rats. However, its

effect is evident only when it is combined with one of its specific binding proteins, such as IGFBP-1 [98, 99].

In clinical studies including those on burn patients, growth hormone can significantly reduce wound closure times and the length of hospitalization. In addition, it may accelerate donor site wound healing rates by 25%. With this increase in healing, patients with massive (>60% total body surface area) burn wounds can undergo further skin grafting procedures earlier [100–102]. The good results obtained with GH therapy in terms of the healing rates for donor sites and burn wounds are encouraging. The adverse effects of GH are multiple and potentially severe: carpal tunnel syndrome, peripheral edema, joint pain and swelling, gynecomastia, glucose intolerance, and possibly increased cancer risk. Caution should be exercised when considering treatment with growth-hormone [103–105].

Oxygen

Chronic wounds are hypoxic and arterial and venous diseases are not sufficient to fully explain the phenomenon. Using new models, mathematical models [106], hypoxia chambers models [39, 107], or local ischemia animal models [108], new tools to improve oxygen availability in wounds are being developed.

In a systematic review of human trials hyperbaric oxygen has been found to be efficient in treating diabetic foot ulcers but has not proven effective on arterial ulcers [109]. Reports of successful topical application of oxygen are encouraging but not completely convincing [110–112].

Gene Therapy

Growth factors are proteins that act as regulators of the cellular mechanisms and are intensely involved in the wound healing process. As some of these growth factors have been found deficient in elderly animal wounds, it has been postulated that the addition of growth factors should be sufficient to stimulate an adequate healing response. Topical application of growth factors has been shown to have a healing effect in animal experiments. PDGF (Regranex, Ortho-McNeil) has been approved by the FDA for the treatment of diabetic neuropathic ulcers [113]. Because of the presence of the wound eschar and proteases, daily application is required and only a marginal effect has been demonstrated, compared to placebo (50 versus 37% of complete healing). Direct injection of naked DNA in the wound requires repeated

injections of high doses, which can actually impair wound healing [114].

In some instances topical application and direct injection can be inappropriate, and hence new methods of delivering the DNA into the cells had to be developed. These methods can be classified as chemical, mechanical, and virally mediated methods. Liposomes directly interact with the cell membranes to transfect the plasmid load [115]. The Gene Gun uses high air pressure to fire gold beads coated with DNA plasmids through the skin [116]. Liposomes and Gene Gun techniques have shown very variable transfection results. Electroporation might be the delivery method, which will be used in clinical settings in the near future. With the application of an electrical field through the skin, the cell membranes are made transiently permeable to charged macromolecules such as plasmid DNA. The cellular uptake is less than with a viral vector but better than the other chemical or mechanical methods and has not shown any associated risk. Electroporation has been used in human beings to treat specific cancers and to improve the efficacy of DNA vaccines [117–119]. Virally mediated transfer (called transduction) has a high transduction efficacy but there are serious concerns about its safety and pathogenicity [120]. The use of Lentiviruses instead of adenoviruses might reduce these risks.

Tissue Engineering

After more than a decade of progress in biomaterials and cell cultures, bioengineered skin substitutes are now available. Different types can be used: Cultured epidermal graphs (Epicel* Genzyme Tissue Repair), dermal substitutes (AlloDerm* LifeCell), dermal and synthetic epidermal substitutes (Integra*, Integra Life Sciences), and bilayered living skin constructs (Apligraf*, Novartis). The primary indications are life-saving immediate coverage of burn wounds, reducing the need for autographs, and closing chronic wounds. The products will improve as the understanding of their mechanism of action increases [121].

Conclusion

It is apparent that the wound healing response is altered in the elderly compared to that in young individuals. Inflammation, angiogenesis, epithelialization, and remodeling show changes that may consequently impair wound healing. However, in elderly patients not suffering from concomitant diseases, the rate of wound healing is normal or slightly

reduced. It is still difficult to reach definite conclusions on certain wound healing processes such as collagen metabolism, and the influence the above changes may have on morbidity and mortality.

Nonetheless, a clear relation is observed between wound healing and certain disease states (i.e., malnutrition, infections, hypoxia and reoxygenation, diabetes, and drug interactions). Patients with these conditions should be carefully evaluated and supplementation with growth factors and nutrient supplements considered. The potential uses of these factors may be of importance for wound healing in critically ill patients.

Local Wound Management in the Elderly

This chapter has reviewed the patho-physiology of wound healing impairment in the elderly and outlined systemic approaches to improve wound healing by improving blood flow, nutrition, oxygenation, and metabolic status. Now attention is turned to the local management of the wound. There are now consensus-based practice guidelines which provide a basis for management of all the major wound types in the elderly. Pressure ulcers are of such importance that the staging system for categorizing these wounds and guidelines for their prevention are included (see Fig. 8.4 and Table 8.1). In addition, we have categorized frequently used wound dressings in Table 8.2. The best practices for the care of chronic wounds including pressure ulcers, diabetic foot ulcers, and venous ulcers are available on line at the website of the Wound Healing Society [122–124]. The best practices in caring for acute wounds and avoiding impediments to wound healing in the elderly are currently only available as a journal article [125]. These guidelines are based on the consensus of experts and the authors of this chapter consider them to be the best guidance available for the care of wounds in patients of any age.

As surgeons, the most important principle to follow is the complete debridement of necrotic tissue. Adequate debridement of a large pressure ulcer often requires a trip to the operating room with adequate anesthesia to debride not only skin, but muscle and frequently bone as well. The days of performing these types of debridements at the bedside, or in the clinic should be behind us. Inadequate debridement will doom an elderly patient to failed healing, chronic wounds, and associated morbidity and mortality.

Surgeons also have to be vigilant in identifying and treating deep necrotizing soft tissue infections. Here, the decision to go to the operating room and excise the area of infection can be lifesaving. Erythema, pain, and swelling may be all that are required to make the diagnosis. Performing a CT

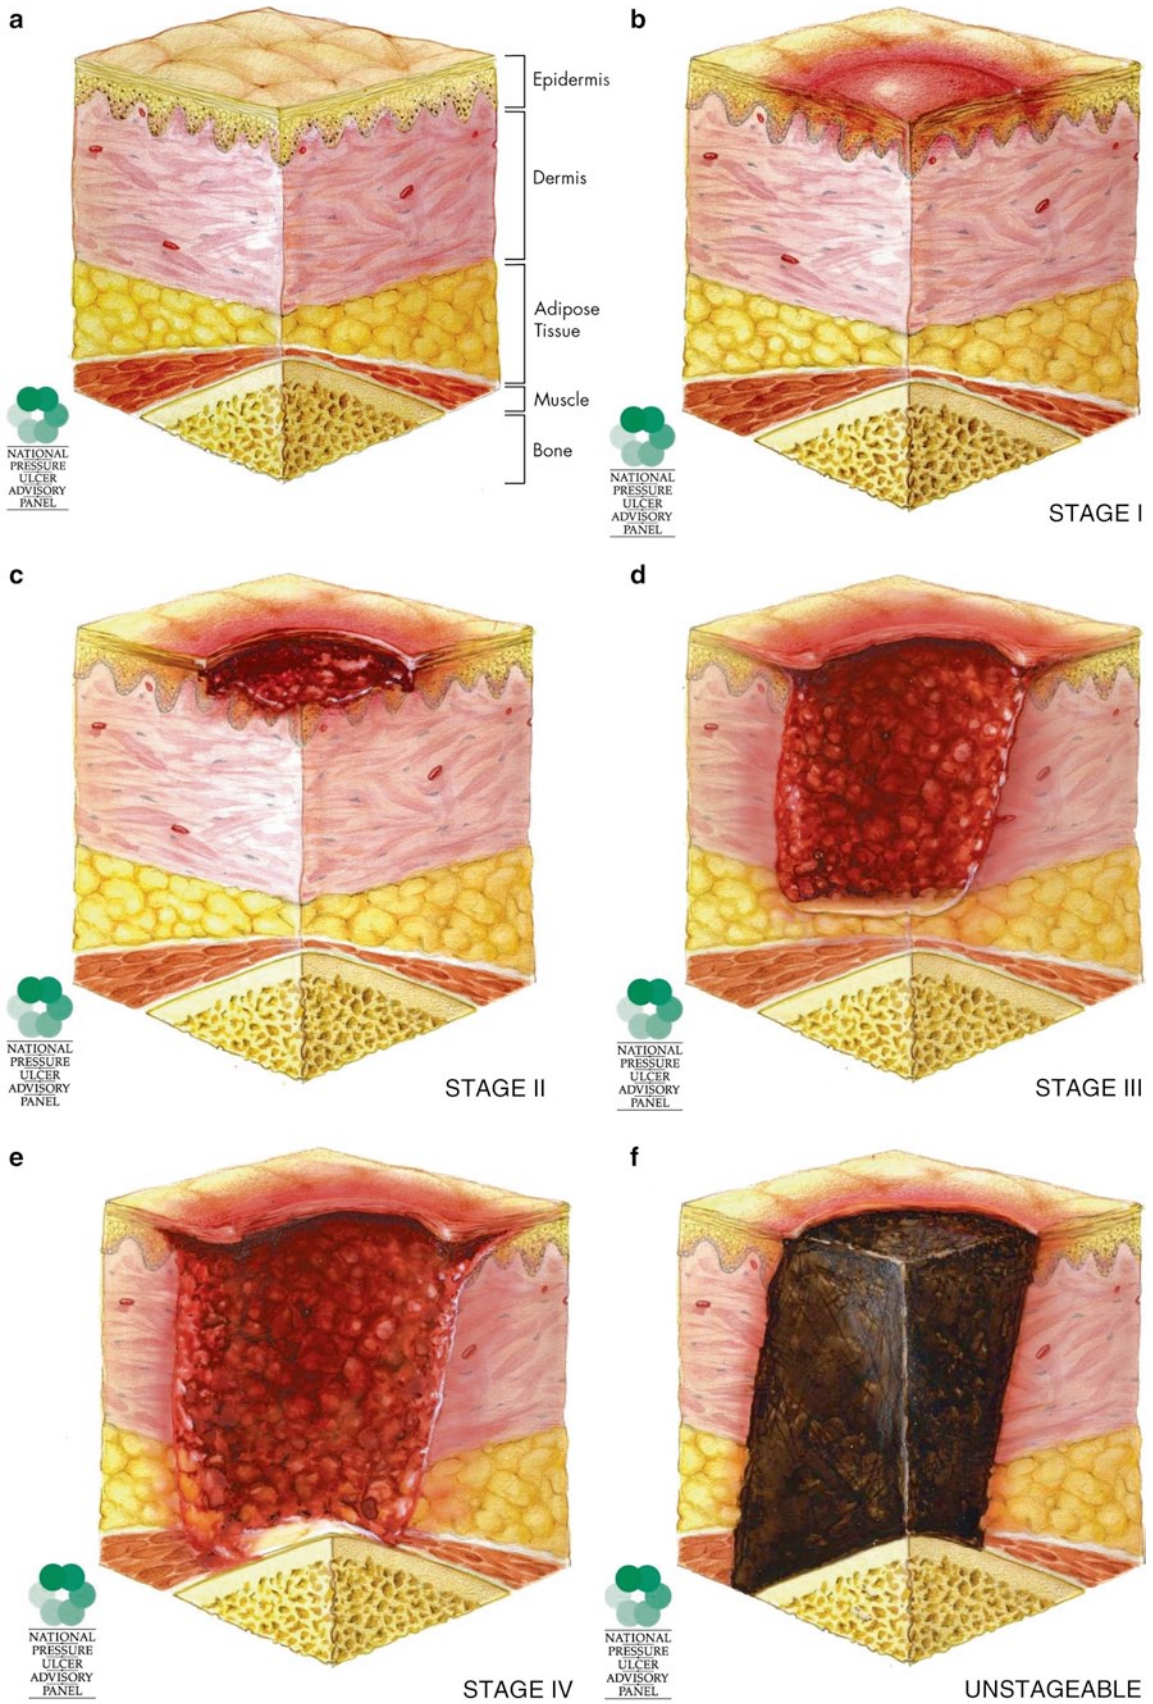

scan, which shows air bubbles in muscle, or a needle aspiration to identify bacteria by gram stain or culture can waste valuable time and lead to poor outcomes, including mortality.

The availability of new dressings has improved outcomes for elderly patients with wounds. The important features of these new dressings include the capacity to hydrate the wound with a gel or alginate and antimicrobial effectiveness based on the presence of silver ion in the dressing. User choice determines which of the many types of dressings is preferable for a given patient.

Negative pressure dressing is an important advance that has been introduced over the past decade. Negative pressure dressing has been engineered to be applicable to open wounds ranging from small to large, including even the open abdomen. The system has revolutionized the nursing care of wounds, making the three times a day dressing changes a thing of the past. Negative pressure dressing can be applied and left in place for up to 3 days with good results. Importantly infection must be controlled in the wound prior to deploying it. Negative pressure dressing does not replace the need for surgical debridement. The wound must be debrided and clean for the negative pressure dressing to be effective. Infection can advance under such a dressing, even with a silver antimicrobial in place, if adequate debridement has not been performed.

Pressure ulcers remain a significant problem in the elderly and preventive methods can decrease their incidence. For this reason the pressure points where bony prominences lie under the soft tissue are highlighted in Fig. 8.5 (see Fig. 8.5). These areas must be carefully protected using the best practice guidelines in Table 8.1. When a stage I ulcer appears with erythema, this is a dangerous signal that ulceration is about to begin. Efforts should be re-doubled to avoid weight bearing on the vulnerable tissue. Pressure reducing strategies include frequent turning and off-loading with pillows as well as the other modalities listed Table 8.1. Prevention of pressure ulcers requires diligent nursing care and may sometimes be impossible for the extremely vulnerable patient with poor nutrition, cachexia, and contractures. Pressure reducing and air-flow mattresses are expensive and their cost effectiveness is unclear. These beds play a role in the management of the very vulnerable patient. Occasionally a colostomy is required to prevent tissue maceration in patients with incontinence. This strategy will sometimes achieve healing of a recalcitrant ulcer, or it may be performed prior to a major surgical tissue transfer procedure to cover a particularly severe pressure ulcer.

Absent from the list of treatment options, is a means to specifically accelerate wound healing. The only FDA approved treatment option of this type is Regranex*

FIGURE 8.5 Pressure points.

(Becaplermin), Systagenix Wound Management, Gargrove England, which is platelet derived growth factor in a gel for topical application. Most clinicians have found it to be only minimally effective, but it may have a place restoring healing, particularly of a diabetic foot ulcer where healing has stalled, and all efforts necessary to off-load weight-bearing and restore blood flow have been exhausted. There are a number of promising agents including VEGF, KGF, and hypoxia inducible factor 1 alpha that are in preclinical and

clinical trials. The delivery of these agents as well as PDGF, using DNA plasmids, or even viral vectors, has the potential to keep therapeutic levels elevated over relevant time periods without requiring frequent applications. In addition these types of delivery systems can place the agent deep in the wound tissue, obviating the need for transfer across a wound eschar. In the coming years as more studies are performed, some of these promising agents will be available in clinics.

← **FIGURE 8.4** Staging system for decubitus ulcers. (a) Normal tissue. (b) Stage I: An observable pressure related alteration of intact skin whose indicators as compared to the adjacent or opposite area on the body may induce changes in one or more of the following: skin temperature (warmth or coolness), tissue consistency (firm or soggy feel), and/or sensation (pain, itching). The ulcer appears as a defined area of persistent redness in lightly pigmented skin, whereas in darker skin tones, the ulcer may appear with persistent red, blue, or purple hues. (c) Stage 2: Partial thickness skin loss involving epidermis, dermis, or both.

The ulcer is superficial and presents clinically as an abrasion, blister, or shallow crater. (d) Stage III: Full thickness skin loss involving damage to, or necrosis of, subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue. (e) Stage IV: Full thickness skin loss with extensive destruction, tissue necrosis, or damage to muscle, bone, or supporting structures (e.g., tendon, joint capsule). Undermining and sinus tracts may also be associated with Stage IV pressure ulcer. (f) Unstageable: Eschar: Thick dry black necrotic tissue.

CASE STUDY: GERIATRIC WOUND HEALING

Background

Medical History

This 67-year old gentleman was referred to our service with a complex wound. Two years prior to admission he had a sigmoid colectomy for removal of a polyp at an outside hospital. He developed MRSA wound infection requiring extensive debridement and reoperation. He was left with the bowel covered with skin graft with a 20 cm diameter ventral hernia (Fig. 8.6). His abdominal wound was complicated by the fact that he has alcoholic cirrhosis with ascites. His co-morbidities include coronary artery disease with a myocardial infarction managed with four coronary artery stents. He has COPD with periodic bronchitis requiring hospitalization. He does not use home oxygen, but he is severely short of breath after climbing one flight of stairs.

FIGURE 8.6 Case report: The ventral hernia with skin graft. There was an ascites leak through a punctate ulceration in the skin graft.

He has insulin dependent Type 2 diabetes.

Considering his life threatening co-morbidities, and the benign status of his hernia, our initial approach was to simply monitor his situation and treat his hernia with a binder. But when he developed an ascites leak we proceeded to urgent repair of the hernia. The repair was carried out excising the skin graft from the bowel

FIGURE 8.7 Case report: "Pinch Test" showing that the skin graft was not densely adherent to the underlying bowel.

(Fig. 8.7). This meticulous dissection was carried out without creating an enterotomy. A subcutaneous flap was raised to the mid axillary line bilaterally to perform component separation and myofascial transfer of the internal oblique to be able to close the defect primarily. With the prior MRSA we elected not to implant a mesh of any type.

The Wound

The wound with which this patient presented is ischemic necrosis at the midline of his abdominal flaps. This necrosis was evident 5 days after the repair of the hernia. This wound was 4 cm wide and extended for a distance of 20 cm along the midline incision.

The management of this wound is a classic problem in geriatric surgery.

Management Strategies

Surgical Debridement

When it became clear that the wound was necrosing, surgical debridement was carried out. Full thickness skin and subcutaneous tissue were excised. The necrotic tissue was excised back to bleeding tissue and a VAC drain was placed (Fig. 8.8).

FIGURE 8.8 Case report: The wound after debridement of the necrotic skin flaps. Skin and full thickness subcutaneous tissue were debrided to the fascial level to remove the tissue that had suffered ischemic necrosis.

Diabetes

This patient has insulin dependent diabetes. Blood sugars were greater than 200 mg% in the face of the sepsis from the wound. Tight glucose control was instituted with continuous IV glucose drip to bring the blood sugar under 150 mg%.

Infectious Disease

The necrosis of the wound appeared to be ischemic, secondary to the raising of the lateral flaps, coupled with his overall debilitated condition. Nonetheless infection was a potential problem. He was covered with intravenous clindamycin to which his prior MRSA had been sensitive. This coverage was maintained for his initial hernia repair for 24 h and likewise at the time of his debridement.

Nutritional Support

During the post operative period after his hernia repair his nutrition was maintained with a Dobhoff feeding tube. The tube was carefully placed in the duodenum using fluoroscopic guidance. Initially a nasogastric tube was placed in the stomach to check gastric residuals. When residuals were

greater than 200 cc with feeding at the rate of 60 cc per hour the feedings were discontinued. After 24 h they were reinstated at 30 cc per hour. They were gradually returned to 60 cc per hour over 4 days.

Ascites

His ascites from alcoholic cirrhosis was managed initially with an intra-peritoneal JP drain following the primary hernia repair. This was to protect the closure from the pressure of intra-abdominal ascitic fluid. The ascites was also controlled medically with Lasix and Aldactone. When drainage from the JP drain was less than 100 cc per day, 72 h after surgery the JP drains were removed. Fortunately the re-accumulation of ascites was less of a problem than expected for this patient.

COPD

This patient developed ARDS with typical patchy infiltrate on chest X-ray and desaturation of O₂ accompanied by CO₂ retention. He required intubation and mechanical ventilation. After 10 days he was converted to a tracheostomy tube. He had gradual remission of his ARDS with this approach.

Coronary Artery Disease

After both surgeries the patient was ruled out for myocardial infarction. Serial troponins and EKG's confirmed that he did not sustain a myocardial infarction

Delirium

The patient developed florid delirium with agitation within 24 h of the initial surgery. The family asserts that he had discontinued alcohol intake; however, he appeared to be suffering from Delirium tremens. He was treated with Atavan and Haldol, and he also required four point restraints briefly. This delirium gradually cleared over 3 weeks of hospitalization.

Outcome

With this multi-pronged approach this patient survived a high risk scenario of ulcerated ventral hernia with ascites leak. After the debrided wound was treated with the VAC it granulated, and after 12 days was closed in the operating room (Fig. 8.9). It healed in a satisfactory manner, and the patient was discharged to a rehabilitation unit after 4 weeks of hospitalization.

FIGURE 8.9 Case report: Closure of the wound after it had granulated. Open wound was treated with VAC* dressing. After it had granulated the wound was closed as shown.

Chapter 9

Frailty and Surgery in the Elderly

Babak J. Orandi, Jordan M. Winter, Dorry L. Segev, and Martin A. Makary

Introduction

Conventional surgical wisdom has long held that the elderly do not tolerate surgery as well as their younger counterparts. Numerous case series comparing outcomes such as morbidity and length of stay often corroborate that viewpoint. However, the older surgical population displays great heterogeneity, and that heterogeneity is not always obvious from preoperative morbidities and preoperative testing criteria. In fact, we have on numerous occasions been surprised by the elderly patient who beats the odds following surgery, and the patient who, ostensibly, should recover well, but does not.

Among older surgical patients, it can be quite challenging to predict who will thrive and who will develop a complication that can trigger a cascade of events that may lead to unexpected demise or permanent disability. In this chapter, we explore the emerging concept that frailty adds significant information to outcome prediction in elderly surgical candidates, beyond that of conventional preoperative criteria.

Limitations of Age as a Predictor

The effect of advanced age on surgical outcomes, independent of other patient-specific factors, is not well understood. The geriatric literature is replete with large series documenting comparable excellent surgical outcomes in the elderly [1–3]. Indeed, the risk factors for poor outcomes in the elderly are the same as for younger patients, namely comorbid illness and poor baseline functional status [4]. These factors have an increased prevalence in the elderly, though not uniformly across the entire elderly population. This varied distribution gives rise to the concept of the heterogeneity of aging.

Selection bias and the failure to account for a heterogeneous elderly population may explain why many other studies have shown that such good surgical outcomes are possible in

older patients. This is particularly important because for many diseases, especially malignancies, age is often a major, if not the most important, risk factor for the development of the disease. With many groups publishing papers on their successful experience operating on octogenarians and nonagenarians, the indications for surgery in the elderly are expanding. For example, after adjusting for preoperative comorbidities, we found that age was not an independent risk factor for perioperative mortality and morbidity following pancreaticoduodenectomy [1]. Filsoufi and colleagues reached the same conclusion for patients over 80 years of age following aortic valve replacement [2]. Another group found that in elderly patients with minimal comorbid illness undergoing colon resection, there was no mortality difference in those over 70 years of age compared with younger patients [3]. In general, age is no longer an absolute contraindication to surgery.

Clinical Decision Making

A major challenge for surgeons in caring for the elderly is to determine which patients are good operative candidates. This estimation requires assessing potential operative candidates for a number of patient-specific factors, particularly comorbidities, disability, and frailty. These three factors, which are frequently used interchangeably in the common vernacular and might demonstrate overlap, are distinct clinical phenomena. In fact, there is near unanimous agreement in the gerontology community that disability and frailty are distinct clinical entities [5]. The conceptual model for frailty maintains that although disability and comorbidity may sometimes coexist with frailty, there is a significant group of frail individuals who present with neither disability nor comorbidity (Fig. 9.1). Disability is defined as difficulty in carrying out those activities that are essential for independent living, such as bathing, dressing, eating, shopping, and preparing meals. Comorbidity is the clinical manifestation of illness in an individual, such as congestive heart failure, osteoarthritis, or chronic obstructive pulmonary disease. The last factor, frailty, is a newer concept in the geriatrics literature.

FIGURE 9.1 A conceptual framework for frailty, in the context of comorbidity and disability.

Frailty

Frailty in the elderly generally refers to patients with poor physiologic reserve who are at an increased risk of adverse events following exposure to stressors such as anesthesia and surgery. These clinically important adverse events include institutionalization in a long-term care facility, falls, and mortality. In 2001, Fried et al. published a standardized definition of frailty using five criteria (Table 9.1) [6]:

1. Slow gait speed
2. Low physical activity
3. Unintentional weight loss
4. Self-reported exhaustion
5. Muscle weakness

Frailty is defined as the presence of at least three of these five criteria. *Gait speed* is measured over a distance of 15 ft, with the criteria based on gender and height. The level of *physical activity* is based on the patient's kilocalorie expenditure over the prior 2 weeks using the Minnesota Leisure Time Activities Questionnaire [7]. *Unintentional weight loss* is present when the patient affirms that he or she has unintentionally lost more than 10 pounds over the preceding year. *Self-reported exhaustion* is based on the Center for Epidemiologic Studies Depression Scale (CES-D), and asks the patient to agree or disagree with these two statements: in the past week, "I felt that everything I did was an effort," and "I could not get going" [8]. Finally, *muscle weakness* is based on grip strength as measured by a hand-held dynamometer. This criterion varies by gender and body mass index. Of note, all of these criteria are quickly and inexpensively assessed in the clinic setting, lending them to easy adoption, even in a busy clinical practice.

Within the gerontology community, there remains considerable debate as to the appropriate definition of frailty. Some

TABLE 9.1 Frailty criteria

Criteria	Notes		
Slow gait speed	Timed 15 foot walk		<i>Height (cm)</i>
			<i>Time (s)</i>
		Men	
Low physical activity	Based on Minnesota Leisure Time Activity Questionnaire		<i>Weekly kcal expenditure</i>
		Men	
		Women	
Unintentional weight loss	>10 lb weight loss in past year		
Self-reported exhaustion	Based on CES-D Depression Scale; quantifies the amount of time in the past week the patient felt the following	I felt that everything I did was an effort	I could not get going
Muscle weakness	Based on grip strength		<i>BMI</i>
			<i>Force (kg)</i>
		Men	
		Women	

of the Fried criteria have been validated, while certain new ones have been proposed. Generally speaking, there is strong agreement amongst experts that the clinical syndrome represents a constellation of diseases, impairments, and/or symptoms, rather than simply the presence of one disease or condition [5]. Rothman and colleagues provided good preliminary evidence to support the use of slow gait speed, low physical activity, weight loss, and cognitive impairment as important indicators of frailty, but not self-reported exhaustion and muscle weakness [9]. In addition, they and others advocate including a number of different domains in the definition of frailty aside from just physical function, such as psychological characteristics and psychosocial factors. Rothman recommends integrating cognitive function into the frailty assessment as it is a strong predictor of adverse outcomes. While the exact definition of frailty may be in flux, there is no doubt that the presence of frailty portends a number of adverse clinical outcomes. We have found the above definition of frailty by Fried to be standardized and easy to implement.

Clinical Outcomes of Frailty

In the longitudinal Cardiovascular Health Study, which included over 5,000 community-dwelling Medicare-eligible people, subjects who met frailty criteria at baseline were more likely to be older, female, and African-American [6]. They also tended to have lower levels of education and income. Frail patients had a significantly higher mortality rate than their non-frail counterparts at 3 and 7 years (18 vs. 3% and 43 vs. 12%, respectively). Frailty was also predictive of a number of other clinically relevant geriatric outcomes, including injurious falls, hospitalizations, and worsening disability, both in terms of performance of activities of daily living and in mobility.

In a separate longitudinal study of community-dwelling people over the age of 70 who were initially disability-free, frail individuals were also noted to experience increased mortality and incidence of chronic disability [9]. The study also found that 22% of frail patients had a long-term nursing home stay (>90 days) over 7.5 years of follow-up. Clearly, the presence of frailty has a number of ramifications in terms of clinical, economic, and quality-of-life outcomes.

Biologic Basis of Frailty

While the biologic basis of frailty remains uncertain, it likely results from multiple etiologies, rather than from one underlying cause, and affects multiple physiologic systems (Fig. 9.2) [10]. A multifactorial basis for frailty is more probable given the broad spectrum of clinical manifestations of the frailty syndrome.

While a detailed review of the current understanding of the biological underpinnings of frailty is beyond the scope of this chapter, it appears that inflammation is central to its pathogenesis. C-reactive protein (CRP), a nonspecific serum marker of inflammation, has been shown to be elevated in frail elderly patients compared to their nonfrail counterparts [11]. This finding holds true across gender and racial lines, as well as across the age spectrum over 65, and is independent of diabetes mellitus and cardiovascular disease status, two disease states associated with chronic inflammation. That same report, part of the Cardiovascular Health Study, found that frail patients were significantly more likely to have congenital heart disease, congestive heart failure, diabetes, and hypertension (Table 9.2). There was no statistically significant increase in cancer rates amongst frail patients, though that likely has more to do with study exclusion criteria, as

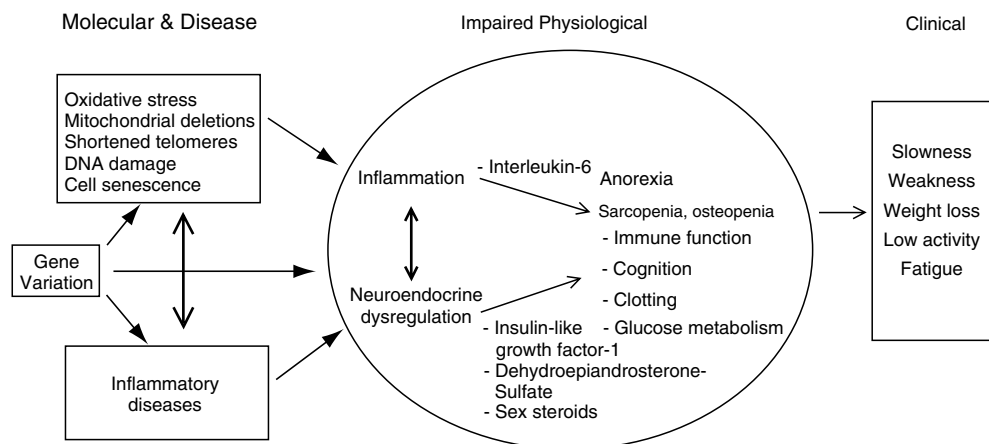

FIGURE 9.2 Overview of hypothesized molecular, physiological, and clinical pathway to frailty. Arrows pointing in both directions illustrate potential interactions between systems (from [5] reprinted with permission from The McGraw Hill Companies).

TABLE 9.2 Baseline disease status by frailty

Frailty indicator	Prevalence					
	Frailty	CHD ^a	CHF	Cancer	Diabetes ^a	Hypertension ^a
Not frail (n=2289)	48.3	15	1	14.8	18.8	37.9
Intermediate (n=2147)	45.3	21	4	15.5	24.5	43.9
Frail (n=299)	6.3	30.8	14	16.4	32.4	48.5

patients actively being treated for a malignancy were not included in the study.

In addition to CRP, the major proinflammatory cytokine Interleukin-6 (IL-6) been shown to be predictive of mortality in the elderly [12]. IL-6 has also been extensively linked to, amongst other adverse clinical entities, osteopenia, sarcopenia (muscle loss), anemia, and insulin resistance, all of which contribute to the frailty syndrome [13]. Leng et al. [29] demonstrated that elderly frail patients have significantly higher IL-6 levels than nonfrail elderly subjects, suggesting that IL-6 may also play a direct role in the pathogenesis of frailty.

Like serum IL-6 and CRP levels, plasma hypertonicity has been linked to adverse outcomes in the frail. Several theories have been proposed to explain this observation. Stookey et al. suggest that abnormalities in any of the myriad organs involved in regulating plasma homeostasis and thirst, from the pituitary to the kidneys, or states of glucose intolerance, as seen in such conditions as cancer, cachexia, diabetes, and chronic renal insufficiency, can lead to plasma hypertonicity [14]. These same underlying conditions may also play a simultaneous role in the development of frailty. As the understanding of frailty's pathogenesis improves, it is likely that biomarkers will become useful tools in screening patients and in predicting medical and surgical outcomes in the frail, similar to the MELD score for predicting 3-month mortality in surgical patients with end-stage liver disease [15].

Clinical Utility

A frailty index has many applications, including epidemiology, policy, and research. However, the most useful application may be at the bedside. In a prospective study of elderly surgical patients, we found that frail patients had a 2.5-fold increased odds of developing complications after surgery compared with their nonfrail counterparts [16]. Their hospital length of stay was twice as long as nonfrail patients for minor surgical procedures and over 80% longer for major operations. The odds of discharge to a skilled or assisted care facility were over 20 times higher in frail patients. Frailty also significantly augmented the predictive ability of other preoperative risk assessment systems, specifically the American Society of Anesthesiologists (ASA) score, and the Lee and Eagle [17–19] preoperative cardiac risk-stratification

tools, in terms of postoperative complications, length of hospital stay, and discharge disposition.

Frailty may be helpful in selecting appropriate patients for surgery, particularly in settings where selection tools are vague and not validated. Clinicians have traditionally used age as a rough surrogate for triaging patients. For instance, the elderly are less likely to receive organ-directed surgery for malignancies of the breast, esophagus, stomach, pancreas, and rectum, as well as for sarcoma and non-small-cell lung cancer [20]. Moreover, a referral bias from nonsurgeons to surgeons has been observed for elective surgical procedures [21]. In a survey of Dutch cardiologists, age was the most important determinant of whether or not referrers would recommend surgery to patients with aortic stenosis 40% of the time [22]. Frailty status, rather than age, would be more helpful in the determination of overall fitness. Nonfrail individuals with resilient physiologic reserve could be selected for surgery, while frail ones could be identified to prevent operations in those patients at highest risk of a catastrophic clinical outcome.

In addition to aiding the selection of appropriate surgical candidates, a frailty index may identify patients who could, with additional interventions, become candidates for elective operations. One's frailty status is not a fixed, permanent entity; rather, frailty can have a waxing and waning course. Studenski and colleagues have developed a measure of change in frailty that quantifies patient mobility, balance, strength, endurance, nutrition, and neuromotor performance over time [23]. While its application for optimizing the timing of an operation has yet to be validated, the concept that frailty is a dynamic condition is an important one. One can imagine a related application as a measuring stick after completing a preoperative intervention aimed at medical optimization.

Indeed, there are a number of possible targets for preoperative intervention that may particularly benefit the frail elderly. Aggressive physical therapy may be of benefit. For major abdominal operations performed on the elderly, better preoperative physical performance status almost invariably predicts better recovery and a faster return to the activities of daily living (ADLs) and the instrumental activities of daily living (IADLs) [24]. While the study that demonstrated this finding was not exclusively focused on the frail, it seems logical that the frail may stand to gain the most from increased physical activity as the syndrome is characterized by low physical activity, slow gait speed, and muscle weakness.

Preoperative nutritional supplementation is another attractive preoperative intervention for the frail. In a Cochrane review of preoperative enteral supplementation in the elderly, there was an overall weight gain for participants in the 31 included trials, as well as a decrease in mortality and a shorter length of hospital stay for those patients who received preoperative supplementation [25]. Just as with preoperative physical therapy, it remains to be seen in clinical trials whether the frail elderly will benefit from this preoperative

intervention, though it does seem likely given the tight association between weight loss and the frailty syndrome.

Congestive heart failure (CHF) has been shown to be an independent predictor of postoperative complications in the elderly [26]. This suggests that, given a sufficiently lengthy window of opportunity preoperatively, frail patients, and elderly patients in general, who suffer from symptomatic CHF may benefit from pharmacologic optimization of their heart function prior to surgery in an effort to prevent postoperative complications.

Given that frail patients are more likely to suffer from postoperative, hospital-acquired complications, a frailty score may help identify which patients ought to be the subject of rigorous preventive measures to avoid the development of delirium, falls, infections, pressure sores, worsened malnutrition, and functional impairment. A number of strategies that are beyond the scope of this chapter have been described to prevent these complications, and identification of those most vulnerable to these complications using the frailty index will likely benefit from these measures.

Better risk assessment through the application of a frailty index has implications beyond just identifying opportunities to intervene: it also has implications for counseling of patients in the informed consent process. The decision to proceed with surgery should balance risk with the probability of survival and a meaningful quality of life as determined by the patient and the patient's family. Important to this discussion is the risk of discharge to a skilled nursing facility, as opposed to the patient's home. While not traditionally viewed as a surgical complication, discharge to a skilled nursing facility has a tremendous impact on patients and their families.

While a number of previously mentioned studies have demonstrated good surgical outcomes in elderly patients, a major criticism of these studies is their inherent selection bias. Patients who receive operations have been vetted by the referral process to a surgeon, as well as the surgeon's decision as to proceed with the surgery. Additionally, many of these results are from centers of excellence that have high patient volumes, as well as the resources, staff, and protocols necessary to care for these patients perioperatively.

It should be pointed out, however, that although frailty status can be an important aide in making decisions about management of patients, the heterogeneity of aging, the dearth of data regarding surgical outcomes in the frail, and the broad spectrum of patients' goals from surgery necessitate a highly individualized approach to care for the frail elderly.

Research Utility

Frailty may demonstrate particular utility in research, as its criteria become more standardized and its prognostic implications better defined. It has been well documented that

the elderly are underrepresented in oncology clinical trials. In a study of 15 types of malignancies, Hutchins et al. found that while 63% of the US population comprises individuals over the age of 65, only 25% of cancer clinical trial participants are elderly [27]. While the reasons for this disparity are many, there is no doubt that clinician bias, at least in some part, is to blame. One half of surveyed oncologists stated that they deem elderly patients inappropriate for referral to clinical trials based on chronologic age alone [28]. A standardized frailty scoring system with predetermined cutoff points could be used as exclusion criteria in place of some of the more subjective and sometimes arbitrary considerations that are widely used, and thereby boost enrollment of elderly patients into clinical trials. Vulnerable elderly patients would still be excluded, while an important subgroup of suitable elderly candidates could be included.

Aside from using frailty to make clinical trial enrollment more equitable and representative of the population, knowledge about the aging process and frailty itself may be the endpoint of many future studies. An aging population and its incumbent economic considerations will likely drive research aimed at delaying or preventing the development of frailty, as well as trials to test interventions intended to minimize the effect of frailty on patient longevity, resource utilization, and quality of life.

Conclusion (Table 9.3)

Frailty is a multidomain syndrome that reflects poor physiologic and functional reserve and predicts a number of adverse clinical outcomes in surgery. We have found that the use of frailty as a clinical predictor adds significant value beyond other preoperative predictors, augmenting their ability to anticipate untoward postoperative events. Utilizing a standardized definition of frailty for future research in this highly vulnerable population may ultimately allow patients to be better risk-stratified for preoperative decision making. Increased awareness of the frailty syndrome and its clinical implications will undoubtedly improve care in older patients and improve their overall health outcomes.

TABLE 9.3 Frailty summary

Frailty is a multifactorial syndrome of poor physiologic reserve that puts patients at increased risk of adverse events following exposure to stressors
The standard definition of frailty uses the following five criteria: slow gait speed, low physical activity, unintentional weight loss, self-reported exhaustion, and muscle weakness
Frailty is a better predictor of postoperative complications than a number of commonly used risk-stratification tools
Frailty can help with patient selection, risk stratification, and identification of patients who would benefit from preoperative risk-reduction interventions

Section II
Social/Societal Issues

Chapter 10

Invited Commentary

Michael E. Zenilman

Introduction

In this new section of our textbook, topics which have been in the background of surgery in elderly patients are now spotlighted. In the 10 years since publication of our first edition, it has been very gratifying for me to watch as more interest in the ramifications of surgery in the older patients – not just technical prowess – has developed; it brings us to the basics of medicine – “*Primum Non Nocere*.”

The increased interest has two mutually-non-exclusive sources. First, there has been more academic attention to the older surgical patient. For example, in 1976, the nine surgical journals I typically read published a total of 358 articles in which patients aged greater than 65 or 85 years were operated, in 1989 there were 368, in 1999 the number was 513, and in 2009 there were 893 articles. My impression is that the quality of the papers has drastically improved. Early articles proved – using simple and then more complex analyses – that we could do surgery safely, and discussed how to deal with the older patients, sometimes via editorial comments. The message was that chronologic age was not equal to physiologic age – especially if we controlled comorbid illnesses and emergency surgery. In fact, these concepts were the main message of our first edition.

Now papers are more scientific, and highly complex statistical analyses of large databases have allowed researchers to focus on outcomes and quality measures. We are only now on the cusp of defining that consequence of chronologic age and the aging process on surgical outcomes, and there is a real effect. The impact of frailty and disability, two non-reversible aging processes, on surgical outcomes is significant. Because of them and not comorbidity, the ultimate outcomes of major interventions may not be as good as we hope. While not reversible, these two processes are to some extent preventable; lifestyle changes can delay their onset.

Second, the sheer increase in number of patients in the older group has affected the population of patients we care for; the baby boomers have come of age. The predictions of the past – that the percentage of patients older than 65 and 85 in our population will grow – are coming true. While some papers wrongly predicted that Medicare would be financially insolvent by now, it is getting there. The shape of the age distribution in the USA has changed from a classic pyramid – where the small number of older population rest on top with increasing numbers of persons at the bottom – to a more rectangular (or trapezoidal) shape, where similar proportions of younger and older persons exist at multiple age levels. As our population pyramid changes, the demands on health care are changing too.

The societal burden for the expansion of the elderly patient population is intuitive, impressive, and expensive. An Institute of Medicine report in 2008 from the National Academy of Sciences entitled “Retooling for an Aging America: Building the Health Care Workforce” showed that the bulk of acute and chronic disease – diabetes, cardiac, hypertension, and cancer – rests in patients over 75 years of age. The older patient population uses more services. For example, 12% of our population uses up to one-third of total hospitalizations, and a similar percentage uses emergency medical responses and prescriptions for medication. The expanding use of nursing homes, short term rehabilitation facilities, and home care also has a cost.

The report suggested three goals to enhance the care of elderly patients: use education to improve the competence of health care providers, increase the number of geriatric specialists, and establish new models of care.

Achieving these goals will not be cheap. The IOM report noted that not only are chronic disease management, multi-disciplinary care, and transitional care important for the elderly population, but also that to date, they have been underfunded. Bluntly, reimbursements for geriatricians, home care nurses, and even surgical care in this population is not very high, and the combination of low funding in all three areas is also problematic.

While surgical training programs have been asked to focus on education in geriatrics, to date it is mostly theoretical, and

very few hospitals or institutions have active geriatric services which work closely with surgeons. The foundation of surgical training is to care for patients, not to just perform procedures. But there is very little in the surgical training for the topics described below.

The American Geriatrics Society has been an advocate in retooling the education practice of surgeons. Through their Jahnigan Scholars program, over 20 surgical specialists, in all disciplines, have been selected to do research, publish scholarly work, and teach geriatrics. Some basic curricula have been developed, and there is even one geriatric surgery fellowship available in the USA.

The real future of geriatric surgery is embedded in the chapters of this section; the foundation of education is evolving to a level of complexity higher than that described in the first edition of this textbook, and the need for multidisciplinary

management is clear. To provide the elderly patient with quality care, we must be well versed in recognizing and addressing frailty and disability, not just controlling the established comorbidities of cardiac, pulmonary, kidney, and endocrine systems. Palliative care, do-not-resuscitate orders, and use of rehabilitation facilities and hospice need to be integrated early in a patient's care. As you will read, the American College of Surgeons, through the National Surgical Quality Improvement Project and the Task Force on Geriatric Surgery, is establishing quality indicators for the elderly patient, which will likely lead the change. In the future, these indicators will be just as important as the "core measures" we now follow.

Last, what about the elderly surgeon? While society has not yet mandated removal of driving licenses from older drivers, the elderly surgeon still has the same mandate as the younger "above all, do no harm."

Chapter 11

The Demography of Aging and Disability

Samir K. Sinha and Colleen Christmas

Over the previous century, there has been an extraordinary demographic shift which will no doubt persist well into this one. The lengthening of life span by over 50% and consequent increase in the proportion of the population that we refer to as the “elderly” has created a new and different social, economic, and medical imperative. We are now faced with the daunting task of providing health and social care for a huge number of persons living well into old age with more chronic illnesses, and increased needs and expectations. Anticipating the kinds of health care services, this population requires coordinated and creative efforts by many sectors of society and considerable educational and research activities to determine the best methods to deliver services. Indeed, this textbook has been written to respond to some of these challenges by addressing the specialized needs of older persons facing surgery.

The Demography of Aging

In the USA, as in other developed countries, the absolute numbers and relative proportions of older populations have continually increased to the point where there is now a higher percentage of older people than at any time in history. Indeed, while the overall US population had almost quadrupled in size over the course of the twentieth century, the portion of the population 65 years and older had increased 11-fold. The older population has grown from 3.1 million (4.1% of the overall population) in 1900 to 35 million (12.4%) in 2000 [1]. Among this latter figure, 18.4 million (53%) were aged 65–74, 12.4 million (35%) aged 75–84, and 4.2 million (12%) age 85 and older [2]. While it is predicted that these figures will increase slowly over the next few years, what follows is a period of marked accelerated growth in the second and third decades of this century. This pattern of shifting demographics

largely reflects the impact of birth rates; the slower change in the near future reflecting low fertility rates during World War II and the preceding worldwide economic depression, while the subsequent growth surge stems from the “baby boom” that characterized the postwar years (1946–1964) in many nations. The first members of this “baby boom generation” will reach age 65 in 2011. As a result, by 2030 the older population is projected to be twice as large as in 2000, growing from 35 million to 72 million, which will then represent nearly 20% of the total US population. Predictions are that this trend persists at least until the mid-century. In 2050, the older population is projected to number 86.7 million [1].

The most rapid and profound change in numbers has been seen among the oldest old individuals, defined here as those aged 85 years and older. In 1900, there were only 122,000 of these individuals, but by 2000, their number had increased 34-fold to 4.2 million. This trend is expected to continue with this population doubling to 9.6 million by 2030 and then more than doubling again to 20.9 million by 2050 [1].

The USA, despite the growth projections for its older population, remains a relatively young population when compared with other developed countries. While its proportion of older adults stood at 12.4% in 2000, at least a dozen developed countries were reporting proportions ranging between 15 and 18% (Table 11.1). Part of what explains this difference is that the USA has experienced higher levels of fertility and immigration in recent decades than those of other developed countries [1]. In 2000, while average life expectancy at birth in the USA reached a high of 76.9 years, the highest rates were being reported for Swedish males and Japanese females at 77.6 and 84.1 years, respectively [1].

Causes and Consequences of Population Aging

The term *population aging* refers to the process through which the proportions of older individuals within an overall population age structure increase. Changes in the age structures of populations principally result from changes over

time in fertility, mortality, and migration patterns [3]. Measures of population aging that can also be used to compare populations and assess changes over time include the median age, aged-dependency ratios or, most commonly, the proportion of a given population that is aged 65 and older. It has been the combined effects of declines in *both* mortality and fertility rates during more recent times that have largely been responsible for the demographic transition that led to the aging of human populations.

The earliest and most important causes of the decline of human mortality during the past few centuries were the general improvements in living conditions resulting from social and economic developments. Innovations in industrial and agricultural production and distribution methods led to significant improvements in nutrition [4]. Industrialization also brought about enhanced standards of living by improving the quality and quantity of available housing, running water, and electricity, which enabled individuals to be protected from the hazards of nature. Thereafter, a complex interplay of advancements in public health efforts, particularly sanitation, and later in medical and preventative health care, coupled with new modes of familial, social, economic, and political organization helped to promote and sustain further gains in human longevity [5].

The decline in human mortality has been the main driver of increased life expectancy throughout the world. The rapid mortality decline particularly among infants, children, and women of childbearing age increased average life expectancy from 47.3 years in 1900 to 68.2 years in 1950 [6]. The need to replace children lost to early mortality waned as the risk of death at younger ages declined rapidly [7]; this eventually led to declines in total fertility rates. Death rates from chronic diseases were stable in the USA from 1954 to 1968; thereafter, research programs around chronic diseases intensified and reductions in mortality from chronic diseases followed. In recent years, continued advances in the management and treatment of chronic diseases are now largely driving reductions in mortality at older ages.

Sex and Racial Differences

Interestingly, reduced mortality rates have not benefited men and women equally, with women having gained several more years of life expectancy than men (Table 11.2). For example, in the USA over the past century, life expectancy had increased by 31.2 years for women (from 48.3 to 79.5 years)

TABLE 11.2 Life expectancy at birth, at age 65, 75, and 85 by race and sex: selected years, 1900–2000

Age and year	All races			White		Black ^a	
	Both sexes	Male	Female	Male	Female	Male	Female
At Age 0

but by only 27.8 years for men (from 46.3 to 74.1 years). It appears that women may have a natural advantage over men that should imply a difference of about 2 years in terms of life expectancy at birth. Several hypotheses have been proposed to explain sex differences in longevity, including more active female immune functioning, the protective effect of estrogen, compensatory effects of the second X chromosome, and the influence of oxidative stress on aging and disease. At present, none of these hypotheses are strongly supported, although weak support is available for the oxidative stress hypothesis [8]. Nevertheless, other factors are thought to contribute to the much larger gap now being commonly observed between the sexes. Differences in life expectancy are attributed to differences in behaviors, social roles, attitudes, and biological risks between men and women, with the near-elimination of maternal mortality in developed countries explaining only a small fraction of this trend [9–12]. While these differential gains have been typical of developed countries, the gap has started to decline in recent years. Between 1900 and 1970, overall life expectancy in the USA increased by 26.4 years for women and 20.8 years for men, thereby increasing the gender gap in life expectancy from 2.0 to 7.6 years. This increase has been largely attributed to higher male mortality due to ischemic heart disease and lung cancer, both of which are related to the widespread and early practice of cigarette smoking among men [13, 14]. However, between 1970 and 2000, overall life expectancy rose by 4.8 years for women and 7.0 years for men, thereby narrowing the gender gap from 7.6 to 5.4 years. This subsequent decrease has been related to the proportionately larger increases in lung cancer mortality among women than men and a proportionately greater decline in heart disease mortality among men than women [13, 14].

In addition to the expected growth of the older population, demographic studies predict that the racial and ethnic diversity of this population in the USA also increases over the coming decades. Comparisons between racial groups in 2003 to what is predicted for 2050 suggest that while non-Hispanic whites decrease from representing 83–61% of the older population, the proportion of Blacks grows from 8 to 12%, Hispanics from 6 to 18%, and Asians from 3 to 8% [15]. While this growing diversity largely reflects the aging of a more diverse younger population, there is evidence that it also represents, to a small degree, the enhanced immigration of older individuals [16]. These demographic changes continue to have important implications, especially since mortality rates among the elderly have also been shown to be unevenly distributed across racial and ethnic groups. These differences appear to reflect different disease profiles for underlying populations, unequal access to health care, and likely other socio-demographic factors, such as income and education that have yet to be completely understood.

What partly explains our lack of understanding is that “minority” older adults have largely been excluded from studies or categorized together as “non-White,” ignoring the significant heterogeneity that also characterize these groups, their differences in physiological aging, access to health care, educational levels, health habits, disease prevalence and progression, response to treatments, and social contributors to health. Indeed, the increasing heterogeneity of the older population in the coming decades will certainly have important implications for the delivery of health and social care services and associated research studies.

Shifting Mortality Patterns

With individuals now being better able to survive acute illnesses, increasing longevity has contributed to the rising incidence of chronic illness and greater likelihood that individuals die as a result of complications associated with chronic conditions. While the proportion of elderly fatalities caused by heart disease, strokes, and cancer fell over the last 25 years, this decrease was partially offset by a concurrent increase in the number of deaths attributable to other chronic diseases, such as diabetes, chronic lung disease, renal disease, and dementia. Today, the pattern of death at older ages generally reflects that of the population as a whole. However, while the leading causes of death are essentially the same, differences in the rankings become apparent when mortality rates across age groups are considered (Table 11.3). While heart disease and cancer remain the leading two causes of death across all older age groups, over the past 25 years the

TABLE 11.3 Changes in most common causes of death in the USA at all ages and those 65 years and older cohorts

Causes of death	Rank in 1900	Rank in 2005				
	All ages	All ages	65+	65–75	75–85	85+
Heart disease	4	1	1	2	1	1

largest decrease in heart disease mortality (-55.5%) was experienced by individuals between the ages of 65 and 74 years, followed by those between the ages of 75 and 84 years (-49.7%), and those 85 years and over (-37.0%). While cancer mortality has increased slightly for individuals 75 years and over ($+3.8\%$), it decreased somewhat for the 65–74 age group (-7.7%). The more significant drop in heart disease as opposed to cancer mortality within the 65–74 age group has meant that cancer mortality is now the most common cause of death among individuals in this subgroup. Further shifts in mortality rates has meant that chronic lung disease and diabetes-related mortality now have their greatest impact among the youngest older age groups, while stroke, dementia, influenza, and pneumonia-related mortality have their greatest impact among the oldest age groups.

Fertility

Historically, the decline in human mortality has been followed, in most regions of the world, with a decline in fertility. This has caused some concern as extremely low levels of fertility, sustained over a period of time, are causing some populations to decline. The implications of population decline in conjunction with population aging can be significant. Governments, for example, may encounter the challenge of financing social security programs and health care costs while facing possible labor shortages. Further, these labor

shortages may disproportionately impact low-wage work, such as those providing personal care to the elderly. These concerns have led some countries to develop progressive immigration policies in recent decades to help counter declining fertility rates and fuel overall population growth.

Developing Countries

Fertility and mortality rates have fallen in most developing countries, but usually not to the same degree as with their developed counterparts. These falls are partly due to economic growth but are mostly due to the adoption of modern medical and public health practices. While the populations of virtually every nation are aging, the level and pace with which they are doing so varies within regions (Fig. 11.1). Surprisingly, the most rapid proportionate increases among older populations are and will continue to be in the developing world. In 2000, 249 million people 65 and older living in developing countries represented 59% of the world's older population; their proportion of the global elderly is projected to rise to nearly 80% or 1.2 billion elderly people living in developing nations by 2050. In contrast, 171 million people were aged 65 and older in developed countries in 2000, and they are projected to grow to 327 million by 2050. Although developing regions had lower overall proportions of older people than developed regions in 2000, these proportions are

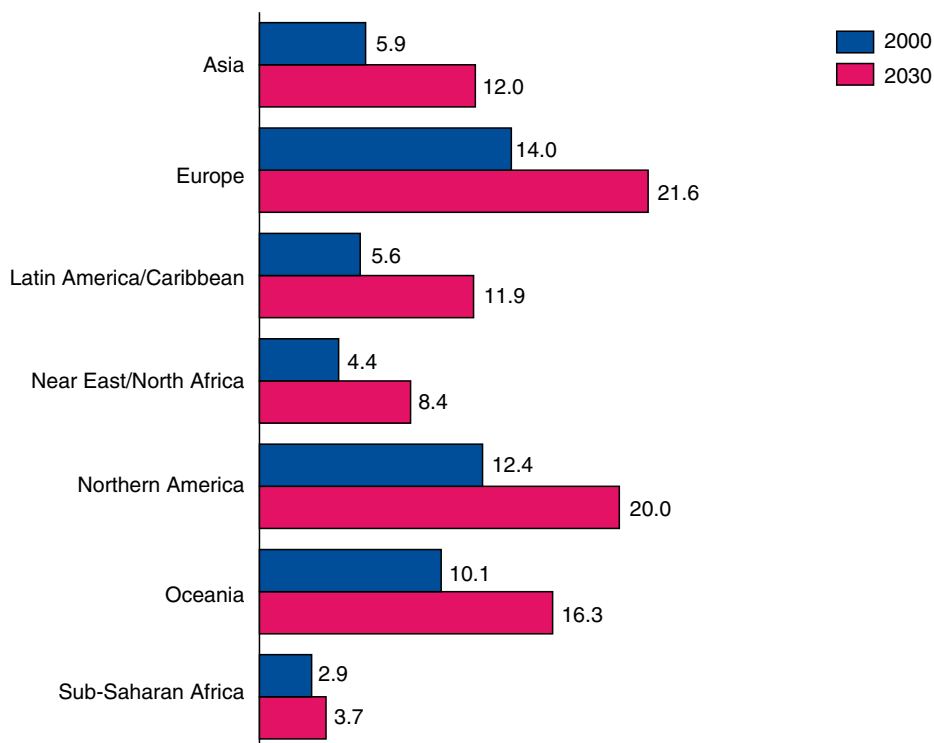

FIGURE 11.1 Percentage of the population aged 65 and over for regions of the world: 2000 and 2030 (from US Census Bureau 2004, International Programs Center, International Data Base, at <http://www.census.gov/ipc/www/idbnew.html>).

expected to double in Asia and the Latin America/Caribbean regions by 2030. Sub-Saharan Africa has the youngest of the world's regions, with only 2.9% of its population being older than 65 years in 2000. It continues to remain the youngest region as the proportion of its older population grows slowly owing to the combined effects of high fertility rates coupled with an overall population decline due to the impact of AIDS. Nevertheless, population aging in many developing countries means they eventually encounter the same debates around intergenerational equity, social security, and increasing health care costs that have already emerged in Europe, the USA, and Canada [17].

Concepts in Individual Aging

Individual aging refers to the length of life for individuals, measured most often in years. A summary measure of individual aging for a population is most often represented by life expectancy [7]. Life expectancy is calculated from death probabilities observed throughout the age range over a selected time period, usually one calendar year, and may be estimated for a given birth cohort or for a population reaching any age or age range [7]. With individuals now living longer on average than ever before, there is growing interest around the degree to which life expectancies at birth and older ages can increase. While the risk of death remains relatively high at birth, it rapidly declines to its lowest point during sexual maturity, followed by an exponential rise until around 85 years of age. Thereafter, it has been demonstrated that the rate at which the risk of death increases actually begins to decelerate [18–21].

Complicating any discussion about individual aging is the idea that there may be some maximal lifespan that is biologically determined for every species, including humans. This belief, interestingly, had its nonscientific origins in biblical references to a human lifespan of 120 years (Genesis 6:6). Indeed, if there is some age x beyond which no one could survive, arguably there must be some eventual limit to the rise in life expectancy. The existence of such a maximal age is becoming increasingly questioned [22]. First, if it is possible to survive to age x , surely it must also be possible to survive to age x plus 1 day. Following this logic, there may be no finite limit, even though survival to very old age is already, from a statistical standpoint, highly unlikely. The oldest individuals whose ages have been reliably documented are a Frenchwoman, Jeanne Calment, who died in 1997 at the age of 122, and an American, Sarah Knauss, who died in 1999 at the age of 119 [23, 24]. Because the chance of death is high at such ages, the probability of observing significantly older individuals in the near future is exceedingly small. Nevertheless, these records are likely to be broken eventually.

Differential, Usual, and Successful Aging

Chronological age (age in number of years) and *physiological age* (age in terms of functional capacity) do not always coincide, and often the physical appearance and health status of an individual belie their chronological age. Increasingly, it is being observed that disparities in the timetable of aging may occur among individuals or among selected populations, or in other words, that some individuals “age” at much slower or faster rates than others. Furthermore, changes with aging are heterogeneous not only among individuals within a select group, but also among various organs within each individual person. The onset, rate, and magnitude of the changes vary depending on the cell, tissue, organ, system, or laboratory evaluation of several parameters [25–27] and the manifestations of aging are a complex interplay between genetic variables, disease states, and environmental exposures.

Attempts to define in humans a physiological “norm” inevitably disclose a range of functional decrements with advancing age. In earlier studies, the comparison of several functions from younger to older age focused on a gradation of decrements with increasing age [25]. However, as the prevalence of chronic diseases increase with age, the functional loss that was noted with age in these early studies, may have been due to the effects of disease rather than the natural concomitants of aging itself. More recent research has further continued to challenge the inevitability of functional impairment with chronological aging. While significant changes in laboratory evaluation of some physiological functions may be erroneously attributed to aging, normal aging changes may also be misinterpreted as evidence of disease. Laboratory values are generally interpreted with reference to a normal range. Many of the age-related levels do not change on average, but the variance (i.e., the deviation from average) tends to increase [26], making deviation from the norm increasingly common with aging.

Regulation of certain functions may remain efficient until advanced age, whereas in others it declines at an early age. Examples of such differential aging may be inferred from fasting blood glucose levels and acid–base balance, which remain stable as late as 70–90 years of age in a nonstressed state. In contrast, the basal metabolic rate declines continuously throughout the life-span, while certain sensory modalities, such as vision and hearing, show functional decrements beginning during early adulthood. Although fasting blood glucose values are minimally affected by aging, when these levels are determined after increased physiological demand, the ability of the organism to maintain normal levels and the rate at which the levels return to normal are markedly different in mature and aged subjects. Similarly, cardiac index parameters, renal function, respiratory function, and conduction velocity in nerves have been demonstrated to tolerate less

stress in the elderly than in younger individuals but are seemingly unimpaired in nonstressed states. Such declining ability of the aging organism to withstand or respond adequately to stress reveals an age difference not otherwise obvious.

Aging is believed to be a slow, continuous process. Therefore, some of its effects can be observed only when they have progressed sufficiently to induce identifiable alterations that can be validated by available testing methods. An illustrative example is atherosclerosis, the consequences of which manifest during middle and old age even though the atherosclerotic lesion may start early in infancy. Whatever organ or tissue is considered, timetables of aging represent an approximation, as the onset of aging cannot be pinpointed precisely by a specific physiological sign.

While a number of functions undoubtedly decline as we age, the extreme heterogeneity of overall functional status even in the oldest cohorts supports the view that aging must be evaluated on an individual basis. In addition to genetic makeup, the elderly individual's health, social status, and economic and environmental conditions all contribute to how they age [28]. Aging processes have thus been categorized as *usual aging*, referring to the average physiological changes associated with some decrements in function, and *successful aging*, referring to advanced chronological age with minimal physical decrements [29].

Accordingly, individuals who age successfully are those who do not exhibit pathology and have minimal functional decrements. The concept of *successful aging* was formulated as "a reconceptualization of the aging process, one that provides a significant and necessary counterbalance to previous research that tended to emphasize age-related declines in functioning and health" [30]. It distinguishes three modalities of aging (1) disease/disabled, characterized by the presence of pathology, disability, or both; (2) "usual" (normal) aging, characterized by the absence of overt pathology but the presence of functional declines; and (3) "successful" aging, characterized by few or none of the physiological losses seen in the usual aging group. The concept is based on (1) the substantial heterogeneity among aged individuals; (2) the observation that aging is not a uniform or inevitable process of disease or disability; (3) the persistence of plasticity well into advanced age, that is, a continuing capacity for adaptive and compensatory rehabilitation; and (4) the identification of predictors of various patterns of aging, especially factors that contribute to more successful trajectories of aging.

Current studies of successful aging provide evidence for continuing good functional competence and recuperative plasticity into old age [31, 32]. The distinction among successful groups supports the hypothesis that extrinsic factors play an important role in age-associated functional decline. In one study, factors promoting maintenance or improvement of functioning included younger age, higher income, being Caucasian, low body weight, good lung

function, the absence of diabetes or hypertension, higher education, and high cognitive performance. Other correlates of high functioning were the absence of hospitalization, participation in moderate/strenuous exercise, and receiving emotional support [30]. Taking all such factors into account, the prospects for avoidance, or eventual reversal, of functional loss with age are vastly improved, and the risks of adverse consequences are reduced [29].

Consequences of Successful Aging

By focusing on the various modalities of aging, the heterogeneity of the aging process is emphasized, and the validity of this concept is extended to all biomedical branches. Interventions may be beneficial at all ages provided they are customized to the individual [33, 34]. The potential for rehabilitation at advanced age is much greater than previously supposed [27, 35–37], and there is a significant probability of regaining function at all levels of disability. Physical exercise, dietary, surgical, and pharmacological interventions have proved successful in enhancing health even at older ages. Identification of "predictors" designed to maximize health and physiological competence enhances the quality of life of the elderly, reduces their burden of disease and disability, and decreases the socioeconomic need for health care resources. This previously underestimated the ability to significantly recover, though sometimes incompletely, portends even more benefit to surgical therapies into advanced age for certain individuals than once anticipated.

Future Trends

Rather than converging toward some biological limit, it seems that mortality trends are now pointing in the direction of further gains in human longevity. Mortality rates continue falling across the age ranges in most developed countries, where the pace of decline has accelerated among the elderly in particular. There is no sign in most demographic data that humans are approaching a mortality plateau imposed by some fixed biological limit [38]. The rapid increases in life expectancy witnessed during the first half of the twentieth century has slowed because the earlier increase resulted from the near-elimination of deaths during infancy and childhood which ultimately yields a much larger increment in average life expectancy than reducing deaths in later life. As measured by the chance of death at any given age, however, the reduction in mortality has been remarkably stable over the past century and shows no sign of decelerating [39].

Current projections based on trend extrapolation anticipate that life expectancy at birth in developed countries will be around 85 years in 2050 [40, 41]. Given the long-term stability of mortality trends and the multiplicity of factors that have contributed to the historical change, it seems naive to believe that the pace of change in the future will be substantially different from that in the past. Thus, it seems unlikely either that the increase in human longevity will end abruptly in the near future or that medical innovations will lead to a significant acceleration in the pace of change. Rather, we should expect continued slow improvements in life expectancy, which will be accompanied by the continued aging of the population and therefore an associated increase in the demand for health and social services.

Aging and Disability

The extent to which a longer life will be a healthier one, rather than one that contains more years of chronic illness or disability will have a significant impact on the future demand for health and long-term care services. While controversy exists among studies in this area, recent studies have generally concluded that most of the gains in life expectancy seem to be occurring without growth in disability and potentially less disability for a given age with time. Thus, the increase in total life expectancy does not specifically correspond to increased time living in severe disability [42–46]. This reflects what Fries [47] described as a progressive compression of morbidity that seems to be characterizing aging populations. Likewise, Manton et al. [48] have characterized the declining rates of disability and associated health care expenditures among the elderly population in the USA. According to Manton [49], what is largely responsible for this continuing trend is that rate of decline in disability prevalence continues to be a faster one than the increase in total expected years of life. For instance, while disability prevalence among older people declined 0.26% per year between 1982 and 1989, the rate of decline increased to 0.38% per year between 1989 and 1994, and further to 0.56% per year between 1994 and 1999 [45]. Multiple factors have been attributed to this progressive decline in the prevalence of disability, and including improvements in medical treatments, overall socioeconomic status, positive behavioral changes, and the more widespread use of assistive technologies. The overall result is illustrated in Fig. 11.2 which demonstrates how the prevalence of chronic disability among older people fell from 26% in 1982 through 23% in 1994 to 20% in 1999 [45]. This, it is argued, not only lessens the upward pressure of demographic change on health expenditures, but also has the potential to lower per capita demands on health and social services as well [50].

Thus, if in addition to living longer, the current generation of older people is healthier and less disabled than their predecessors, the important question then becomes – what level of disability is present in those extra years? With disability representing the inability to perform a specific task because of health or age, resulting in impaired functional performance, the concept of active life expectancy has been developed to measure the number of years that people can expect to live on average without disability. Manton and Land [51] estimate that a woman of 65 with a life expectancy of 22.2 years remains fit and active for 15.7 years and a man of the same age, with a life expectancy of 15.7 years for 13.7 years.

In the classification of functional dependency, the Activities of Daily Living (ADLs) and Instrumental Activities of Daily Living (IADLs) are two classes of measures, based on an individual's ability to perform specific tasks, that are widely utilized in home-dwelling populations to determine the capability for independent living or, vice versa, as indicators of disability. ADL tasks refer to those that are required to carry out basic self-care activities, such as transferring out of a bed or a chair, walking, toileting, bathing, and eating [52–54]. IADL tasks refer to those that are required to maintain an independent household, such as doing light housework, preparing meals, using the telephone, shopping for personal items, managing money, and getting around the community [55]. Within older populations, ADL dependency is less common than IADL dependency, and in the community dwelling population, 85 years of age and older, only 16% required help with one ADL, 10% with two or three ADLs, and 9% with four or more ADLs [56]. More than half of the community dwelling population, 80 years of age and over can still perform IADL tasks independently [56] which generally demand a combination of both cognitive and physical abilities.

Kane et al. [56] note that because health care professionals tend to see the sick, they may form a distorted picture of the health and functional status of older individuals. Indeed, most older people are self-sufficient and able to function on their own or with minimal assistance. Even though they carry a greater burden of chronic conditions and impairments, 72% of older people report being in good to excellent health. Among all older adults, 95% are able to move about within their homes independently, 80% are able to leave their homes without assistance and had no difficulty with any personal care task, 68% had no difficulty with any domestic task, and 69% had no difficulty with any locomotor task [57]. As well, of those ages 75 and over, about one-fifth report taking no medication on a regular basis, two-fifths report needing medication regularly to control medical problems, while the remainder report having multiple medical problems and using three or four medicines on a regular basis [58].

FIGURE 11.2 Percentage of people aged 65 and over with chronic disability: 1982–1999 [45].

Note: The reference population for these data is the Medicare enrollees aged 65 and older.

Aging and Health Services Utilization

Notwithstanding the low degree of dependency among the majority of older people, this 12.4% of the population are the principal users of health care systems. In being the predominant user of more expensive institutional services, they account for over one-third of health expenditures in the USA [56]. The 1997 National Medical Expenditure Survey demonstrated that the annual per capita costs of health care for older persons in the USA was \$5,947 as compared to \$3,226 for those aged 45–64 years and \$1,666 for those aged 18–44 years. Increasingly, questions are being raised around whether societies with aging populations are able to cope with the concomitant ever-increasing costs that seem to be

associated in providing care for them. Clearly, new cost-conscious models of care delivery to meet the needs of the aging populations are needed.

While expenditure projections have traditionally examined the effect of age on health care costs, it is being increasingly argued that well-founded estimates should account for the influence of remaining life expectancy, declining disability rates and the concentration of costs that often occurs toward the end of life. Lubitz and Riley [59] demonstrated that just under a third of annual Medicare payments are made on behalf of persons in their last year of life, with over half of their costs being incurred in the last 60 days of life, reflecting the fact that over half the deaths among elderly persons occur in the hospital [60]. In considering remaining life expectancy

on future health care spending, Seshamani and Gray [61] demonstrated that despite the pressure of population increases and aging demographic structures on overall hospital expenditures, these will be partially countered by the postponement of death-related hospital costs later in life. The heterogeneous pattern of health care expenditures was further demonstrated when Lubitz et al. [62] determined that the average calculated Medicare expenditure for those who died at age 70 was \$35,511 compared to \$65,633 for those who survived to age 101 in the USA. Thus, the average Medicare expense per year from age 65 on for those who died at age 70 was \$7,100 per year compared to only \$1,823 for centenarians. While overall Medicare expenditures continue to increase, this should be properly attributed to the combined forces of cost inflation, therapeutic advances, and a growing number of beneficiaries with chronic illness requiring long-term maintenance therapy as opposed to aging itself.

When it was implemented, Medicare was designed to deal primarily with the effects of acute illness, which was then seen as the major threat to the health and financial security of older individuals. Now, the implications of having increasing numbers of older people living increasingly longer with chronic illness is becoming readily apparent, when 68% of current Medicare spending is accounted for by the 23% of Medicare beneficiaries having five or more chronic conditions [63]. Furthermore, federal outlays for Medicaid and Medicare are expected to grow substantially, from 21% of current government spending to an estimated 31% in 2017 [64]. The increasing cost pressures associated with financing public health insurance programs likely affect public spending around other priorities, and overall economic growth, especially as the ratio of nonelderly taxpayers to elderly beneficiaries contracts. It is likely that unless the financing mechanism for Medicare is changed, or its benefit structure altered, the Medicare Trust Fund will be depleted in 2019 [65]. Increasing consideration is being given to determine to what extent the government will be willing to shift the costs of providing care to current recipients and to what extent it will look at shifting resources to support the provision of preventive care or health promotion services – not currently covered by Medicare or Medicaid – that may help to lessen the burdens associated with managing chronic disease. Finally, the significant indirect costs associated with treating chronic diseases in the elderly should also be noted when relatives may shoulder an enormous personal and economic burden when caring for an older spouse, parents, or other relations unable to live independently.

The pattern of increasing Medicare expenditures, however, remains in distinct contrast to the accumulated liability that increased life expectancies have on Social Security expenditures, without any foreseeable countering mechanisms. While the Social Security trust fund will have resources until

2041, the more critical dates are when Social Security and Medicare begin paying out more in benefits than they are receiving in taxes because that represents the time the government must start redeeming the bonds in the trust funds that support these programs. To do that, the government will have to increase its borrowing on financial markets, raise taxes or divert money from other government programs. For Medicare, the threshold when benefits exceed program income already occurred a few years ago. For Social Security, it is estimated that this threshold will be crossed in 2017.

Effective Interventions in the Elderly

With the growing expectation that future older cohorts will live longer and be in better health at later ages, greater consideration is being given to how treatment interventions can be extended to mitigate morbidity and mortality within older populations. While more comprehensive evaluations of the efficacy of treatment interventions at later ages will better inform practitioners about how and for whom these interventions should be extended, overcoming agism around treating illness at later ages will be just as important.

Agism is a term that describes the negative stereotyping of older adults and discrimination because of older age. As Salzman [66] notes, health concerns and symptoms in the elderly are sometimes overlooked or dismissed as part of the normal aging process. Consequently, several conditions in older adults continue to go significantly underdiagnosed and undertreated which continues to provide further evidence of age discrimination still occurs in the delivery of health care [67–69].

While health care professionals do not necessarily intend to behave in a discriminatory fashion, it is clear that a lack of skills and confidence in working with older people can lead to behavior which may be perceived as discriminatory. Nevertheless, the quality of the care older individuals receive has also been demonstrated to be affected at times by negative staff attitudes in a number of settings [70, 71].

Denying access to services on the basis of age alone is not acceptable. Decisions about treatment and health care should be made on the basis of a patient's health needs, the overall health status of the individual, their own wishes and aspirations and, where appropriate, those of their carers, and the patient's ability to benefit as even complex treatments, used appropriately, can benefit older people.

The extension of surgical interventions to individuals at increasingly later ages is an area of active research. Largely, this body of literature demonstrates that the benefits of surgery in advanced age may have been underestimated. Hosking et al. [72] examined how intraoperative mortality rates in patients over 90 years of age had significantly declined from 29 to 8%

over a 20-year period. Furthermore, the 5-year survival rate of this group at 21%, which had a mean age of 93.5 years, was determined to be better than that of the comparable general population cohort at 16%. Elayda et al. [73] demonstrated similar results in demonstrating the efficacy and improved 5-year survival rates in patients 80 years of age and over undergoing aortic valve replacement. Ko et al. [74] demonstrated the increasing efficacy of elective coronary artery bypass surgery versus conventional medical treatment in patients 80 years of age and over with coronary artery disease.

Interventions with low mortality risks that have been demonstrated to significantly improve function and thus disability burden in older patients include cataract extractions and joint replacements. In regards to cataract extractions, Lundstrom et al. [75] demonstrated in one of few studies that looked specifically at individuals 85 and over that about 85% of patients achieved improved visual acuity from the surgery. Therefore, despite the higher risk of complications, cataract extraction remains a highly effective procedure for the very elderly [76]. In a recent review of 36,711 hip and knee replacement performed among nonagenarians and centenarians, the low in-hospital mortality data suggest that arthroplasties should not be denied to centenarians solely because of their relatively short remaining life expectancy estimates, when they can significantly improve functional status in these individuals [77].

The ability of pacemakers to improve survival and quality of life outcomes in elderly patients has become well established [78, 79]. In reviewing patients 80 years and over receiving pacemakers, Schmidt et al. [80], determined that pacemaker therapy is both a clinically and economically effective therapeutic option to control bradyarrhythmia-related symptoms, considering the median survival time of their patients stood at 8 years. Interestingly, while practice guidelines recommend dual rather than single-chamber pacing for patients with high-grade atrioventricular (AV) block, Toff et al. [81] noted that not only were elderly patients less likely than younger patients to receive more sophisticated dual-chamber pacemakers, but also 51% of elderly patients with this diagnosis were receiving them, despite their perceived association with improved quality of life and lower mortality risk. Nevertheless, their UKPACE trial, the first to evaluate and compare the long-term clinical impact and cost utility of dual versus single chamber pacing in patients aged 70 years and over with high-grade AV block, suggested no mortality benefit of dual over single-chamber pacing in this population [82].

In the field of organ transplantation, common practice has been to exclude older recipients because of the chronically limited supply of organs and lower expected survival of older patients after transplantation. While consensus guidelines for the selection of transplant recipients often recommend an upper age limit of 65 years, the number of people 65 years

and older in the USA who have received organ transplants nearly tripled between 1996 and 2005, going from 1,145 to 3,154 [83]. Currently, elderly patients including those into their early 80s have come to represent 12% of the annual transplant recipients. Furthermore, Mahidhara et al. [84] have suggested that the idea that younger patients do better than older patients may not actually be valid after demonstrating that 73.6% of their elderly lung recipients were alive 3 years after surgery, compared with 74.2% of younger patients.

There is increasing evidence to support the greater use of nonsurgical interventions in the management of conditions common to the elderly patient as well. While the benefits of treating of hypertension in the very elderly were unclear as to whether they could be countered by an increased risk of death, the HYVET Trial demonstrated that treating hypertension in patients 80 years and older to a target of 150/80 was associated with a 64% reduction in the rate of heart failure, a 23% reduction in the rate of death from cardiovascular causes, a 30% reduction in the rate of fatal or nonfatal stroke, a 39% reduction in the rate of death from stroke, and a 21% reduction in the rate of death from any cause [85].

The increased recognition of osteoporosis as a preventable and treatable disease common in older individuals would aid in the dissemination of proven medical therapies that could significantly impact on the excess morbidity and mortality associated with this disease. Nevertheless, Kamel et al. [86] demonstrated that the failure of surgical and medical specialists to diagnose and initiate the treatment of osteoporosis in elderly patients hospitalized with hip fracture remains problematic when those treating the consequences of osteoporosis may often be ignoring the underlying condition [87].

Even though near complete vaccination coverage rates have been achieved in children, significantly fewer adults are being vaccinated against serious and even deadly diseases, such as influenza, pneumonia, and shingles. The CDC has established a goal to vaccinate at least 90% of individuals 65 years of age and over against influenza and pneumococcal disease, however, coverage estimates in this age group were just 69 and 66%, respectively in 2007. Despite being available for 1 year and having been integrated into the US Preventive Services Task Force guidelines as a recommendation for all elderly, only about 2% of eligible older adults appeared to have been vaccinated against shingles by 2007. While their effectiveness with aging is debated, estimates are that many of the 63,000 deaths in the USA in 2005 due to influenza and pneumonia could have been prevented by immunization against influenza and pneumococcal infections [88].

Because the aging population carries the greatest burden of illness and disability, it not only poses the most complex diagnostic and therapeutic problems, but also reaps the most benefit from medical and nursing care. The health problems

of older people are also inseparable from their social relationships and circumstances. As a result, their problems challenge various health and social care professionals to understand their patients through the organic, social, and psychological dimensions of their lives. Furthermore, evaluating the potential benefits of therapeutic interventions for elderly individuals with specific health profiles, and understanding in general what service increases are needed to meet the needs of the growing numbers of older patients is not only necessary, but as Manton et al. [48] assert, require consideration of the long-term demographic and health changes that are constantly evolving integrated with an understanding of both personal and cultural values. For older patients, especially those at late ages, it is clear that the cost-benefit ratios of therapeutic medical and surgical interventions have been commonly underestimated – because life expectancies, mortality benefits, the amount of functional capacity that can be regained is usually underestimated. In the management of elderly patients, understanding the heterogeneous nature of this population and that the use of physiological age, rather than chronological age is becoming increasingly more relevant in the prognostication of an individual's disability and mortality profile is important.

Chapter 12

Providing Surgical Care to an Aging Population: Implications for the Surgical Workforce

David A. Etzioni and Clifford Y. Ko

Introduction

The demographic trends underlying the “aging population” have already been discussed in Chap. 12. As a result of increasing life expectancy and the aging of the baby boomers, the United States (US) population will see a dramatic increase in the number of older individuals. Between 2010 and 2030, those aged 65 years and older are projected to rise by 78%, an absolute increase of over 30 million individuals. These unprecedented changes in the demographics of the US population will lead to significant growth in the demand for surgical treatment.

This chapter comes with an acknowledgement. In the interest of simplicity, we examine these trends within the context of the US population only. Furthermore, we focus more on general surgery and its subspecialties than on other areas of surgical specialization. This is in the interest of developing a succinct, circumscribed report. The analyses described here are easily applicable within other fields of medicine, as well as to other countries.

Another acknowledgement is also important. This chapter could easily be its own textbook. In selecting which points should be made, we focus on a survey of existing opinions and concepts that are driving policy. We will also offer some original analysis regarding how the aging population will affect the delivery of surgical treatment. Our hope is at the end of this chapter, the reader will be familiar with the methods used to forecast the impact of the aging population on the healthcare delivery system, and be able to differentiate the relative importance of the various factors that will drive health care expenditure in the immediate and more distant future.

Older Individuals in the US Population: Disproportionately High Use of Resources

In general, older individuals use medical and surgical services at higher rates than do younger individuals. To illustrate and characterize this fact, we will rely on analyses of the National Hospital Discharge Survey (NHDS), a data source which deserves at least a brief explanation. Since 1965, the National Center for Health Statistics has conducted an annual survey (sampling) of domestic discharges. Each year, over 350,000 discharges from approximately 500 hospitals within the US are sampled, and the sampling strategy is designed to yield a dataset that is representative of the universe of domestic discharges [1]. The NHDS reports specific information about each discharge, including age, gender, race/ethnicity, diagnoses, procedures, diagnosis-related grouping (DRG) admission source (emergency room, home, etc.), and admission type (emergency, elective, etc.). At several points in this chapter, we will rely on analyses of the NHDS to give a quantitative analysis of historical and projected trends in the patterns of hospital-based health care delivery in the US.

Hospital-Based Care

According to data from the US census, in 2006, individuals over the age of 65 comprised 12.5% of the US population [2]. However, according to data from the NHDS, individuals over the age of 65 were responsible for:

- 32% of cholecystectomies
- 38% of hospitalizations
- 43% of hospital days of care
- 54% of colon resections
- 55% of total hip replacements
- 60% of total knee replacements

This disproportionate use of services can be considered in terms of an incidence rate curve, demonstrating the likelihood of an individual in the population requiring a specific

FIGURE 12.1 Incidence rate curves: admissions for medical vs. surgical DRGs.

type of hospital-based medical or surgical service. Figure 12.1 represents such an analysis based on data from the 2006 NHDS. We categorized admissions as “surgical” or “medical” based on DRG, according to nomenclature used by the Centers for Medicare and Medicaid Services (CMS) [3]. Admissions for children in their first year of life or those related to childbirth were excluded.

These incidence rate curves clearly demonstrate the difference in the rates at which younger vs. older individuals are hospitalized. Compared with an individual aged 40–50, an individual aged 70–79 is 2.6 times more likely to be hospitalized for a surgical cause and 4.2 times more likely to be admitted for a medical reason. The duration of hospitalization also varies widely across different age groups, with average lengths of stays (LOS) being higher in older individuals admitted for both surgical and medical DRGs (Fig. 12.2).

Inpatient Procedures

The demand for specific types of inpatient surgical procedures can also be conceptualized as an incidence rate curve. Several examples are illustrated below, namely for knee replacement, coronary artery bypass graft (CABG), colectomy, cholecystectomy, carotid endarterectomy (CEA), and hysterectomy (vaginal or trans-abdominal) (Fig. 12.3). These curves illustrate very clearly the higher rates at which older individuals undergo surgical treatment. In fact, for each of these procedures (except for hysterectomy), individuals in their eighth or ninth decade of life have the highest frequency of surgery.

Outpatient Procedures

Outpatient surgical procedures are, in general, also performed much more commonly in older individuals. The following graph (Fig. 12.4) examines rates of seven of the most frequently performed outpatient procedures based on data from the State of Florida [4]. Two procedures – myringotomy tubes and tonsillectomy/adenoidectomy – are performed more commonly in younger patients and less so in older individuals. For the remaining five procedures, the age range with the highest rates of surgery is individuals aged 60 years and older. This is particularly true for cataract operations, which could not be included in the figure below for reasons of scale. The rate of cataract surgery among individuals aged 70–79 is 74 per 1,000 population, greater than the other seven procedures combined.

Older Patients are Different

In this section, we will explore how an older domestic population will affect not only the numbers of procedures, but also the types of procedures and the intensity of care provided for them.

A brief examination of the “top ten” surgical procedures performed on patients over vs. under the age of 65 tells some of this story. For this analysis, we once again turn to data from the NHDS and examine only the primary procedure performed during each hospitalization [5]. For patients under the age of 65, the most commonly performed procedures were hysterectomy (abdominal), followed by cholecystectomy then

FIGURE 12.2 Mean LOS: medical vs. surgical DRGs.

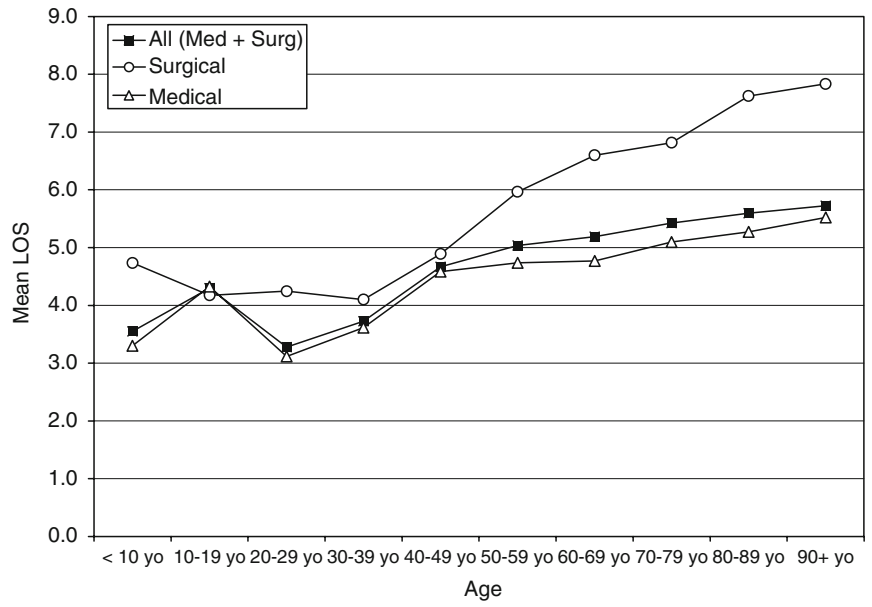

FIGURE 12.3 Incidence rate curves: commonly performed inpatient procedures.

FIGURE 12.4 Incidence rate curves: commonly performed outpatient procedures.

knee replacement. For older patients, the top four inpatient procedures were all orthopedic. Seven out of these top ten procedures were orthopedic or neurosurgical in nature.

In addition to generating an increased demand for surgical procedures, the aging population presents a more fragile population of patients (Tables 12.1–12.3). As shown below

TABLE 12.1 Top ten procedures performed in individuals <65 years old

ICD code	Procedure description	Procedures in 2006
68.4	Total abdominal hysterectomy	418,588
51.23	Laparoscopic cholecystectomy	386,444
81.54	Total knee replacement	309,341

Unadjusted totals		826,947	3.3	0.07	0.07	4.8	1.1	0.7

in Table 12.3, older patients require a greater amount of care. The average length of stay was higher for older patients (4.8 vs. 3.3), and the likelihood of an in-hospital myocardial infarction (MI) was approximately ten times greater (0.7 vs. 0.07%). The greatest difference in outcomes is mortality, with patients over the age of 65 having an in-hospital mortality rate nearly 15 times higher (1.1 vs. 0.07%). Longer lengths of stay and higher rates of myocardial infarction and postoperative mortality only tell part of this story. In order to minimize the impact of medical comorbidity on peri-operative outcomes, surgeons will need to work closely with non-surgeon physicians to optimize medical management. There is already evidence that medical hospitalists are increasingly involved in the care of surgical patients. In a recent analysis of Medicare claims data, Kuo et al. found a more than fivefold increase in the percent of surgical admissions that involved care from a medical hospitalist [6]. A new paradigm of inpatient care may be emerging, with surgeons and non-surgical physicians working together to manage patients who are elderly and/or morbid.

As the number of elderly individuals in the US population continues to increase, another area that will require focused attention is the clinical effectiveness/appropriateness of different types of treatment in older patients. Many types of major surgery that historically were considered too risky to undertake in elderly patients are now widely considered safe [7–9]. The bias against aggressive surgical treatment for patients considered empirically “too old” appears to be diminishing, and the rates at which elderly individuals are undergoing several types of major surgical procedures are increasing [10]. There is still, however, evidence that elderly patients are under-treated for many types of conditions, especially oncologic diseases [11–13]. These findings are behind a movement advocating more focused research on clinical outcomes in elderly patients [14].

Current Capacity

As the number of older individuals in the US rises, it should be intuitive that the use of medical resources will increase at a rate faster than population growth. Before discussing the impact of *forthcoming* demographic changes on the surgical workforce, we will first consider the capacity of the *current* health care delivery system to provide surgical care. In doing so, we examine capacity in terms of two complementary components – physician workforce and hospital infrastructure.

Physician Workforce Capacity

Two main types of research have emerged to gauge the adequacy of the current physician work force relative to population-based demand, yielding conflicting results. The first type is a “macro” analysis, examining regional relationships between physician density and quality of care. A classic example of this type of research was performed by Baicker et al., who analyzed state-level measures of the quality of medical care provided to Medicare recipients and found *poorer* quality of care delivered to patients in states with *higher* per capita Medicare expenditures and physician density [15]. Furthermore, they found that quality of care was proportional to the density of general practitioners and *inversely* proportional to the concentration of specialist physicians. These findings were refuted by Cooper et al. who examined within-state variations, and concluded that states with more spending and more physicians – both generalist and specialists – had better quality of care [16, 17].

The second type of research examines the ability of the health care workforce to meet the demands of the regional population at a “micro” level. Several studies have examined hospital-based care, using the ability of emergency departments (EDs) to obtain consultations from surgical specialists as a measure of access to care. In a study of ED directors at over 4,000 US hospitals, the American College of Emergency Physicians found that 73% of EDs had problems with inadequate on-call coverage by specialist physicians [18]. Also, this figure had increased from 67% only the previous year. Difficulties with obtaining specialist consultations are also documented as worsening, both in terms of the ability to access on call specialists, and in the ability of EDs to initiate transfers to hospitals where a higher level of care can be provided [19]. Areas with lower mean zip code income had a lower likelihood of timely response to a request for surgical consultation [20].

If the network of available surgical specialists begins to fray, and access to care is compromised, how will we know? Is a state-level analysis sufficiently sensitive to capture life-threatening shortages in the availability of surgeons capable

and willing to tackle acute surgical problems in the middle of the night? In considering these issues, it should be readily apparent that the areas of the country that are likely to experience the most acute shortages are rural areas of the US. Within the US, rural areas represent 75% of the country’s land mass and 17–20% of the population, but only 10% of the domestic workforce of general surgeons [21]. Two recent front-page articles, one in the *Washington Post* and one in the *Wall Street Journal*, have highlighted the difficulties facing rural general surgeons and their surrounding communities [22, 23]. The departure of these physicians from the workforce – resulting either from harsh conditions/job dissatisfaction or simple age-related attrition – stands to have a significant impact on patient access to care and the financial viability of community hospitals [21, 24].

Several physician leaders within the field of general surgery have called attention to the growing problem of surgeon shortages in rural areas [24–28]. We refer the reader to this literature for a thorough discussion of this emerging issue, and plans to address it. In considering the plight of the rural communities, however, it is important to bear in mind that the rural surgical workforce does not exist separately from the non-rural surgical workforce, but rather in equilibrium with it. The acute shortage of surgeons in these areas is probably best considered as the first manifestation of a growing national problem.

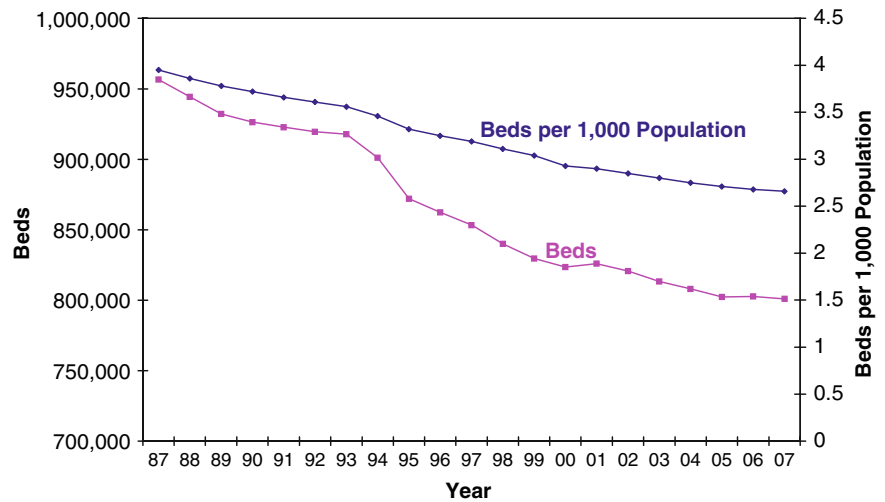

Hospital Capacity

The ability of the existing hospital infrastructure to meet increased demand for inpatient care is an often-overlooked consideration. According to 2007 data from the American Hospital Association, there are currently 4,897 hospitals and 800,892 staffed hospital beds in the US [29]. Longitudinal trends in the number of beds and number of beds per 1,000 population between 1981 and 2006 are shown in Fig. 12.5.

Over the last decade, the use of hospital-based care has remained remarkably constant, in terms of age-specific rates of hospitalization (Fig. 12.6a). The annual number of hospitalizations and inpatient days of care used per year in the US between 1996 and 2006 are presented using data from the NHDS (Fig. 12.6b). Forecasts between 2006 and 2030 were calculated based on 2006 patterns of hospitalization in terms of age-specific rates of admission and lengths of stay.

Between 1996 and 2006, numbers of hospitalizations increased by 12.8% and inpatient days of care by 5.0%. The differential rates of growth are explained by an overall trend in decreased LOS. Based on the patterns of hospitalization from 2006, between 2006 and 2030 we forecast that the number of annual hospitalizations will increase by 39% and days of inpatient care by 43% (Fig. 12.6b).

FIGURE 12.5 Number of hospital beds in the US: 1987–2007 (data from the American Hospital Association Annual Survey, 2007, for community hospitals, Avalere Health, Washington, DC).

Given that the number of beds per population is decreasing and the population-based demand is increasing, the capacity of the current hospital network to cope with future growth in the numbers of domestic hospitalizations is worthy of investigation. At the time of writing this chapter, the authors know of no comprehensive studies of the occupancy rates within US hospitals. One study of New Jersey hospitals found occupancy rates on average well below 80%, implying ample capacity [30]. Are these levels of utilization representative of other communities in the US? The ability of hospitals to handle growing demand for inpatient care engendered by the aging population needs to be examined at every level.

Forecasting Utilization

The fact that older individuals use more health care resources than younger individuals is important, but other important forces also drive changes in utilization of medical services. These forces include population growth, changes in health care delivery, and economic expansion. In the past, several approaches have been applied to project the amount by which population-based use of medical resources will increase in the future. The methods behind these approaches are rooted in varying methodologies, and have yielded conflicting results over time. Broadly speaking, models used in forecasting medical expenditure can be categorized as needs-based, demands-based, or economic in terms of the approach taken.

Needs-Based Models

A needs-based model is predicated on estimating the population-based need for medical services and applying this estimate of need to the population as it will be in the future. For the purpose

of this discussion, we will first define the “need” for medical services based on an existing definition:

That quantity of medical services which expert medical opinion believes ought to be consumed over a relevant time period in order for its members to remain or become as “healthy” as is permitted by existing medical knowledge [31].

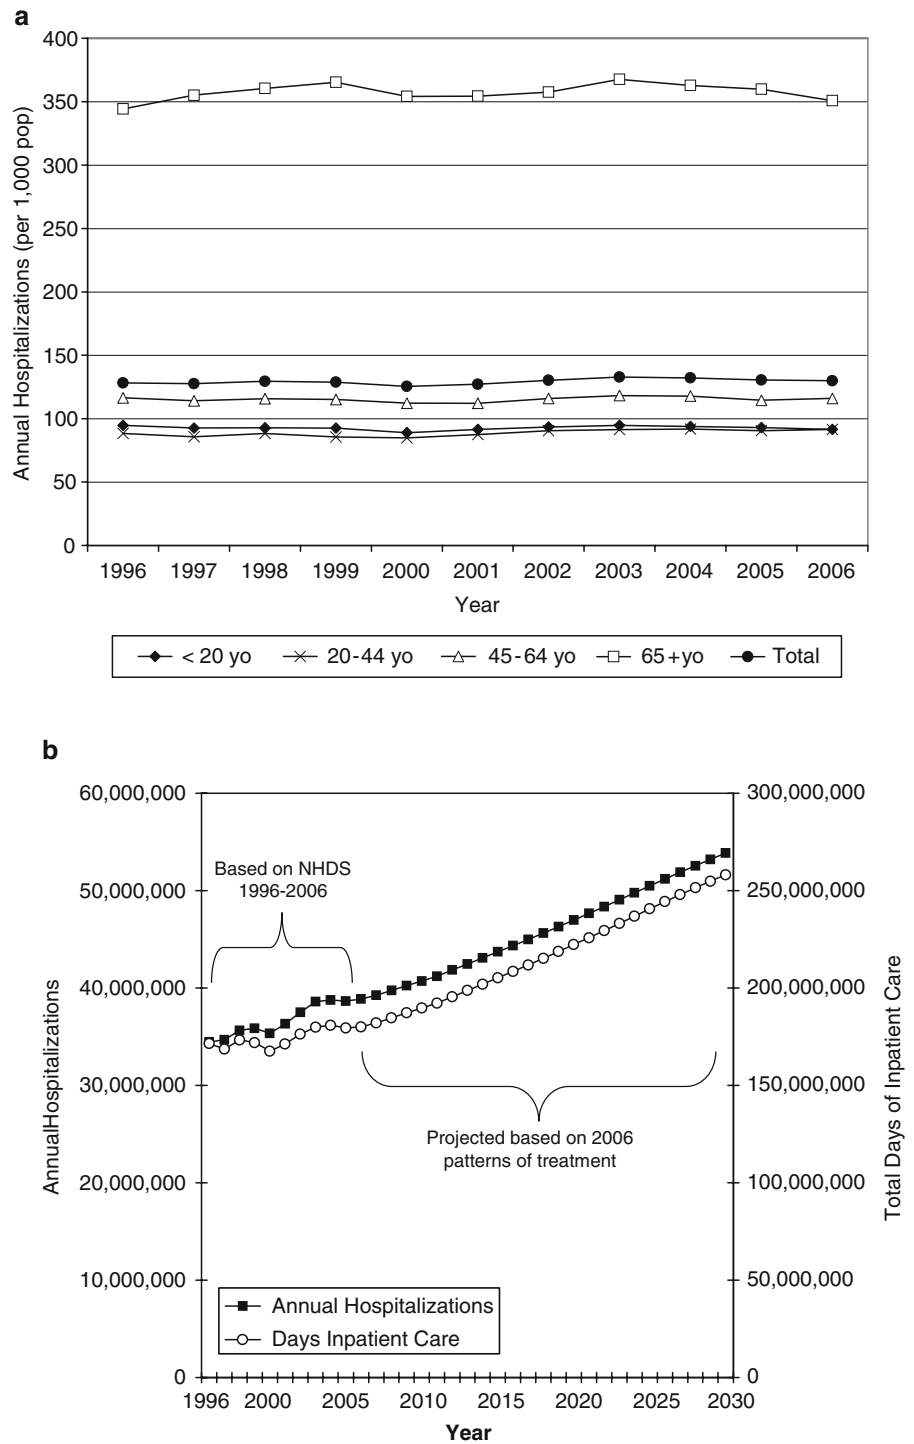

Translating a needs-based model into prediction requires two main steps. First, an epidemiological estimate of disease frequency is developed. Second, the amount and type(s) of care necessary to adequately treat the disease is compiled. A needs-based model can also be “adjusted” to reflect predicted changes in either of the two elements of the model. The Graduate Medical Education National Advisory Committee (GMENAC) report, published in 1980, is an example of a needs-based approach [32]. In the GMENAC report, a panel of medical experts (6–10 for each specialty) estimated the profile of care required by the general population. The estimation was targeted at predicting patterns of care as they “should be,” rather than as they actually were at some baseline point in time. Based on this needs-based model, the GMENAC report suggested that by the year 2000, there would be approximately a 25% physician surplus.

Inherent in any needs-based model is a prediction regarding what patterns of treatment will be in the future. This type of estimation can be a strength or a weakness, depending on its ability to move a prediction model in a way that makes it more or less accurate. While in retrospect it is easy to dismiss the GMENAC model as poorly conceived, in its time this effort was a significant driver of health policy.

Demands-Based Models

A demands-based model is based on interpreting the desires or “wants” of a population, and placing these motivations in the context of market forces, especially price. We defer, once

FIGURE 12.6 (a) Age-specific rates of hospitalization: 1996–2006; (b) annual hospitalizations and days inpatient care: 1996–2030.

again, to a preexisting definition for “demand” in order to ground this discussion:

A multivariate functional relationship between the quantities of medical services that its members desire to consume over a relevant time period at given levels of prices of goods and services, financial resources, size and psychological wants of the population as reflected by consumer tastes and preferences for (all) goods and services [31].

Generating a demands-based model for predicting use of medical services is relatively straightforward, and relies on two core components. First, rates of surgical procedures can be calculated based on any one of a number of existing data sources. Second, these rates can then be applied to forecasted population changes in order to project trends in the use of different types of surgical procedures. A demands-based approach benefits from simplicity and objectivity. The major

Sources: Physician supply: R.I. Lee and L.W. Jones, *The Fundamentals of Good Medical Care* (Chicago: University of Chicago Press, 1933); W.H. Stewart and M. Pennell, "Health Manpower, 1930-75," *Public Health Reports* 75, no. 3 (1960): 274-280; American Osteopathic Association; and Bureau of Health Professions. Population: Bureau of the Census. Gross domestic product: Bureau of Economic Analysis. Supply projections based on authors' model; see Note 4 in text.

Notes: "Physician supply 1929-2000" includes active physicians only ($r^2 = 0.94$). "Projected supply" includes all active physicians. "Effective supply" represents the number of active physicians reduced by the decrements in work effort associated with increasing numbers of female and older physicians in the workforce. "Added NPCs" represents the sum of "effective supply" plus the incremental contributions of nonphysician providers (NPCs). Per capita GDP is expressed in chained 1996 dollars. "Physician demand" is projected based on average annual GDP growth rates of 1.5 percent (dotted rule) and 2 percent (continued solid rule).

FIGURE 12.7 Physician supply and gross domestic product, 1929-2000 and projected to 2020 (from Cooper et al. [34]).

shortcoming of this approach stems from the underlying assumption that per capita demand will remain constant over the time period of interest.

In 1989, a private consulting firm (ABT Associates) was contracted by the Bureau of Health Professions to conduct a follow-up to the GMENAC study. The methods used in this report were demands-based, and findings included a projected increase in the use of general surgical care of 32.7% between 1990 and 2010. We published the results of a similar type of model in 2003, and found a projected increase in the demand for general surgical procedures of 31% between 2001 and 2020 [33].

Economic Models

Economic models add another important dimension to the science of forecasting growth in the use of medical resources. The arguments underlying a need to consider economic factors are elegant. In the US, the per capita use of medical resources has risen steadily over time, and this rate of rise is linear when compared with increases in gross domestic product (GDP). Economic models attempt to account for the

impact of economic factors, and incorporate projected growth in GDP into a predictive model. The use of economic models in physician workforce forecasts has been predominantly advocated by Cooper et al., and published initially in 2002 [34]. Their approach, termed a "trend model," incorporates four factors (1) economic expansion, (2) population growth, (3) physician work effort, and (4) services provided by non-physician clinicians (NPCs) (Fig. 12.7).

This model is notably different from demands-based and needs-based models in that it (1) defines and quantifies a direct relationship between economic expansion [gross domestic product (GDP)] and physician supply, and (2) assumes that this relationship will remain constant into the future. An economic model also has special usefulness in characterizing the relationship between economic growth and specific subtypes of physician services. Based on a cross-sectional analysis of States (in the US) in 1995, this model documents a relationship between regional per-capita income and the supply of three types of physicians: general practitioners, surgical specialists, and medical specialists (Fig. 12.8). The implication of this finding is that continued economic growth will lead to a relatively greater growth in the demand for medical and surgical specialists than for general practitioners.

FIGURE 12.8 Physician supply in States, by major specialty group and State per capita income, 1995 (from Cooper et al. [34]).

Sources: Bureau of Economic Analysis; American Medical Association; and Bureau of the Census.

FIGURE 12.9 US population age distribution: 2000–2050.

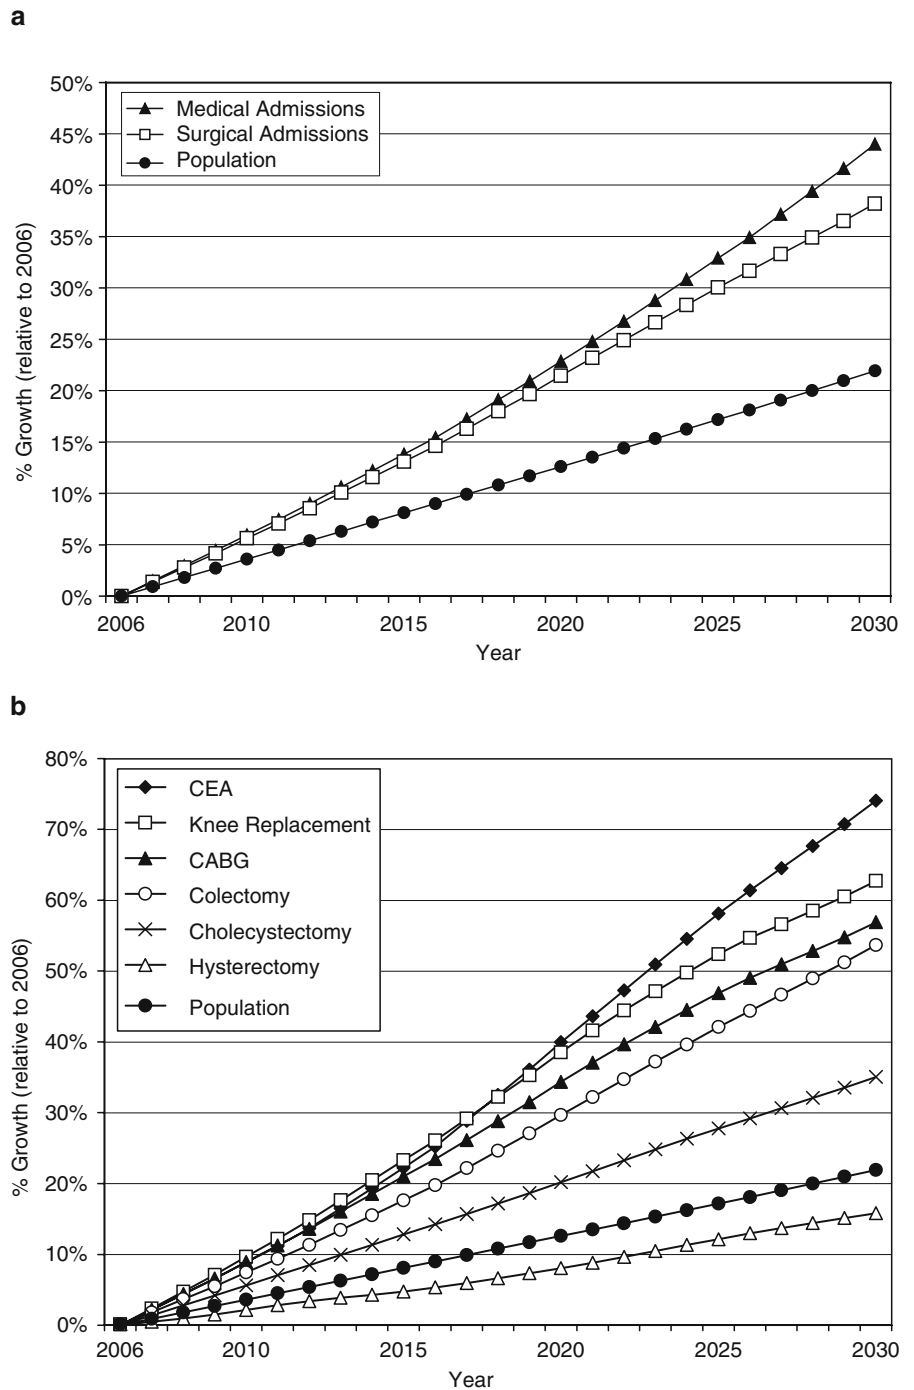

In forecasting the demand for physician services, economic models make an explicit assumption which might also be considered a weakness – that economic expansion will continue at rates that are roughly similar to those in recent history. At the time of the writing of this chapter, that assumption might be called into question. In a period of lesser economic growth or even recession, the actual demand for physicians (according to this type of model) would be lower than forecasted. It is also notable that this model explicitly fails to incorporate any acknowledgement of the aging of the US population. The extent to which the aging of the population is a significant driver of future expenditures is a topic of great debate. Several notable economists have argued that population aging is *not* a primary driver of growth in expenditures [35, 36]. Their argument is based on demonstrating that the demographic profile of the US population will not actually change dramatically in the coming decades (Fig. 12.9).

While at first glance, the demographic shift toward an aging population might appear minimal or modest, this type of display hides a subtle but important truth. Based on figures from the US census, in 2000 12.4% of the US population were aged 65 years or older; by 2030, this figure will increase to 19.7%, and between 2030 and 2050 the proportion of the population 65 years and older will remain stable at approximately 20%. Meanwhile, the overall US population is forecasted to increase by 29% between 2000 and 2030, and 49% by 2050. In the future, what proportion of growth in medical expenditures can be accounted for by population growth as opposed to population aging?

In Fig. 12.10a, b, we address this question looking at medical/surgical admissions and procedures using a forecasting method that is based on data from the 2006 NHDS. During a 25-year period that sees 22% growth in the US population, there will be a projected 44% increase in medical admissions and a 38% increase in surgical admissions for

FIGURE 12.10 (a) Projected growth in population and medical vs. surgical admissions: 2006–2030; (b) projected growth in selected surgical procedures: 2006–2030.

hospital-based care. Growth in specific surgical procedures varies widely, from 16% (hysterectomy) to 74% (CEA). In general, these rates of procedure-based growth are significantly greater than simple population growth.

So why do economists de-emphasize the aging of the US population in their forecasting models? The answer may lie in that their perspective encompasses a more global view of health care finance. In recent years and in the near future,

domestic health spending has grown by an estimated 6–7% per year [37–39]. From the perspective of national policy planning, it is clear that population expansion and aging are not the only (and perhaps not even one of the most important) drivers of growth in expenditures. This point of view – while valid – has the potential to overlook problems related to the adequacy of the supply of specific types of physicians relative to the projected demand for their care.

The Surgical Workforce

The forecasting models described above all predict a significant increase in the demand for health care services. These models tend to group all physicians together in considering workforce, or at best into “surgical specialists.” In this section, we will describe the training pipeline that produces physicians in the US, and examine the general surgery workforce as a case in point.

Training: Medical Schools

Medical education is the first gateway through which physicians must pass en route to independent practice, and there are finite means through which this can occur. Between 1980 and 2005, the number of graduates from domestic medical schools (allopathic plus osteopathic) has remained at approximately 16,000–18,000 per year [40]. A significant number of physicians practicing in the US did not attend a domestic medical school. Physicians who graduated with a medical degree from a school listed in the World Health Organization directory of medical schools or the Foundation for the Advancement of International Medical Education and Research (FAIMER) are eligible to obtain licensure within the US. In 2007, 29% of entrants into graduate medical education (GME) training programs were international medical graduates (IMGs) [41]. The Association of American Medical Colleges recently recommended increasing the number of medical school positions in the US by 30% in the decade starting 2005 [42]. Recent projections place the estimated actual growth in positions at 21% [43].

Residency Training

Graduate (residency) medical education is funded both directly and indirectly through a variety of sources, most notably Medicare. The adequacy of these training programs is supervised by the American Council for Graduate Medical Education (ACGME) through Residency Review Committees (RRCs). The vast majority of physicians working in the US are trained through an ACGME-accredited residency program, and gauging the output of this pipeline over time is important to understand the current and future physician workforce.

Between 1980 and 1993, the number of residency training positions in the US increased from 61,819 to 97,370 (58%), a rate significantly more rapid than population growth [44]. By the early 1990s, however, general and academic consensus was that a period of physician oversupply was imminent

[45, 46]. The Balanced Budget Act (BBA) of 1997 placed limits on the number of such training positions that would be funded by Medicare, and this cemented a halt in the increase of graduate medical education. In the 10-year period after the passage of the BBA, there has been an 8% increase in training positions, primarily the result of increased trainees, but also due to increased sub-specialization and longer training programs [41].

The number of fully-trained physicians that can be trained each year in the US is a function primarily of the number of residency training positions. An increase in the number of qualified domestic medical school graduates without accompanying growth in residency slots will only result in a lower proportion of IMGs in domestic GME programs or a body of domestic graduates who are unable to find appropriate training positions. Despite the significant movement toward expanding the number of medical school slots, there has not yet been a co-existing mandate to increase GME expenditures or positions. In the context of a recessionary economy, it seems unlikely that Federal spending on GME will increase.

Work Effort

The work output per surgeon is another important element of the workforce equation. The economic model developed by Cooper et al. forecasts a decrease in work effort over the next 15–20 years as a result of an aging surgical workforce and the rising number of female physicians [34]. They assumed a reduction in work effort of 10% for physicians aged 55–65, and 20% for those aged >65, and that female physicians work output is 20% lower than male physicians. Within their model, these assumptions resulted in a net 5% reduction in overall physician effort in 2010, and 10% in 2020 (relative to 2000).

Another important factor affecting physician work effort/efficiency is the shifting paradigm of work hours during surgical training. In July 2003, the ACGME issued standards for all accredited residency programs, mandating an 80-h work week. Most recently, in December 2008, the Institute of Medicine (IOM) released a report entitled “Resident Duty Hours: Enhancing Sleep, Supervision, and Safety” [47]. While this report did not go beyond the ACGME standards in further limiting the number of hours worked by residents, it advocated significant changes to how those hours should be structured. As part of this report, the IOM commissioned an analysis of how many additional physicians would be required to meet staffing needs if its recommendations were implemented. This analysis found a need for an additional 5,001 attending physicians and 8,247 resident physicians.

It may also be a matter of time before the hours worked by surgeons in practice are reduced. This may be a result of the

decreased hours in training carrying over into a desire by graduates to work less, or a more global shift on the part of medical students towards a desire for a controllable lifestyle [48, 49]. Another emerging trend that may affect the work output per surgeon in the US is the trend away from independent physician practice. According to data from the Center for Studying Health System Change, in 1996–1997 the proportion of surgical specialists who are full or partial owners of their practice was 75.5%, but by 2004–2005 this figure had decreased to 68.4% [50]. How does a shift away from independent practice affect overall clinical productivity? The relative productivity of surgeons in independent practice compared with surgeons in other types of practice environments is unknown. Regardless of the impact of this emerging trend on physician productivity, the loss of surgeon practice autonomy may have significant implications for the field which should be addressed at the highest level of leadership.

The aging of the surgical workforce is a significant challenge not only in terms of declining work effort, but also in terms of exit from the workforce. According to data from the American Medical Association, over 40% of active general surgeons, urologists, thoracic surgeons, and orthopedic surgeons are over the age of 55 [51]. Estimating the likelihood of retirement is difficult, given that physician self-report of retirement plans may not be entirely predictive of actual behavior [52]. Also, there is evidence that practice environment and work satisfaction can impact plans for retirement vs. continued practice [53].

General Surgery: A Case in Point

The American Board of Surgery (ABS) has certified diplomates in general surgery since 1938, and over the last 70 years, the field has changed dramatically. In the year 1938, 102 surgeons were board-certified, and in 2005 this number had increased to 1,026. Over the last 25 years, however, the number of general surgeons certified per year has been remarkably constant. Based on data obtained through the ABS regarding historical rates of certification, we have developed a basic model to estimate the number of general surgeons in practice. This model is based on the following assumptions (1) 1,000 annual certifications after 2005, (2) 30-year career in active clinical practice, and (3) 0.5% annual attrition rate. Based on this model, between 2005 and 2025 the number of active general surgery diplomates will increase by 2.1% (Fig. 12.11a). The numbers of active diplomates relative to the US population are shown in Fig. 12.11b.

The ratio of active general surgeons to the US population was highest in 1988, and declined by 7–8% by 2006. Based on our model, in 2025 the general surgical workforce relative to population-based demand will have decreased by 26%

relative to 1988. Importantly, this figure is refractory to immediate changes in rates of surgical training. If in 2010, the number of diplomates per year is increased to 1,100 per year, the ratio of workforce to population-based demand will be only 5% higher in 2025 than if the rates of graduation remain at 1,000 per year.

These estimates and projections are limited in that all board-certified general surgeons are considered “general surgeons,” regardless of sub-specialization in training/practice. A recent study based on data from the American Medical Association’s Physician Masterfile estimated that between 1981 and 2005 the number of active general surgeons decreased precipitously from 7.68 to 5.69 per 100,000 [25]. This estimate only included surgeons who listed their primary area of specialty as general surgery, abdominal surgery, trauma surgery, or critical care. Over the last two decades, the proportion of graduating general surgical residents who pursue additional subspecialty training has grown, and is currently over 70% [54]. The amount of general surgery performed by diplomates with subspecialty training is largely unknown and difficult to measure.

Health Care Reform: Will It Solve the Problem?

There is no argument that US residents pay a greater amount for health care than any other country in the world. According to recent statistics, the annual per capita expenditure was \$6,401, and between 1970 and 2005 the rate of increase in the proportion of GDP directed toward health care spending was faster in the US than in any other country [55]. In return for its investment, it does not seem that the US population receives a concomitantly higher quality of care [56]. Waste is considered rampant:

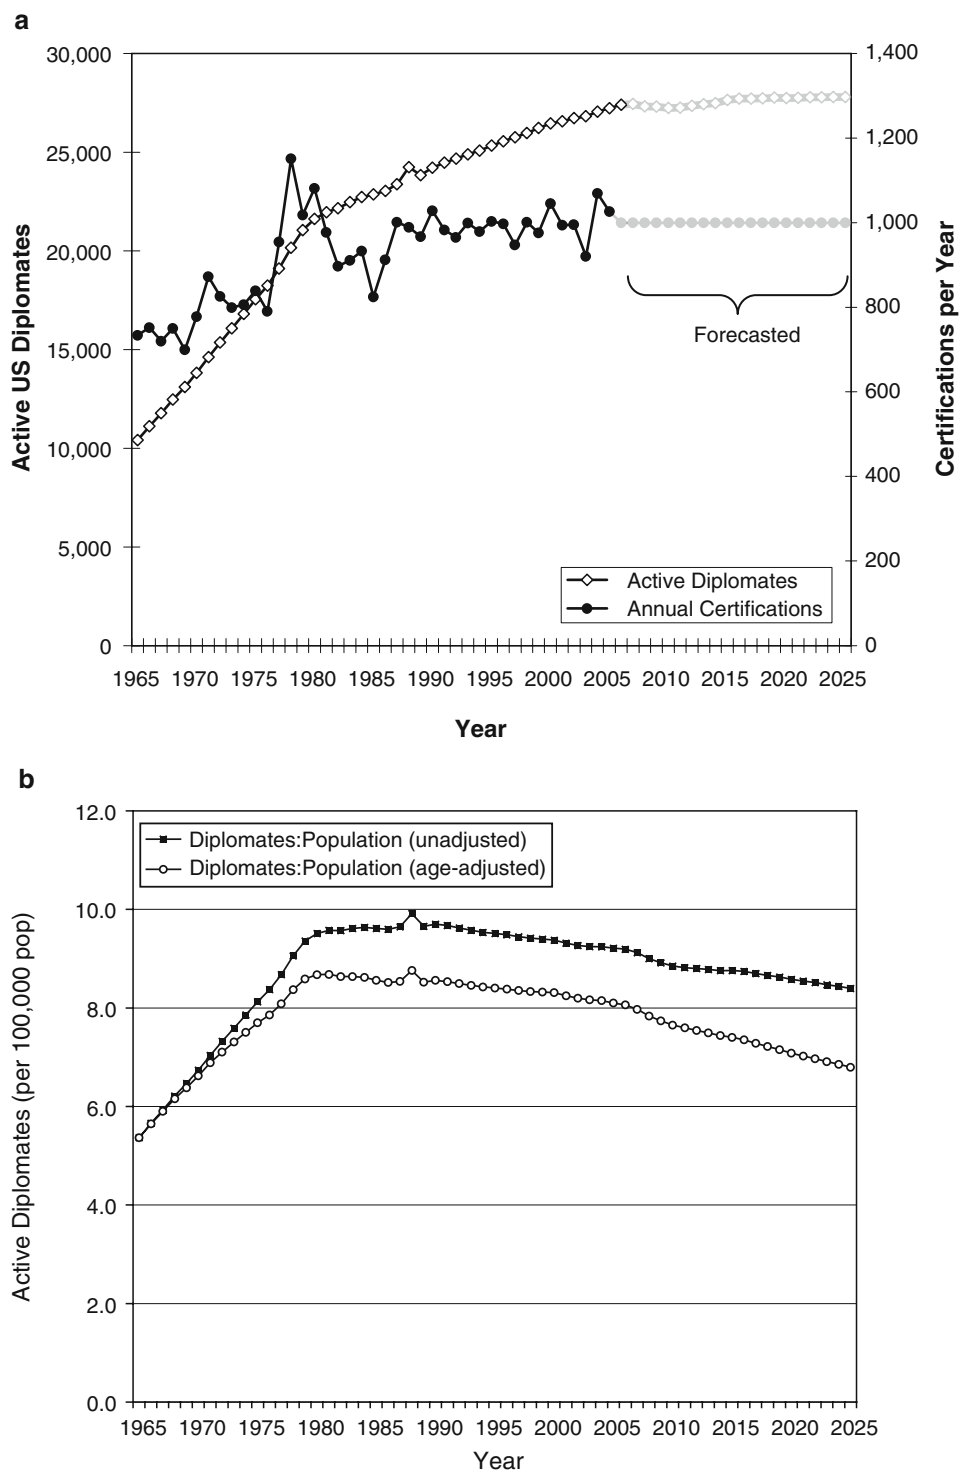

As much as \$700 billion dollars a year in health care services are delivered in the US that do not improve health outcomes.

Peter Orszag, Director of Congressional Budget Office [57].

The \$700 billion figure listed above represents approximately 5% of the GDP. It has been further estimated that reducing the administrative overhead costs associated with healthcare expenditures would save an estimated \$400 billion (2003 dollars) per year [58].

Given these dramatic figures, it seems reasonable to consider ways in which the US health care system might reduce waste and improve the value returned on spent health care dollars. In this section, we will focus on three key areas (access to care, regional variation, and technological change) that are targeted by policy makers in their quest to improve the value and effectiveness of health care, and consider the impact of changes in these areas on the supply and demand for surgical services.

FIGURE 12.11 (a) ABS certifications: 1965–2025; (b) active general surgeons in US: 1965–2025.

Access to Care

Changes in the type of health insurance held by the US population have the potential to dramatically alter the way in which individuals access surgeons and surgical treatment. Two main ways in which this might occur is (1) through increased use of managed care models for health care delivery or (2) through universal (or expanded) health coverage.

The managed care boom of the 1990s led to a growing belief that these new systems would regulate the inefficient and fee-driven use of specialist care. In one controversial prognostication, Weiner et al. in a 1994 *JAMA* article anticipated that the increased use of managed care (to 40–65% penetration) would lead to a 60% surplus of “specialists” in the year 2000 [59]. As with some of the prediction models discussed earlier, these forecasts were based on assumptions that proved erroneous.

In a similar vein, universal health coverage (or simply improved access to health care) has the capacity to nearly instantaneously improve the ability of millions of US residents to access surgical care. What would be the effect of these changes on population-based demand for surgical procedures? In an AAMC report published in 2008, the impact of universal health coverage on the number of full-time physicians was modeled [60]. Their model found a 3.6% estimated increase in the physician workforce. This relatively small effect stems from the fact that the uninsured population is relatively young and healthy. It should also be noted that a significant amount of surgical care for nonelective conditions is already provided to this population through safety-net institutions. Expanded health care coverage may, however, result in increased demand for elective procedures, especially those performed in younger, healthier patients.

The impact of a burgeoning elderly population on Medicare – the primary payor for healthcare delivery for individuals over the age of 65 years in the US – also needs to be considered. In the 2008 annual report, the Social Security and Medicare Boards of Trustees painted a grim picture of the financial health of both of these entitlement programs. Beginning in 2008, the Medicare Hospital Insurance Trust Fund will pay out more in hospital benefits than it receives in taxes and revenues. As more and more baby boomers enter retirement age, this trend will accelerate, and the Medicare reserves may be exhausted before 2020. In 2008 there were an estimated 3.3 workers per retiree; by 2020 this ratio is projected to decrease to 2.1 by 2031 [61]. Several approaches have been proposed to help cope with the emerging problem of funding healthcare for a growing population of retirees. One mechanism that generated initial enthusiasm was the Medicare advantage plans, whereby Medicare beneficiaries could enroll in private health

insurance plans [62]. The privatization of portions of the care provided through the Medicare benefit has thus far failed to produce significant cost savings. Innovative practice plans and chronic disease management models have shown some promise, but not yet sizable enough to make an impact on forecasted deficits. New types of payment models, including the prospective payment system have some benefits, but have resulted in the shifting of in-hospital care to pre- and post-hospital environments. Other proposals, such as the Breaux–Thomas proposed legislation to increase the eligibility of age to 67 or increase co-payments/deductibles have proven politically difficult [63]. It is safe to say that the costs associated with providing healthcare to the aging US population will be an issue of growing importance for politicians, payors, and providers.

Regional Variation in Procedure Utilization

The rate at which physicians provide services to the population varies widely from region to region. This concept of regional variation was originally described by Wennberg and colleagues at Dartmouth, and continues to be a core concern of health policy makers at all levels [64, 65]. The annual Dartmouth Atlas of Health Care uses Medicare data to describe variation in care, and spur health care reform efforts.

Figure 12.12 shows an analysis of publicly available data from the 2005 Dartmouth Atlas, which reports regional utilization using hospital referral regions (HRR) as the geographic unit of interest. Within the Atlas, each patient is assigned to one of 306 HRRs. The boundaries that encompass each HRR are derived based on documenting the referral patterns of

FIGURE 12.12 Regional (HRR) variation by procedure. Data from the Dartmouth Atlas of Health Care 2005.

patients who are referred for major cardiovascular procedures and for neurosurgery. In order to provide some data for a discussion regarding regional variation in procedure use, we will provide some preliminary data analysis.

Broadly speaking, these variations can only be the result of regional differences in either (1) the rates of disease or (2) the patterns of care received, and the extent to which each of these two explanations is responsible for the observed variations is difficult to assess. Why are there differences in the amount of variation between procedures? An elegant answer has been proffered by Birkmeyer et al., who note that procedures where the diagnosis does not linearly lead to a procedure (e.g., peripheral arterial disease \Rightarrow lower extremity bypass) may have greater variation than one where a procedure is the only logical next step (e.g., non-metastatic colon cancer \Rightarrow colectomy) [66].

For many, these variations are the manifestation of physician-induced demand, with subspecialists driving higher rates of potentially unnecessary procedures [67]. The extent to which this phenomenon exists has been hotly debated for decades. Another way of conceptualizing the debate over physician-induced demand is to consider part of the regional variations in rates of care as resulting from differences in the relative rates of underuse and/or overuse of surgical treatment. In moving forward with this concept, some definitions are important:

Overuse: Occurs when a health care service is provided under circumstances in which its potential for harm exceeds the possible benefit

Underuse: Failure to provide a health care service when it would have produced a favorable outcome for a patient

Chassin and Galvin [68]

In determining the potential for a surgical procedure to provide an acceptable ratio of likelihood of benefit to possibility of harm – one estimate of value – the best available resources are evidence-based guidelines developed by professional organizations and consensus panels. The extent to which these guidelines reflect a significant body of evidence is not always perfect, but they are at least a starting point [69].

Generally speaking, it is much easier to accurately assess the presence of overuse than it is to quantify underuse. This is simply due to the availability of the denominator population. In a recent study by Keyhani et al., the appropriateness of tympanostomy tubes for otitis media in five New York hospitals was examined [70]. Of 682 pediatric patients who underwent the procedure, a majority (70%) were considered inappropriate overuse based on existing guidelines. In this study, the denominator population was easily identified – patients undergoing tympanostomy placement. A study examining underuse of tympanostomy tubes would be much more challenging, as it would involve examining primary care physicians' records for all patients with confirmed or

suspected otitis media in a large population. If one was to examine the population-based need for tympanostomy tubes within New York, what would the actual use of the procedure be if there was no (or minimal) underuse or overuse?

Studies examining underuse yield dramatic findings as well. One classic study examined rates of coronary angiography after acute myocardial infarction (MI) within the Veterans Affairs (VA) system and Medicare [71]. The study cohort (denominator population) was defined a needed angiography based on American College of Cardiology guidelines. Cohort patients within the VA system received a needed angiography 43% of the time, whereas those in Medicare 51%.

Why are these types of studies important? As the demand for value in health care delivery increases, so will the expectation that procedure-based specialties justify the work they perform, in terms of outcomes for their patient population.

Technological Advance

The possibility that advancing medical technology will obviate the need for surgical care (and surgeons) is a source of great intuitive appeal and worthy of mention. Rates of surgical treatment for specific disease processes have been dramatically reduced, some nearly eliminated by innovation in medical (non-surgical) treatment. Some examples include peptic ulcer disease, tuberculosis, and coronary artery disease. The war on cancer also appears to be having some significant recent successes in reducing the incidence of certain malignancies, most notably lung, colorectal, breast, and prostate cancer [72].

On the other hand, minimally invasive surgical technology has resulted in a lower clinical threshold to perform specific surgical procedures (e.g., cholecystectomy) [73, 74]. With the increasing use of laparoscopic and other minimally invasive surgical approaches, more latent demand for procedures may be unlocked. Some surgical disease processes are actually becoming much more common (e.g., diverticulitis) [75]. And, surgical treatment is being applied to conditions that may have been historically managed only medically, for example obesity, with an estimated 113,000 inpatient surgical procedures for obesity per year in 2005 (800% increase from 1998) [76].

What is the overall impact of evolving technology on the profile and quantity of surgical procedures? In one study based on California data from 1990 to 2000, Liu et al. quantified trends in the volumes of 32 inpatient surgical procedures [77]. Total procedural volume increased by 20.4%, during a period in which the State population increased by 13.8%. Technological advance has the capacity to increase, decrease, and change the demand for surgical treatment.

Summary: Looking Toward the Future

The task of predicting what health care delivery will look like in the near (or distant) future is potentially foolhardy. In this chapter, we have demonstrated some of the most important variables that need to be considered in estimating the ability of the current and future systems of care to provide treatment to the US population. Despite the obvious difficulty in making accurate predictions and the historical problems with them, there is a growing consensus that the aging of the US population represents a looming crisis. Whatever magnitude of crisis evolves, efforts to minimize its impact on patient care will require action on multiple fronts and at multiple levels.

First and foremost, there is strong evidence that in the future demand for surgical procedures will outstrip the supply of surgeons. Solutions to this emerging problem will need to occur on multiple fronts. Training more surgeons is the most apparent solution, but this can only be part of the answer to the problem. In the immediate and near-term future (10–15 years) growth in surgical training programs can provide only a minimal boost to the active surgical workforce. Other informal pathways, such as allowing trained surgeons from other countries to become licensed in the US after an abbreviated domestic training may have some appeal, but the idea of draining these resources from less developed countries is ethically untoward [27, 78, 79]. In addition to increasing the number of new surgical trainees, attention may need to be focused on retaining those in practice. While the current state of the economy (and most retirement investment portfolios) may cause this even without any policy planning, steps may be taken to encourage physicians to remain in practice. This may call for developing means for surgeons in or near retirement to maintain reduced workloads with only proportionate reductions in professional income. Also, vanishingly little research has been conducted examining the relative efficiency of surgeons employed in private practice vs. academic practice vs. health maintenance organizations. The use of non-physician clinicians may have an important and widening role in enabling surgeons to focus more completely on operative and associated responsibilities and a reduced role in administrative and non-essential clinical activities.

The aging population will result not only in an increased demand for surgical procedures, but also in a different profile of surgical patients. Operations for disease processes specific to older patients will become more frequent, especially orthopedic and spinal operations. Patients will be older and more comorbid, and will require an increased focus on optimizing medical management. A greater partnership with medical hospitalists is already occurring, and will almost certainly continue to grow. In order to care for these patients in a way that provides the greatest benefit to the population

at hand, surgeons need to be proactive in analyzing the outcomes, effectiveness and appropriateness of the surgical treatment provided to elderly patients. Rigorous quality monitoring and improvement efforts are a key part of how our field can rise to meet these demands.

In considering the impact of these forthcoming changes, surgeons of all specialties need to have a seat at the leadership table. The perspective of prominent health care economists envisions the physician workforce *en masse*, and in doing so may completely ignore crises within a particular field. Surgeons of all types will need to ensure that their needs and the needs of their patients are heard.

Chapter 13

Defining Quality of Care in Geriatric Surgery

Marcia L. McGory, Hiroko Kunitake, and Clifford Y. Ko

Introduction

Emphasis on Patient Safety and Quality of Care

Since the Institute of Medicine (IOM) reports *To Err is Human* and *Crossing the Quality Chasm* were released a great deal of attention has been focused on improving both patient safety and the quality of care. The IOM estimates that 98,000 people die per year in hospitals due to preventable medical errors, with higher error rates and more serious consequences occurring in intensive care units, operating rooms, and emergency departments [1, 2]. Surgeons not only care for patients in high-risk environments including intensive care units and operating rooms but also care for high-risk patients who may require a procedure under emergency circumstances or have multiple comorbid medical conditions. These patients are at the greatest risk for adverse outcomes and will likely have the largest benefit from improvements in the quality of health care. Elderly patients undergoing surgery are one example of such a population at risk and therefore attention has been focused on elderly surgical patients and the potential importance of geriatric surgery as a surgical specialty.

The IOM also recently addressed the health-care issues of our aging population through the Committee on the Future Healthcare Workforce for Older Americans in their 2008 report entitled *Retooling for an Aging America: Building the Healthcare Workforce* [3]. The committee proposed three mechanisms for improving the ability of our health-care system to care for older Americans: (1) Enhance the competence of all individuals in the delivery of geriatric care; (2) increase the recruitment and retention of geriatric

specialists and caregivers; and (3) redesign models of care and broaden patient and provider roles to achieve greater flexibility. In addition, the committee noted that although general surgeons treat large numbers of older patients, there is no specific requirement for geriatric training or subspecialty certificate available in geriatric surgery. In contrast, there is a requirement for education in pediatrics within general surgery, as well as the subspecialty of pediatric surgery. The IOM recommendations are timely given the aging of the population and recent research efforts to improve the quality of care for elderly surgical patients.

Quality of Care Definitions

The conceptual framework driving quality improvement is based on the Donabedian model of quality evaluation, where care can be categorized into three types: structure, process, and outcomes [4]. As shown in Fig. 13.1, structural items are thought to influence both process and outcomes. Specifically, structural items include characteristics of the clinician (e.g., board certification), hospital (e.g., staffing patterns, procedure volume), and patients (e.g., insurance type, severity of comorbidities). Process items are the activities that occur between the patient and practitioner. Process refers to whether the medically appropriate decisions are made and whether care is provided in an effective and skillful manner. Outcomes data apply directly to patients and include mortality, morbidity, functional status, and quality of life. With respect to quality of care in geriatric surgery, examples of structural items include presence of a hospital ward designed for elderly patients or presence of a geriatric care coordinator. Examples of process items unique to geriatric surgery may include co-management of a geriatric surgery patient by a geriatrician or internist, and preoperative completion of a comprehensive geriatric assessment (CGA). Examples of outcomes unique to the geriatric surgery population may include postoperative delirium, change in functional status, and discharge to a skilled nursing facility.

The Impact of the Aging Population

The aging of the US population will place significant stress on the current health-care system. According to the US Census Bureau, in the last century the rate of growth of the elderly population (aged 65 and older) greatly exceeded the growth rate of the population as a whole. Between 1900 and 1994, while the total population tripled, the elderly population increased by a factor of 11. This rapid growth is expected to continue. In 2010, the elderly are predicted to account for 13% of the US population but by 2050 the elderly will comprise 20% of the US population. In addition, the elderly population is responsible for a disproportionate amount of health-care utilization and cost. According to the National Hospital Discharge Survey in 2006, patients aged 65 years and older contributed to 38% of hospital discharges and 43% of days of inpatient care [5].

The impact of the aging population has become especially apparent within the surgical disciplines. The field of surgery is undergoing a largely unrecognized paradigm shift due to the expanding and aging population in combination with an increasing emphasis on patient safety and quality of care. Patients aged 65 and older currently make up 60% of cases within general surgery and this is expected to increase 13% by 2010 and 31% by 2020 [6]. The impact of the aging population will be even more significant in some of the surgical subspecialties. The proportion of work performed on patients aged 65 and older is highest for ophthalmology (88%), cardiothoracic surgery (70.3%), and urology (64.8%) [6]. The anticipated increases in the number and proportion of elderly surgical patients are likely due to multiple factors – not only has the elderly population increased in absolute numbers, but the threshold for performing surgery in the elderly has likely decreased with time [7]. These two factors will significantly increase the demand for surgical services and surgeons must develop strategies to maintain high quality care despite an increased and increasingly complex workload.

While the performance of the surgeon may largely be identical in the operating room with respect to surgical technique, there are a significant number of unique aging-related issues that must be addressed when caring for an elderly surgical patient. The potential needs of an elderly surgical population include increased attention to preoperative risk assessment, explicit communication with the patient and family regarding functional outcomes, and an emphasis on postoperative rehabilitation. The new focus on patient safety and quality no longer revolves solely around conventional

surgical morbidity and mortality but probably should include the equally important issues of quality of life and return to preoperative level of functioning for the elderly surgical patient. The combination of these forces has created significant demand for the development of a new model for elderly surgical care which would improve efficiency and provide optimum care for this vulnerable population.

Unique Processes of Care and Outcomes in Geriatric Surgery

One of the first steps to improve the quality of care in geriatric surgery revolves around the concepts of preoperative assessment as well as prevention of perioperative complications. The comorbid disease burden is higher in elderly patients and in combination with decreased physiologic reserves requires closer attention to preoperative assessment and optimization of cardiovascular, pulmonary, renal, and endocrine status. Prevention of untoward events (e.g., infection, myocardial ischemia, delirium) should become the emphasis for this vulnerable population. In addition, preoperative assessment should not be limited to traditional comorbid disease but should extend to include geriatric issues such as cognitive impairment, malnutrition, risk of falls, and pressure ulcer development. Assessment of baseline functional, nutritional, and cognitive status will not only guide the perioperative care of the elderly patient but may influence patient–provider discussions regarding the aggressiveness of surgical intervention. Appropriate goals of surgery may range from palliation of malignant bowel obstruction to curative colorectal cancer resection. Further work is needed to identify processes of care unique to the geriatric surgery population that address preoperative assessment, optimization of comorbidities, and prevention of complications.

The second step to improve the quality of care in geriatric surgery may involve expanding the traditional outcome measures in surgery (e.g., morbidity and mortality) to include items that emphasize quality of life, functional outcomes and symptoms rather than solely prolongation of life. This move to identify such outcomes would highlight and emphasize the importance of these priority issues in the geriatric patient. The typical definition of postoperative morbidity might be expanded to include such postoperative events as episodes of postoperative delirium, in-hospital falls, development of pressure ulcers, and maintenance vs. decline of functional or cognitive status. One of the primary outcomes of interest after surgical intervention in the elderly population could also be return of the patient to their previous environment as well as their functional level prior to surgery. Therefore, the location of discharge after surgery (e.g., home vs. skilled nursing facility) as well as the functional status as measured

by activities of daily living (ADL), instrumental activities of daily living (IADL), or ambulation might be important to include as outcomes for the elderly patient undergoing surgery.

Potential Mechanisms for Improving the Quality of Elderly Surgical Care

The discipline of geriatrics is becoming an important part of the daily perioperative care of elderly patients on the surgical ward which has implications for how to restructure the surgical unit and train and teach both surgeons and other health-care providers. A multitude of tools exist for restructuring surgical training and include involvement of the surgical boards and societies, pay-for-performance, the use of risk-adjusted outcomes, voluntary restructuring of the way we care for surgical patients, and feedback.

First, surgical boards and societies may need to become more directly involved with this paradigm shift. Similar changes have been performed in the field of Internal Medicine. The Residency Review Committee for Internal Medicine (RRC-IM) of the Accreditation Council for Graduate Medical Education (ACGME) recently proposed an outcomes-based accreditation strategy which shifts the emphasis from an external audit of education to a continuous assessment and improvement of the trainee's clinical competence [8]. The overarching goal of the change in the accreditation process of residency programs is to ensure that the emphasis on quality of care is also translated into quality of training [9]. Similar opportunities exist for surgical boards and societies to become leaders in this necessary paradigm shift. A partnership between the American College of Surgeons (ACS) and the American Geriatrics Society may help to address the necessary training and education issues of this intersection between the fields of geriatrics and surgery. Certainly, the Residency Review Committee (RRC) and ACGME are important in these endeavors as well. The ACS has already identified geriatric surgery as an important topic area through the development of a Geriatric Surgery Task Force, development of an online web portal with a geriatric surgery community, and identification of potential "geriatric-specific" variables for inclusion in the ACS National Surgery Quality Improvement Program (NSQIP) in order to help measure and improve the quality of care for geriatric surgery. More collaborative efforts of groups such as these are needed if we are to make headway with a paradigm shift toward the uniqueness, necessity, and importance specific to geriatric surgical care.

A second tool includes the potential use of incentivization for better care, or what is more commonly known as pay-for-performance. The Center for Medicare and Medicaid Services

(CMS) is currently performing a Hospital Quality Incentive demonstration project utilizing widely accepted process and outcome measures for the conditions of acute myocardial infarction, heart failure, pneumonia, coronary artery bypass graft, and hip and knee replacement. Hospitals scoring in the top 10% for a given condition will receive a financial bonus while hospitals scoring in the second 10% receive a lesser bonus [10]. Potentially, Medicare could opt to reward hospitals for the presence of structural items such as a geriatric care unit or process items such as adherence to geriatric surgery-related process measures (see below), or even outcomes. To date, many of the quality metrics in surgery are derived from the Surgical Care Improvement Project (SCIP), which has identified specific process measures related to surgical site infection, thromboembolism, cardiac complications, and ventilator associated pneumonia. What has been demonstrated is a substantial increase in process measure adherence – from around 40% adherence at the start of the project – to rates well above 80%, with many measures gaining adherence above 90%. Identifying important measures whether structural, process, or outcomes, goes a long way toward recognition and improvement.

A third tool includes the use of risk-adjusted outcomes. The current prototype for the assessment of risk-adjusted surgical outcomes is the Department of Veterans Affairs (VA) NSQIP, an ongoing quality improvement program that relies on the accurate and timely collection of prospective data by trained clinical nurse reviewers. The analysis of data within NSQIP provides the information necessary to create predictive models for morbidity and mortality for specific surgical procedures as well as compare the expected and observed numbers of deaths/complications across VA hospitals [11]. Since the inception of NSQIP in the mid-1990s, the 30-day mortality rate in the VA Medical Centers has decreased by 27% and the 30-day morbidity has decreased by 45%. These results demonstrate the usefulness of providing risk-adjusted outcomes as a benchmark, which assists with identification of areas for surgical quality improvement.[12]

Similarly, the ACS NSQIP has demonstrated that providing risk-adjusted outcomes also results in improvement in private sector hospitals. For example, an analysis of the most recent 3 years of data shows that 66% of hospitals were able to reduce their risk-adjusted mortality rates while 83% of hospitals reduced their risk-adjusted complication rates. Prior internal analyses by the ACS has also demonstrated interesting results regarding risk-adjusted outcomes in the elderly. While it is not surprising that the elderly had up to three times higher rates of complications and up to 20 times higher rates of mortality compared to nonelderly cohorts, it was interesting to note how the complications differed between the elderly and nonelderly. Specifically, the rates of surgical site infection, thromboembolism, postoperative bleeding, and return to the OR did not differ by age while the

elderly had significantly higher rates of acute myocardial infarctions, pneumonias, unplanned reintubations, urinary tract infections, and renal failure. These specific complications may lend themselves to identifying important processes of care to reduce these untoward events. Further stratification by age as part of the risk-adjustment analysis may also help identify procedures and age groups (e.g., octogenarians) with the most variability in morbidity and mortality which could potentially lead to large improvements in the outcomes of surgical procedures performed in the elderly [13].

A fourth option is a voluntary restructuring of the way we take care of surgical patients. In the traditional surgical model, surgeons often round on their patients twice a day while the nursing staff traditionally has been trained to a large degree to care for the technical aspects of the patient's post-op recovery. A new model for elderly surgical care may be required which incorporates more of a collaborative team approach with the integration of providers including surgeons, anesthesiologists, geriatricians, general internists, medical specialists, rehabilitation medicine, and nursing. Additional services will also play a critical role including physical/occupational therapists, nutritionists, and others. The team approach is central to the success of this model because the elderly surgical patient often brings a complex mix of both medical and surgical comorbid disease in addition to a variable level of functionality with respect to cognition, ambulation, and degree of independent self-care. Few, if any, single providers can give the optimal care needed for an elderly patient undergoing a major surgical procedure and completely address the interwoven issues of nutrition, cognition, rehabilitation, management of comorbid disease burden and postoperative surgical care. The prevention of postoperative delirium, for example, may include specialized nursing care with minimal use of restraints and specialized equipment for hearing or visual impairment. Physical and occupational therapy may start in the immediate postoperative period with specific goals set based on the results of the preoperative functional assessment. Specialized geriatric care units could increase the role for the elderly patient's family in the preoperative, in-hospital, and postdischarge aspects of care. Physicians should probably limit certain medications such as narcotics. Family assistance with self-care and rehabilitation while the elder is in the hospital can ultimately facilitate the discharge planning process and transition to home.

However, none of these options for implementation of a new model for elderly surgical care will likely be as successful without some sort of level of feedback mechanism (transparent or not) to return information to the providers and hospitals. The concept of quality improvement relies on the return of information to the provider so that outcomes are acknowledged (e.g., rates of postoperative delirium, percentage of patients with a change in functional status requiring

discharge to a skilled nursing facility), improvements are noted and changes can be implemented.

Current Research on Geriatric Surgery Quality of Care

A review of the literature demonstrates multiple ongoing research efforts on the topic of geriatric surgery quality of care. Potential mechanisms for quality improvement include the use of quality indicators specific to geriatric surgery, preoperative assessment of geriatric surgery patients, co-management of these patients by geriatricians, a geriatric surgery consult service for nursing home patients and nursing programs focused on the needs of hospitalized elderly patients.

The first avenue of research to improve geriatric surgery quality of care is the development of quality indicators. Health-care regulatory agencies are now beginning to use quality indicators, defined as process measures that signify or result in higher quality, to measure quality of care. CMS and JCAHO are using quality indicators to evaluate care in nonsurgical diseases but the main reason for their lack of use in the surgical domain is that appropriate surgery-related quality indicators are still being developed. The quality of medical care for the elderly population has been the target of a significant amount of research through the RAND Health Assessing Care of Vulnerable Elders (ACOVE) project [14, 15]. The most recent update to the ACOVE project specifically identified quality indicators for elderly surgical patients including quality indicators for hospitalization and surgery in vulnerable elders [16] and quality indicators for the treatment of colorectal cancer in vulnerable elders [17].

In another effort to identify both necessary and important process measures that must be performed when taking care of an elderly surgical patient, McGory et al. gathered a twelve member expert panel consisting of physicians in surgery, geriatrics, anesthesia, internal medicine, pulmonary and critical care, and rehabilitation medicine to identify important processes of care for elderly patients undergoing major abdominal surgery [18]. The validity of the process measures was assessed using a modification of the RAND/UCLA Appropriateness Methodology [19–25]. Eighty-nine candidate indicators were identified and categorized into seven domains: comorbidity assessment (e.g., cardiopulmonary disease), elderly issues (e.g., cognition), medication use (e.g. polypharmacy), patient-to-provider discussions (e.g., life-sustaining preferences), intraoperative care (e.g., preventing hypothermia), Postoperative management (e.g., preventing delirium), and discharge planning (e.g., home health care). Of the 89 candidate indicators, 76 were rated as valid by the expert panel. Importantly, the majority of indicators rated as

valid address processes of care not routinely performed in younger surgical populations (Table 13.1). Currently, with support from the National Institute on Aging, this research group is attempting to identify process measures that are applicable to all of inpatient elderly surgery (rather than just major abdominal surgery) in addition to elderly specific structure and outcome measures.

A second avenue of research involves the comprehensive preoperative assessment of elderly surgical patients. The preoperative assessment in elderly cancer patients (PACE) was a prospective study of patients 70 years and older undergoing

elective cancer surgery [26]. PACE components included a mini-mental state exam (MMSE), ADLs, IADLs, Geriatric Depression Scale (GDS), brief fatigue inventory (BFI), performance status, American Society of Anesthesiology Scale (ASA), and Satariano's index of comorbidities (SIC). Multivariate analysis demonstrated that IADL, BFI, and ASA were the most important components of PACE to explain postsurgical complications. Further work is needed to determine if PACE can predict postoperative outcomes including length of stay, morbidity, and mortality. Similarly, Harari et al. evaluated proactive care of older people undergoing

TABLE 13.1 Process measures unique to the elderly undergoing surgery vs. perioperative care items universal to all surgical patients

Domain of care	Process measures unique to elderly undergoing surgery	Process measures universal to all surgical patients
Comorbidity assessment	Complete standardized cardiovascular risk evaluation per ACC/AHA guidelines Estimation of creatinine clearance	Standardized preoperative lab panel Pulmonary physical exam/review of systems Obtain history of diabetes Assess use of tobacco/alcohol Smoking cessation
Evaluation of elderly issues	Screen for nutrition, cognition, delirium risk, pressure ulcer risk Assess functional status including ambulation, vision/hearing impairment, and ADLs/IADLs Referral for further evaluation for impaired cognition or functional status, high risk for delirium, or polypharmacy	Not applicable
Medication use	Indications for inpatient bowel preparation Evaluation of medication regimen and polypharmacy Avoid delirium-triggering medications and other potentially inappropriate medications (e.g., Beers criteria)	Instruction on preoperative medication management Perioperative beta blockade Intravenous antibiotic prophylaxis Endocarditis prophylaxis Deep venous thrombosis prophylaxis
Patient-provider discussions	Assess patient's decision-making capacity Specific discussion on expected functional outcome, life-sustaining preferences, and surrogate decision maker	Informed consent about treatment options, and risks/benefits of surgery Treatment preferences (e.g., do not resuscitate) should be followed
Intraoperative care	Not applicable	Prevent hypothermia Proper positioning
Postoperative management	Prevent malnutrition, delirium, deconditioning, pressure ulcers Daily screen for postoperative delirium and standardized workup for delirium episode Make staff aware if hearing/vision impairment Patient access to glasses, hearing aid, dentures Consider home health for assistance for ostomy care Infection prevention with daily assessment of central line and indication for use, early foley catheter removal, and standardized fever workup	Appropriate restraint use Measure daily input/output Aspiration precautions Use of incentive spirometer Use of translator or interpreted materials for deaf or non-English speaking Education about ostomy self-care Pain assessment with each set of vital signs
Discharge planning	A discussion with the patient or caretaker about purpose of drug, how to take it, and expected side effects/adverse effects for all medications prescribed for outpatient use Assess social support and need for home health prior to surgery Assess nutrition, cognition, ambulation, and ADLs prior to discharge	A complete list of medications and dosages to continue upon discharge from the hospital Assess need for medical equipment, home health, skilled nursing facility prior to discharge Written and oral discharge instructions Discharge summary to indicate follow-up labs, tests, appointments Follow-up visit within 6 weeks Communication to primary-care doctor

Source: Reprinted with permission from [17]. Copyright Elsevier 2005

elective surgery (POPS), a CGA service for older elective surgical patients [27]. The POPS team consisted of a geriatrician, geriatric nurse specialist, physical and occupational therapists, and social worker. The preoperative assessment included the abbreviated mental test score, GDS, Barthel index, timed up and go, 180° degree run, body mass index, continence screen, orthostatic blood pressure, numeric pain score, and peak expiratory flow rate. A comparison of outcomes before and after the POPS intervention revealed significantly decreased rates of delirium, pneumonia, wound infection, uncontrolled pain, presence of a urinary catheter for more than 4 days without indication, pressure sores, bedridden patients, and length of stay.

A third avenue of research is the use of a dedicated geriatric service for the co-management of geriatric surgery patients. Friedman et al. evaluated the outcomes of a geriatric fracture center co-managed by orthopedic surgeons and geriatricians [28]. The principles of the geriatric fracture center included the following: (1) most patients benefit from surgical stabilization of the fracture; (2) timely surgical intervention decreases the time in the hospital for development of iatrogenic illness; (3) co-management and frequent communication between the orthopedic surgery and geriatric teams decreases iatrogenesis; (4) standardized protocols decrease variability in care; and (5) discharge planning starts at the time of admission. During a 1-year time period, the geriatric fracture center managed 195 patients. The average time to the operating room was 24.1 h, length of stay was 4.6 days (expected length of stay was 5.2 days using a large health-care database that determined expected outcomes while adjusting for patient characteristics), readmission within 30 days was 9.7% (expected 19.4%), and in-hospital mortality was 1.5% (expected 3.2%). Similarly, Fallon et al. evaluated the outcomes of geriatric trauma patients when evaluated by a geriatrician within 24 h of admission [29]. A standardized geriatric trauma consultation was utilized which included the following components: demographics, clinical information (e.g., trauma mechanism, primary and secondary diagnoses), physical function (e.g., ADLs, ability to ambulate), cognitive function (e.g., orientation-memory concentration exam, MMSE, confusion assessment method), mood (e.g., geriatric depression scale), medications (focus on potentially inappropriate medication), and pain control. In addition to providing input on geriatric trauma patient management, the geriatric trauma team participated in weekly multidisciplinary rounds as well as monthly performance improvement meetings. During a 1-year time period, 114 out of 285 geriatric trauma patients were seen in consultation by the geriatric trauma team. The most common issues addressed by the geriatricians were pain control, rehabilitation, delirium/dementia, hypertension, and decreased use of adverse drugs. The geriatric trauma patients seen by geriatricians had higher rates of discharge to rehabilitation and a

statistically significant lower mortality rate (4% vs. 18%). Both of these studies clearly demonstrate the benefits of geriatric assessment and co-management for two diverse patient populations (hip fracture and trauma) suggesting that routine geriatric co-management should be an essential component of improving the quality of care in geriatric surgery.

A fourth avenue of research is the use of a geriatric surgery consult service for frail nursing home patients requiring surgical intervention. This model was evaluated by Zenilman et al. [30]. Maintenance surgical care included monitoring of pressure ulcers, stomas, and enteral feeding tubes. However, abdominal, breast, and vascular disease were also commonly treated. The goals and indications of consultation for surgical intervention in an elderly patient vary widely and must be explicitly stated. The goals of surgery could potentially range from palliation to curative resection. Common procedures such as placement of a feeding tube may be secondary to severe malnutrition, cognitive decline (severe dementia), or loss of the ability to care and feed oneself. In addition, many procedures such as those relating to access (e.g., enteral, vascular) or wound care may be chronic in nature. The success of a geriatric surgery consult service depends on the ability to focus on the patient's goals for treatment rather than solely on a surgical cure.

Finally, a fifth avenue of research is the development of a nursing program that specifically addresses the needs of hospitalized geriatric patients. Nurses Improving Care for HealthSystem Elders (NICHE) was developed through the Hartford Institute for Geriatric Nursing at New York University College of Nursing. Components of NICHE include a geriatric institutional assessment profile, staff development tools, nursing care models (e.g., use of a geriatric resource nurse and acute care of the elderly unit model), and research-based clinical protocols (e.g., improving detection and management of delirium). Boltz et al. evaluated the changes in the geriatric care environment associated with NICHE in a sample of eight acute care hospitals in the USA [31]. After NICHE implementation, both perceptions of the geriatric nursing practice environment by nurses and the quality of geriatric care increased. This research is vitally important because of the important role of nurses as part of the team approach to delivering high quality geriatric care.

Conclusion

Just as pediatric surgery became a specialty unto itself, the expanding and aging population has created a potential niche for the specialty of geriatric surgery at the opposite end of the age spectrum. The field of geriatric surgery may indicate a focus on elderly patients for the surgeon, but more importantly the specialty of geriatric surgery represents a

collaboration between surgeons, geriatricians, internists, and many other health-care providers who together will address the complex interdisciplinary issues unique to the growing elderly surgical patient population. A great deal of effort is currently being spent on the means of improving the quality of care for geriatric surgery patients through the process measures of developing appropriate quality indicators, improving preoperative assessments and collaboration between surgeons and geriatricians in novel ways such as co-management of elderly surgical patients and surgical consult services in nursing homes. However, to evaluate the quality of care for these elderly surgical patients we must have quality metrics. One possibility is to use adherence to process measures as representative of quality. However, adherence to these process measures may not correlate well with the outcomes of lower morbidity and mortality and improved quality of life which are the ultimate goals of the patient and providers.

Another option is to use outcomes to measure quality – the question becomes which outcomes should we employ to evaluate the quality of elderly surgical care? Should we use traditional outcomes such as mortality and complications or patient reported items such as quality of life and functional status? An important limitation to the use of any quality metric is the ability to measure the quality metric. Some outcomes such as mortality are easily quantified and measured while others such as quality of life are difficult to define and evaluate. And with all quality measures, are there potential unintended consequences to their use as a quality measure? If we decide to use urinary tract infection as a quality measure, is everyone then required to have a urinalysis or urine culture to ensure there is no urinary tract infection? Finally, when we decide on our quality measures, who will be held responsible for the quality of care – the surgeon, the geriatrician, or one of the many other members of the team caring for the elderly surgical patient? Certainly, there are a number of issues to address with the use of quality metrics, but progress in evaluating and improving geriatric surgical care should not be stalled.

Defining quality of care in geriatric surgery is an evolving process with many yet unresolved issues. However as increasing attention and effort is focused on the growing population of elderly surgical patients, we will better understand how to improve and define the quality of surgical care for this unique patient group.

Chapter 14

Ethics in Clinical Practice

Margaret Drickamer

Introduction

Normative ethics addresses the criteria or standards by which we judge whether an action is considered to be right or wrong. Medical ethics is built on a utilitarian ethical structure; it bases what we *ought* to do on competing principles that are applied in the context of the clinical setting and not on overarching deontological moral imperatives. The guiding principles of American medical ethics are those of respect for autonomy, nonmaleficence, beneficence, and justice (Table 14.1). Autonomy is defined as the right to self-determination, the right to make one's own choices. The principle of nonmaleficence, often equated with the phrase *primum non nocere*, first do no harm, is better described as the obligation not to knowingly do harm by either an action or the omission of an action. Beneficence is the act of doing the most possible good; to take the action which will result in the most beneficial outcome for the patient. Justice, in the context of health care, refers to equality of medical treatment and the access to care. For any given clinical situation, the application of each of these principles may give different answers to what is right or wrong [1].

Weighing these competing principles in cultural, societal, and the individual contexts may lead to different actions. Not all cultures approach ethics in the same manner. For example, some religion-based cultures may feel that there are specific rules or god-given imperatives that may never be compromised and therefore all competing interests are secondary. The relative value of the four stated principles may be different for someone in a family-centered culture where individual autonomy may be less important than it is for American culture [2]. In this chapter, we discuss how these principles are applied in modern, mainstream American medicine with a special focus on the geriatric population.

Appropriate treatment of the geriatric patient involves a shift in perspective and priorities. The physician must recognize the multifactorial nature of illnesses, the need to fully understand the goals of care prior to initiating workup, and the need to continually review these goals as events unfold. Most illness states in older patients do not follow the paradigm of a unifying pathologic event. There may be many factors that need to be identified and addressed; factors that have predisposed the individual to the event, changes that have precipitated the event, and consequences of the situation. With age, the patient's perspective on the relative values of quantity and quality of life may change. A patient might wish to live a full, vital life to the age of 100, but may not want to merely survive that long in an incapacitated state. What is seen as a benefit, what weighs heavier as a burden, or what risks that individual is willing to take may change with time and experience.

Truth-Telling

The principle of nonmaleficence has, for millennium, been cited to justify the withholding of "bad news" from patients. The edict to withhold bad news was little challenged until the 1950s when the validity of this assumption came under scrutiny. In surveys conducted during the late 1950s and early 1960s, less than one-third of responding physicians stated that they always tell the truth to their patients about the diagnosis of cancer [3]; and in one survey 69% stated that they usually do not or never tell the patient the diagnosis of cancer [4]. By 1979, a similar survey revealed that 97% of responding physicians thought that a patient should be told the diagnosis of cancer [5].

This profound shift in practice in less than 20 years reflects both advances in medical knowledge and shifts in the emphasis in medical ethics. The development of treatment options for cancer initially drove this shift in communication. Patients could not undergo chemotherapy or irradiation unless they consented to the treatment and in order for them to be able to consent they needed to be informed of their diagnosis.

TABLE 14.1 Definitions in medical ethics

Respect for autonomy	Maximize the individual's ability for self-determination
Nonmaleficence	Do no harm by direct action or negligence
Beneficence	The weighing of benefits, risks, and burdens for the greatest good
Justice	The fair and equitable distribution of resources, greatest good for the greatest number of people

In this case, recognizing the patients' autonomous right to choose treatments, or to forego treatments, was felt to be stronger than what was perceived to be the avoidance of the catastrophic harm that would be done by telling them their diagnosis (nonmaleficence). Interestingly, disclosure of information has not been found, in and of itself, to do harm. It does, in fact, allow the patient to discuss their goals and preferences more fully, as well as their emotional reactions, and to plan how they wish to approach this phase of their life.

Even when treatment options are still limited or nonexistent, as is the case with patients diagnosed with Alzheimer's disease, the weight of the argument is in favor of autonomy and therefore for truth-telling [6]. As we place an increasing emphasis on advance health care planning, the obligation to inform patients while they are capable of making decisions about their own future has become paramount. This is especially true when there is a risk of the patient becoming incapable of participating in decision-making, whether the patient is in the early stages of cognitive decline or facing the possibility of complications during surgery which might render them incapable of decision-making.

Older patients may have their right to know their diagnosis subverted by family members who feel that the patient would be unable to handle by knowing the information. On occasion, because of cultural values or for other personal reasons, a patient may not wish to be told a diagnosis. Patients may waive their right to be informed, but this must be an explicit decision between the patient and the physician [7]. Surveys have shown that 90–95% of elderly patients would want to know their diagnosis if they have cancer, which is not different than the percentages for younger patients.

Informed Consent

Every adult patient who has decisional capacity has the right to accept or decline any treatment that is offered. Informing the patient of the benefits, side effects, and alternatives of even common and simple therapies (such as medications) is the first step toward the patient's consent as represented by their compliance with that therapy [8]. The process of informed consent when obtaining consent for invasive procedures is

TABLE 14.2 Principles of informed consent

Assess the patient's ability to understand the consequences of the decision
If the patient is incapable, identify an appropriate surrogate
Document the goals/values of the patient (or surrogate) expressed as the most important for the decision
Explain how the goals would be affected by the benefits/burdens/risks of the intervention
Document the decision and those present for the discussion

TABLE 14.3 Proposed communication skills for discussing evidence with patients

Ability to communicate complex information using nontechnical language
Tailoring the amount and pace of information to the patient's needs and preferences
Drawing diagrams to aid comprehension
Considering the values of the patient while weighing choices
Explanation for the probability and the risk for each option
Facilitative skills to encourage patient involvement
Evaluation of internet information that patients might bring to them
Creating an environment in which patients feel comfortable to ask questions
Giving patients time to take in the information
Declaration of equipoise when present
Checking patient understanding
Negotiation

much more complex, but the same principles hold true (Table 14.2). The patient must understand the benefits of the procedure and the possible risks and burdens associated with it. The patient should also be informed of the benefits, risks, and burdens of all alternative therapies, including doing nothing. The quality of this discussion is as important as the content [9] (Table 14.3) [10]. Long lists of unlikely complications may not serve a useful purpose [11]. The discussion should be based on patients' values, fears, and goals and should inform them about the risks that either are common or, although rare, devastating. Documentation of the discussion should reflect the entire discussion, including the basis on which patients agreed or declined intervention and their ability to make the decision.

What information individual patients will want to know about their condition and possible treatments may differ with age. The 5-year prognosis may no longer be of as much significance as the quality of life to be had with different treatment options. The trade-offs between the burden of an intervention and its benefits will shift with different patient priorities [12]. An older person, or their surrogate, may wish to forego a diagnostic workup if they have already decided that they would not act on that information even if it was positive for disease. For example, a 90-year-old patient with multiple other medical conditions may decide to forego a

biopsy of a lung lesion, having decided that she would not agree to surgery, radiation, or chemotherapy.

Many interventions other than those traditionally referred to as invasive are now requiring formal informed consent. The use of physical and chemical restraints in psychiatric and long-term care settings requires documentation of acceptance either by the patient or a surrogate. Appropriately informing patients of the meaning (i.e., positive and negative predictive value) of screening tests has been a recent focus, especially for cancer screening, in view of the patients' prognosis and preferences.

The corollary to a patient's right to informed consent is their right to decline treatment. In the 1991 case, *Cruzan v. the State of Missouri* the US Supreme Court ruled that patients have a right to refuse interventions and expanded this to include the right to refuse treatment for future care [13]. Chief Justice William H. Rehnquist wrote that a competent patient has a "constitutionally protected liberty interest in refusing unwanted treatment." The ethical conflict that the practitioners find themselves in is between the autonomous right of the patient to choose and practitioner's wish to do what they see as beneficent or nonmaleficent. This conflict often causes discomfort in the clinical setting. For example, a patient may choose to decline the repair of an abdominal aortic aneurysm despite what the physician knows is a very high risk of rupture and death.

The patient may decline a treatment before the intervention has been initiated or after it has been instituted. There is no legal or ethical distinction made between discontinuing and not initiating the same intervention [14], although frequently there is a stronger emotional component to the former. For example, if a patient has end-stage kidney disease and opts to forego dialysis, he or she will die from uremia. If patients who have been on dialysis for a period of time decide to stop dialysis, they too will die from their kidney disease.

Two areas often present a particular difficulty in the clinical setting: the discontinuation of ventilatory support and the discontinuing or noninitiation of artificial food or hydration. The discontinuation of ventilatory support parallels that of dialysis. The intervention has been instituted to maintain the patient through artificial means because of the failure of a vital organ to function. The patient will die from the effects of the underlying disease and resultant organ failure [15]. The conflicts cited in the case of discontinuation of ventilatory support are threefold: (1) that it is an active act (an act of commission) versus a passive act (act of omission) causing the demise of the patient; (2) that the proximity of the action to the death of the patient causes discomfort for the person stopping the ventilator; and (3) that the physician may not have a comfort level with palliation of the symptoms that may occur when ventilatory support is discontinued.

Much has been made of the arguments of "passive" versus "active" acts. Neither the legal nor the ethical literature

supports it as a valid distinction [1], but it can make a major difference in the physician's level of comfort. Although the proximity of an action to the patient's death is uncomfortable for the physician, the need to discontinue invasive treatments for a patient who does not desire them is the more compelling duty. Being familiar with a routine of dignity and comfort care at the time of withdrawal of ventilatory support is crucial.

Discontinuing or foregoing artificial food or hydration in a dying patient also may cause discomfort on the part of physicians or patients' families, but not necessarily to the patients themselves [16]. Neither nutrition nor fluid support is necessary for comfort care, and there is evidence that fluids near the end of life cause discomfort by increasing secretions and suppressing the patient's endogenous endorphin responses. The duty to withhold artificial food and hydration if it is the patient's wish has been upheld in both state and federal courts and was confirmed in the *Cruzan* case. See the section below on "Decisions Near the End of Life" for more discussion of this topic.

Assessment of Decisional Capacity

Decisional capacity refers to the patients' ability to understand the consequences of the decision they are making, to make that decision, and to communicate the reasons for the decision. Understanding the consequences of the decision includes both the ability to understand the relevant information and to appreciate the situation and the impact of the decision [17, 18] (Table 14.4). Decisional capacity is decision specific, i.e., there are different standards of decisional ability needed to make different types of decisions (e.g., medical or financial) as well as different levels of complexity involved in the decision (e.g., simple procedure versus a complex procedure).

The ability to understand may be impaired because of temporary conditions such as delirium, transient coma, intoxication, or depression; or it may be permanently impaired by cognitive damage or psychiatric illness. Whatever the cause of the impairment, the key to the determination of capacity is the patient's ability to comprehend the advantages and disadvantages of treatment options and to make a decision. Whether we believe that the patient's decision is rational is not a determinant of capacity. Our society allows people to make what most would label as "irrational" decisions but, as part of our respect for autonomy, we cannot force what we would see as the right decision on others [19]. For example, we cannot prohibit alcoholics from drinking, even when it has been shown to impair their health or shorten their longevity. Patients' religious or ethnic beliefs may conflict strongly with our own beliefs, but they have the right to refuse any treatment option they believe is in conflict with their beliefs.

TABLE 14.4 Legally relevant criteria for decision-making capacity and approaches to assessment of the patient

Criterion	Patient's task	Physician's assessment approach	Questions for clinical assessment*	Comments
Communicate a choice	Clearly indicate preferred treatment option	Ask patient to indicate a treatment choice	Have you decided whether to follow your doctor's [or my] recommendation for treatment? Can you tell me what that decision is? [If no decision] What is making it hard for you to decide?	Frequent reversals of choice because of psychiatric or neurologic conditions may indicate lack of capacity
Understand the relevant information	Grasp the fundamental meaning of information communicated by physician	Encourage patient to paraphrase disclosed information regarding medical condition and treatment	Please tell me in your own words what your doctor [or I] told you about: The problem with your health now The recommended treatment The possible benefits and risks (or discomforts) of the treatment Any alternative treatments and their risks and benefits The risks and benefits of no treatment	Information to be understood includes nature of patient's condition, nature and purpose of proposed treatment, possible benefits and risks of that treatment, and alternative approaches (including no treatment) and their benefits and risks
Appreciate the situation and its consequences	Acknowledge medical condition and likely consequences of treatment options	Ask patient to describe the views of medical condition, proposed treatment, and likely outcomes	What do you believe is wrong with your health now? Do you believe that you need some kind of treatment? What is the treatment likely to do for you? What makes you believe it will have that effect? What do you believe will happen if you are not treated? Why do you think your doctor has [or I have] recommended this treatment?	Courts have recognized that patients who do not acknowledge their illnesses (often referred to as "lack of insight") cannot make valid decisions about treatment Delusions or pathologic levels of distortion or denial are the most common causes of impairment
Reason about treatment options	Engage in a rational process of manipulating the relevant information	Ask patient to compare treatment options and consequences and to offer reasons for selection of option	How did you decide to accept or reject the recommended treatment? What makes [chosen option] better than [alternative option]?	This criterion focuses on the process by which a decision is reached, not the outcome of the patient's choice, since patients have the right to make "unreasonable" choices

*Patients' responses to these questions need not be verbal

On the other hand, understanding the patient's goals and preferences, their priorities as they age, is of fundamental importance to helping the physician to be comfortable and understand the decisions a patient may make as well as giving them the

appropriate options from which to choose. Respect for each individual's unique point of view, needs, and desires is fundamental not just for respecting their autonomy, but for truly doing no harm with and maximizing the benefit of interventions.

Every physician obtaining informed consent should be able to do a basic assessment of decisional capacity. The physician should be able to diagnose delirium and, if needed, assess basic cognitive function. Tools focused on parietal lobe function, as do many of the commonly used cognitive mental status tests, are relatively poor predictors of the ability to make decisions, per se, but instruments that have a larger emphasis on frontal lobe or executive function, such as the clock drawing and other executive function examinations, may be more useful. What is most important is the physician's thoughtful discussion with the patient and the real-time assessment of the patients' understanding of the consequences of the decision they are making. Since the standard for decisional capacity is situation specific, it is important that one is able to assess their ability to understand the level of information needed for the decision at hand.

There are many other decisions that a patient may need to make other than informed consent where their capacity will need to be assessed and differing standards met. For example, a very high standard for decisional capacity must be met for a patient to agree to participate in a research study [20, 21], whereas a very low standard is applied to their ability to make a last will and testament. Of particular concern to the clinician is deciding whether patients retain the ability to decide on care options and whether they can return home or need a more intense environment in order to remain safe [22, 23] (Table 14.5) [24].

If the physician is unsure of a patient's capacity, a psychiatric consultation may be requested if the question arises from a psychiatric illness; or a neuropsychologist or geriatrician may be consulted about cognitive or functional problems. The patient's decisional capacity at the time of any decision, whether they decide to accept treatment or to decline treatment, should be recorded in the medical record.

TABLE 14.5 Levels of decisional capacity

Medical decisions

Ability to understand relevant information
Ability to understand the consequences of the decision
Ability to communicate a decision

Research subject

Ability to understand the probability of a lack of benefit
Appreciation of risks and the uncertainty of the risks
Appreciate their right to withdraw from the study

Decisions of self-care

Ability to care for oneself *or*
Ability to accept the needed help to keep oneself safe

Finances

Ability to manage bill payment
Ability to appropriately calculate and monitor funds

Last will and testament

Ability to remember estate plans
Ability to express logic behind choices

Source: Modified from [24]

Competence is a term that has legal implications beyond what a physician judges on examination. Physicians should avoid using this term unless a court has ruled on the patient's competence. The court recognizes two major categories of competence; competence for financial decisions and competence to make decisions of person. Only if the court has ruled the individual to be incompetent *of person* should the individual be assumed to lack decisional capacity for medical decisions.

Decision-Making for Incapacitated Patients (Table 14.6)

If a patient is found to lack the capacity to make an informed decision, a surrogate decision maker must be identified. The principle of autonomy guides us to seek a surrogate who is the person most capable of representing the patient's wishes. If the patient has completed an Advance Directive that names a proxy decision maker, this is the person to whom questions should be deferred if the patient has lost decisional capacity. This designee may be variously referred to as the Durable Power of Attorney for Health Affairs or the Health Care Proxy, Surrogate, or Agent. It needs to be emphasized that this person can only make decisions for the patient if the patient no longer has decisional capacity. A patient may also choose a person in a less formal manner, and documentation of such a choice should help to guide the decision. A person who holds Power of Attorney for Finances does not, simply by having this limited power of attorney, have the ability to make other decisions for the person.

If the patient's choice of surrogate is not known, usually the next-of-kin is utilized. The hierarchy of authority is

TABLE 14.6 Hierarchy of decision-making

Patient's current wishes

If the patient has decisional capacity, this ALWAYS takes precedence

Substituted judgment

Done by the surrogate decision maker only when the patient is not fully capable of making the decision
Based on the patient's prior values and wishes
Advance directive is used as a guide
Patient input is used when possible even if the patient is not fully capable of making the decision

Beneficence

Done by the surrogate decision maker when the patient lacks decisional capacity and evidence does not exist for substituted judgment
Weighing of benefits and burdens as based on the patient's present indications of pleasures and burdens
Input from caregivers is very important

Source: Modified from [24]

spouse, adult children, parents, siblings, nieces, or nephews. Adult friends may sometimes be able to act as surrogate if the relationship with the patient is such that they can act on his or her behalf. If it is thought that the person identified by this procedure cannot, in fact, act as an appropriate surrogate, if there is conflict about identifying a decision maker, if there is a lack of consensus among individuals, or if there is no one to take on this role, the court may need to decide who will act for the patient. In emergent situations, where the decision-making process is unclear, physicians should apply the “best interest rule” and proceed with any interventions necessary to save the patient’s life or preserve function until the situation is clarified. Each institution may have different procedures for obtaining such permission to act, such as an agreement to act by the Chief of Staff. If there is time, emergency conservatorship from a court can be sought. As the situation and the patient’s wishes become clear, and an intervention that had been started as an emergency procedure is found to be against the patient’s wishes, then the intervention must be discontinued.

The task of making the decision for the incapacitated patient should honor the patient’s autonomy by maximizing the individual’s continued influence on the ultimate decision. If a patient gave explicit directives that apply to the situation at hand at a time when he or she was capable of decision-making, they must be followed. For example, if a patient with a terminal illness requests that no further interventions be done, including artificial food and hydration, a family member cannot reverse this directive once the patient is in a coma.

If patients have not been explicit about their wishes, the surrogate decision maker and the physician are then obliged to apply substituted judgment. This term is defined as “the application of the patient’s preferences and values ... trying to choose as the patient would have wanted” [25]. In studies comparing hypothetical decisions made by would-be surrogates and patients with decisional capacity, there is a 66% correlation. Previous discussions between the patient and the surrogate help to make these decisions much more representative of the patient’s wishes [26]. Helping a family to understand that their obligation is to do what their relative would have wanted often relieves them of some of the burden of decision-making and helps clarify their thinking. Living Wills may be useful in this context. Living Wills may be formal documents executed by a lawyer, but they may also be readily available forms completed by the patient with or without assistance or simply a written statement or narrative. If patients are still capable of making decisions, all treatments must still be discussed with them even if they have a Living Will.

The Living Will is a “what if” statement – a hypothetical situation. The patient is saying, “*If* one of these conditions occurs to me (e.g., permanent coma), *then* do not attempt resuscitation.” It does not necessarily mean that the patient

does not desire this intervention in their present state of health. For example, a patient who is fully capable of making decisions has a Living Will that states that he or she would decline resuscitation if in a vegetative state. If this patient was to have a cardiac arrest in their present state, resuscitation should be attempted. If after the resuscitation the patient is found to be vegetative, the Living Will would take effect and no further resuscitation attempts should be made were the patient to arrest again.

Frequently, the exact circumstances outlined in a Living Will are not met, but it can still give a good indication of the patient’s preferences and values, which then can be applied to the current situation [27]. Living Wills cannot cover all circumstances that may arise, and most patients wish to have a proxy decision maker to interpret their intent. State laws vary as to whether the Living Will or the proxy decision maker takes precedence when there is a conflict with the decisions. Encouraging the family to remember other health care decisions or comments the patient made when other family members were ill is also helpful in trying to define what someone “would have said.”

If there is no information that helps the surrogate decision maker to reconstruct what the patient would have said, the guiding principle becomes that of beneficence, defined as weighing the benefits, risks, and burdens of an intervention in the context of the individual. With beneficence, although a patient may no longer be fully capable of making a decision, their voice can still be an important one. Their stated preferences and fears can be used to guide the decision about relative benefits and burdens [28]. This can be true for even markedly demented patients.

For example, the relative burden of an intervention in two patients, equally cognitively impaired, can be quite different. One patient may not become agitated when an intravenous line is started, and intravenous treatment would not be a great burden. Another patient may fight such an intervention, repeatedly pulling out the intravenous catheter and needing restraints. Although the second patient is not making an informed decision to forego intravenous therapy, the relative burden of the intervention is greater in this patient and therefore the relative benefit would need to be greater than other less noxious alternatives for the burden/benefit ratio to be the same.

There can, at times, be conflicting interests in adhering to this hierarchy as circumstances change and the patient’s condition alters what is a burden and what is a benefit. Surrogate decision-making often uses a combination of substituted judgment and beneficence to arrive at a treatment decision [29]. What is most important is that these discussions occur as they can have major impact both on patients’ quality of life and on the bereavement adjustment of the relatives [30].

As previously stated, decisional capacity is decision specific and capacity is often not black or white. Utilizing an Assent/Consent modal is commonly being accepted.

This allows for different levels of patient involvement in the decision-making process. If the patient seems to be capable of making the decision but, due to memory problems or waxing and waning mental status, there is some question as to their ability to retain information, the family may be asked for their “assent,” i.e., they agree that it is what the patient wants. If the patient cannot make the decision, the family may give the formal consent but the patient may need to “assent” in order to carry out the procedure. For example, a family may consent to chemotherapy but the patient must be willing to cooperate. The consent/assent modal balances the prior statements of the patient (future-looking autonomy) with beneficence for the person they are at this moment in time [31].

DNR Orders in the Operating Room

A patient’s previously stated wish to forego intubation or attempts to resuscitate may be suspended at the time a patient undergoes surgery. Elective intubation in order to perform surgery or a cardiac arrest that occurs under general anesthesia where an immediate response is possible and where the cause may be readily reversible is different from a cardiopulmonary arrest under other circumstances. It may therefore be perfectly compatible with a patient’s goals to have these procedures done in the operating room but not want them initiated in other circumstances. Indeed, intubation may be necessary if a procedure which the person does desire is to occur.

If a decision is made to reverse a do-not-resuscitate or do-not-intubate order during surgery, there must be a clear understanding prior to surgery of how postoperative events should be handled in case the patient is not then capable of making decisions. How long should an intubation continue if the patient is not quickly able to be extubated? If the patient does arrest and is resuscitated but has lost decisional capacity, what other treatment modalities would be an unwanted burden? Discussions with the patient, surgeon, anesthesiologist, and primary care physician can help safeguard against confusing and distressful situations [32].

Confidentiality

The Health Insurance Portability and Accountability Act (HIPAA) of 1996 has greatly enhanced the confidentiality of written records and communications [33]. It has also impacted verbal communication, but not to the same extent.

Sharing information with patients’ relatives or friends is appropriate in only two circumstances: when patients have specifically stated that the physician may discuss their

condition with the individual or when the patient has lost decisional capacity and a surrogate decision must be made. It is advisable to ask patients well in advance who they wish to have informed and how much they wish to have told.

The sharing of information among colleagues should be done in private and with respect for the patient’s right to confidentiality. Casual conversations in public places, rounds in the hallways, and discussions in lobbies or waiting rooms with multiple families present can be a breach of a patient’s right to privacy. Our sensitivity to this issue must be heightened, and the policing of each other should become everyone’s responsibility.

Sharing medical information among health care providers without the patient’s explicit authorization, if the clinical circumstances so require, is permitted. The use of clinical material for teaching purposes can be done only with sufficient safeguards to anonymity so the individuals involved are not identifiable. Other information can be released only with the patient’s or surrogate’s authorization unless it is required by law, as in the case of public health reporting of communicable and sexually transmitted diseases.

Limits to Autonomy and Choice (Futility)

The previous sections have dealt heavily with the respect for and safeguards of the patient’s right to exercise autonomy. There are circumstances where this autonomy is tempered by other forces. Autonomy may be limited if the patient is a danger to others, a danger to self, or for the good of society. Laws may govern what procedures or interventions may be available to an individual. For instance, physician-assisted suicide is explicitly illegal in most states in the USA.

Although the US Supreme Court has affirmed an individual’s right to refuse treatment, there is no corollary right to demand treatment [34]. In addition to the healthcare professionals’ responsibility to understand the patient’s goals of treatment and respect patient’s own assessment of their quality of life, they also have the responsibility of knowing if an intervention is futile and not offering such treatments to the patient.

There are two perspectives on the definition of futility; referred to as quantitative and qualitative. An intervention is said to be quantitatively futile if it cannot achieve its physiologic objective. Because it is difficult to know what level of evidence is needed for what cut-off to call something physiologically futile, this concept has limited utility. A therapy is said to be qualitatively futile if it is unlikely to help patients achieve their primary goal even if it has a physiologic effect [35, 36]. An example is the foregoing of antibiotic therapy in a patient who is in the terminal phase of an illness. Although the antibiotics might have the physiologic effect of treating

the infection, it would have no effect on comfort and a negative effect if it prolongs the patient's suffering. This concept, of futility in the light of the treatment goals, is paramount to the appropriate treatment of the geriatric patient.

If a procedure is judged futile, the physician does not have to offer the intervention to the patient or the surrogate. The very act of offering conveys the sense that there must be some benefit, some chance of success. Why else would it be offered? Therapies the patient and family might expect to have performed but that have become futile, such as an attempt to resuscitate a patient when circumstances clearly demonstrate that it would be futile, should be discussed in the context of their futility. For example, the patient or family should be told that where the patient's heart to stop, attempts to restart it would be futile and therefore would not be initiated. Simply ignoring the subject may engender mistrust, as most individuals are aware of the spectrum of treatments available. One in 20 patients who die in the ICU do not have a surrogate decision maker. The majority of the time physicians decide to cease life-sustaining interventions on the basis of their futility [37].

Defining a therapy as futile is simple under some circumstances and more difficult under others. The decision that someone is "not a surgical candidate" is frequently made when the relative risks and benefits clearly demonstrate that the treatment is not indicated. The decision to stop a therapy may also be made on the grounds of professional judgment. For example, if a tumor is not responding to chemotherapy, it can be unilaterally stopped by the clinician. The difficulty lies more in defining which therapies near the end of life still hold enough of an advantage for the patient that they should be offered.

Prognostication

In order for patients to be able to set goals, they need to be able to understand their prognosis and how interventions may or may not change that prognosis. Unfortunately, we are not very accurate in being able to prognosticate. Being able to predict short-term mortality in the acute care and intensive care unit setting has been explored through the SUPPORT Study [38] and through the use of the APACHE III instrument [39]. These instruments use a combination of diagnosis, cause of illness, and a scale for physiologic parameters to predict mortality risk, but the ability to apply them clinically remains a challenge [40]. The patients' physical and cognitive function prior to their hospitalization is the strongest predictors of outcome after an intervention [41].

Such legislative acts as the Medicare Hospice Benefits, and the Oregon Death with Dignity Act define the terminal

phases of disease as the last 6 months of life. Our ability to accurately prognosticate this length of time is relatively poor, with only one-third of predictions being within 50% confidence intervals (i.e., if prognosis is 3 months, "accurate" would be from 1.5 to 6 months). Most physician prognoses are too optimistic [42].

Individuals in their eighth and ninth decades may define their goals similarly to patients with terminal diagnoses. Quality of life and relief from the burdens of illness and interventions may be more important than longevity per se. On the other hand, it should not be assumed that this is true for all individuals of advanced age. Although some elderly patients may look forward to more years of life, they may not wish to do so under any or all circumstances. In surveys of patients with and without terminal illnesses about why they might be motivated to avail themselves of physician-assisted suicide, fear of disability and dependence are the two most common motivators for wishing to end one's life. Predicting the risk or progression of disability is even more difficult than predicting death [43].

Decisions Near the End of Life

As has been emphasized in previous sections of this chapter, goal-oriented care is of the utmost importance to all geriatric care, but it is the sine quo non of end of life care. When a patient has a terminal illness or is faced with chronic, disabling, and progressive disease, decision-making must become very goal-focused. We have already discussed foregoing and discontinuing interventions when they no longer meet the goals of care. Treatment of suffering, physical, mental emotional or spiritual may lead to actions where the physician is seen as hastening death, either inadvertently or deliberately.

The potential for hastening the death of a patient is highest where there is a narrow therapeutic window between the dose of medication needed to control a symptom and the dose that could cause suppression of respiratory drive. The underlying ethical principle of "double effect" rests on the physician's intention and an acknowledgement that treatment may have two effects: one on symptoms and one on longevity. This is an acceptable risk to take if the physician and patient or surrogate have agreed that comfort is more important than longevity and the medication or treatment is given with the *intention* of relieving symptoms.

At some point in the patient's clinical course, interventions that we normally think of as prolonging life may have shifted to prolonging death. An example of this may be antibiotics for pneumonia. The symptoms of pneumonia can be treated (e.g., with scopolamine to control secretions and morphine for dyspnea) without treating the underlying

pathophysiology of the pneumonia. Since every patient will, eventually, die of something, there comes a time when it makes sense to allow the clinical course to determine the mode of death. Aggressively treating the symptoms is often preferable to a prolonged dying process with the occurrence of increasingly hard-to-control symptoms.

Physician-assisted suicide and euthanasia (physician-assisted death) are instances when a therapy is prescribed, provided, or administered with the *intention* of ending that patient's life. The acceptability of such actions from both a moral and a practical point of view is under wide debate within the profession and in society in general. Those who argue for the practice of physician-assisted death point out that there are some symptoms that cannot be alleviated short of death (e.g., the discomfort and indignity of destructive head and neck cancer), and individuals should have the right to determine the time and mode of their death. Arguments against physicians assisting in suicide point out that the medical profession's obligation is to "care and to cure" and not to end life [44]. The four principles of autonomy, nonmaleficence, beneficence, and justice are active parts of this debate. Some argue that out of respect for autonomy, individuals should be allowed to determine the time and mode of their death, especially if it is within the last 6 months of their "natural" lives. Others argue that if there is unbearable suffering that cannot be relieved by other means, then the principle of beneficence tells us that they should be allowed to end their lives. Many feel that physicians prescribing or acting with the intent of ending a patient's life would be professionally wrong because it would mean intentionally doing harm to the patient (nonmaleficence). Finally, many fear that the practice will be a "slippery slope" leading to the premature death of certain segments of society such as the elderly and the disabled. As of now, physician-assisted dying is legal in two states in the USA (Oregon and Washington) and many countries in Europe. Although the debate remains open, the fear of abuse has not proven to be a reality in any locale where it is legal, where it has remained a small minority of patients (less than 5% of deaths) who decide to actively end their lives.

Conclusion

As an individual ages and the accumulation of both life experience and illness burden increase, decisions need to be made on the basis of the individual's goals and preferences. Patients need to be informed of their situation, their prognosis and their options as best we can define them. They have a right to decide their course of action within choices that are not futile and they have a right to influence decisions made for them if they have become incapacitated. Weighing autonomy and

beneficence is often hard for the patient who has lost the ability to make decisions. Finding appropriate surrogate decision makers and helping them to understand their role is paramount to this process.

Chapter 15

Teaching Geriatrics to Surgeons

Hugh L. Willcox III, Darin L. Passer, and Richard M. Bell

Introduction

The 1970s is considered by many as the rise of geriatrics as a specialty – what Solomon refers to as the beginning of the “geriatrics renaissance.” [1] At that time, a few individuals recognized the need for improved care of the elderly and the opportunity for a specialty to encompass its principles. Over time, geriatrics has grown into a recognized branch of medicine that has its own society, multiple journals, thousands of fellows, and hundreds of teaching attendings. Now, the ideals that led to this renaissance are spreading into the surgical and medical subspecialties. However, this growth is meeting with some resistance. Many surgeons have the attitude of “I already know how to take care of older patients – that’s half of my practice.” And, many do take care of the aged patient well. However, improvement in the care of the elderly can be realized through utilization of the available resources discussed in this chapter.

Like the pediatric patient, the geriatric patient is unique. The development of a curriculum addressing the perioperative care of the elderly surgical patient needs to embrace the fact that the normal end points of therapy should be adjusted to a population that is nearing the end of life. These patients respond differently and unpredictably to interventions that have been tested primarily on younger patients.

With the work hour restrictions firmly in place and potentially subject to further limitations, one of the challenges facing surgical residency program directors is how to incorporate all that has been the traditional purview of the general surgeon. The addition of new information, including the principles of geriatric care for the surgical patient, complicates the issue. Fortunately, many tools already exist. The John A. Hartford Foundation, the Donald W. Reynolds Foundation, and the American Geriatrics Society in particular have

invested time and money for the development of programs to increase the exposure of surgical residents to geriatric issues.

The goal of this chapter is to serve as a reference for program directors and academicians as they begin modifying their own curriculum by integrating geriatric issues. What follows is a summary of the available resources and content that may be helpful for teaching geriatrics to surgeons.

Assessment of Need

“What makes me mad is how aging, in our language and culture, is equated with deterioration and impairment. I don’t know how we’re going to root that out, except by making people more aware of it.” – Dr. Erdman Palmore from an interview with the Detroit News, September 5, 2004.

Though the assertion may be made that every surgical resident needs more exposure to geriatrics issues, determining what barriers exist, particularly in the form of subtle, and sometimes not so subtle, “ageism,” is essential when targeting learners for a change in curriculum. Assessing the attitudes of the individual residents will help program directors delineate existing barriers to learning about geriatric issues and to maximize the benefit gained from changes to their curriculum.

Palmore’s publication “The Facts on Aging Quiz” in 1977 is considered by many the landmark effort to address the issue of attitudes towards aging. His survey has been modified by many authors, and additional attitude assessment tools have been developed. Although these have been tested mostly on primary-care residents, they are applicable to residents in the surgical and medical subspecialties.

Palmore’s survey has been updated, most recently by Breyspraak et al., of the University of Missouri-Kansas City, and can be found at the web site <http://cas.umkc.edu/cas/AgingFactsQuiz.htm>. Debate continues as to whether Palmore’s tool and subsequent iterations are valid for research purposes, but the qualification of learner attitude should be helpful when developing a curriculum [2].

TABLE 15.1 UCLA Geriatrics Attitude Scale (GAS): answers using the Likert scale 1 to 5

1. Most old people are pleasant to be with
2. The federal government should reallocate money from Medicare to research on AIDS or pediatric disease
3. If I have the choice, I would rather see younger patients than elderly ones
4. It is society's responsibility to provide care for its elderly persons
5. Medical care for older people uses up too much human and material resources
6. As people grow older, they become less organized and more confused
7. Elderly patients tend to be more appreciative of the medical care I provide than are younger patients
8. Taking a medical history from elderly patients is frequently an ordeal
9. I tend to pay more attention to and have more sympathy for my elderly patients than my younger patients
10. Old people in general do not contribute much to society
11. Treatment of chronically ill old patients is hopeless
12. Old persons do not contribute their fair share towards paying for their health care
13. In general, older people act too slow for modern society
14. It is interesting listening to old people's accounts of their past experiences

1=Strongly disagree, 2=somewhat disagree, 3=neutral, 4=somewhat agree, 5=strongly agree

A lengthy and more detailed survey was constructed by Maxwell and Sullivan in 1980 [3]. Subsets of questions from this survey have been abstracted, decreasing the length of the survey but hopefully maintaining the accuracy of the responses to quantify an individual's attitude regarding the elderly.

Another commonly used and validated assessment tool for determining the attitude of a resident towards geriatric issues is the UCLA Geriatrics Attitude Scale (GAS) [4]. Like the Maxwell and Sullivan survey, the GAS uses the Likert scale but consists only of 14 questions. Initially published in 1998, Dr. Reuben and colleagues have evaluated this device for validity and reproducibility, publishing their results in 2005 [5] (see Table 15.1).

Once the attitude of the residents towards the elderly have been established, determining the geriatrics knowledge base of the residents can provide a starting point for program directors when making curriculum changes. In order to better gauge what that knowledge base is, the University of Michigan has developed a questionnaire consisting of 20 items that range from acute abdominal pain to palliative-care options and appropriate pain control. This test can be found at <http://www.med.umich.edu/geriatrics/educationalprograms/gme.htm>. Table 15.2 lists the topics covered by this test.

Krain et al. from the University of Michigan utilized the UCLA's Geriatrics Attitude Scale and the University of Michigan's Geriatrics Clinical Decision Making Assessment tools to determine the effectiveness of their faculty

TABLE 15.2 University of Michigan's Geriatrics Clinical Decision Making Assessment quiz topics

1. Postoperative pain management
2. Constipation
3. Metastatic abdominal pain
4. Analgesia in presence of confusion
5. Assessment of in-hospital mortality
6. Competency and patient wishes
7. Delirium diagnosis
8. Reducing subsequent hospital utilization
9. Causes of incontinence
10. Medical management-only requests
11. Recognition of depression
12. Prevalence of mood disorders
13. Elder abuse suspicion
14. Postoperative respiratory distress
15. Return of ambulatory function predictors
16. Evaluation of syncope
17. Foot pain following immobility
18. Postoperative delirium and agitation
19. Medication-induced acute renal insufficiency
20. Evaluation of alcohol withdrawal

development program [6]. The program was designed to increase the knowledge and to improve the attitude of the nonprimary-care residents towards the elderly. This was accomplished by identifying faculty within the nonprimary-care departments and giving them resources to incorporate geriatric issues into their curriculum. The program demonstrated an improvement in both knowledge and attitude toward the aged.

Establishing the attitude and knowledge of the residents prior to initiating any new curricular changes, and then measuring the effects of the interventions, can help guide whether the changes were successful or other changes are needed. Additionally, these tools can be used in completing research, as shown by Krain et al. [6].

Integrating Geriatrics into a General Surgery Curriculum

Many difficulties exist to insert geriatrics into an already overloaded general surgery curriculum. What is the best approach? What is sufficient time and coverage? How do you assess the effectiveness of the modality chosen? While there are many different approaches and tools such as didactic lectures in multiple formats, small group discussion tools, case-based simulation, and others, how best to integrate these tools into the tight educational schedule is a challenge.

To try to help surgical and medically related training programs (Emergency Medicine, Anesthesia, and Physical Medicine and Rehabilitation) meet this challenge, the

American Geriatrics Society in partnership with the John A. Hartford Foundation introduced a grant program, titled Geriatrics Education for Specialty Residents (GSR). Beginning in 2001, as a part of the larger Geriatrics for Specialists Initiative, the GSR began funding programs to develop educational models to improve the care that residents in surgical and medical subspecialties give to elderly patients. Every 2 years, a new round of grants was given to these specialty programs. To find out more about the Geriatrics Education for Specialty Residents, such as descriptions of projects that have received grants, please go to The American Geriatrics Society home page and follow the link to the Geriatrics for Specialists section. The web site address is <http://www.americangeriatrics.org/specialists/gsr/default.asp>.

Funding from the GSR has been used by several recipients to develop projects focusing specifically on how to integrate geriatrics into a surgical curriculum. One such example comes from Dr. Cox et al. at East Carolina University, which in 2002 used the grant to include geriatric issues into the 4th edition of the *Surgical Residency Curriculum*, published by the Association of Program Directors in Surgery. The authors provide a “structural basis for increasing resident expertise in caring for the special needs of elderly patients.” Specific curriculum goals include understanding the principles of normal aging, pathophysiology in the elderly patient, preoperative assessment, operative management, and perioperative care of the aged patient, long-term recovery and rehab, financial and reimbursement issues, and lastly, analyzing outcomes of the geriatric surgical patient. To achieve these goals, each section of the curriculum has “geriatric objectives” associated with it and is clearly delineated in the table of contents where those objectives can be found within that specific section. This curriculum can be found at the web site of the Association of Program Directors in Surgery.

The curriculum mentioned above provides an outline of specific goals to obtain competence in caring for older patients. However, other grant recipients of the GSR have developed products to teach the specific geriatric issues. Bell et al. at the University of South Carolina designed “Top Blade,” a simulation, case-based project used to cover the major geriatric topics at the learner’s own pace. The learner is given a scenario and asked to develop an evidence-based response to complete the task. The solution to the scenario, which is to be written as if it is to be published as a case presentation, is reviewed by a faculty member with an interest in geriatrics who then provides feedback to the resident. There are a total of 22 different Top Blade cases to choose from. This type of integration takes a fair amount of time from one individual faculty member to review the cases but can be completed by the residents in between their clinical duties and does not use valuable conference or lecture time. Each time the project has been completed, feedback has been

received from the residents that has been, overall, positive. To access Top Blade, please go to <http://topblade.med.sc.edu> and request a password to begin.

In another effort, also supported by the AGS and the Hartford Foundation, Sharon Levine, MD, at Boston University Medical Center, in association with the Association of Directors of Geriatric Academic Programs (ADGAP), has developed an intensive 2 and a half-day program for chief residents of nonprimary-care specialties, known as the CRIT (Chief Resident Immersion Training) program. This program, which is conducted off campus at an attractive location in one weekend, allows specialty chief residents to combine some time with family with concentrated interactive learning of geriatric principles with enhancing leadership skills and teaching skills. By the end of the weekend, the residents will have designed a simple project to bring geriatrics education back into their training programs. Information about the CRIT program can be found at <http://www.americangeriatrics.org/adgap/crit/default.asp>.

Individual universities have also developed their own programs to teach geriatric issues. The University of Chicago has made available its Curriculum for the Hospitalized Aging Medical Patient (CHAMP) program, which is described below. Also included is the E-Learning for Licensed Professionals from the University of Iowa, the Texas Tech Medcast series, and the Elder Care project from the University of Iowa.

Champ

The CHAMP Program (Curriculum for the Hospitalized Aging Medical Patient) is a 12-week faculty development program aimed primarily at primary-care faculty to help teach geriatric issues. However, each module has been separated out from the program and is available at <http://champ.bsd.uchicago.edu>. The topics covered include Foley catheter use, delirium/dementia/depression, drugs and aging, falls, wound care, identifying frail elders, nausea, deconditioning, palliative care, pain control, advance directives, nursing-home care, and discharge plans. Also included is a module on teaching techniques and a module regarding OSTEs (Observed Structured Teaching Exercise). Each module has a PowerPoint slide presentation, a bedside teaching triggers section, a pocket teaching card (where applicable), references, links, and a session evaluation form.

E-Learning for Licensed Professionals

The University of Iowa Geriatric Education Department has developed a variety of tools to advance geriatric education.

Under the heading of E-learning, five different types of products are available. The first is GeriaSims. GeriaSims is an interactive case-based tool that has a virtual mentor who guides you through the care of a geriatric patient, focusing on a specific topic of interest. Topics of interest to surgeons include delirium, functional assessment, polypharmacy, and palliative care.

The second product is a video streaming lecture series with slides that covers a variety of geriatric topics. Pain control, delirium, peripheral arterial disease, polypharmacy, pressure ulcers, and renal failure among many are presented here.

The third product consists of didactic modules from the Geriatric Consult Service Inpatient Curriculum at the University of Iowa. The residents that rotate on this service must complete these modules. Nutrition, delirium, adverse drug events, and an overview of aging are included in this product. Adobe Acrobat Reader is required for these modules.

The last two products deal with oral hygiene and train the preceptor in functional assessment. By going to the following web site, <http://www.healthcare.uiowa.edu/igec/index.html>, the user has access to the E-learning products as well as other resources. Many of the individual products can also be accessed through portals such as POGOe (see below).

Texas Tech Medcast Reynolds Geriatrics Series

This is a series of podcasts that covers subjects from polypharmacy, falls, incontinence, and functional assessment of the elderly. They come with a fact sheet as well as the podcasts themselves. These can be found at POGOe.

Elder Care

The University of Arizona has a series of articles in a journal format that review contents such as delirium/depression/dementia, urinary incontinence, falls, elder abuse, and health literacy. These are succinct and concise explanations of these topics. Access to these can be found at POGOe.

These are a few broad examples of how to begin integrating geriatrics into a surgical curriculum. However, once a program director has completed a needs assessment and has evaluated what the specific residency program may need, or if an academician or resident decides that a certain issue needs to be addressed, there exist topic-specific resources. The following section describes, in general, where these resources can be found, such as POGOe, and then lists specific products based on the disease process.

TABLE 15.3 Seventeen frequent and preventable hazards

1. Acute renal failure
2. Adverse drug events
3. Inappropriate bladder catheterization
4. Deconditioning and immobility
5. Dehydration
6. Delirium
7. Depression
8. Electrolyte disturbances
9. Falls
10. Functional decline
11. Incontinence
12. Infection
13. Malnutrition
14. Pressure ulcers
15. Stress-induced gastrointestinal ulceration
16. Thromboembolism
17. Untreated or undertreated pain

Resources

The John A. Hartford Foundation and the American Geriatrics Society, along with representatives from ten surgical and medical subspecialties, compiled a list of the 17 frequent and preventable hazards of the inpatient care of the elderly (see Table 15.3) [7]. Educational resources have been developed to facilitate the recognition, treatment, and most importantly, the prevention of these occurrences. Included in this section is a discussion of the broad resources available for improving geriatric education followed by specific geriatric issues and the tools that are available for each one.

General Online Resources

The internet has become an easily accessible repository for educational materials. The geriatrics community is amassing a set of portals to access these educational tools. The Portal of Geriatric Online Education (POGOe), developed by the Mount Sinai School of Medicine in partnership with Vanderbilt University School of Medicine, is a free resource of educational materials that cover the gamut of geriatric topics. Many are evidence-based and are relevant to surgical and medical specialty patients. Many of the products listed below can be found on this site, located at <http://www.pogoe.org/front2>. Access to the site requires registration, which is easily completed at no cost.

The Consortium of E-Learning in Geriatrics Instruction (CELGI) is also a web site devoted to providing access and awareness of geriatric educational materials on the internet. By going to <http://www.celgi.org>, the user can read discussions regarding advances made in E-learning and also find

TABLE 15.4 GeriatricWeb topics

1. <i>Geriatric syndromes</i> – Dementia, delirium, urinary incontinence, osteoporosis, falls/gait disorders, decubitus ulcers, sleep disorders, failure to thrive
2. <i>Organ specific disease/syndrome</i> – Ear, eye, cardiovascular, musculoskeletal, neurological, communicable diseases, respiratory, oral, gastrointestinal, endocrinological, sexual dysfunction and gynecology, hematology and oncology, kidney/prostate, skin diseases
3. <i>Geriatric psychiatry</i> – Mood disorders, anxiety disorders, personality disorders, substance-related disorders, memory disorders (nondementia)
4. <i>Patient care</i> – Geriatric assessment, hospitalization, emergency medical services, surgical procedures, long-term care, preventive health services, rehabilitation, pain management/palliative care
5. <i>Aging</i> – Age distribution/demography, basic sciences, pharmacology/polypharmacy
6. <i>Economics</i> – Organizations/Medicare, health service research
7. <i>Medical ethics</i> – Advance directives/decision capacity, artificial nutrition/feeding tubes
8. <i>Miscellaneous topics</i> – Elder abuse, automobile driving, geriatric medical education

links to other learning resources. CELGI was established with the support of the Miami Jewish Home and Hospital for the Aged, Florida's teaching nursing home and is also affiliated with the VA Medical Center in Miami. Membership in CELGI is free.

GeriatricWeb is a resource for practitioners that have access to guidelines for treating many of the geriatric syndromes. Found at <http://geriatricweb.sc.edu/>, it is a collaborative effort between the Division of Geriatrics at Palmetto Health Richland Hospital and the University of South Carolina School of Medicine and its medical library. It is funded by a grant from the National Library of Medicine. Its web-based geriatric digital library is broken down into eight broad topics (see Table 15.4), and it is free to access.

MedEdPortal is a peer-reviewed resource for general medical information but includes geriatric topics. It is funded by the AAMC and is found at <http://www.aamc.org/mededportal>. Several universities have developed their own web sites with access to geriatric topics.

Resources by Topic

When making changes to a curriculum, the program director may have identified particular areas of need, or an academician or resident may have a particular interest in a certain geriatric topic. Provided below is a list of specific geriatric issues and the educational tools that are available to learn about them. Each item that follows will contain how to find the tool, a description of the type of learning

method used – lecture vs. standardized patient vs. interactive video presentation, etc., the author and institution where the product originated, and a brief summary of the product.

Delirium

1. *An Unfolding Case of Delirium, Dementia, and Depression* – University of California at San Francisco; Author – Bree Johnston, MD

This is a problem-based learning exercise in a Word document to be used in small groups. The case explores the concept of recognizing and managing the cognitive impairment in the hospitalized elderly patient and is suitable for learners from medical students to faculty. Find this at POGOe.

2. *Delirium in the Perioperative Elderly* – University of Nebraska Medical Center; Author – Ed Vandenberg, MD

The University of Nebraska Medical Center has two case-based tools that reviews perioperative delirium – diagnosis, pathophysiology, risk factors, prevention, and management. These are designed for M3 and M4 and PGY-1 learners. Find this tool at <http://app1.unmc.edu/geriatricsed/delirium>, or through POGOe – <http://www.pogoe.org/productid/18401>.

3. *Postoperative Delirium in the Elderly Patient* – Saint Louis University; Author – Miguel Paniagua, MD

This is an interactive video lecture series with exercises imbedded in the presentation that expounds on the breadth of the topic of delirium in the surgical patient – from preoperative risk factors to diagnosis and management options. This is found at POGOe – <http://www.pogoe.org/productid/20118>.

4. *Delirious: You or the Patient?* – University of North Carolina; Author – Debra Bynum, MD

This is a lecture presented in a PowerPoint format. The lecture has a few slides regarding delirium in the perioperative patient but with a primary focus on recognition of patients at risk, diagnosis, and management. The lecture can be found at POGOe – <http://www.pogoe.org/productid/18928>.

5. *Delirium: An Interactive Learning Experience* – Emory University; Author – Ugochi Ohuabunwa, MD

This is an interactive case presented in a Word format designed to facilitate discussion among small groups. Initially developed for medical students but can be applied to residents as well. This product has been peer-reviewed at MedEdPortal and can be accessed through that portal, as well as POGOe – <http://www.pogoe.org/productid/20184>.

Additional materials on delirium can be found at the CHAMP program and the E-Learning for Licensed Professionals web sites (see above).

Adverse Drug Events and Polypharmacy

1. *Health Promotion for Older Adults: Drug Use and Misuse* – University of Washington; Author – Shelly Gray, PharmD

This is described as a curricular module that is essentially a very extensive review of drug use in the elderly, looking at the epidemiology of adverse drug events, treatment strategies to prevent these, and a case study and self-study questions to put into practice the concepts presented. This can be found at GeriatricWeb <http://geriatricweb.sc.edu/>.

2. *Management of Polypharmacy in Community Dwelling Older Persons* – Spital Bern Ziegler, Switzerland; Author – Andreas Stuck, MD

Dr. Stuck presents this topic in a PowerPoint presentation that is accessible at GeriatricWeb. He discusses definitions, risk factors, risk reduction strategies, compliance issues, and overall polypharmacy management options. This can be found at <http://www.healthandage.com>.

3. *Geriatric Pharmacology* – Texas Tech University; Author – Kathryn McMahon, PhD

Dr. McMahon provides a case-based exercise for use in small groups to evaluate pharmacology issues in the elderly. There are three segments to this product – a didactic handout, the cases, and then a posttest. This can be found at POGOe – <http://www.pogoe.org/productid/20116>.

4. *Pharmacology Exercises For Small Groups of Medical Students* – University of California San Francisco; Author – Bree Johnston, MD

Initially designed for medical students, this device is made up of three cases. The second and third cases in particular may be of use to surgery residents as they discuss topics such as the impact of renal function on drug clearance and how to compensate for this as well as prescribing concerns. This can be found at POGOe – <http://www.pogoe.org/productid/18817>.

Polypharmacy and adverse drug events are topics also covered by both the CHAMP program and E-Learning for Professionals (see above).

Renal and Prostate Disorders

1. *Renal Failure in the Older Adult* – University of Iowa; Author – Rebecca Hegeman, MD

This is a video streaming lecture that is available from the University of Iowa Geriatrics Education web site – <http://www.healthcare.uiowa.edu/igec/index.html>, and is one of

many video lectures available from them regarding geriatric issues. This is also available through POGOe – <http://www.pogoe.org/productid/18472>. The lecture addresses four objectives: To describe how to evaluate a patient's GFR from readily available clinical information, to identify the timing of referral to a nephrologist, to understand drug use in chronic kidney disease/end-stage renal disease, and to provide primary care in patients with end-stage renal disease.

2. *Renal and Prostate Disease* – University of Nebraska; Author – William Lyons, MD

Three PowerPoint modules are dedicated to discussing renal and prostate disease, with a focus on the association with elderly patients. Module #1 deals with chronic kidney disease, while modules #2 and #3 are concerned with BPH and prostate cancer respectively. This is not a peer-reviewed resource, but the recommendations are made from evidence-based sources. It is found on POGOe – <http://www.pogoe.org/productid/18990>.

Urinary Incontinence and Inappropriate Bladder Catheterization

1. *Incontinence and Urinary Catheters for the Inpatient Physician* – University of Colorado Denver; Author – Jeannette Guerrasio, MD

This is a product from Guerrasio et al. that is a “small group, preceptor-mediated, PowerPoint-guided workshop,” designed to educate participants about the indications and pitfalls of catheterization. There are four different sections – one is a PowerPoint lecture, with the other three being devoted to facilitating the small group discussion on incontinence and urinary catheter use. This can be found at POGOe – <http://www.pogoe.org/productid/20296>.

2. *Urinary Incontinence in Older Adults for Practicing Physicians* – University of Cincinnati; Author – Gregg Warsaw, MD

There are six segments to this tool, including a PowerPoint didactic lecture, a patient handout, references, and a facilitators guide. This can be found on POGOe.org – <http://www.pogoe.org/productid/19042>.

Electrolyte Disturbances

1. *Evaluation and Management of Hyponatremia in the Elderly* – The University of North Carolina; Author – Debra Bynum, MD

Dr. Bynum has tackled the topic of hyponatremia in the elderly through the use of a case-based PowerPoint presentation. The recognition, management, and understanding of the etiologies of hyponatremia is the focus of this tool. Find this on the Web at http://www.med.unc.edu/aging/documents/gercurhyponatremia_000.ppt, or through POGOe – <http://www.pogoe.org/productid/18931>.

Falls

1. *Falls* – Mount Sinai School of Medicine; Author – Christine Chang, MD

From Mount Sinai School of Medicine comes a teaching tool that has five different components. First is the case of a 70-year-old female presenting in the outpatient setting with arm pain after a fall. To better use this case, a faculty guide explanation is included. Also included is a PowerPoint lecture discussing falls, as well as a resource for other information regarding falls and a comprehensive handout. This can be found at POGOe – <http://www.pogoe.org/productid/20200>.

2. *Falls and Gait Assessment: A Must for the Aging Population* – Ohio State University; Author – Bonnie Kantor, Sc.D

Instead of using a virtual patient or a fictional case patient, this product utilizes a “senior partner,” a patient designated to the learner for which the learner has a list of assignments to accomplish. The learner is required to then go through their findings with the senior partner. The assignments cover the basics of falls and gait assessments, the significance of the findings, management, and prevention options. The concept is to learn about the concept of falls in the context of real-time patient care. This can be found at POGOe – <http://www.pogoe.org/productid/18832>.

3. *Falls and Mobility Problems in Older Adults* – University of Kansas Medical Center; Author – Shelley B. Bhattacharya, DO

Dr. Bhattacharya has developed a PowerPoint lecture that evaluates falls by looking at the 12 ACOVE (Assessing Care of Vulnerable Elderly) indicators. This is the one of the few presentations that uses the ACOVE indicators as the primary teaching tool. Also included is a brief discussion of the epidemiology of falls. Find this at POGOe – <http://www.pogoe.org/productid/20273>.

4. *Falls for the Inpatient Physician: Translating Knowledge Into Action* – University of Colorado; Author – Ethan Cumbler, MD

This is a PowerPoint module that is unique in that it discusses falls primarily in the elderly inpatient. Dr. Cumbler also briefly discusses the barriers to treating complex geriatric syndromes like falls, referencing the concepts of “multiple alternative bias” and “possibility paralysis.” He includes a facilitator’s manual in a Word document that gives suggestions as to how to lead group discussions with the use of the PowerPoint presentation. This can be found on POGOe – <http://www.pogoe.org/productid/20212>.

Both the CHAMP program and the E-Learning for Licensed Professionals have modules regarding falls in the elderly (see above).

Functional Decline

1. *Functional Assessment in the Older Adult* – University of Cincinnati College of Medicine; Author – E. Gordon Margolin, MD

Included is a case, a detailed discussion of the functional assessment of older patients, including definitions for ADLs and IADLs, and a document that explains the rehab services available at the University of Cincinnati. After the student has learned about the functional assessment, he or she is videotaped interviewing a standardized patient and her daughter, then critiqued by a geriatrician. This can be found at POGOe – <http://www.pogoe.org/productid/18715>.

2. *Functional Assessment WebCt Module for Medical Students* – University of New Mexico; Author – Carla Herman, MD

This is a module in PDF format for the third year medical students at the University of New Mexico that defines the functional assessment. Included is a thorough explanation of all aspects of the function assessment, from ADLs to recognizing cognitive dysfunction, and how to use the assessment tools, such as the clock drawing task. This can be found on POGOe – <http://www.pogoe.org/productid/18486>.

Malnutrition

1. *Involuntary Weight Loss in the Elderly* – Mount Sinai School of Medicine; Author – Beatriz Korc, MD

This is a PowerPoint lecture that discusses the significance of malnutrition for the aged patient. The etiology, management options, and overall importance are expounded upon. This can be found at POGOe – <http://www.pogoe.org/productid/20367>.

Pressure Ulcers

1. *Pressure Ulcers* – University of Kansas; Author – Shelley Bhattacharya, DO

Using the ACOVE-3 guidelines, Dr. Bhattacharya has developed a PowerPoint presentation focusing on risk factors, prevention, and treatment strategies. This can be found at POGOe – <http://www.pogoe.org/productid/20274>.

Preoperative Evaluation of the Elderly Patient

1. *Geriatric Anesthesia Modules for Perioperative Evaluation and Management* – University of Nebraska Medical Center; Author – Ed Vandenberg, MD

The University of Nebraska has provided five modules that look at a variety of different aspects of the perioperative evaluation of a geriatric patient, ranging from cardiac evaluation to assessing for delirium risk factors. These can be found at the web site through POGOe – <http://www.pogoe.org/productid/18967>.

2. *Five Practical Tips for the Older Surgical Patient: From a Geriatrician's Perspective* – University of South Carolina School of Medicine; Author – G. Paul Eleazer, MD

Dr. Eleazer has developed a PowerPoint lecture designed to give tips to physicians taking care of the older surgical patient. He describes the change in the physiology of older patients as well as topics such as postoperative delirium, polypharmacy, and fluid management. It can be found at POGOe – <http://www.pogoe.org/productid/18530>.

Pain Control

1. *Postoperative Pain Management in the Elderly* – University of Nebraska Medical Center; Author – Ed Vandenberg, MD

This is one of several modules from the University of Nebraska Medical Center that addresses perioperative issues in the geriatric patient. In the same format as the other modules, this particular module focuses on postoperative pain control using a case-based approach. The module is broken up into segments. To move onto each segment, the learner must answer a question, which is then given an explanation for the correct answer. At the end of the case are links to topics related to pain control. Also within the module itself are links to related topics. This can be found on POGOe – <http://www.pogoe.org/productid/18774>.

Summary

As the patient population ages, patients on surgical services will grey and present unique management challenges not commonly seen in a younger cohort. Issues for the elderly are complex, and the margin for error is small. Educators, surgical as well as nonsurgical, have begun to recognize the need to construct an infrastructure to insure that the surgeons graduating from training programs have the knowledge base and skills to recognize and manage these problems. Curricula must be designed to incorporate the problems associated with senescence, the response of the elderly patient to surgical stress, and the special needs of these patients after hospitalization. End-of-life questions and issues concerning palliative care have taken common place in dealing with the elderly surgical patient. Education in these areas cannot be left to chance.

Steps have been taken to begin the acquisition of resources to assist in this process. While the initial efforts are promising, they are far from complete. This chapter has been developed to serve as a general guide, not as a detailed road map. By the time this textbook has been published, additional resources will be available. The links found in this chapter will lead to some of the new materials, e.g., POGOe, but others will be available as well. The Association of Programs Directors in Surgery and the Association for Surgical Education will no doubt continue to develop resources for the education of tomorrow's surgeon that will include geriatric-specific topics. It is hoped that surgical educators will recognize the importance of specific educational curricula for surgical trainees that address the unique needs of an older population, introduce these objectives into their training programs, and develop new programs and ideas that can be shared with the entire surgical community.

Chapter 16

Palliative Care and Decision Making at the End of Life

Melissa F. Perkal

CASE STUDY

Mr. O is an 82-year-old man living independently with his wife of 57 years. He presented to the surgery clinic with 2–3 months of left lower quadrant pain radiating to his groin, a mild increase in abdominal girth, and a small nontender umbilical hernia. Computerized tomography revealed a 24×17×7 cm retroperitoneal mass consistent with a liposarcoma, a moderate left-sided pleural effusion and atelectasis of left lower lobe. He described his bowel movements as normal and his pain was well-controlled with Tylenol. He had some early satiety, mild shortness of breath but was ambulating comfortably for 1–2 blocks with a walker. After a long discussion regarding the risks and benefits of surgery, he wished to proceed. His wife was identified as the surrogate decision maker.

His son had died many years prior and he felt that the son had suffered pain and indignity. At that time, Mr. O was the decision maker to decide to withdraw care (he states he had to “pull the plug”) and he did not want to place his family in the same position. Therefore, he was given the opportunity to meet with the palliative care team preoperatively with his daughter-in-law and wife. He was adamant that if his surgery did not go well that he would opt for a transition to palliative care.

The patient underwent an 8 hr en-block resection of the tumor with positive margins and placement of a left chest tube. Postoperatively he remained intubated for 1 day in the surgical intensive care unit. He developed some

mild delirium which cleared by postoperative day 5. He then did well, ambulating, his diet was advanced, and the chest tube was removed. Postoperatively he was followed by both the geriatrics and palliative care teams. His pain was well-controlled with codeine products.

He was working with physical therapy, ambulating, tolerating a regular diet, and ready for discharge to short-term rehab by postoperative day 11. He had lengthy discussions with his care team, understood his diagnosis, and was looking forward to eventually returning home. He made sure that everyone knew his long-term wishes.

On postoperative day 12, he developed new shortness of breath, increased work of breathing, a pulmonary infiltrate, and leukocytosis consistent with pneumonia. After discussion with his family and the patient, he was intubated for short-term treatment of the acute problem. On postoperative day 15, he self-extubated and stated that he wanted no further intubation if needed; a DNR/DNI order was written. He received continued antibiotics, nutritional support, and was transferred to the step-down unit. Again he developed some mild delirium treated with haldol. He again improved and was looking forward to discharge to a rehab facility. However, on a Sunday, postoperative day 26, he developed the acute onset of bradycardia, hypotension, and depressed mental status. Family visiting from the West Coast insisted on transfer to an increased level of care. The wife and primary surgeon felt pressured and Mr. O was transferred back to the intensive care unit for closer observation and

CASE STUDY (continued)

pressors. An urgent family meeting with the chaplain, social worker, palliative care team, the surgeon, the nurse, the visiting family, his wife, and daughter-in-law was held to discuss the patients' previously stated wishes.

All were finally in agreement and comfort care was then initiated. He was started on morphine and ativan drips. The patient expired on postoperative day 29 surrounded by his wife and family.

This case represents both good and bad aspects of approaching the elderly patient who is at the end of life.

Palliative Care

Palliative care is the interdisciplinary care focused on improving the quality of life for patients and families who face life-threatening illness. It provides pain and symptom relief, spiritual and psychological support from diagnosis to the end of life, and bereavement [1]. Palliative care is offered simultaneously with life-prolonging and curative therapies for persons living with serious, complex, and advanced illness [2]. Ideally, palliative care is provided at the same time as curative care. As a disease progresses and the goals of care change, the proportion of palliative care increases (see Fig. 16.1). Palliative medicine treats serious illness regardless of prognosis and patients can receive it at any point in their illness, with or without curative treatments [3]. It should provide care for the patient over time and not just crisis management at the end of life [4]. There is increasing support for the idea that having surgeons actively involved in the process provides the most effective means of helping surgical patients who need palliative care [5]. Surgeons bring unique expertise to palliative medicine because surgeons have a special relationship with their patients; this helps them in providing total care in complex medical circumstances [6]. Providing palliative care has become more universally accepted and palliative care programs are expanding dramatically. According to the Center for Advancement of Palliative Care, there has been an almost 50% increase in hospital-based palliative care programs from 2000 to 2008 (632 programs to 1,299 programs) [3]. Nearly 50% of hospitals located in cities with populations larger than one million have these services. However, research in and clinical guidelines for palliative care have predominantly focused on younger adults, especially those with cancer.

FIGURE 16.1 The continuum of palliative care: from presentation to death (from [2] with permission from Elsevier).

The proportion of the US population past the age of 80 has increased dramatically. At the age of 80, about four of every ten men and three of every ten women will die within 5 years [7]. National data reveal that marked variations were found in the number of days spent in the hospital in the last 6 months of life for the population over the age of 80. The local availability of hospital beds is the most powerful predictor of site of death in this age group according to a study by Goodlin et al. [7]. In general, regions with high rates of inpatient care were located in the states of New York, Pennsylvania, New Jersey, West Virginia, Kentucky, Maryland, South Carolina, Mississippi, Alabama, and Arkansas. Those with low rates were likely to be in the West (Oregon, Utah, and Washington). In this study, physicians reported the most significant difficulties for many patients included assistance with self-care, pain, need for emotional support, and cognitive impairment.

Older patients are still systematically disadvantaged in their access to palliative care. Although death occurs far more commonly in older people than in any other age group, the evidence base for palliative care in older adults is sparse [8]. A study of palliative care consultations comparing patients aged 80 and older to younger patients gives insight into how caring for these older adults is unique and challenging [9]. The researchers studied 1,184 patients referred to an academic palliative care service over a 38-month period. The three most common conditions for seeking consultation were: dementia, stroke or coma, and heart disease; only 38% of the elderly patients had cancer. Results showed that 37% of patients aged 80 and older already had a DNR order present at the time of consultation and that the remaining patients were more likely to have a DNR order issued at the time of consultation (73%) when compared with younger patients. There were significantly more recommendations (34–43%) to withhold or withdraw artificial nutrition, hydration, phlebotomy, and antibiotics in this age group when compared with those less than 80 years. In addition, there were fewer interventions for pain, nausea, anxiety, and other symptoms in the 80 and over age group. These significant results may be the result of the palliative care team communicating with the patient families and not with the patient directly in designing goals of care.

In 2001, the Assessing Care of Vulnerable Elders project (ACOVE) [10] published quality indicators for the end of life care. The 14 indicators aim to achieve a “good death” by focusing attention on patient preferences for care and on palliation. Nine of these measures tailor care so that it is matched

with the patients' preferences. The first guideline recommends that all vulnerable elders have an advance directive with a surrogate decision maker identified on their chart. "When a vulnerable elder is admitted to the hospital and survives 48 h then the patient's prior preferences regarding life-sustaining therapies should be documented in the medical record" [10]. Out-patient advance directives should be acknowledged when the patient changes care settings and honored in the new care setting. The remaining measures address ventilator withdrawal, treatment of dyspnea and pain, spiritual issues, and searching for next of kin.

Geriatric care and palliative care have many similar areas of concern and have much to offer in improving the care to this fragile population. Both emphasize the quality of life as the key determinant of choices in care and treatment options; both make "the person" and "the family" the unit-of-care; and both have placed a strong emphasis on multidisciplinary models of care [11]. Both disciplines also have difficulty in establishing prognosis and time course in noncancer illnesses. Elderly people have distinct needs when providing palliative care. At a time when social support is most needed, many of our elderly patients have diminished financial resources and a lack of caregivers. The potential for isolation and loneliness is increased because of the deaths of loved ones, adult children (with their own medical problems) taking care of elderly parents, and families that are now spread over wide geographic areas [12].

Most elderly patients have at least two chronic medical disorders, which complicates palliative care. By the age of 74, the most common comorbid ailments are hypertension, angina and coronary artery disease, respiratory disease, diabetes mellitus, and previous solid tumors [13]. Symptoms associated with comorbid diseases need to be integrated into the overall palliative care plan. In addition, Bernard Isaac described the "giants of geriatric medicine" (dementia, delirium, urinary incontinence, and falls), which need to be taken into account when delivering high-quality palliative care. The more recently described syndrome of frailty adds an additional diagnosis to be considered in providing palliative care. Frailty manifests the following core clinical features: loss of strength, weight loss, low levels of activity, poor endurance or fatigue, and slowed performance. The presence of three or more of these features is associated with adverse outcomes including falls, new or worsened functional impairment, hospitalization, and death [14]. However, a recent study has shown that while patients with the diagnosis of frailty have a steady decline in functional ability in the last 2 years preceding death, there is only a slight acceleration in decline as death approaches. This study found there was no clear point before death where there was a marked increase in the prevalence of functional impairment [15]. Therefore, the hospice model which relies on a short-term period of decline and on the ability to care for oneself before death does not work for this population [15]. Older palliative care

patients are more likely to suffer and die from chronic illnesses preceded by lengthy periods of decline and functional impairments [9].

Symptom Management

The transition from "cure" to "comfort" encompasses shifts in philosophy and practice for both physicians and patients. As the traditional medical model shifts to palliation and end-of-life care, aggressive care comes to a halt. Disease progression is no longer a focus of attention and the reduction of symptoms assumes primacy. Families and patients need to know that as the dying process continues, the frequency of contacts with the health care system will stay the same (or may even increase) as care shifts from curative to palliative. Assessing symptoms can be challenging in patients who have difficulty in verbalizing their needs. The most common physical symptoms in terminally ill elderly patients include pain, dyspnea, nausea and vomiting, anorexia, constipation, and fatigue. Certain symptoms are common no matter what the cause of death; nearly three quarters of all dying patients experience pain and half have difficulty in breathing and loss of appetite [16]. Physical symptom management is as important in elderly dying patients as in younger patients [9, 17]. Many symptoms near the time of death are more common with advancing age. Those aged 85 years and older are more than twice as likely as those younger than age 55 to experience confusion (52% vs. 21%) or loss of bladder control (51% vs. 24%) [17]. Elderly patients are also more likely to experience dizziness or loss of bowel control.

Pain

A full discussion of the physiology and treatment of pain can be found in Chap. 26. However, because pain is one of the most distressing and disabling problems which palliative medicine addresses, several points deserve repeating here [18].

The goals of a clinical assessment for pain in the elderly may be similar to those established for younger patients; however, unique characteristics of aging make this assessment more challenging for clinicians. These characteristics include the reluctance of older individuals to report pain, the assumption that pain is a normal part of aging, sensory and cognitive impairments, and fear of the consequences of acknowledging pains (such as further testing and hospitalization). In addition, older adults often have multiple comorbidities that may have an impact on the pain presentation. The pain experience can influence mood, physical functioning, and social interactions. The many factors that can contribute to pain in the older, dying adult are summarized by Gibson and presented in Table 16.1 [19].

TABLE 16.1 Factors that contribute to pain in the older, dying patient

However, despite an increasing focus on pain research over the past decade, the precise incidence and prevalence of pain in older people is still not well described. It has been suggested that 45–80% of nursing residents have substantial pain and that many of these patients have multiple pain complaints and multiple potential sources of pain [20]. Studies have suggested that the prevalence of pain in community-dwelling older adults may be as high as 25–56%. In addition, a body of research indicates that pain is often present prior to death [21]. In one retrospective study, interviews with survivors representing 200 deceased older community residents, randomly selected from the death certificate list in a large American city, indicated that pain increased over the final year of life when compared with a matched comparison group of living persons [22].

Pain is also common in hospitalized elder patients. The Hospitalized Elderly Longitudinal Project (HELP) was a subset analysis of a controlled prospective study of hospitalized patients 80 years and older with one or more high-mortality diseases [23]. HELP evaluated the prognosis, symptoms, and decision making in these adults. Pain was reported by 45.8% of patients in the hospital with 12.9% being dissatisfied with their pain control while they were in the hospital. Pain was moderate to severe in 16.8–19% of the patients. Pain persisted after discharge, with 49.8% having pain for 2 months and 53.6% for 1 year follow-up [23].

In patients with terminal cancer, the high prevalence of pain is well documented. Treatment for pain in this population is commonly inadequate. A multicenter study of outpatients

with metastatic cancer done by the Eastern Cooperative Oncology Group found that nearly half those with pain did not receive the type of analgesics recommended by the guidelines of standard cancer-pain management. Elderly patients, particularly those older than 70 years of age, and women from minority racial groups were at greatest risk of inadequate analgesia [24].

Pain assessment in older adults with delirium is extremely challenging. No single diagnostic test exists to determine the presence of either pain or delirium. Since there is considerable overlap between delirium behaviors and nonverbal pain behaviors, clinicians may need multiple assessment tools in addition to their own assessment and caregiver input to assess pain accurately. Close attention must be paid to nonverbal signs (vocalizations, grimacing, bracing, restlessness, rubbing, and agitation) in addition to the usual cues. Guidelines to pain assessment in nonverbal adults include: obtain self-report if possible, investigate for possible pathologies that could produce pain, observe for behaviors that may indicate pain, solicit surrogate report, and use analgesics to evaluate whether pain management causes a reduction in the behavioral indicators thought to be related to pain [25].

However, many patients with dementia can express that they are experiencing pain, and most are able to complete a pain assessment instrument [26]. In one study, 65 of 66 patients with moderate dementia [mean mini-mental status exam (MMSE) score of 16] were able to respond to at least one of the three scales including the Iowa pain Thermometer, the Verbal Descriptor Scale, and the Numeric Rating Scale [27]. Even in the most demented patients (MMSE < 11), 59% were able to complete a pain tool [28, 29].

Gibson et al. provide an excellent guideline for alleviating pain in the older dying patient. These management strategies do not rely only on medication (see Table 16.2). Non-pharmacologic interventions that may potentiate the analgesic effect or improve subjective well-being for older individuals with chronic pain include relaxation techniques, cutaneous stimulation (i.e., heat, cold, and vibration), modulated exercise, distraction and relaxation, and cognitive-behavioral therapy [19].

Once medication is needed, the American Geriatric Society (AGS) Guidelines for the management of chronic pain in older persons is an excellent resource to pain management [30]. The AGS guidelines caution to “start low, and go slow” allowing for the safe titration of effective pain treatment while avoiding adverse effects. These guidelines emphasize the optimization of the analgesic regimen and provision of medication “around the clock,” rather than “as needed” for constant pain. A critical component of pain management is anticipation of breakthrough pain due to incident pain (pain related to specific events such as movement, coughing, and personal care or treatment procedures) and end of dose failure.

TABLE 16.2 Factors that alleviate pain in the older, dying patient

<i>Chronic conditions</i>	<i>Malignant disease</i>	<i>Breakthrough pain</i>
<ul style="list-style-type: none"> • Optimal analgesic management • Around-the-clock dosing for constant pain • Modulated exercise • Relaxation • Cutaneous stimulation (e.g., heat and cold vibration) • Cognitive-behavior therapy 	<ul style="list-style-type: none"> • Optimal analgesic management • Comfort measures (e.g., positioning) • Nonpharmacologic interventions 	<ul style="list-style-type: none"> • Treatment of underlying causes • Optimal analgesic regimen • Rescue dosing • Education • Participation
<i>Care procedures</i>	<i>Emotional/cognitive state</i>	<i>Response of others</i>

The guidelines recommend acetaminophen as the initial and on-going pharmacotherapy in the treatment of persistent pain, unless the patient has liver failure. The maximum daily recommended dosages of 4 g per 24 h should not be exceeded and must include “hidden sources” such as from combination pills. Nonselective nonsteroidal anti-inflammatory drugs (NSAIDs) and COX-2 selective inhibitors may be considered rarely, and with extreme caution, in highly selected individuals [30]. Older patients taking these agents should use a proton pump inhibitor or misoprostol for gastrointestinal protection. The risk of gastrointestinal bleeding increases with age from 1% in the general population to 4% in those over the age of 60 [31, 32]. Older persons are also known to be at greater risk for NSAID-related renal toxicity [33]. Nonopioid agents are usually effective for mild pain (1–4 on a 0–10 scale) while opioids are often needed for moderate [5, 6] or severe (>7) pain.

Opioids are the mainstay of therapy with pain of moderate or greater intensity. Doses must be high enough to relieve pain and given frequently enough to prevent pain recurrence. Clinicians should anticipate the potential for opioid-associated adverse effects. For all patients on opioids, a stool softener and laxative is needed on a regular schedule. Fiber should be discouraged because it can exacerbate opioid-induced constipation in patients with poor oral intake [34]. The nausea and sedation often associated with the initiation of opioids usually abates within a few days; if these symptoms persist, a trial of a different opioid is warranted [35] (see Chap. 26). When switching between opioids, the dose of the new agent

should be 50–67% of the calculated equianalgesic dose because patients are incompletely tolerant to the respiratory and sedative effects of the new opioid [36]. Methadone should be initiated and titrated cautiously only by clinicians well versed in its use and risks [30]. When long-acting opioid preparations are prescribed, breakthrough pain should be anticipated, assessed, prevented, and treated using short acting immediate-release opioid medications. For breakthrough pain, a “rescue” dose of an immediate-release opioid at 10% of the total daily opioid dose to be given every 2 h as necessary is indicated [37].

Dyspnea

One of the most common and distressing symptoms found in many end-stage disease processes is dyspnea. Dyspnea is the subjective sense of breathlessness or the uncomfortable awareness of breathing. It occurs at the end of life with a prevalence of 21–70% [38]. Dyspnea is not well correlated with the degree of hypoxemia or hypercarbia on arterial blood gas, airway obstruction on pulmonary function tests, or the presence of cyanosis or tachypnea on physical exam [38]. Initially, all reversible causes should be sought and aggressively managed (e.g., pleural effusion, pericardial effusion, congestive heart failure, bronchospasm, and bronchial obstruction). However, it remains a significant symptom even after maximal disease treatment. Nonpharmacologic interventions for dyspnea, such as positioning, dehumidification of ambient air, the use of fans, and soothing environmental changes, are often highly effective adjuncts to pharmacologic treatment.

Opioids, particularly morphine, provide highly effective relief for most patients and are the mainstay of therapy. For severe dyspnea, a dose of morphine of 5–15 mg orally is used. For breakthrough dyspnea, a dose can be repeated every 2 h. The mechanism of action is poorly understood but is likely the suppression of the central ventilatory drive in addition to the central effects of analgesia and euphoria that palliate dyspnea [38]. Fear and anxiety are often a component of dyspnea and the use of an anxiolytic can be beneficial. Benzodiazepines, and to a lesser extent phenothiazines, have also been used to treat dyspnea. These should be started at very low doses with frequent repeat administration to titrate for the reduction of symptoms. Benzodiazepines will occasionally contribute to delirium in the elderly and need to be used carefully. There is no clear evidence as to which category of medication will be most effective in any given patient, and clinical judgment combined with therapeutic trials is the best approach.

The use of oxygen is common in the treatment of dyspnea, but is not always effective. Hypoxemia does not necessarily correlate with the subjective symptom of dyspnea and its correction may not produce symptom relief. The drawbacks of

oxygen therapy include cost, the intrusive and noisy apparatus, restrictions on activity, and difficulties in keeping tubing or masks in place in many elderly patients. Oxygen should only be used if the patient finds it to be of benefit. [39].

Constipation and Obstruction

Decreased gastrointestinal motility occurs frequently near the end of life and is also a common condition in the elderly. Ileus, mechanical obstruction, and metabolic abnormalities can lead to constipation. In addition, constipation is a frequent adverse drug effect of many drugs including opioids and those with anticholinergic side effects. Routine laxative therapy should not be initiated in patients with severe constipation until fecal impaction has been excluded.

Regular administration of stimulant laxatives (e.g., senna and bisacodyl) or osmotic agents (e.g., milk of magnesia, sorbitol, lactulose, and polyethylene glycol) is often necessary for the management of constipation in the terminally ill. It is important to titrate to an effective dose of a single agent before adding additional agents [39]. Recent studies have shown encouraging results relieving constipation with administration of the μ -opioid-receptor antagonists: methylnaltrexone and naloxone. Oral naloxone accelerates transit through the transverse and rectosigmoid colon and is poorly bioavailable; therefore, very little naloxone appears in the systemic circulation. Methylnaltrexone has a limited ability to cross the blood–brain barrier. Therefore, treatment does not affect central analgesia or precipitate opioid withdrawal. Methylnaltrexone given subcutaneously often results in relief of constipation within 4 h [40].

Differentiating bowel obstruction from constipation is an important consideration. For patients with a history of either completely resected abdominal malignancy or an earlier nonabdominal malignancy with known potential for intra-abdominal metastatic disease (breast cancer, lung cancer, and melanoma), malignant obstruction should be high on the differential diagnosis list if bowel obstruction is seen on radiographic evaluation. There are no comparative studies comparing cost, patient comfort, and diagnostic accuracy of different radiographic techniques but the data currently suggest that CT scanning should be used in the evaluation of malignant bowel obstruction [41]. One must remember that a large percentage of bowel obstructions even in patients with intra-abdominal malignancies are from benign causes, such as simple adhesions, and may have a straightforward surgical solution.

Although surgical approaches can be an option to treat malignant bowel obstruction, this does not mean that every patient should undergo surgery [41]. Appropriate patient selection is imperative because operative mortality is frequent (5–32%), morbidity is common (42%), and reobstruction after operation is high (10–50%) [41]. The primary goals

of treatment are to relieve obstruction-related nausea and vomiting, to allow the patient to eat and to permit the patient to return home or to a nursing facility under hospice care. Literature suggests that patients less likely to obtain a benefit from surgery include those with ascites, carcinomatosis, palpable intra-abdominal masses, multiple bowel obstructions, and very advanced disease with poor overall clinical status [41]. Surgical options should provide the quickest and safest procedure that can alleviate the obstruction (resection, intestinal bypass, or stoma).

Nasogastric suction is the mainstay for temporary treatment of bowel obstruction where surgical intervention may be indicated, however, it is poorly suited to the management for those patients where surgical intervention is not an option. Numerous endoscopic options provide more durable and comfortable benefit. Endoscopic stent placement has successfully relieved obstruction at many sites of malignant bowel obstruction in both the upper and lower GI tracts. Percutaneous endoscopic gastrostomy (PEG) tubes can alleviate the symptoms of intractable nausea and vomiting. This method has proved quite useful for patients with end-stage gynecologic malignancies even in the face of ascites [42].

There are many pharmacologic therapies available to relieve the signs and symptoms of bowel obstruction. Opioids can effectively alleviate pain related to intestinal obstruction. If cramping is not present, prokinetic agents such as metoclopramide can provide temporary relief of partial obstruction. Macrolide antibiotics have been shown to be beneficial for improving gastrokinesis by acting as a motilin receptor agonist [43]. Erythromycin which stimulates gastrointestinal motility has been useful in patients with both gastroparesis and colonic pseudo-obstruction [43]. Octreotide, a somatostatin analog, is one of the most effective medications for the relief of nausea, vomiting, abdominal distension, and pain in patients with permanent obstruction [44]. Somatostatin inhibits gastrointestinal hormones decreasing acid secretion, bile flow, mucous production, and splanchnic blood flow. Octreotide stimulates myoelectric activity within the gut leading to faster esophageal contractions and greater motility within the rectosigmoid [45]. The inhibitory effect of octreotide on secretion seems to reduce pain and vomiting by decreasing distension. Control of vomiting is rapid, often 2–4 h within achieving the correct daily dose of octreotide. Typical doses are from 0.3 to 0.6 mg per day, usually given subcutaneously. There are few side effects, mostly pain at the injection site.

Anorexia and Nutritional Concerns

Elderly patients are at risk for malnutrition. An estimated 35–65% of hospitalized older persons are malnourished and almost half have decreased appetite [46, 47]. This leads to

negative nitrogen balance and then to significant muscle loss which reduces patient mobility, decreases respiratory function, and is associated with poor performance status and outcomes. Early in the course of palliative care, adequate nutrition to stabilize muscle loss or regain lean tissue mass is the goal in sustaining functional status, quality of life, and preventing events such as skin breakdown and pressure ulcers. Therefore, efforts should be made to assess the potential for nutritional intervention. Reversible causes of reduced food intake should be treated. These include inadequately treated pain, nausea, an inability to swallow, poor fitting dentures, malabsorption, gastroparesis from autonomic dysfunction, and clinical depression [46, 47]. However, data supporting the use of commercial nutritional supplements are varied. A systematic review of 31 randomized controlled trials of nutritional supplementation, involving 2,464 elderly hospitalized or community-dwelling participants, found that supplements containing protein and calories had a small effect on weight gain but no effect on strength, function, quality of life, or morbidity [48]. However, the rate of mortality was reduced in the supplemented group when compared with the control group.

There is little evidence of a benefit for artificial nutritional support in the context of cancer cachexia. Studies on cancer patients using oral or parenteral nutrition have found no difference in body weight, quality of life, or survival, despite a significant increase in nutritional intake [46, 47]. Therefore, the most cost effective and easy solution would be to encourage the patient to attempt small frequent meals and add easy to eat snacks that are energy-dense. This may provide help to patients experiencing early satiety and reduced appetite.

No drugs are approved by the US Food and Drug Administration to promote weight gain in older people. Corticosteroids have been used to improve appetite and general well-being in patients with advanced cancer, but they do not improve muscle mass [49]. A study on hypertensive women receiving ACE inhibitors reported superior muscle strength when compared with women treated with other antihypertensives [50]. Progestins, such as megastrol acetate and medroxyprogesterone, are the best established drugs for increasing appetite and reversing weight loss in patients with cancer, end-stage AIDs, and in frail nursing home residents [49–53]. Responses to megastrol acetate are observed up to a dose of 800 mg/day [49]. Testosterone levels drop in both elderly men and women. In the acute surgical setting, testosterone replacement was associated with a significant improvement in the ability to stand after knee replacement [54]. Many clinical studies report that testosterone and its analogs can facilitate muscle growth, yet the results of anabolic therapy in wasting disorders remain equivocal [49]. It seems a reasonable approach to determine the patient's hormonal status and to offer testosterone to patients with abnormal levels and clinical evidence of androgen deficiency [49].

At the end of life, persistent anorexia and inanition are markers for the terminal stage of several illnesses and may

reflect a final common pathway to death. Unfortunately, anorexia is a common source of distress for caregivers. Many families worry that their loved one will “die of thirst” or “starve to death.” In our food-centered culture, feeding is seen as a sign of love and many worry that withholding food and hydration will hasten death. A study of 32 mentally aware, terminally ill patients who were receiving minimum nourishment revealed that 63% never expressed feelings of hunger and 34% expressed feelings of hunger only initially [55]. Discomfort was noted when patients ate to please their families. By contrast thirst was expressed by 37% of study participants until death. Reassurance from the physician that it is natural to lose interest in eating in advanced illness is usually well-received and an important source of relief and comfort [55, 56]. Nonoral administration of fluids or calories in actively dying patient does not prolong life and it may make the time remaining less comfortable by increasing pulmonary congestion and peripheral edema or by enhancing tumor growth [57].

In patient with advanced dementia, tube feeding has been shown not to be beneficial [55]. It is unlikely to prevent aspiration, prolong survival, reduce the risk of pressure sores or infections, improve function, or provide palliation [58]. However, in most cases, the decision falls to family members, and their choice is then influenced more by cultural factors and family dynamics than by clinical benefit.

Delirium

Delirium is an acute change in a patient's level of consciousness and thought processes that develop over a short period of time; it is often waxing and waning and is a significant change from previous functioning. Attention, concentration, speech, memory, or perceptions may be impaired. Patients with delirium can be agitated or quietly confused [18]. Delirium is a common syndrome that affects sick or frail older adults at high rates. Approximately 30% of all hospitalized older adults [59] and as many as 50% of older patients undergoing surgery may develop delirium [60]. Greater than 70% of all patients admitted to the medical intensive unit experience delirium [61]. More than 80% of dying palliative care patients become delirious as part of the syndrome of imminent death [62].

The diagnosis of delirium is made clinically at the bedside. One useful and validated diagnostic tool is the confusion assessment method (CAM) [63]. To meet the criteria for delirium using the CAM, a patient must have an acute onset of a change in mental status, a fluctuating course, and an inability to hold attention. In addition, the patient must display one of the two criteria: disorganized thinking or altered level of consciousness [64].

Differentiation between delirium and dementia is not always clear, and the features of the two syndromes sometimes overlap. The onset of delirium is rapid; dementia

usually develops slowly. In delirium, the ability to attend is primarily affected. In early stages of dementia, memory rather than attention is affected, although in late stages attention may be severely impaired.

Delirium is best treated by addressing the underlying cause (i.e., a urinary tract infection, dehydration, or untreated pain). Multicomponent nonpharmacologic interventions are effective and should be utilized first [65]. These include frequent reorientation with voice, calendars, and clocks, maintaining a quiet calm environment, eliminating the use of restraints, having familiar objects in the room, and ensuring that the patient has the use of assistive devices (glasses and hearing aids). Pharmacologic therapy should be saved for those patients who are suffering from agitation and hallucinations. Haloperidol starting at low doses (0.5–1.0 mg) is the first line of therapy. It is fast acting and can be administered orally, intramuscularly, or intravenously.

Adverse Drug Reactions

Management of many different symptoms creates an additional burden for clinicians who must also be vigilant for adverse drug reactions and interactions resulting from polypharmacy. Adverse drug reactions are more frequent and severe in the elderly population [66]. Elderly people may be more susceptible to adverse drug reactions because of age-related changes in body composition, metabolic rate, hepatic mass, blood flow, and glomerular filtration rate which affect how the body absorbs, distributes, and eliminates exogenous chemicals. For example, antibiotics commonly cause gastrointestinal side effects including nausea and antibiotic-associated diarrhea. Antibiotic-associated diarrhea has an incidence ranging between 2 and 25%. However, in older patients, the incidence of positive assays for *Clostridium difficile* toxin can be 20–100 times more frequent than in those 10–20 years of age [67]. Another example of the effect of age on adverse drug reactions is with the use of nonsteroidal anti-inflammatory drugs. Perforated peptic ulcer disease secondary to the use of nonsteroidal anti-inflammatory drugs in patients over 65 years is statistically higher than in younger people [68]. However, in order to avoid inadequate symptom management, it is more important for clinicians to monitor for the occurrence of adverse effects rather than withhold medications to avoid these potential side effects.

Prognosis

Understanding prognosis is particularly important in older patients because it can be the key piece of information affecting how the individual makes decisions. In addition,

miscommunication about prognosis in older patients often occurs [69]. Even though predictive models can result in an accurate survival curve for a large group of people with various conditions such as organ failure and cancer, these models cannot accurately predict prognosis for individual patients [83, 84]. This becomes even more complicated in geriatric patients, who may have multiple illnesses, making it even more difficult to predict the ultimate cause and timing of death [8].

The National Hospice and Palliative Care Organization (NHPCO) guidelines for noncancer diagnoses were published in 1996 [70] as an attempt to help clinicians decide when it was appropriate to refer patients for hospice care based on a prediction of less than 6 months survival. The committee developing the guidelines used the best medical evidence at the time to establish clinical prognostic indicators. Hospice programs across the country have adopted these guidelines at the time of referral into the admission process to decide if the patient meets reimbursement criteria under the Medicare hospice benefit. Insurers have similarly adopted most aspects of the guidelines as criteria to use for determining payment eligibility. However, since 1996 many quality research projects looking at the validity of these prognostic criteria have shown that the disease-specific NHPCO guidelines are not accurate in determining whether a patient with end-stage heart or lung disease or dementia will survive more or less than 6 months. For example, both heart failure and chronic end-stage pulmonary disease have unpredictable disease trajectories. In addition, advances in medication and device therapies have changed the prognostic factors used in the NHPCO guidelines [70]. The palliative performance scale (Table 16.3) is a reliable and valid tool that correlates well with actual survival and median survival for a heterogeneous group of palliative care patients and may present more accurate information than individual disease prognoses [71–73].

Advance Directives

Advance directives, referred to as living wills, are applicable when individuals are terminally ill and unable to make their wishes known. Advance directives authorize another individual to execute a treatment directive that specifies which life-sustaining procedures would be “offensive and unwanted” and are based on the Congressional Uniform Rights of the Terminally Ill [74]. Another form of advance directive is the durable power of attorney for health care. A person can appoint another individual to make medical decisions. This delegation of authority over health care decisions becomes effective when individuals are incompetent to make decisions for themselves. Since a primary goal of palliative medicine is patient centered care, determining the patient’s ability to make decisions is fundamental to respecting their true wishes.

TABLE 16.3 Palliative performance scale

Percentage	Ambulation	Activity level <i>Evidence of disease</i>	Self-care	Intake	Level of consciousness	Estimated median survival in days		
						(a)	(b)	(c)
100	Full	Normal <i>No disease</i>	Full	Normal	Full	N/A	N/A	108
90	Full	Normal <i>Some disease</i>	Full	Normal	Full			
80	Full	Normal with effort <i>Some disease</i>	Full	Normal or reduced	Full			
70	Reduced	Cannot do normal job or work <i>Some disease</i>	Full	As above	Full	145		
60	Reduced	Cannot do hobbies or housework <i>Significant disease</i>	Occasional assistance needed	As above	Full or confusion	29	4	
50	Mainly sit/lie	Cannot do any work <i>Extensive disease</i>	Considerable assistance needed	As above	Full or confusion	30	11	41
40	Mainly in bed	As above	Mainly assistance	As above	Full or drowsy or confusion	18	8	
30	Bed bound	As above	Total care	Reduced	As above	8	5	
20	Bed bound	As above	As above	Minimal	As above	4	2	6

The distinction between competency and decision-making capacity is important. Competency is a legal term in which an individual retains their legal rights; decision-making capacity is a medical determination, made for a particular situation and at a particular point in time [2]. Capacity determinations are based on four key aspects: a person's ability to understand the relevant information and the decision at hand, appreciate the significance of the decision and relate it to his or her own life, reason through the options and potential outcomes of a decision, and make and articulate a choice [18]. In the elderly with cognitive impairment, impairment of capacity may be temporary as a result of delirium or depression. Even people with dementia may still participate in their decision making. One study showed that the majority of mildly to moderately demented patients had acceptable decision-making capacity [75]. In another study, 92% of patients with mild-to-moderate dementia indicated that they wanted to be involved in their treatment decisions, and the majority of caregivers supported this [76].

When the patient lacks decisional capacity, a surrogate is held to these same standards. A surrogate is asked to apply substituted judgment, that is, promote the patient's wishes and express the beliefs that the patient holds. The surrogate is encouraged to act as an advocate by being a voice for the

patient. The distinction of substituted judgment is important not only to maintain the ethic of patient autonomy, but also to avoid the burden of the question of deciding to end the patient's life. Instead, the surrogate can be the advocate for the patient's interests in avoiding prolonged suffering [2]. For a more complete discussion of decision-making capacity, see Chap. 14.

Hospice

Current hospice care is modeled on patients who have diseases that are characterized by rapid declines in the ability to care for oneself shortly before death. Hospice provides a multidisciplinary team of professionals including physicians, nurses, home health aides, chaplains, social workers, and volunteers working in collaboration to provide for the needs of the patient and family during the last stage of an illness. The benefit includes care that can be provided in the home setting, skilled nursing facility, or inpatient hospice unit. Hospice provides symptom control, pain management, and emotional and spiritual support expressly tailored to the patient's needs and wishes. Family members also receive

support, caregiver training, and help coping with the loss of their loved one.

Experts agree that hospice is most beneficial when provided for at least 3 months. NHPCO reports that the median length of service was 26 days in 2005 with 30% of people served by hospice in the USA dying in 7 days or less. Furthermore, while eight out of ten Americans have indicated they would prefer to spend their final days at home, those who received hospice for 7 days or less were more likely to be cared for outside of their homes. Families who felt their dying loved ones were referred “too late” to hospice care reported more unmet needs and lower satisfaction with the quality of care provided at the end of life. One of the ten families (11.4%) indicated that hospice care was not provided soon enough according to the research recently published in the *Journal of Pain and Symptom Management*. Inadequate symptom management, poor care coordination, and insufficient emotional support were some of the problems associated with late referrals [77].

The hospice Medicare benefit was introduced in the USA in 1982. To qualify for the Medicare hospice benefit, a patient must have Medicare and be terminally ill; the physician must choose to receive hospice care reimbursement instead of the standard Medicare benefits for the illness; and the care must be provided by a Medicare-participating hospice program [78]. Medicare reimbursement requires careful documentation and considers the patient to be terminally ill if one of the following conditions applies [79]:

1. “The medical documentation meets the criteria in the NHPCO prognosticating guidelines that the patient is terminally ill (i.e., there is no conflicting or inconsistent information in the record to suggest that the patient is not terminally ill even though the guidelines are met).
2. The medical documentation in the record supports that the patient is terminally ill even though the NHPCO guidelines are not met or the patient’s condition is not covered by the NHPCO guidelines.
3. The patient dies from the illness for which he or she elected the hospice benefit.”

The hospice medical director or attending physician provide clinical documentation to support the certification of terminal illness. Documentation may include results of tests or narrative descriptions of the clinical indicators or progression of disease. The patient must have a prognosis of 6 months or less for most hospice programs, including those under Medicare [80]. Unfortunately, older people dying with progressive frailty are poorly suited to taking advantage of this benefit because the course of their illness can be protracted beyond the 6-month limit and there is no clear point where a rapid decrease in functional abilities predicts imminent death [15].

Communication and Establishing Goals of Medical Care

One of the best ways to incorporate palliative care medicine and end-of-life issues into the care of the elderly patient is with a systematic approach at the time of diagnosis or when planning surgical care. Formal advanced care planning including a conversation regarding goals of treatment, living wills, power of attorney for health care decision making, surrogate decision making, and preferences for life-support measures, such as cardiac resuscitation and ventilator support, should be incorporated into the overall care plan of every patient undergoing major surgery, particularly the elderly. A discussion of goals of care is a core competency of geriatric medicine and palliative medicine, and it should be one in surgical specialties as well. As the burden of therapies increase, the patient’s wishes for therapy and outcome become more relevant. Patient preferences can and should be formulated into therapeutic goals, for example, the desire to be discharged to home, surviving to a particular event, being able to communicate and say goodbye, or achieving a more rapid and certain death [2]. Once goals of care are established, they can be used to construct advance directives about specific care interventions, such as cardiopulmonary resuscitation, ventilator support, hospitalization, and appointment of a health care proxy. It is in the initial phase of working with a patient and family that the groundwork is laid for palliation and adherence to a person’s goals and preferences [2]. Goodlin et al. [80] developed a process to improve the medical care for the very old. This involves clarifying and stating the goals of care with the family and patient, documenting that plan on the chart, and then carrying out that plan with careful attention to the patient’s symptoms (see Fig. 16.2). This same process could apply to any surgeon and patient at any entry point into the medical system.

With the increasing age of the population and more complicated treatment regimens, increased communication is needed regarding disease trajectory, goals of care, and transitioning to an end of life setting. Patient’s families are more likely to have overall satisfaction with their loved ones care if they are regularly informed about the patient’s condition, if they are provided with emotional support, if they are given accurate information about the patient’s medical treatment, and if they can identify one medical practitioner as being in charge of their loved one’s care [81]. The addition of a palliative care specialist, if available, could be an effective addition to the team in helping to negotiate patient-directed goals of care and facilitate dialogue regarding the complex issues surrounding care at the end of life. No matter who is in charge, our goals should focus on what the Institute of Medicine defines as a good death: “one who is free from avoidable distress and suffering for patients, families, and

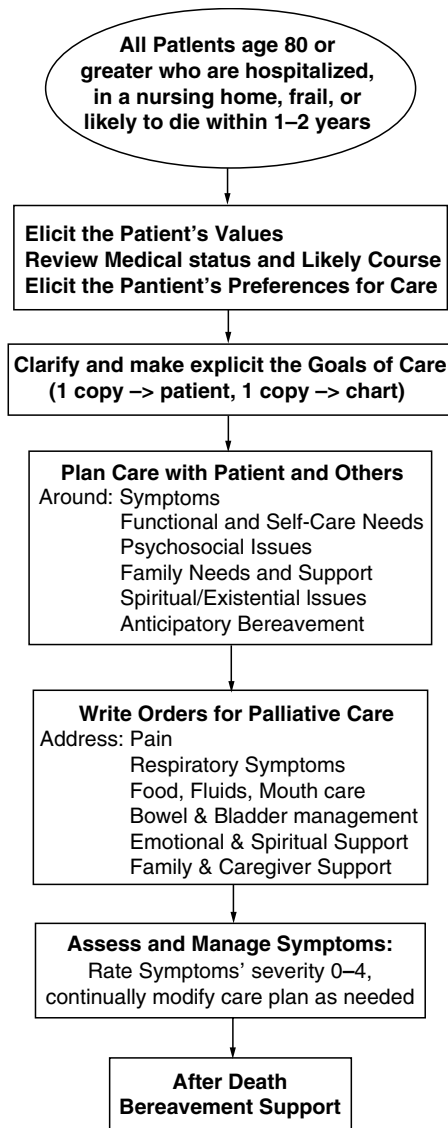

FIGURE 16.2 A process diagram for improving care of dying patients (from [7] Copyright © 1998 American Medical Association. All rights reserved).

caregivers; in general accord with the patients' and families' wishes; and reasonably consistent with clinical, cultural, and ethical standards" [82].

Chapter 17

Surgery in Centenarians

Mark R. Katlic

Ninety years is old, but 100 is news.

– Belle Boone Beard [1]

The 100th anniversary of an individual's birth still bestows an aura, a mystique, as the centenarian is as close to immortality as a human can be. This special prestige has been afforded the imprimatur of scientific study by Baker [2], who found that centenarians represented a striking exception to the inverted U curve of status across the life-span in Western culture. Baker's data, derived from factorial survey analysis, fit the postulate that there is an "American arc of life" that gives maximum prestige to middle age and least prestige to young and old persons. Centenarians, however, were given unique status nearly equal to that of middle-aged individuals (Fig. 17.1), because "like four leaf clovers or quintuplets, centenarians are rare."

Even those who care for centenarians are affected. Nishikawa [3] found that family members who care for centenarians had a lower accumulated fatigue level, despite being older themselves and despite their subjects' worse performance status, than those who cared for individuals aged 70–90 years. Webb and Williams described a case of acute tenosynovitis of the right wrist and hand (centenarian hand syndrome) resulting from the congratulatory handshakes of many friends and relatives on a man's 100th birthday [4].

We have an inherent curiosity about our oldest old. What does he eat? What is her secret? Can it be bottled and sold? Decades ago one entrepreneur, Dr. Marie Davenport, became a professional centenarian, offering to teach her secrets of longevity to others for a fee [1]. Jeanne Calment, the world's presumed oldest person when she died at 122 years, was interviewed weekly by the foreign press who sought her out in Arles, France [5]. In 1997, a popular magazine devoted its cover story to "How to Live to 100" [6].

The mystique may wane, however, as more of us reach this milestone. The present paucity of centenarians results from high mortality rates and a much smaller overall population a century ago. Over the past 40–50 years the number of centenarians has nearly doubled every decade, owing chiefly to improved survival from the age of 80–100 years [7]. When Beard began her monumental, sedulous study of centenarians in 1940, there were 3,700 possible subjects living in the United States; when she ended it during the late 1970s there were at least 14,000 [8]. This number had reached 50,000 by the year 2000 [9], and may be over 200,000 in 2020, and 500,000 to 4 million in 2050 [10]. Some authors argue that even these projections are too conservative because they discount the possibility of future baby booms and assume slow rates of mortality decline and low levels of immigration [11]. Vaupel and Gowan calculated that if mortality is reduced 2% per year, by the year 2080, the number of centenarians in the United States would approach 19 million [12].

Surgical problems do not end on a person's centennial. Surgeons will become increasingly familiar with these most senior citizens.

History

Surgeons have written with increasing frequency about operations in the elderly, but the definition of "elderly" has changed. A report in 1907 listed 167 operations performed on patients older than 50 years [13], and even 20 years later Ochsner taught that "an elective operation for inguinal hernia in a patient older than 50 years was not justified" [14]. Brooks used a limit of 70 years as "advanced age" in his series of 293 operations reported in 1937 [15], and over the next few decades most authors considered patients above age 60–70 years to be elderly. More recent studies show that good results can be expected in octogenarians and

nonagenarians [16, 17], even in those undergoing complex vascular [18, 19], cardiac [20], and cancer operations [21].

An occasional centenarian is included in these series, but most papers devoted to centenarians per se are case reports, some written 40 years ago. Welch and Whittemore [22] in 1954 presented a 100-year-old woman who recovered well from abdominoperineal resection of the rectum for carcinoma. The next year Maycock and Burns [23] discussed prostate surgery in two patents in this age group, and in 1957 Childress [24] successfully treated three femoral fractures under spinal anesthesia. In 1971, isolated cases of pacemaker placement [25] and below-knee amputation [26] were reported. A basket-size ovarian leiomyoma was excised from a 103-year-old woman because of bowel obstruction in 1979, allowing her to live at least two additional years [27]. Six patients aged 100–106 underwent pacemaker procedures with good results in the 1989 report of Cobler et al. [28].

During the 1990s greater numbers of patients were reported. There were three deaths (12.5% mortality) in McCann and Smith's series of 24 patients undergoing a variety of operations, such as colon resection, ruptured aortic aneurysm repair, and hip prosthesis placement [29]. Cogbill's 1992 series of 16 patients reported perioperative mortality of 6% and a 1-year survival of 69% after a variety of small operations [30].

In 1998, Warner [31] reported 42 procedures in 31 patients aged 100–107 years. There was one major complication

FIGURE 17.2 Survival following surgery for patients ≥ 100 years of age. *Numbers in parentheses* represent number of patients alive and followed at yearly intervals during the first 3 years after surgery. (Reprinted with permission from Warner [31]).

(3%) and no mortality within 48 h of operation; 30-day mortality was 16.1%, none directly related to the operative procedure or perioperative morbidity. Subsequent mortality of these patients equaled that of matched peers from the general population (Fig. 17.2). Grey [32] reported a case of revision total hip arthroplasty. This author reported a series of major and minor procedures in six patients aged 100–104 years, all of whom survived (Table 17.1) [33]. The illustrative cases below are from that series.

TABLE 17.1 Clinical summary of centenarians undergoing an operation

Patient no./sex	Age (years)	Medical problems	Operation	Status	Anesthesia	Complications	Death	Follow-up
1/M	100	Old MI, sick sinus syndrome with pacemaker, CHF, prostatectomy, cataract extraction, gout, arthritis, chronic renal failure	Pacemaker generator replacement	Urgent	Local	None	No	Died, age 102 years of CHF
2/F	100	Old MI, left radical mastectomy (13 years), arthritis	Excision of right femoral head, cemented Moore prosthesis	Urgent	General	None	No	Died, age 102 years of cerebrovascular disease
3/M	100	Hypertension, severe peripheral vascular disease, prostatectomy, chronic lung disease	Above-knee amputation	Urgent	General	None	No	Died, age 101 years of "old age"
4/F	100	Old MI, CHF, aortic stenosis, cataract extraction, cystocele repair, left hip open reduction internal fixation, arthritis, hiatus hernia	Open reduction, internal fixation of right hip fracture	Urgent	General	Acute gangrenous cholecystitis, protruding Enders rod pins	No	Died, age 102 years of "old age"
			Cholecystectomy	Emergency	General	Pneumonia, resolved; abdominal abscess, percutaneously drained		
	101		Removal of Enders rod pins	Elective	Local	None		
			Colonoscopic resection of villous adenoma	Elective	Local	Bleeding at excision site		
			Suture ligation of bleeding rectal polypectomy site	Emergency	General	None		
5/F	101	CHF, atrial fibrillation, blind, basal cell carcinoma of face excised, adult-onset diabetes	Right inguinal herniorrhaphy	Elective	Local	None	No	Died, age 102 years of CHF
6/M	104	Squamous cell carcinoma of neck excised, basal cell carcinoma of nose excised and irradiated	Gastroscopy with biopsy	Emergency	Local	None	No	Died, age 105 years of gastric carcinoma

MI myocardial infarction, CHF congestive heart failure

CASE STUDIES

Case 1

A 100-year-old woman fractured her right hip in a nursing-home fall. She had a history of myocardial infarction, congestive heart failure, aortic stenosis, arthritis, and hiatus hernia. She had previously undergone cataract surgery, cystocele repair, and open reduction/internal fixation of a left hip fracture. Open reduction/internal fixation of her new fracture was performed under general anesthesia. During her second postoperative week she developed acute gangrenous cholecystitis, requiring emergency cholecystectomy. This episode was complicated by left lower lobe pneumonia, which resulted in antibiotic treatment, and by a localized intra-abdominal abscess, which was successfully treated with percutaneous drainage and antibiotics. Six weeks after admission she returned to her nursing home. Protruding Enders rod pins in her right leg led to pin removal under local anesthesia 8 months later. At 101 years of age, she underwent elective endoscopic resection of a rectal villous adenoma containing carcinoma in situ. Postoperative bleeding from the resection site mandated suture ligation under general anesthesia. She returned to her nursing home, where she lived two years. She died two weeks before her 103rd birthday.

Case 2

A 100-year-old retired laborer was ambulatory at his nursing home until his toes became painful. He had a history of hypertension, chronic lung disease, and severe peripheral vascular disease and had undergone prostatectomy. On examination, he had a gangrenous right foot with *Proteus* cellulitis extending to the calf and an absence of leg pulses below the femoral arteries. He underwent amputation of the right leg above the knee while under general anesthesia (spinal anesthesia was aborted because of the patient's agitation) and was discharged 11 days later. He had one later 4-day admission for bronchitis and died at age 101 years of "old age."

Case 3

A 101-year-old woman was ambulatory and independent at home, but suffered from a large right inguinal hernia. Her past history included congestive heart failure, atrial fibrillation, adult-onset diabetes mellitus, blindness, and a resected basal-cell carcinoma of the face. Elective right inguinal herniorrhaphy was completed under local anesthesia in the outpatient surgical unit. Postoperatively, stating that she would "rather wear out than rust out," she took a 3-month cruise around the world and later lectured at a local college geriatric course. On the penultimate day of her life she completed a political poll. She died of congestive heart failure at age 102.

Discussion

Centenarians recover surprisingly well from surgery, leading one to speculate that the 100-year-old patient who has not already succumbed to a myocardial infarction or pulmonary embolus is less likely to do so, even in the perioperative milieu. The Mayo Clinic study of surgery in nonagenarians supports this finding, as neither pneumonia nor atherosclerosis with myocardial infarction was a major cause of postoperative death [15].

Certainly all that has been learned about surgery in the elderly should be applied to the centenarian. Clinical presentation of surgical problems may be subtle, preoperative preparation is essential, and scrupulous attention to detail intraoperatively and perioperatively yields great benefit. Virtually all studies of surgery in the elderly have also shown an up to threefold greater risk for emergency surgery than elective surgery. The worst complications in the author's

series, pneumonia and intraabdominal abscess, did occur after emergency surgery, but the patients generally tolerated even urgent operations well.

Centenarians may be considered a natural model of successful aging. What is it about the 100-year-old that allowed him or her to enter this select age group?

Physiologic Changes in Centenarians

The oldest-old manifest low frequencies of the E4 form of gene coding for apolipoprotein E, a protein linked to an increased risk of acquiring Alzheimer's disease. Among healthy subjects age 90–103 years, 14% had at least one E4 gene, in contrast to 25% of subjects younger than age 65 [10]. It may be that many of those with E4 suffer early Alzheimer's disease and do not survive to become centenarians. This *cohort effect* may explain some of the other

physiologic and pathologic changes in centenarians described below. Silver found that dementia is not inevitable with aging and that dementia in centenarians is often not attributable to Alzheimer's disease [34–36].

Morphologic changes occur in the brain with age – decreased brain weight, atrophy of the cerebral hemispheres, fall in the number of Purkinje cells in the cerebellum – but healthy aged subjects show little difference from young adults with respect to cerebral blood flow and oxygen uptake [37]. Hubbard et al. studied electroencephalograms in centenarians and found slowing of the posterior dominant rhythm, but there was no evidence of a progressive decrease in frequency between the ages of 80–100 years [38]. Well-preserved mucociliary clearance in the lung of a centenarian was documented by Pavia and Thomson despite 80 years of smoking history [39].

An even more paradoxical finding was described by Mari's group [40]. They found that a high proportion of 25 healthy centenarians had laboratory evidence of activation of the coagulation system, shown by high levels of enzymes, activation peptides, and enzyme-inhibitor complexes. Levels of factor X activation peptide were equal to those found in patients with disseminated intravascular coagulation. Even procoagulant proteins such as fibrinogen and factor VIII – predictors of cardiovascular disease in young adults – were elevated in centenarians; yet these individuals had no current or past thrombotic events. The authors concluded that significant alterations of these markers are still compatible with health and long life. A more recent study by this group found that the 4G allele and 4G/4G genotype associated with elevated levels of plasminogen activator inhibitor 1 (PAI-1), which predicts recurrence of myocardial infarction in young men, were even more frequent in centenarians than young adults.

The homozygous genotype for the deletion of polymorphism of the angiotensin converting enzymes, which predisposes to coronary artery disease, is also paradoxically more frequent in centenarians than in adults of age 20–70 years [41]. Mannucci et al. speculated that occult factors compensate for these putatively unfavorable genotypes in centenarians (e.g., linkage disequilibrium with a locus counteracting the bad effect of elevated PAI-1 levels offsets the risk of hypofibrinolysis). It may be that if an elderly person has already escaped thrombotic disease, it is advantageous to have decreased fibrinolysis [42]. A different genetic finding in centenarians – decreased frequency of the E4 allele of the gene, which encodes apolipoprotein E – would go along with decreased risk of ischemic heart disease [41].

Laboratory values in healthy centenarians may differ even from those of younger elderly adults: widening of the range for sodium levels to 132–146 mmol/L, slightly higher potassium and chloride, decreased total calcium, slight increase in ionized calcium, increased blood glucose, increased alkaline phosphatase and lactate dehydrogenase, slightly decreased

bilirubin and total protein, increased amylase likely due to decreased renal function, increased serum urea nitrogen and slightly increased creatinine, increased urinary albumin, elevated urate, decreased albumin, elevated carcinoembryonic antigen, decreased cholesterol and triglycerides, decreased vitamin B₁₂, decreased zinc, slightly decreased thyroxine, increased prolactin, no change in corticotropin, decreased testosterone and estradiol, marked decrease in dehydroepiandrosterone, decreased progesterone, unchanged cortisol, slightly higher gastrin, lower erythrocyte, leukocyte, and platelet counts, slight decreases in hemoglobin, hematocrit, and iron [43]. Higher functioning centenarians appear to have higher levels of serum albumin [44]. Discussion of possible mechanisms for these findings is beyond the scope of this chapter.

Franceschi asserted that a complex remodeling of the immune system occurs in healthy centenarians in contrast to the presumed progressive deterioration (especially with the T-cell branch) [45, 46]. Peripheral blood T cells and major T cell subsets are only slightly decreased despite age-related thymic involution. B lymphocytes are decreased despite data that several immunoglobulin classes are elevated in the serum. Interestingly, peripheral blood lymphocytes in centenarians appear resistant to the oxidative stress that causes irreversible cell damage in younger individuals; such stress may retard entrance into the cell cycle rather than cause permanent damage [47].

Centenarians are more likely to have low body weight [48, 49], possibly due to loss of muscle and fat [50]; a number of investigators have reported short stature even when the effects of aging are considered. Decreased bone mass, however, is not universally present [51]. Both male and female centenarians are more likely to have feminine or androgynous personality traits, rather than masculine ones and are more likely to have a type B behavior pattern (easy-going) [52].

Pathology in Centenarians

Although atherosclerosis has been found in coronary, cerebral, femoral, and abdominal aortas of centenarians [53], the ascending aorta may be spared [48, 54]. Myocardial fibrosis is located chiefly in the left ventricle and septum, and cardiac amyloid deposition is characteristic [53]. Coronary disease at autopsy is common [55, 56], though perhaps less so in Japanese centenarians [57]. Pneumonia was found in 15 of 23 patients in Ishii and Sternby's series and was also the most common cause of death [53]. Alveolar ectasia and decreased elastic fiber were also seen in the lungs. Interestingly, recent or old thromboembolism in the pulmonary arterial tree was common at autopsy despite the absence of clinical pulmonary emboli during life [53].

In the kidney, chronic pyelonephritis and atherosclerosis are usually pronounced; and the testes, ovaries, and uterus show atrophic changes [58]. In the gastrointestinal tract, the liver also shows atrophy and colonic diverticula are common. Gallstones are common (13/23 patients), and peptic ulcer is rare [58]. Osteoporosis is common [59], but not universal [51]. Similarly, in the brain, changes of Alzheimer's disease are common but not universal; when present these may not correlate with clinical neurologic findings [60, 61].

Cancer as a cause of death was unusual in Ishii and Sternby's autopsy series [59]; it represented 7.1% of Stanta's 99 autopsies in centenarians [62], and 31% of Klatt and Meyer's 32 patients [54]. The 7.1% rate in Stanta's series was significantly different ($p < 0.001$) from that in age groups 75–90 years (25%) and 95–99 years (9.5%). Metastases in this series were found in 23.5% of the centenarians with cancer and 63.2% of those 75–90 years old; local infiltration did not differ among groups. Many of the cancers in centenarians (70%) were undiagnosed during life, a fact that may explain the exceptionally low incidence of cancer (4%) as a cause of death in epidemiologic studies [63]. Of all the types of cancer, only the prevalence of gallbladder adenocarcinoma was increased in Stanta's series [62]. Germ-line polymorphisms may play a role in the decreased susceptibility of centenarians to cancer [64]. In exploring an animal model of extreme longevity, Cooley found that only 19% of extreme aged dogs died of cancer versus 82% of dogs with usual longevity ($p < 0.0001$) [65] (Fig. 17.3). In summary, cancer in the oldest-old is less frequent and less aggressive.

Centenarians, like younger individuals, die of specific organ failure, not "old age" [66]. Berzlanovich [67] reviewed autopsy records of forty Austrian centenarians, 60% of whom had been described as healthy before death; all had a specific cause of death, including cardiovascular in 68%, respiratory 25%, gastrointestinal 5%, and cerebrovascular 2%.

Determinants of Extreme Longevity

Despite our fascination with centenarians, little is known about the influences – genetic, environmental, and medical – on their longevity. Vaupel's group, in extensive studies of nearly 3,000 Danish twin pairs born during 1870–1900 estimated the heritability of longevity to be 0.26 for men and 0.23 for women; the sex difference resulted from the greater impact of unshared environmental factors in the women [68]. Other family studies have shown weak correlations for life-span between parents and offspring (0.01–0.05) and somewhat higher correlations between siblings (0.15–0.35) [69, 70] (Fig. 17.4) suggesting either that the genetic factors are nonadditive (genetic intralocus interaction) or there is a higher degree of shared environmental influences among sib-

FIGURE 17.3 Comparison of age-specific cancer and noncancer mortality for 345 Rottweiler dogs. Age-specific cancer and noncancer mortality rates were calculated at 2-year intervals from 0 to 14 years of age and expressed as the number of cancer or noncancer deaths per 100 dogs that entered the interval. (Reprinted with permission from Cooley [65]).

FIGURE 17.4 Percentage of siblings of centenarians and controls who reached age 90 years, when controlling for extrinsic or unknown causes of mortality. (Reprinted with permission from Willcox [70]).

lings than parents. The offspring of centenarians nevertheless manifest less cardiovascular disease than the general population at similar age [71–73], and, in one study, less cancer-specific mortality [73].

Several specific genetic factors have been associated with extremely long life [74]. In a study of Japanese centenarians, Takata et al. [75], showed a significantly lower frequency of HLA-DRw9 and a higher frequency of HLA-DR1 among centenarians compared to younger adults; these antigens are

negatively associated with autoimmune diseases in Japan, suggesting mediation of the genetic influence through a lower incidence of disease. The low prevalence of the E4 allele of apolipoprotein E (APOE) and increased prevalence of the DD genotype for angiotensin-converting enzyme (ACE) have been mentioned above [42]; neither of these, however, was associated with longevity in a Korean study [76]. Puca reported evidence for a specific locus (D451564) on chromosome 4 associated with longevity in a sibling pair linkage study [77]. The role of inherited and somatic mutations of mitochondrial DNA (mtDNA) in centenarians remains unclear [78]. Short chromosomal telomeres have been associated with increased mortality in persons over the age of 60 [79], but this has not held true for the oldest old [80, 81]; nevertheless, Terry [82] found that healthy centenarians have significantly longer telomeres than unhealthy centenarians (Fig. 17.5).

The mediation of genetic influences on longevity via genetic influences on smoking and body mass index – two factors associated with longevity in epidemiologic studies – was disproved by Herschind [83]. Even smoking status has shown no definite association with extreme longevity, nor has alcohol consumption, diet, or exercise [84]. Such “lifestyle” factors may, however, influence one’s functional status at the age of 100 [44]. Environmental factors such as socioeconomic status and early life nutrition appear to have little influence [85]. Although no “fountain of youth” medicine has been discovered, the inverse correlation of blood levels of dehydroepiandrosterone (DHEA) with mortality has prompted ongoing clinical trials of its administration [86],

FIGURE 17.5 Mean telomere length measured in base pairs (bp) in 19 healthy versus 19 unhealthy centenarians. Bars: interquartile ranges (Q75% to Q25%) of telomere length. Diamonds: mean; horizontal line within bars: median telomere lengths; Vertical lines: overall range of telomere lengths. (Reprinted with permission from Terry [82]).

not all of them salutary [87]. Some environments, e.g., Sardinia and Okinawa, appear to be conducive to extreme longevity as do personal factors such as activity, discipline, altruism, spiritual faith [88], musical instruments, and humor. In a study of 483 Italian centenarians, 88.6% had never smoked cigarettes [89]. Centenarians themselves attribute their longevity to God, singing, pickled herring, shochu (sugar cane liquor), honey, port, abstinence, boiled onions, whiskey, red wine, fish, luck, chocolates, olive oil, weakness for women (or men), and more.

In summary, it is likely that a large number of factors interact to determine longevity, three-fourths of them being environmental (Table 17.2). The involvement of a number of genes, each contributing a little, might influence longevity directly or, more likely, through determining susceptibility to disease at different ages.

Selective Survival Hypothesis

A 100-year-old is as likely to survive surgery as are his sons and daughters, and one may speculate that he is even more likely to do so. The man or woman who has endured ten decades of life’s labors enters a select group whose physiological resilience is greater than that of many who are chronologically younger. – M.R. Katlic, 1985 [33]

This selective survival concept was discussed by Thomas Perls, principal investigator with the New England Centenarian Study [10]. Perls postulated, supported by his research and that of others, that certain individuals are resistant to the diseases that cripple and kill most people before age 90. These individuals – although 95% have some form of chronic disease [90], including cardiovascular disease [91] – not only

live longer lives, they also live relatively free of debilitating infirmities.

Mortality rates for centenarians, for example, are lower than would be anticipated by extrapolating the death rates of younger adults. Mortality can be reasonably predicted up to approximately age 80, but the linear decline in health not only slows at advanced age, but varies more among individuals, thus selecting the most fit [92]. Selection is more than sufficient to overcome the effects of aging and is greater in men, probably because of their higher mortality at younger ages [93, 94]. This “gender crossover” resulting from the selection of fit men can be seen as early as age 80, but is more evident in centenarians: men make up 20% of 100-year-olds and 40% of 105-year-olds. Female-to-male ratios, however, may range from 2:1 to 7:1 in different provinces within the same country [95]. Age 95–97 years appears to be the age at which a person’s chance of dying increases in a linear rather than an exponential manner with time (Fig. 17.6) [10]. Carey [96] found the same phenomenon in medflies.

Whether due to compositional change in the cohort (selection of the fittest) or better intrinsic cellular defense mechanisms (see peripheral blood lymphocyte data above), the very old have a higher threshold for acquiring disease and a decreased mortality rate, allowing them not only to survive, but to do so in relatively good health (Fig. 17.7). In 1990, the Medicare costs for those who died at age 70 was \$6475 during each of the last 5 years of life compared to \$1,800 per year for those who died at age 100 [97]. In 1995 medical

FIGURE 17.6 Observed mortality rate slows after age 97 years compared to the expected mortality rate. (From Perls [10]. Copyright© 1995 by Scientific American, Inc. All rights reserved).

expenses for the last 2 years of life average \$22,600 for people who died at age 70 and \$8,300 for those who died after age 100 [6].

Perls’ group has described three morbidity profiles for centenarians [98]. *Survivors* had an age-associated illness prior to age 80 years (24% of men and 43% of women); *Delayers* experienced an age-associated illness after 80 years (44% of men and 42% of women); *Escapers* reached age 100 without a diagnosis of common age-associated illness (32% of men and 15% of women). With respect to the most lethal diseases – heart disease, cancer, and stroke – 87% of male centenarians and 83% of female centenarians either delayed or escaped. Motta [99], who studied 602 Italian centenarians, writes that even those who are free of disease, autonomous, and bright should not be considered prototypes of “successful aging”, as they have not maintained any social or productive activities. Most consider centenarians to be models of healthy aging from which we can learn, in order to improve the health of all elderly [100].

Supercentenarians

Supercentenarians, those aged 110 years or more, likely number less than 500 worldwide; most are women [101]. Schoenhofen [102] studied 32 such individuals, 84% of them women. Cardiovascular disease and stroke were rare, Parkinson’s disease absent, and cancer successfully treated in 25%; 41% were independent or required minimal assistance. The parents and siblings of supercentenarians also manifest a survival advantage [103].

Conclusions

All that has been learned about surgery in the elderly should be applied to the centenarian: clinical presentation of surgical problems may be subtle, preoperative preparation is essential, emergency surgery carries high risk compared to elective operation, and scrupulous attention to detail intraoperatively and perioperatively yields great benefit. It is not unreasonable to speculate that the 100-year-old who has not already succumbed to a myocardial infarction or pulmonary embolus is unlikely to do so, even during the perioperative period. Survival to the centenary indicates that one has been tested by life and has been found exceptionally fit. Elective surgery should not be deferred nor emergency surgery denied the centenarian on the basis of chronologic age.

Chapter 18

The Effect of Advancing Age on Physician Performance

Jennifer F. Waljee and Lazar J. Greenfield

Introduction

Regardless of profession, aging is ubiquitous and profoundly influences performance throughout one's career. Often, advanced age is considered to bring wisdom and knowledge through longitudinal experience. A common quote is frequently heard in the hallways of hospitals on rounds and at morbidity–mortality teaching conferences: “Good judgment comes from experience, and often experience comes from bad judgment.”

However, there is considerable evidence to suggest that advanced age is associated with a decline in an individual's performance. One of the earliest examples of such research that has changed public policy is the ability to operate a motor vehicle. Prior research indicates that older adults have less visual field acuity and visuospatial attention compared with younger individuals, which has been correlated with a decreased ability to operate a motor vehicle [1]. Age-related factors associated with motor vehicle collisions include decreased attention, reaction time, memory, executive function, mental status, visual function, and physical function. Such individuals frequently lack insight into their cognitive, sensory, and physical limitations [2].

In recent years, there has been increasing interest in the effects of age on physician performance and healthcare quality. While not only a sensitive and controversial topic, understanding the effects of the aging process on medical practitioners is important for the assessment of competence and the mechanisms and timing for retirement. This review will examine recent data regarding the effects of age on physician performance and consider the implications for physicians in practice and for those who develop healthcare policy.

The Physiology of Aging in Relation to Performance

The physiologic effects of aging are complex and multifactorial. Previous studies have demonstrated that advancing age is correlated with a decline in motor skills (both gross and fine), decreased visual acuity, and impaired cognitive functioning. However, in practice, it is difficult to assess any individual factor in isolation, as they work in concert to enable an individual to complete a task. For example, over time, older individuals are not only less adept at learning a new motor skill by practice, but also less able to integrate these with cognition and to coordinate movement sequences. Older individuals also have slowed cognitive and motor responses to stimuli compared with younger individuals. Similarly, individuals who err in cognitive tasks are more likely to err in concurrent motor tasks as well [3].

Several aspects of cognition have been shown to decline with age. For example, older individuals are less able to learn new tasks through repeated training and subsequently to execute complex tasks. Additionally, age-related declines exist in several aspects of attentive skills, such as sustained attention, selective attention, and inhibition tasks [4, 5]. Previous studies have documented age differences with respect to memory retrieval, but not necessarily memory encoding or motor memory [3]. For example, new motor memories can be retained for at least 2 years without rehearsal in individuals up to 95 years in age [6].

Of interest to surgeons and those physicians in procedural subspecialties, hand dexterity and visual acuity are significantly influenced by the aging process [7, 8]. Older adults have more difficulty maintaining and varying manual force compared with younger individuals. Changes in ocular optics and neural pathways with age result in decreased visual perception, and an individual's ability to discriminate color, contrast, and motion. Older individuals may also have slower visual processing speeds compared with their younger counterparts [9, 10]. Recent encouraging studies indicate that some age-related declines in visual acuity and hand functioning can be prevented with more extended practice which may allow the development of training protocols to prevent age-related decline in skills for practicing physicians [11, 12].

The Effect of Age on Physician Skill

Several studies have looked specifically at the effect of aging on physicians. In 1994, Powell et al. demonstrated a progressive decline in cognitive function among aging physicians, with a notable decline after age 65. These authors assessed physicians and age-matched controls using the Assessment of Cognitive Function (ACF) test, a series of neuropsychological tests assessing one's ability to process and retrieve new information, attention and language ability, visuospatial operations, and reasoning [13, 14]. The study demonstrated that age-related declines occur in both physicians and non-physician control subjects affecting verbal memory, reasoning, attention span, and visuospatial ability.

Bieliauskas et al. recently surveyed 359 surgeons over a 6-year period to identify an association between aging and cognitive functioning. Unlike previous studies addressing the effects of physician aging on performance, this study is longitudinal in design. These authors used the Cambridge Neuropsychological Test Automated Battery (CANTAB) instrument to assess several aspects of physician performance. First, surgeons were tested on measures of rapid visual information processing (RVIP), which also assesses stress tolerance. Surgeons were also tested on reaction time (RTI), and visual learning and memory (paired associates learning, PAL). The authors found age-related declines across all domains. Figure 18.1 demonstrates the effect of age on the RVIP task. There was a nearly linear decline in mean rapid visual processing response with advancing age. Additionally, older surgeons had notably slower movement and reaction time with response to stimuli (Fig. 18.2). Finally, with respect to visual learning and memory, older subjects experienced more incorrect responses per trial, and a lower proportion of correct responses on the first attempt of each

exercise (Fig. 18.3). Of note, these effects were more pronounced among those surgeons who had voluntarily decreased their operative caseloads compared with higher volume surgeons, implying that procedural volume may be an important factor in the correlation between aging and technical skill (Fig. 18.4).

Interestingly, recent data suggest that physicians may adapt to the aging process differently due to the technical and cognitive demands of their profession. Physicians may retain some skills that decline faster in age-matched counterparts. Boom-Saad et al. used CANTAB to determine the effect of age on psychomotor functioning among surgeons and trainees, specifically looking at efficiency of motion, reaction time, sustained visual attention, and visuospatial memory [15]. These authors also demonstrated a linear decline in functioning with respect to RTI, RVIP, and the visual paired associates learning test (PAL). However, compared with age-matched controls, surgeons outperformed age-matched controls despite the decline in age. Surgeons had greater efficiency of movement, shorter response time, and greater accuracy with PAL tasks compared with age-matched controls (Figs. 18.5–18.7), despite the overall decline with age.

To what extent these phenomena represent innate abilities compared acquired skill through the practice of surgery is not clear. However, it is encouraging that studies have shown that many cognitive and motor tasks can be learned and modified with practice. Wanzel et al. and Risucci et al. have studied the relationship between visuospatial ability and competency to perform surgical procedures. These authors have shown that visuospatial ability is easily tested and improves with practice and feedback. Such observations suggest that these and similar tasks could be an important tool for systematically assessing physician competence and skill [11, 12].

The Effect of Physician Age on Patient Outcomes

Clearly, age-related declines in functioning exist, but to what extent these changes influence patient outcomes is less clear. A recent systematic review demonstrated that older physicians may have less up-to-date factual knowledge and may have poorer patient outcomes [16]. Older physicians are less likely to adhere to established screening guidelines or to standards of therapy use [17, 18]. Some authors have postulated that the effect of age may be related to difficulties in adapting to new techniques, such as laparoscopy or endovascular therapies. For example, Neumayer et al. studied 1,629 patients who underwent laparoscopic herniorrhaphy [19]. These authors found that surgeon age (≥ 45 years) was correlated with a higher incidence of hernia recurrence following laparoscopic hernia repair, particularly among surgeons inexperienced in laparoscopic repair. Conversely, surgeon

age was not correlated with recurrence among patients undergoing open herniorrhaphy.

Previous studies have demonstrated a correlation between physician age and procedural mortality. O'Neill et al. evaluated the association between surgeon characteristics such as age, procedural volume and specialty training, and operative morbidity and mortality following carotid endarterectomy (CEA) [20]. Patients cared for by older surgeons, defined as surgeons in practice longer than 20 years since licensure, experienced a higher operative mortality rate following CEA compared with patients treated by younger surgeons, after adjustment for patient age and mortality risk. Hartz et al. also identified a significant correlation between advanced surgeon age and higher operative mortality following coronary artery bypass grafting (CABG) [21]. Waljee et al. examined the correlation between surgeon age and operative mortality following both cardiovascular and oncologic surgical procedures in a sample of Medicare patients in the USA. In this study, patients cared for by surgeons older than 60 years had a small but significantly higher risk of perioperative death following CEA, CABG, and pancreatectomy (Fig. 18.8) [22]. Conversely, surgeon age was not correlated with operative mortality for elective aortic aneurysm repair, aortic valve replacement, esophagectomy, cystectomy, and lung resection. Of note, for those procedures in which older surgeon age was correlated with higher patient operative mortality, this association was limited to those surgeons with low procedural volumes (Fig. 18.9). These findings suggest that procedural volume may have a protective effect against age-related decay in performance, and those surgeons who remain active with high operative caseloads may attenuate the effects of advancing age on their skill set. Conversely, surgeons who recognize diminishing skills may begin to voluntarily reduce their caseload.

In contrast to these findings, other authors have demonstrated that increasing physician age confers better outcomes for some procedures. Risucci et al. demonstrated that surgeon age and years since graduation were positively correlated with lower procedural times and better acquisition of laparoscopic skills [23]. Prystowsky et al. evaluated morbidity and mortality following complex alimentary tract procedures by physician age. In this study, patients of younger surgeons were more likely to have higher morbidity and mortality rates following highly complex alimentary tract procedures compared with older surgeons [24].

Implications for Practicing Physicians and Policy Makers

Although many studies have examined the relationship between physician aging, professional performance, and patient outcomes, it is unclear how best to utilize these data with respect to

a Cardiovascular Procedures

FIGURE 18.8 Adjusted operative mortality among Medicare patients in 1998 and 1999, according to surgeon age, for four cardiovascular procedures (a) and four cancer resections (b)[†]. (Reprinted with permission

health policy and guidelines for physicians approaching retirement age. We do not know the age limits of physician performance nor the role of other provider and practice setting characteristics on the effects of aging, such as acquiring subspecialty training or practicing in a teaching hospital. Previous studies are often limited by a lack of longitudinal data or reliance on administrative data which may not identify subtle factors that influence the relationship of age and performance.

Regardless, there have been efforts to improve healthcare quality through assessment of physician performance throughout one’s career. Many fields in medicine today require recertification examinations at periodic intervals to ensure competence and test medical knowledge. However, written evaluation may not suffice for those in procedural-based fields. In recent years, the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) has

FIGURE 18.9 Adjusted operative mortality among Medicare patients in 1998 and 1999, according to surgeon age, and stratified by surgeon volume.[†] (a) Cardiovascular procedures; (b) cancer resections. (From Waljee et al. [22]). [†]Adjusted for patient gender, race, admission acuity, age, and Charlson score. **p*<0.05.

developed a standardized curriculum and assessment of surgical trainees acquiring laparoscopic skills, the Fundamentals of Laparoscopic Surgery (FLS) curriculum. The FLS program is designed to teach both the cognitive and psychomotor aspects of laparoscopy through didactic teaching modules as well as specific technical skill sets [25]. Early studies have shown these programs to be successful in improving performance, and they are increasingly becoming a requirement for surgeons seeking credentialing at certain hospitals [12, 26, 27]. Similar concepts could be applied to the recertification process for surgeons in practice to assess both medical knowledge and technical skill. However, there is no current

systematic assessment for the technical aspects of surgery for surgeons in practice, and few guidelines for surgeons considering or nearing retirement.

This research has also prompted debate regarding the optimal timing of and approach to retirement. A recent survey of surgeons revealed that many surgeons in practice begin to decrease their workload after the age of 60, but a substantial number continue to operate well beyond the age of 70 [28]. The reasons for retirement commonly cited relate to the medical business climate and fear of malpractice, rather than an innate sense of waning competence or inability to complete tasks. In fact, younger surgeons may be more likely to consider

retirement due to increased rates of self-reported burnout, emotional exhaustion, depersonalization, and sense of reduced personal accomplishment [29, 30]. In addition to variation in timing of retirement, physicians also vary in their approach to retirement. Many surgeons gradually taper off their clinical practices and operative volumes [28, 31]. However, recent data indicate that those surgeons who maintain high procedural volumes can preserve their technical skills and have improved patient outcomes. It is well established that surgeons who perform certain procedures less frequently have poorer outcomes compared with those who perform these operations more frequently [32–34].

Physicians may lack self-awareness regarding the effects of aging on their professional skills. Recent data indicate that physicians do not report difficulties with memory recall or name recognition, despite age-related changes demonstrated on testing. Interestingly, self-awareness of cognitive changes may be the marker surgeons expect to use for the decision to retire. [31] Approximately 40% of surgeons report that they will retire when they feel their skills are waning, but only 27% report that they will retire at a predetermined age. In fact, there may be a significant delay between the onset of cognitive changes and retirement, and the extent to which this affects patient care is not known. It is also unclear what mechanisms should be in place for those surgeons who may not recognize deterioration in their skills. Greenfield and Proctor found that the majority of surgeons believe that withdrawing operating privileges should be based on peer-review measures or the onset of disability, and not on the basis of age alone [28]. However, this approach may be problematic for several reasons. In community hospital settings, senior surgeon influence and medicolegal concerns regarding disclosure of surgeon performance can inhibit objective peer review. Although an external reviewer could provide an objective viewpoint, the most appropriate method to assess performance has not been established. Instead, data on adherence to best processes of care, length of procedures, length of stay, and specific postoperative complication rates may be more helpful to assess the quality of patient care and could be used in conjunction with standardized tests of knowledge and technical skills to guide retirement.

In conclusion, current research has only begun to define the effects of aging on physician performance, but has raised important questions concerning physician competence and quality of healthcare delivered. While current data may not support the use of age alone as an indicator of performance, understanding the effects of aging and the mechanisms behind decline in performance can provide valuable insight for future policy decisions regarding recertification and retirement. Efforts to refine cognitive and procedural tests should continue with emphasis on confidentiality so that ultimately, surgeons will be able to track their own performance over time facilitating appropriate decisions regarding retirement.

Section III

Perioperative Issues

Chapter 19

Invited Commentary

Ben Eiseman

Since the publication of the first edition of this book, geriatric surgery has achieved recognition of its professional independence. Like an adolescent youngster or an equivalent recently liberated nation, it now faces a number of policy decisions as it matures and seeks stability. This invited commentary is therefore for the founding mothers and fathers of Surgical Geriacistan. It comes from a veteran of similar wars of independence of Thoracic, Pediatric, and Vascular Surgcalistan, and many years ago as an invited outside founding father of Family Practistan.

Defining the Borders of Your Professional Turf

An essential early step in the maturing process for a person, a nation, or a clinical specialty is to define where it differs – and excels – from everyone else: to define its borders. This is of practical importance if, as for Surgical Geriacistan, it is surrounded by aggressive neighbors such as Intensivistan, Hospitalistan, and the bearded mullahs of Fundamentalistan. The political paradigm for Surgical Geriacistan resembles the diplomatic Great Game of Central Asia, the Balkans, and Central Africa.

Geriatric surgery has a unique focus: its primary concern is the elderly and those near the end of life when operation is under consideration. Such patients have a diminished life expectancy, suffer multiple comorbidities and most of their diseases are incurable and, therefore, palliation is the best that can be expected. Their quality of life is limited; their physiologic reserves and defensive mechanisms compromised, and they are uniquely dependent on support of family and society. Finally, their management is enormously expensive. Skills required to provide operative care to such

a population requires special training, which must be codified by the founders of geriatric surgery.

Unique Skills

Essential skills for geriatric surgery are familiar to its practitioners but include familiarity with the following unique features of the elderly and the oldest old.

- Response to the stress of operation.
- Cumulative effects of comorbidities.
- Risks of polypharmacy.
- Communication skills with the elderly and their families.
- Economic implication of the cost of care in this high-risk, high-cost, low-outcome benefit population.

Once requirements for achieving these and other essential skills are identified, definition of the content and duration of the required training period will follow.

Defending Your Borders

Leaders of geriatric surgery must be skilled practitioners and good politicians because they are surrounded by acquisitive competitors with whom they must work in harmony. Sharing authority is seldom an inherent charm for most surgeons who prefer unity of command but such are the rules of engagement in geriatric surgery. The fact that their neighbors are often the source of patient referrals asserts a modulating force on authoritarian instincts.

Geriatric surgeons like any good diplomat should be prepared to protect their turf when all else fails. Clearly defined and accepted boundaries help avoid misunderstandings, but inoffensive traffic through gates in the fence should be encouraged. Poaching is unacceptable, but recent diplomatic experiments involving hubris have clearly demonstrated its destructive folly.

Allies

Warfare with neighbors, as mentioned, is to be avoided, but allies in peaceful negotiation should be cultivated by a newly independent specialty. The most obvious ally for the geriatric surgeon are the geriatricians who themselves only recently achieved their own independence. Even more powerful support, however, can come from those who pay the enormous cost of geriatric health care. The two big payers are the government and health insurers. Once they are convinced that geriatric surgical specialists are cost-effective, the war for specialty survival is assured. Subsequent bloody battles may be necessary, but independence will follow. Geriatric surgeons are well advised to improve and document their cost-effectiveness.

Internal Stability

Independence inevitably creates temporary turbulence and instability. Examples such as internal conflicts of the Sunnis and Shias or the Tutsis and Hutus abound in foreign affairs. The health care specialty equivalents are the internal disputes among vascular surgeons or invasivist vs. noninvasivist gastroenterologists or cardiologists.

Founders of surgical geriatrics should promptly settle self-destructive internal disputes among tribal leaders and present a united front to professional competitors.

The Slippery Slope of Health Care Specialization

Pioneer health care specialists routinely deny intent to become involved in the complexities that characterize administration of other new specialties. They inevitably fail

and so will surgical geriatricians who might as well resign themselves to the frustrations and pangs of the required rites of transition. Steps on this slippery slope are familiar. An early manifestation is a web page, which now serves to advertise a new faith and as did the church door for Martin Luther. Subsequent steps include definition of training requirements for the new specialty. Fellowships precede specialty residencies which soon follow. This leads to Residency Review Committees, formal requirements for accreditation, an examination, one's very own Board, a Central Office, a Director and his or her staff, annual meetings and dues, and endless black-tie dinners and speeches. Soon thereafter, a large multiauthored textbook appears. A separate journal inevitably follows.

This formal professional minuet absorbs an unbelievable amount of time, energy, and stress on one's family but apparently is unavoidable.

Health Policy Decisions

Founders of geriatric surgery struggling for recognition can benefit from realizing their unique opportunity to influence US health-care policy at a moment when it is anticipating significant change. The high cost, low societal and personal yield of their patient population constitutes a particularly vulnerable segment of health-care patients whose most cost-effective care would be ideal for critical review and change when our society is ready to include cost-benefit analysis in the formulae dictating government reimbursement. Involvement in such medical political pioneering by the leadership in geriatric surgery would have enormous collateral benefit to this new specialty.

You are well launched and will thrive. You also predictably will resent future efforts of young whippersnappers who will suggest further separation from your then established authority.

Chapter 20

Principles of Geriatric Surgery

Mark R. Katlic

With a few obvious exceptions, those of us who are surgeons must become geriatric surgeons. The population as a whole is aging, with the most explosive growth in the over 85 year group, and the conditions that require surgery (atherosclerosis, cancer, arthritis, prostatism, cataract, and others) increase in incidence with increasing age. Improving our care of the elderly surgical patient – the *raison d’etre* of this book – will become progressively more important to us all.

Admittedly, surgeons have always cared for the elderly, but the definition of “elderly” has changed. A threshold of 50 years was chosen for the 167 patients described in a paper in 1907 [1], and 20 years later influential surgeons still wrote that elective herniorrhaphy in this age group was not warranted [2]. Now, though, we are performing complex operations in octogenarians, nonagenarians, and occasionally centenarians [3–7]. In addition, the salutary results of such surgery can even influence general sentiment about medical care of the elderly. Linn and Zeppa’s study [8] of junior medical students reported that the surgery rotation, in contrast to other clerkships, positively influenced the students’ attitudes about aging regardless of the students’ career choices, as the elderly surgical patients were admitted and treated successfully.

Surgery therefore has much to offer the geriatric patient, but that patient must be treated with appropriate knowledge and attention to detail. Discussions of physiologic changes

in the elderly and results of specific operations comprise the bulk of this book and are not presented here. The author’s quarter-century study in this area, in addition to caring for an elderly thoracic oncology population, has led to a distillate of several general principles (Table 20.1) which are relevant to all who care for the aged. These principles are worthwhile chiefly for propaedeutic purposes, as they can-

TABLE 20.1 Principles of geriatric surgery

-
- I. The *clinical presentation* of surgical problems in the elderly may be subtle or somewhat different from that in the general population. This may lead to delay in diagnosis
 - II. The elderly handle stress satisfactorily but handle severe stress poorly because of *lack of organ system reserve*
 - III. Optimal *preoperative preparation* is essential, because of Principle II. When preparation is suboptimal, the perioperative risk increases
 - IV. The results of elective surgery in the elderly are reproducibly good; the results of emergency surgery are poor though still better than nonoperative treatment for most conditions. The risk of *emergency surgery* may be many times that of similar elective surgery because of Principles II and III
 - V. Scrupulous *attention to detail* intraoperatively and perioperatively yields great benefit, as the elderly tolerate complications poorly (because of Principle II)
 - VI. A patient’s age should be treated as a *scientific fact, not with prejudice*. No particular chronologic age, of itself, is a contraindication to operation (because of Principle IV)

FIGURE 20.1 Operative mortality in the national Medicare population has declined for some, but not all, procedures. Adjusted odds ratios (average change in mortality) and 95% confidence intervals for the 6-year period 1994–1999. Adjusted for age, gender, race, comorbidities, admission acuity, income, and hospital volume (from Goodney et al. [10], reprinted with permission from Elsevier).

not apply to every patient or every clinical situation. Some principles also apply to surgery in the young patient, but the quantitative differences in the elderly are significant enough to approach qualitative status. Risks of many emergency operations in the young, for example, are indeed greater than the risks of similar elective operations, but the differences are small compared with the threefold increase in the elderly. With respect to these principles, the elderly need not be treated as a separate species but perhaps as a separate genus or order within the same larger group of surgical candidates.

Although our results have generally improved over the years [9], this improvement has not been universal [10] (Fig. 20.1), and emergency surgery is still risky (Fig. 20.2). So, how do we do better?

Principle I: Clinical Presentation

The clinical presentation of surgical problems in the elderly may be subtle or somewhat different from that in the general population. This may lead to delay in diagnosis.

FIGURE 20.2 Decline in surgical mortality in elderly over time (emergency always much higher) (from Thomas and Ritchie [9], with permission from Blackwell Publishing).

CASE STUDY

This brief case report illustrates several of the six Principles of Geriatric Surgery outlined in this chapter.

An 88-year-old man was referred for evaluation and treatment of a right lung mass. He had been a cigarette smoker for 40 years but quit 25 years prior to evaluation. He had fully recovered from a cerebrovascular accident 8 years before – playing golf several times each week, had undergone inguinal herniorrhaphy, and took only nifedipine. A chest radiograph ordered because of a nagging cough showed a hazy perihilar density that, on computed tomogram (Fig. 20.3), proved to be a 4-cm right lower lobe mass. His family physician told him that he was too old for surgery, but he and his wife wanted another opinion.

Examination showed a tall man with a strong regular pulse and blood pressure 140/82 mmHg. Lungs were clear, heart without murmur, abdomen benign. Computed tomograms showed no adenopathy and no evidence of metastatic disease. Pulmonary function was greater than 100% of predicted. Bronchoscopy was grossly and cytologically unremarkable. After a discussion of risks and alternatives, he chose to undergo resection.

Right lower lobectomy was performed for what proved to be a 3-cm squamous cell carcinoma with negative hilar and mediastinal nodes. Stapled vessel and

bronchial closures were reinforced with sutures. Venous compression stockings and monitoring of oxygen saturation and cardiac rhythm were maintained overnight. He had an uncomplicated postoperative course.

He resumed golfing and social life. I saw the patient and his wife of 70 years having dinner on Valentine's Day 1 month prior to his death from pneumonia, without evidence of cancer, at an age of 92.

FIGURE 20.3 Computed tomogram of 88-year-old patient with right lower lobe cancer.

Classic symptoms of appendicitis are present in a minority of elderly patients, as few as 26% in Horattas' series over 20 years [11] (Table 20.2). Rebound tenderness was present in fewer than half the patients in another series [12] and leukocytosis in only 42.9% in a third series [13]. Clouding the picture further, objective tests may suggest alternative diagnoses: one in six patients has an elevated bilirubin and one in four has signs of ileus, bowel obstruction, gallstones, or renal calculus on abdominal radiographs [14]. Even astute diagnosis may not prevent perforation, present in 42–60% of elderly patients despite operation within 24 h of symptom onset [11, 13].

Biliary tract disease is the most common entity requiring abdominal surgery in the elderly, yet the diagnosis is often delayed. More than one-third of patients with acute cholecystitis are afebrile, one-fourth are nontender, and one-third are without leukocytosis [15–17]. Cholangitis may appear only as fever of unknown origin or as confusion [18]. Consequently, the elderly predominate in series of patients with complications of biliary disease (gallbladder perforation, empyema, gangrene, gallstone ileus, and cholangitis) [19],

TABLE 20.2 Classic symptoms of appendicitis are present in a minority of elderly patients, resulting in perforation despite expeditious operation

and the complication may result in the first apparent symptom [16, 20]. Saunders [21] reported that abdominal pain was a less prominent symptom and that the bilirubin

level was nearly double in elderly patients presenting with bile duct carcinoma, compared with the findings in young patients seen during the same time period.

Peptic ulcer disease may present as confusion, malaise, anemia, or weight loss as opposed to pain [22]; even with perforation pain may be absent or minimal. Rabinovici and Manny [23] found a discrepancy between “severe intraoperative findings” and preoperative objective findings such as heart rate (mean 88/min), temperature (37.2°C), and white blood cell count (10,900/dl). Some have suggested that the elderly and possibly their physicians become tolerant over the years to abdominal pain, loss of energy, and other symptoms, resulting in a delay in diagnosis or an emergency presentation. In Mulcahy’s [24] series of patients with colorectal carcinoma, for example, elderly patients were nearly twice as likely (18%) as younger patients (11%) to present emergently. Elderly patients with perforated diverticulitis are three times more likely to have generalized peritonitis at operation than young patients [25].

Gastroesophageal reflux disease in the elderly is less likely to cause heartburn and more likely to cause regurgitation or cough ($p=0.001$) [26]. In Pilotto’s study of 840 consecutive patients [27], typical heartburn/acid reflux, pain, and indigestion were more likely in the young ($p<0.001$); older patients more often experienced dysphagia, anorexia, anemia, or vomiting ($p<0.001$ each) or weight loss ($p<0.007$) (Table 20.3).

Head and neck disease may also present differently in the elderly. Sinusitis may lead to subtle signs such as delirium or fever of unknown origin [28, 29]; and head and neck cancers are less likely to be associated with smoking ($p<0.01$) [30] and alcohol use ($p<0.001$) [30, 31]. Hyperparathyroidism is more likely to cause dementia or skeletal complaints and less likely to cause renal stones [32]. In Thomas and Grigg’s series [33] of patients with carotid artery disease, stroke was

TABLE 20.3 Symptoms of gastroesophageal reflux disease may be different and more subtle in the elderly

^aPercentage of patients

the most common indication for surgery in octogenarians and was the least common indication in younger patients. Unstable angina is as likely to present with dyspnea, nausea, or diaphoresis as it is with classic chest pain [34].

Even the eureka moments that keep us energized as diagnosticians [35] may be “subtler and less electric” [36] in the elderly.

The clinician who understands that classic presentations of surgical disease occur in a minority of elderly patients will maintain the high index of suspicion needed to minimize delay in diagnosis.

Principle II: Lack of Reserve

The elderly handle stress satisfactorily but handle severe stress poorly because of lack of organ system reserve.

Functional reserve may be considered the difference between basal and maximal function (Fig. 20.4); it represents the capacity to meet increased demands imposed by disease or trauma. Although there is variability among individuals, this organ system reserve inexorably declines in one’s 70s, 80s, and 90s (Fig. 20.5). With excellent anesthetic and perioperative care, the aged patient may tolerate the stress of even complex surgery – particularly if elective – but not the added stress of exceptional or emergency surgery.

The elderly patient with lung cancer, like our case report patient, can undergo routine pulmonary lobectomy with results nearly indistinguishable from those of the general population [37, 38], but the added stress of concomitant chest wall resection leads to a disparate increase in risk. In Keagy’s series [39], the one death and two of the three respiratory

FIGURE 20.4 Organ system functional reserve is the difference between maximal function and basal function; reserve declines with age (reprinted with permission from Muravchick [192], copyright Elsevier 2000).

FIGURE 20.5 Lack of reserve: with increasing age cardiac function is maintained at rest but not under stress. Linear regression at rest and during maximal cycle ergometry in healthy sedentary men (solid lines)

and women (dotted lines). All subjects are healthy, community-dwelling volunteers screened to exclude hypertension and occult coronary artery disease (reprinted with permission from Lakatta [193]).

failures were in patients who underwent the *en bloc* chest wall resection. An elderly patient, entering the operating room with decreased chest wall compliance and strength and decreased elastic recoil as a baseline, may tolerate lung resection but lacks the reserve to tolerate an extended operation. Other researchers have reported increased mortality in septuagenarians and octogenarians following pneumonectomy, especially right pneumonectomy or completion pneumonectomy [40–42].

On the other side of the spectrum, more limited procedures, such as video-assisted thoracic surgery, may decrease stress further by preserving respiratory muscle strength [43–46]. Yim [46] reported no deaths or pulmonary complications following thoracoscopic surgery in 22 patients over an age of 75, 5 with major resections; and Jaklitsch et al. [44] found decreased mortality, length of hospital stay, and post-operative delirium after 307 video-assisted procedures in patients aged 65–90 compared with that associated with open thoracotomy. Video-assisted pulmonary lobectomy in half of a group of elderly lung cancer patients resulted in fewer complications ($p=0.04$) and decreased length of stay ($p<0.001$) compared with the half who underwent open (thoracotomy) lobectomy [47]. Patel et al. [48] reported shorter hospitalization and similar late outcomes following endovascular thoracic aortic procedures in patients greater than 75 years, compared with open procedures.

Left ventricular functional reserve assumes critical importance in elderly patients undergoing cardiac surgery. In general, results in the elderly diverge from those of young age groups only in the worst functional classes. Bergus et al. [49], for example, found that the length of stay following aortic valve replacement was significantly longer ($p<0.05$)

in septuagenarians in New York Heart Association class IV but not in class III, compared with patients under the age of 70. Patients over an age of 75 in Salomon's large series [50] had significantly higher mortality after coronary artery bypass grafting if they had suffered a myocardial infarction less than 3 weeks preoperatively compared with more than 3 weeks (14.1 vs. 5.2%); there was much less difference in patients younger than age 75 (3.5 vs. 2.3%). When patients over an age of 70 undergo a third coronary reoperation, only those in the worse Canadian Functional Class experience increased mortality, an increase not seen in young patients in a similar class [51]. Elayda et al. [52] reported that mortality for isolated aortic valve replacement in patients over an age of 80 was acceptable (5.2%), but addition of concomitant procedures increased this figure significantly (27.7%).

Similar findings pertain to major abdominal surgery. Fortner and Lincer [53] found that the increased number of deaths among elderly patients undergoing hepatic resection for liver cancer were nearly all in the extended-resection group (i.e., extended right hepatectomy or trisegmentectomy), among whom 60% of deaths were due to hepatic insufficiency. In another group of hepatic resections done for metastatic colon cancer, where cirrhosis and functional hepatic reserve are less important factors, there was no difference in mortality between young and old patients [54]. Even the addition of common duct exploration to open cholecystectomy significantly increased mortality in the elderly (3.5 vs. 1.8%, $p<0.05$) [55]. For some oncology cases (e.g., gastric cancer and lung cancer), a more limited operation in the elderly need not decrease survival [56–59].

The elderly can return to normal function after stressful operations (such as colectomy and hepatectomy), but after

FIGURE 20.6 Return to activities of daily living after major surgery (function returns rapidly after stressful operations but not the most stressful, speaking to lack of reserve). From Lawrence et al. [60], reprinted with permission from Elsevier.

the most stressful operations (such as Whipple pancreaticoduodenectomy) it will take longer [60] (Fig. 20.6).

With modern anesthetic and critical care management, an elderly patient can tolerate the stress of even complex operations. However, if the most extended procedures are contemplated, a comprehensive preoperative evaluation of functional reserve is recommended.

Principle III: Preoperative Preparation

Optimal preoperative preparation is essential because of Principle II. When preparation is suboptimal the perioperative risk increases.

A patient's advanced age is immutable but some factors can be improved preoperatively, with benefits in excess of those to a younger patient. No universal threshold of blood hemoglobin applies to every patient, but correction of anemia and dehydration do assume greater importance in the elderly because of their general lack of reserve and particularly the physiology of the aged heart and kidney. Among the predictors of an overall good postoperative course in Seymour's series of 288 elderly general surgery patients were a hemoglobin level of more than 11.0 g/dl and absence of volume depletion [61]. Contrary to this, Dzankic found that routine blood testing in the elderly surgical patient rarely showed abnormal results and even when abnormal did not correlate with adverse postoperative outcome [62].

Few would argue that pulmonary problems are among the most common perioperative complications in the elderly, in part due to decreased respiratory muscle strength. Nomori et al. [45] showed that following thoracotomy patients older than 70 years experience significant reductions in both maximum inspiratory and expiratory pressures, unlike their younger counterparts; this effect persists for 12 weeks

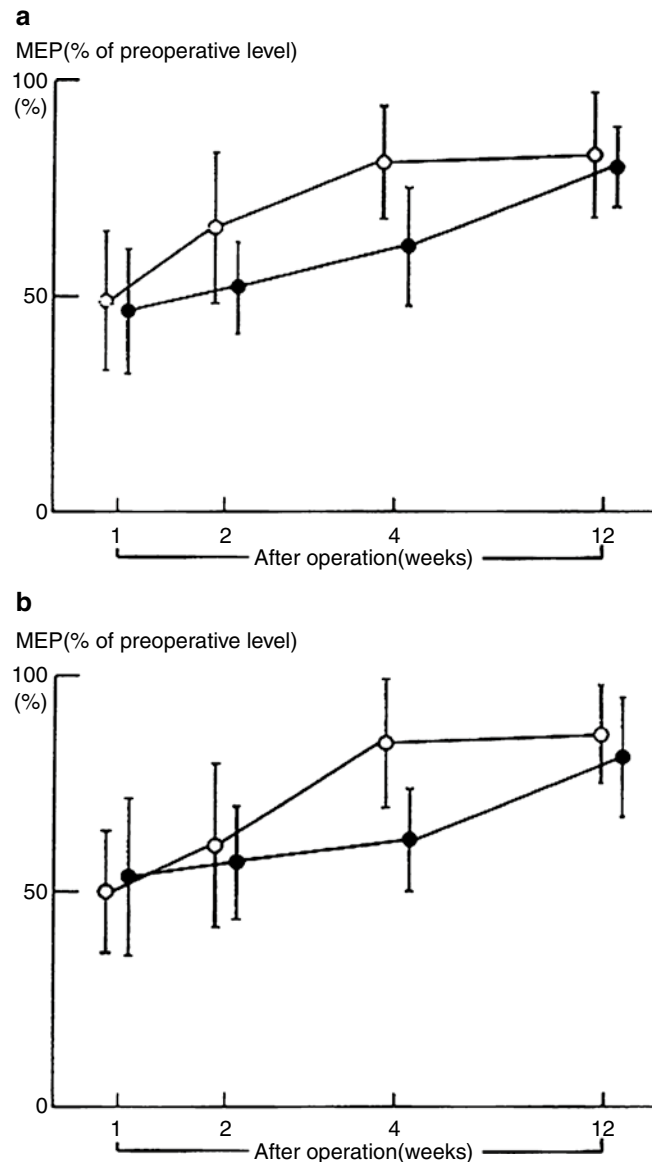

FIGURE 20.7 Postoperative changes in mean (a) maximum inspiratory pressure (MIP, percent of preoperative level) and (b) maximum expiratory pressure (MEP, percent of preoperative level) following pulmonary resection in 36 patients younger than 69 years (*open circles*) and 12 patients older than 70 years (*closed circles*). From Nomori et al. [45], reprinted with permission from Elsevier).

(Fig. 20.7). Although few data exist to support the routine use of preoperative pulmonary conditioning or rehabilitation, most authors strongly advocate smoking cessation [63] and treatment of bronchitis and reactive airways disease such as asthma [64, 65]. Prophylaxis against deep vein thrombosis (DVT), clearly a risk in the elderly [66], and against pulmonary embolism should be routine [67].

The value of preoperative optimization of cardiac function (e.g., via placement of a pulmonary artery catheter) is controversial. Some authors have shown clear benefit [68], whereas others [69, 70], citing methodologic flaws in

the former studies, reported no reduction in perioperative morbidity or mortality. These studies do not include exceptionally high risk or very elderly patients, who could well be helped by such treatment. Another unsettled issue concerns the value of aggressive preoperative screening for coronary and carotid artery disease, particularly in patients scheduled for peripheral vascular surgery. Leppo [71] considered age over 70 years to be one of the several risk factors (the others being a history of angina, congestive heart failure, diabetes mellitus, prior myocardial infarction, and ventricular ectopy) that should trigger further cardiac assessment. Echocardiogram and dobutamine stress testing have been shown to bear incremental value over clinical evaluation [72] (Fig. 20.8).

There is some evidence that performance testing may hold value. Maximal oxygen consumption (VO_2 Max) tests

may not be readily available in all hospitals, but reasonable surrogates – stair climbing [73, 74], shuttle walk [75], long distance corridor walk [76], metabolic equivalent (MET) – have been shown to correlate. Weinstein [77] reported prolonged length of stay following thoracic cancer surgery in those patients with METs ≤ 4 (equating to calisthenics or walking briskly). The International Society of Geriatric Oncology has studied a standardized Preoperative Assessment in Elderly Cancer Patient (PACE); postoperative complications were associated with poor preoperative performance status and lower score on Instrumental Activities of Daily Living but major complications correlated only with American Society of Anesthesiologists (ASA) Physical Status ≤ 2 [78] (Table 20.4). However, as Internullo et al. recently concluded that “a practical and reliable individual risk assessment tool is still lacking” [79].

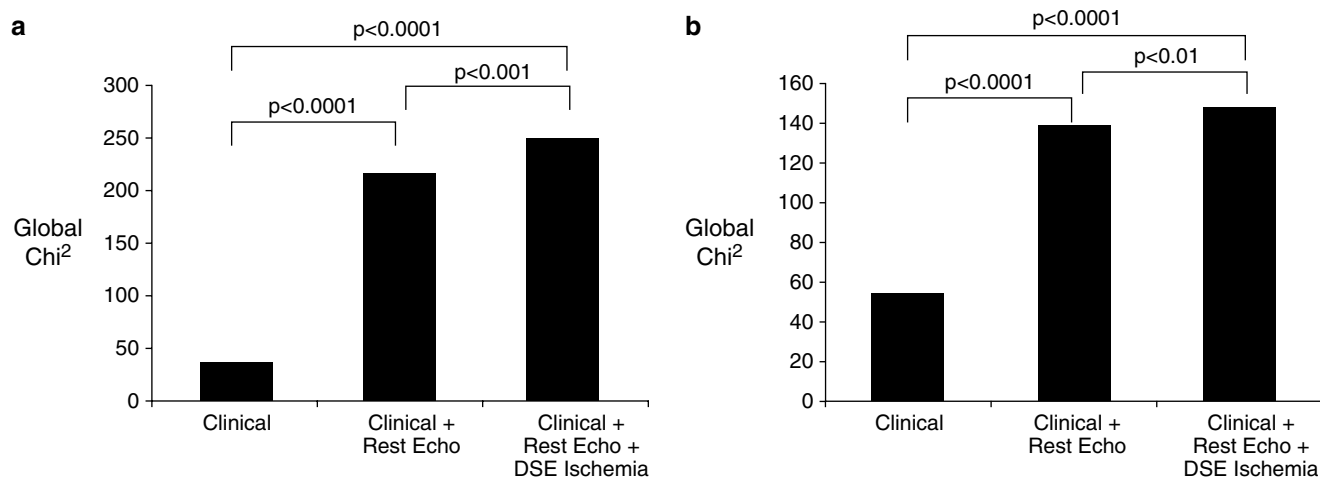

FIGURE 20.8 Incremental value of echocardiogram and dobutamine stress echocardiogram (DSE) over clinical evaluation for the prediction of cardiac events (a) and all-cause mortality (b) in the elderly (from

Biagini et al. [72], reprinted with permission from the American Gerontological Society of America).

^aBold italics represent significant relationship ($p < 0.05$)

Preoperative antibiotics are not necessary for every type of elective surgery, but researchers agree that advanced age is a risk factor for nosocomial infection. Iwamoto et al. [80] studied 4,380 patients who underwent general anesthesia for thoracic, abdominal, or neurologic surgery and concluded that advanced age is a risk factor for nosocomial pneumonia, especially after thoracic surgery. Age greater than 70 years has been shown to be a risk factor for both positive bile cultures ($p < 0.001$) [81] and septic complications of biliary surgery compared with younger patients [82]; antibiotic prophylaxis can reduce these complications [83].

Efforts to improve our elderly patients' preoperative nutritional state would seem desirable – even active, community-dwelling older adults manifest impaired recovery of strength after major surgery [84] – but it is unclear how to do this. Low levels of serum albumin, for example, correlate strikingly with postoperative problems [85] (Fig. 20.9), but cannot be improved to a great degree preoperatively. Souba [86] reviewed the literature on nutritional support and concluded that preoperative support should be reserved for severely malnourished patients scheduled to undergo major elective surgery and then should be provided for no more than 10 days.

In addition to those already cited, a number of surgeons have attributed their improved results in elderly patients to compulsive preoperative preparation. Bittner et al. [87] believed that the significant decrease in mortality after total

gastrectomy in septuagenarians (32% in 1979 to 4.4% in 1996) was the result of standardized perioperative antibiotics, thromboembolic prophylaxis, “a systemic analysis of risk factors and their thorough preoperative therapy,” and nutritional support for the malnourished. Our presented patient was neither anemic nor an active smoker; he received preoperative antibiotics and perioperative DVT prophylaxis.

Hypovolemia is tolerated poorly by the elderly patient and it must be corrected. Smoking should be stopped. Treating other correctable aberrations such as anemia, bronchitis, and hypertension preoperatively increases the elderly patient's chance for a smooth postoperative course.

Principle IV: Emergency Surgery

The results of elective surgery in the elderly are reproducibly good; the results of emergency surgery are poor though still better than non-operative treatment for most conditions. The risk of emergency surgery may be many times that of similar elective surgery because of Principles II and III.

The results of elective surgery in the elderly are good, frequently indistinguishable from the results in younger counterparts [88–90]. Coyle [91] reported the results of carotid endarterectomy in 79 octogenarians and summarized the results of five other series (634 total patients); mortality and morbidity were similar to those in a younger cohort. Maehara et al. [92] had 0% operative mortality in 77 patients over an age of 70 who underwent resection of gastric carcinoma, and Jougon's [93] results for esophagectomy in 89 patients of age 70–84 years were identical to those in 451 younger patients. Our 88-year-old patient with lung cancer could anticipate mortality and survival after pulmonary lobectomy statistically identical to that of younger patients with similar stage disease [64, 88, 94–96]. Identical operations performed emergently in the elderly, however, carry at least a threefold (and as much as a tenfold) increased risk [97] (Fig. 20.10). Keller [98], for example, reported 31% morbidity and 20% mortality in 100 patients over an age of 70 who underwent emergency operations, which is significantly more ($p < 0.0005$) than the 6.8% morbidity and 1.9% mortality following elective operation in 513 similar patients. Elective cholecystectomy can be performed in young and old patients with the risk of death approaching 0% [20, 99, 100]; the risk of mortality for emergency cholecystectomy increases somewhat in the younger group (1–2%) but increases greatly in the elderly (5–15%) [20]. Surgical priority clearly affects cardiac surgery risk [101, 102]. Elective operative mortality for colorectal surgery is as low as 1.5–3.0%, rising to over 20% for emergency operation [103, 104].

A patient's advanced age therefore weighs in favor of commencing rather than deferring needed elective surgery.

Albumin levels and incidence of surgical complications by procedure

FIGURE 20.9 Preoperative albumin level and major postoperative complications (from Kudsk et al. [85], reprinted with permission from the American Society for Parenteral and Enteral Nutrition).

FIGURE 20.10 Elective vs. emergency surgery in the elderly (from Thomas and Ritchie [9], reprinted with permission of Blackwell Publishing).

Principle V: Attention to Detail

Scrupulous attention to detail intraoperatively and perioperatively yields great benefit, as the elderly tolerate complications poorly (because of Principle II).

Perioperative blood loss is the *bete noire* of geriatric surgery, as the elderly lack the responsive compensatory mechanisms necessary to restore equilibrium. Fong et al. [54] reported that the only independent predictor of postoperative complications in 138 patients over an age of 70 who underwent pancreatic resection was intraoperative blood loss exceeding 2 l. This finding has been mirrored in reports from cardiac surgery and neurosurgery. Sisto et al. [105] reported that 6 of 23 octogenarian coronary bypass patients who required reexploration for tamponade died; Logeais et al. [106] found that reoperation for tamponade following aortic valve replacement placed the elderly patient at high risk for mortality ($p < 0.001$). Hemostasis is exceptionally important in the elderly craniotomy patient, possibly because the elderly brain is less likely to expand to obliterate dead space. Maurice-Williams and Kitchen [107] reported that postoperative bleeding following resection of meningioma occurred in 20% of 46 elderly patients and 0% of 38 young patients ($p < 0.05$).

Meticulous surgical technique is important in any patient, but it becomes crucial in those of advanced age. Anastomotic leak after esophageal or gastric resection, a dreaded complication in any patient, embodies an exceptional risk of mortality in the elderly [108]; yet this complication can be minimized by careful technique [109, 110]. Only one of Bandoh's [111] elderly patients who underwent gastrectomy for cancer experienced a leak, as did only 2 of 163 patients over an age of 70 in Bittner's series [87]. Despite having significantly greater preoperative comorbidity, the elderly patients undergoing gastrectomy in Gretschesel's series experienced no greater

postoperative morbidity [57]. The elderly cardiac surgery patient may benefit from extra care when they have a calcified aorta (e.g., intraoperative ultrasound or modified clamping and cannulation technique) or a fragile sternum (e.g., additional or pericostal wires) [112]. Operative speed is less important than technique: in Cohen's series of 46 nonagenarians undergoing major procedures [7], the duration of operation did not correlate with mortality.

Perioperative monitoring is more important in the elderly, since they may manifest few signs or symptoms of impending problems (see Principle I above). Bernstein [113] credits intensive hemodynamic monitoring in his lack of mortality among 78 patients over an age of 70 who underwent abdominal aortic aneurysmectomy. Such monitoring and intensive care were also emphasized by Alexander et al. [3], who reported excellent results for 59 octogenarians having major upper abdominal cancer operations, and by Lo [114] for 85 elderly patients undergoing adrenal surgery at the Mayo Clinic. Giannice [115] credits attention to perioperative care (DVT prophylaxis, antibiotics, monitoring, respiratory care, pain management, and early mobilization) for his group's improved recent results in gynecologic oncology patients. Our case report patient had reinforcement of vascular and bronchial closures in addition to compulsive hemostasis and minimization of parenchymal air leaks. He was monitored postoperatively. If he had developed an atrial arrhythmia, it would have been aggressively treated; if he had developed tracheobronchial secretions, he would have promptly undergone therapeutic bronchoscopy.

We should continue to teach the surgical aphorism, "Elderly patients tolerate operations but not complications" (Table 20.5).

TABLE 20.5 Importance of postoperative complications in failure of octogenarians to return to normal function following major abdominal surgery

	Odds ratio	95% confidence interval
All cases		
Emergency operation	2.7	0.99–7.24
ASA III or IV	1.0	0.29–3.56
Comorbidity index >5	1.8	0.48–6.66
Dependence on activities of daily living	1.8	0.42–7.73
Preexisting cardiac disease	1.9	0.69–5.44
Preexisting chronic pulmonary disease	2.0	0.54–7.47
Preexisting cerebrovascular disease	2.0	0.43–9.06
Development of postoperative complications	24.5	3.08–194.88
<i>Elective cases only</i>		
Comorbidity index >5	11.2	1.08–116.26
Development of postoperative complications	10.6	3.08–194.88

Principle VI: Age is a Scientific Fact

A patient's age should be treated as a scientific fact, not with prejudice. No particular chronologic age, of itself, is a contraindication to operation (because of Principle IV).

Great biologic variability exists among the elderly, with some octogenarians and nonagenarians proving to be healthier than their sons and daughters. Even our 88-year-old patient has a life expectancy exceeding 4 years [116, 117], so why not offer him resection of his lung cancer? No other treatment is likely to give him those 4 years. Yet even in 2005, this does not always happen: prejudice against the elderly, so-called "ageism" exists.

Despite the fact that elderly patients treated for lung cancer have survival equal to their younger matched counterparts, Nugent et al. [118] found that patients older than 80 years

colon cancer are less likely to undergo extensive lymph node dissection ($p < 0.0001$) [132]. Selection bias in the elderly may also lead to delay in referral for abdominal aortic aneurysm surgery [133] and coronary artery bypass surgery [134].

Some studies do report increased operative mortality [97, 135, 136] (Fig. 20.11), increased complications [137, 138] (Fig. 20.12), and increased lengths-of-stay in the elderly [139–143], but overall results do not differ from the young for a wide variety of procedures: neurosurgery [107, 144], head and neck surgery [30, 145, 146], carotid endarterectomy [147, 148], cardiac surgery [52, 112, 134, 149–153], esophagectomy [79, 93, 109, 154–156] (Fig. 20.13), gastrectomy [3, 92, 157, 158] (Fig. 20.14), colectomy [159–161] (Fig. 20.15), hepatectomy [54, 162–165] (Fig. 20.16), pancreaticoduodenectomy [54, 166, 167], radical hysterectomy [168], total knee/hip replacement [169–171], microvascular free tissue transfer [172], cardiac transplant [173], lung

were significantly less likely ($p < 0.05$) to be treated surgically. Kuo et al. [119] similarly reported that octogenarian patients with lung cancer were more likely ($p < 0.01$) to receive only palliative care; when offered chemotherapy they tolerate it [120]. Elderly patients with ovarian cancer are less likely to undergo aggressive chemotherapy and surgery [121, 122], despite results equal to the young [123]. Older women with breast cancer were less likely to have had screening mammograms [124, 125] and were more likely to present in advanced stages than younger women [125]; once diagnosed, they tolerated surgery well [126, 127]. Guadagnoli et al. [128] presented evidence against ageism in the treatment of early breast cancer, but Hebert-Croteau et al. [129] found that only the use of tamoxifen was similar in women over and under an age of 70 ($p < 0.41$), while all other treatments (breast-conserving surgery, radiotherapy, axillary node dissection, and chemotherapy) differed significantly ($p < 0.0001$). When elderly patients do receive chemotherapy for breast cancer they tolerate it [130] and they benefit from it [131]. Elderly patients with

FIGURE 20.14 Surgical outcome in elderly (≥75 years) and middle-aged (45–65 years) patients with gastric cancer (from Kunisaki et al. [158], reprinted with permission from Elsevier).

FIGURE 20.16 Major hepatectomy. Overall survival for patients ≥70 years (solid line) and <70 years (dashed line), $p=0.89$; $n=517$ (from Menon et al. [165], reprinted with permission from Elsevier).

transplant [174], endovascular surgery [175], gastric bypass [176], laparoscopic colectomy [177], and hernia [178]. Return to preoperative quality of life (QOL) is gratifying after elective surgery for gastric or colorectal surgery [179], joint replacement [171], thoracic aneurysm [180] (Fig. 20.17), and aortic valve replacement [181, 182] (Fig. 20.18).

For most patients, general medical condition and associated medical problems are more important than age. Dunlop et al. [183] studied 8,889 geriatric surgical patients in Canada and concluded that severity of illness on admission was a

much better predictor of outcome than was age; Akoh et al. [184] had similar findings in 171 octogenarians undergoing major gastrointestinal surgery. Comorbidities were a greater influence on survival than age in several series of elderly patients with lung cancer [37, 38, 185]. Mehta et al. [186] reported that separation of mitral valve replacement patients into low-, medium-, and high-risk medical groups was more important than stratification by age within these three groups. Within the American Society of Anesthesiologists Physical Status system [187], the ASA status influences results more

FIGURE 20.17 Return to normal functional activity after thoracic aneurysm repair depending on age: <70 years (solid circles) and ≥70 years (open circles); n = 110 (from Zierer et al. [180], copyright Elsevier 2006).

FIGURE 20.19 Probability of a major postanesthesia complication based on age and the American Society of Anesthesiologists Physical Status (ASA) system (reprinted with permission from Muravchick [194]).

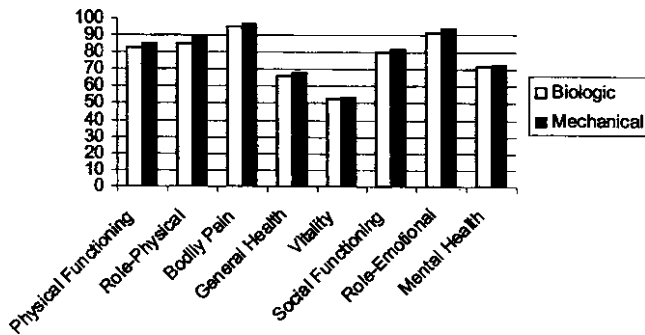

FIGURE 20.18 Scores for the domains of the Medical Outcomes Survey Short-Form 36 Health Survey following aortic valve replacement in octogenarians; biologic (open boxes) and mechanical (filled boxes) valve prostheses; n = 345 (reprinted with permission from de Vincentiis et al. [181], copyright Elsevier 2008).

than age (Fig. 20.19). For elderly patients undergoing surgery for cancer, the stage of malignancy also influences outcome more than age [38, 188–191].

Many geriatric surgery patients, including nonagenarians, have survival rates equal to those expected in the general population; even the sobering results of emergency surgery in the elderly are better than the results of nonoperative treatment for the same conditions. A patient’s age should therefore be considered but not feared.

CASE STUDY: FOLLOW-UP

Following his death, our patient’s wife wrote me this note: “Dear Dr. Katlic – on 3/2/99 you removed part of Bob’s lung – on 3/1/03 he died of pneumonia – four lovely years – he played golf was independent and happy (Fig. 20.20). I was with him when he died and he was peaceful and in no pain. I am grateful to you for every moment of those four ‘extra’ years.”

FIGURE 20.20 Eighty-eight-year-old man following right lower lobectomy for lung cancer. “I am grateful to you for every moment of those four ‘extra’ years”.

Conclusion

Surgical problems abound in the elderly and the numbers of elderly are increasing worldwide. Surgeons must become students of the physiologic changes that occur with aging and, guided by a few general principles, apply this knowledge to daily clinical care. The results of surgery in the elderly do not support prejudice against advanced age. We owe it to our elders to become good geriatric surgeons and in so doing we will become better surgeons to patients of all ages.

Chapter 21

Geriatric Models of Care

Elizabeth A. Capezuti, Marie Boltz, and Hongsoo Kim

Introduction

Models of care addressing the unique needs of older hospitalized patients can be traced to the comprehensive geriatric assessment (CGA) programs first developed in the 1970s [1]. CGA programs screen older patients at high risk for geriatric-specific problems, assess for modifiable risk factors, and implement evidence-based strategies consistent with the patient's treatment goals. Over the last 30 years changes in the health-care system, coupled with the increasing older adult population, has led to development of several geriatric models of care across all health-care settings. In general, the goals of these geriatric models of care in the hospital focus on (1) prevention of complications that occur more commonly in older adults and (2) address hospital factors that contribute to complications. This chapter provides a brief overview of complications that are more frequently found in older patients, care delivery issues that are addressed by geriatric models of care and a description of the most commonly employed hospital models.

Complications of Older Hospitalized Patients

Although patients aged 65 and over represent about 13% of the US population, they account for 40% of those undergoing surgical procedures in American hospitals [2]. In addition to the high proportion of older patients, the most troublesome finding is that older patients also represent a higher complication rate for certain conditions which subsequently lead to higher health-care costs. Age may be viewed as a proxy for multiple chronic diseases. Postoperative complications that are known determinants of short and long-term survival following major surgery such as

myocardial infarction and sepsis are associated with age due to the increased likelihood of co-morbidities such as cardiac disease [3].

Older adults are more likely to experience additional types of complications that, in addition to reducing survival, can result in loss of independence and lead to hospital readmission, increased usage of rehabilitation services, and new placement in a nursing home. Physical frailty and cognitive impairment [4–6] (either chronic dementia and/or delirium) can further compound an older person's vulnerability to complications during hospitalization [7, 8]. Frailty refers to "decreased reserves in multiple organ systems" [9] that is highly associated (after controlling for age, race, sex, and comorbid illness) with an increased risk for falls, cardiovascular disease, hypertension as well as reduced mobility, decreased functional status, institutionalization, and death (see Chap. 10) [10, 11].

Persons with dementia are more prone to negative outcomes related to disease management and hospitalization. Older patients with dementia hospitalized for exacerbation of a chronic disease have significantly longer lengths of hospital stays (LOS) as compared to older patients without dementia. For example, the LOS of older patient with COPD is 121 days/1,000 persons as compared to older patients with both COPD and dementia, who have a LOS of 361 days/1,000 persons [12]. For those who develop delirium (for both those with and without an underlying chronic dementia) during hospitalization, increased LOS and higher hospital costs is well documented [13]. The complex challenges of those adult patients with cognitive impairment are often not adequately addressed. Table 21.1 provides examples of common behaviors of cognitively impaired persons that can lead to complications.

Although geriatric models of care can improve the overall outcomes and experiences of hospitalization, in general, these programs are designed to target those adverse events that occur more commonly in older patients. Table 21.2 provides a summary of these complications and the clinical and cost outcomes associated with these complications. These complications are often referred to as "geriatric syndromes"

TABLE 21.1 Behaviors of cognitively impaired patients contributing to high complication rate

Behaviors	Example	Potential complication
Inability to follow directions	Does not use call bell to ask for assistance and gets out of bed without needed assistance	Fall-related injury
Removal of treatments	Pulls out central lines	Hemorrhage Infection Physical restraints and associated complications
Not able to communicate needs	In pain but not able to verbally communicate this to nurse	Functional decline
Wandering	Leaves unit and exits hospital in gown	Hypothermia Other injuries Use of physical and chemical restraints that increase likelihood of delirium, falls, fall-related injury, nutritional problems
Misinterprets visual and auditory cues	Resists staff attempts to assist the patient to get out of bed which is perceived as an assault and then hits staff	Agitation-related injury Overuse of psychoactive medication that increase likelihood of delirium, falls, and fall-related injury
Decreases inhibition of inappropriate behaviors	Removes clothing and walk down hallway nude	Agitation-related injury Overuse of psychoactive medication that increases likelihood of delirium, falls, and fall-related injury

which refer to “clinical conditions in older persons that do not fit into discrete disease categories.” [14]

A US congressional mandate instituted on August 1, 2007 significantly changed the Inpatient Prospective Payment System that the Centers for Medicare & Medicaid Services (CMS) use to reimburse hospitals [15–17]. As of October 2008, hospitals will no longer receive payment for eight hospital-acquired conditions; three of these eight are complications that are known to occur most frequently in older inpatients and have been found to be reduced when geriatric models of care are employed [18]. These three complications (fall-related injury, pressure ulcer, and catheter-associated urinary tract infection) are among the six adverse events or complications specifically associated with hospitalization of older adults. Although there are other geriatric syndromes (e.g., incontinence) and other potential complications associated with older inpatients (e.g., sleep deprivation, inadequate pain management, dehydration, adverse drug effects), many of these syndromes and complications are either risk factors or outcomes of the following.

Functional Decline

Functional decline refers to the loss of the ability to perform basic activities of daily living (ADL). A systematic review of 30 studies examining correlates of functional decline found that between 15 and 76% of hospitalized elders experience diminished performance in at least one ADL at discharge [19]. Of those with decline at discharge, only half will recover function at 3 months postdischarge, and, for many, this decline will result

in permanent loss of independent living [20, 21]. Functional decline is considered a “profound marker of morbidity and mortality” [22, 23] resulting in longer lengths of stay, greater costs and increased rate of nursing home placement [24]. Among the ADLs, the ability to walk independently is considered the most critical in predicting health outcomes. Functional Mobility Decline, defined as new walking dependence, is associated with poor posthospitalization outcomes such as discharge to a nursing home, continued impaired mobility and higher mortality rates [25]. The incidence of functional mobility decline occurs in 15–59% of hospitalized elders [26]. For older hip fracture patients, especially those with cognitive and affective disorders, there is a greater risk of functional decline and new nursing home placement [27, 28].

Fall-Related Injury

Roughly 2–5% of older adults fall during hospitalization [29]. The number of falls per 1,000 patient days is highest in hospital units admitting mostly older adults such as geropsychiatry, rehabilitation, and geriatric medicine. Among hospitalized older adults, falls from bed account for approximately one-third of all falls. Almost one-third of all fall-related injuries occur among persons 85 years of age or older. Approximately 3–10% of falls happening in hospitals result in either serious or minor injuries [30]. Hip fractures, occurring in about 1–4% of hospital falls are particularly significant because older adults are more likely to suffer from a substantial decline in physical functioning and often require longer periods of active rehabilitation services as compared to younger persons [31].

Undernutrition/Malnutrition

Undernutrition and malnutrition are deficiency syndromes caused by inadequate intake or absorption of macronutrients. Malnutrition has long been associated with important adverse outcomes, such as increased morbidity and mortality and decreased quality of life. Weight loss and hypoalbuminemia are both strongly correlated with increased mortality in ill adults [32]. Body weight and body composition have important implications for physical functioning of older persons and the prevalence of malnutrition in older hospitalized patients has been estimated to be between 40 and 60% [33].

Pressure Ulcers

Pressure ulcers continue to present a major health problem for hospitalized adults with reported nosocomial incidence rates between 0.4 and 38% [34]. Pressure ulcers are highly correlated with age [35]. At least a fifth of pressure ulcers will progress to a more advanced stage of deterioration. Most ulcers develop in the sacrum and coccyx areas with rates higher in patients with mobility impairment. Pressure ulcers remain a major cause of morbidity and are associated with longer lengths of hospital stay. Nosocomial pressure ulcers and their progression in severity during hospitalization have been used as a quality care indicator [36].

Urinary Tract Infection

Approximately 4% of patients with urinary tract infection (UTIs) will develop bacteremia which is known to significantly increase in length of stay and is associated with higher mortality in older patients [37]. The major care-associated practice leading to UTI in older inpatients is the overuse of urinary catheters, defined as catheter use for longer than 2 days [38]. Catheter-associated urinary tract infection (CAUTI) is the most common nosocomial infection [39]. A study using a random sample of almost 36,000 Medicare patients undergoing major operations from 2,965 US hospitals reported that 86% had perioperative indwelling urinary catheters and among these 50% had catheters for longer than 2 days postoperatively. These patients' risk of developing a urinary tract infection was twice as likely compared to patients with catheterization [40]. Among another sample of approximately 39,000 Medicare patients undergoing major surgery who were discharged to a nursing home it was found that those patients discharged with catheters were at higher risk for rehospitalization for UTI and death within 30 days than patients who did not have catheters [41].

In addition to infection, catheter use is associated with immobility, delirium, and pain [42].

Delirium

Delirium, a transient state of cognitive impairment, may develop in both cognitively intact and impaired older adults. It is estimated that between 14 and 24% of older persons are admitted to the hospital with delirium, and an additional 6–56% of hospitalized elders will develop delirium during their hospitalization especially if they are admitted to an ICU [43]. Postoperative delirium is more likely to occur following hip fracture, cardiac, non-cardiac thoracic, aortic aneurysm, and abdominal surgery. Postoperative delirium is more likely in those deemed vulnerable. Patient vulnerability including presence of previous brain pathology, decreased ability to manage change, impaired sensory function, multiple co-morbidities and changes in pharmacodynamic responses to medications, are all suggested possible causes for delirium. In surgical patients both preoperative (use of narcotic analgesics, history of alcohol abuse and depression) and perioperative (greater intraoperative blood loss, more postoperative transfusions, postoperative hematocrit less than 30%, and severe postoperative pain) risk factors have been identified for delirium postoperatively [44]. Additionally, hospital practices that lead to iatrogenic events including use of physical restraints, malnutrition, more than three medications and urinary catheterization are also significantly associated with delirium [45]. There are no significant differences in incidence of postoperative delirium following general vs. epidural anesthesia.

Despite high incidence, most delirium goes undetected [46, 47] thus contributing to many negative consequences. Delirium is associated with poor hospital outcomes such as higher mortality rates, increased length of hospital stay, increased intensity of nursing care, greater health-care costs as well as increased risk of several adverse outcomes after discharge, including functional decline, persistent cognitive impairment, rehospitalization, and nursing home placement [48].

The occurrence of each of these complications leads to interventions that can often prolong the hospital stay. Following hospital discharge, they frequently contribute to death, institutionalization as well as disproportionately high rehospitalization rates, high emergency department usage, and increased need for rehabilitation therapy services. As illustrated in Table 21.2, the *interrelationships* among these various complications during hospitalization is obvious and also well documented [12]. The data supporting the importance of prevention, early detection, and treatment of these complications in older surgical patients is described in the ACOVE (Assessing Care of Vulnerable Elders) report, Quality Indicators for Hospitalization and Surgery in Vulnerable Elders [49].

TABLE 21.2 Complications in the older surgical patient^a

Complication	Hospital factors ^b	Clinical outcome	Cost implications
Functional decline	<ul style="list-style-type: none"> • Immobility • Bed rest without medical/surgical indication • Physical restraint • Inappropriate medication prescribing • New psychoactive drug use • Obstacles in the hospital physical environment 	<ul style="list-style-type: none"> • Reduced/loss of independence in function (activities of daily living) • Reduced/loss of ambulation • Pain • Increased rate of pressure ulcers, falls, fall-related injuries, and development of contractures 	<ul style="list-style-type: none"> • Longer length of stay (LOS) • Increased rate of institutional or home-based rehabilitation • Nursing home placement
Fall-related injury	<ul style="list-style-type: none"> • Immobility • Physical restraint • Inappropriate medication prescribing • New psychoactive drug use • Obstacles in the hospital physical environment 	<ul style="list-style-type: none"> • Pain • Fracture requiring surgical intervention • Reduced/loss of independence in function (activities of daily living) • Reduced/loss of ambulation 	<ul style="list-style-type: none"> • Medicare will not pay for treatment^c • Surgery • Longer LOS • Institutional or home-based rehabilitation • Nursing home placement
Under/malnutrition	<ul style="list-style-type: none"> • Immobility • Inattention to oral care • Lack of feeding assistance for those with physical or cognitive impairments 	<ul style="list-style-type: none"> • Reduced wound healing • Discomfort due nasogastric tube placement • Percutaneous enteral access procedures (gastrostomy) • Delirium • Physical restraint to prevent tube removal • Aspiration • Functional decline 	<ul style="list-style-type: none"> • Longer LOS • Surgery • Institutional or home-based enteral nutrition therapy
Pressure ulcer	<ul style="list-style-type: none"> • Immobility • Physical restraint • Under/malnutrition • Dehydration 	<ul style="list-style-type: none"> • Immobility • Sleep deprivation • Pain • Sepsis • Septicemia • Surgical debridement • Surgical techniques (direct closure, flaps, and skin grafting) 	<ul style="list-style-type: none"> • Medicare will not pay for treatment^b • Longer LOS • Institutional or home-based skilled nursing treatment
Urinary tract infection (UTI: secondary to catheter use or CAUTI)	<ul style="list-style-type: none"> • Emergency room placement without indication • Incontinence treatment • No postsurgical monitoring of catheter use 	<ul style="list-style-type: none"> • Immobility • Pain • Delirium • Acute pyelonephritis • Bacteremia • Sepsis • Prosthetic joint infection • Higher risk for death 	<ul style="list-style-type: none"> • Medicare will not pay for treatment^b • Longer LOS • Rehospitalization

^aGeriatric syndromes refer to “clinical conditions in older persons that do not fit into discrete disease categories.” This may also include other conditions highly associated with aging such as frailty, sleep disorders, self-neglect. For the purpose of this review, these syndromes and potential complications are more narrowly defined

^bHospital factors. There is a myriad of patient and hospital factors that contribute to each complication, however, this list provides examples of those specific hospital practices that place the older adults at high risk and which are the focus of geriatric care model interventions

^cAs of October 2008, hospitals will no longer receive payment for 8 hospital-acquired conditions; 3 of these 8 indicated in the table are complications that are known to occur most frequently in older inpatients and have been found to be reduced when geriatric models of care are employed (fall-related injury, pressure ulcer, and catheter-associated urinary track infection)

Although patient characteristics, especially multiple co-morbidities, frailty, and cognitive impairment, may increase vulnerability of older inpatient to negative consequences, the hospital environment plays an independent and significant role in determining staff practice and subsequent patient outcomes such as iatrogenic complications. This has led to the development of geriatric models to address these hospital-based or institutional factors that are likely to contribute to complications among older patients. Effective resolution of these negative consequences is dependent on geriatric models that target both patient and environmental (institutional) risk factors.

Geriatric Care Model Objectives

Although geriatric models of care differ in their approach to prevent complications and address care delivery problems that can contribute to complications, all share a common set of general objectives. Although these objectives could be applied to any patient regardless of age, it is how geriatric care models apply these that are age-specific. Table 21.3 provides examples of processes and interventions to meet these six general objectives.

The six general objectives of geriatric care models are as follows.

TABLE 21.3 Geriatric care models: objectives, processes and interventions

Objective	Examples of processes	Examples of interventions
Educate health-care providers in core geriatric principles	<ul style="list-style-type: none"> Resident training includes required geriatric rotation <i>or</i> mandatory geriatric rotation for residents Institutional continuing education includes geriatric-specific training <i>or</i> Geriatric-specific interdisciplinary continuing education programs Geriatric specialist responsible for geriatric training initiatives 	<ul style="list-style-type: none"> Hospital intranet includes geriatric programming Journal club includes geriatric journals and/or articles focusing on geriatric outcomes Medical, surgical, nursing, and interdisciplinary rounds includes geriatric case studies
Target risk factors for complications	<ul style="list-style-type: none"> Policies, protocols, and documentation system includes assessment tools and practices that identify older adults at risk for complications Assessment tools prompt providers to consult geriatric specialists for evaluation of high-risk problems Geriatric specialist provides individual evaluation of risk factors 	<ul style="list-style-type: none"> Electronic medical record (EMR) provides alerts for medications prescribed that are known to increase fall risk EMR prompts providers to document daily cognitive testing results Hospital policy for daily cognitive assessment of at-risk patients Cognitive assessment indicates delirium that leads to geriatric specialist consultation
Incorporate patient (family) choices and treatment goals	<ul style="list-style-type: none"> Policies and protocols support and documentation system includes forms that elicit patient choices as well as family involvement in care Geriatric nurses are prepared to coordinate an interdisciplinary evaluation and promote development of <i>informed</i> patient/family treatment goals and plan of care Palliative care is consulted and provides informed choices to patients/families in situations of life-threatening illness 	<ul style="list-style-type: none"> Admission history includes evaluation of patient's preferences for postdischarge rehabilitation Unlimited visiting hours and bedside recliners encourage family participation in recovery Patient and family preferences for type and degree of family involvement is documented Patient with Alzheimer's disease who is unable to verbally indicate needs is evaluated by palliative care specialist for pain evaluation/treatment
Employ evidence-based interventions	<ul style="list-style-type: none"> Policies and protocols integrate geriatric specific implications Education and training for all clinicians include core geriatric content 	<ul style="list-style-type: none"> Hospital protocol for urinary catheter removal within 2 days postsurgery Unit-based mobility program Physical environment reduces injury risk for nonambulatory patients with dementia such as low-height beds and bedside mats
Promote interdisciplinary communication	<ul style="list-style-type: none"> Medical record facilitates patient information across disciplines Processes in place to encourage face-to-face interaction among disciplines Unit-based and hospital-wide committee includes geriatric specialist representation 	<ul style="list-style-type: none"> Interdisciplinary team rounds held bi-weekly Programmatic initiatives include all applicable disciplines, e.g., physical and occupational therapy in unit-based mobility program Co-manage patients across specialties such as geriatric oncology Collaborate with other programs such as palliative care in providing symptom management
Emphasize discharge planning or transitional care	<ul style="list-style-type: none"> Documentation system provides comprehensive hospital course information to primary care provider and other postdischarge providers (home care, nursing home, etc.) as well as elicits pertinent information <i>from</i> other providers 	<ul style="list-style-type: none"> Patient and caregiver receive comprehensive documentation of hospital treatment, changes in treatment plan, and postdischarge instructions Understanding of instructions is evaluated before discharge Phone follow-up postdischarge to evaluate patient condition and needs

Educate Health-Care Providers in Core Geriatric Principles

The complications most frequently encountered among older patients are often due to system-level problems. These include inadequate educational preparation of health-care providers to recognize age-specific factors that increase risk of complications. All geriatric care models require a coordinator or clinician with advanced geriatric education; however, the implementation of any model depends on direct care staff with the knowledge and competencies to deliver safe and evidence-based care to older patients. Thus, the coordinator or other geriatric clinician role includes teaching of other staff through rounds, journal clubs, conferences, and other internal institutional educational venues.

Target Risk Factors for Complications

Given the disproportion of certain complications or geriatric syndromes among hospitalized older adults, the clinical focus of all geriatric models is prevention via risk factor reduction and early detection of these problems. Some models may focus on a particular syndrome; however, the interrelationship of these complications and their shared risk factors often result in a reduction of the other geriatric syndromes. Targeting risk factors requires standardized assessment tools known to be valid and reliable for older adults. See the Hartford Institute's Try This and How to Try This series for examples of assessment instruments (<http://www.hartfordign.org/trythis>). Implementation of geriatric care models often include institutionalizing these practices such as incorporating these tools in the medical record as well as hospital policies, procedures, and protocols.

Incorporate Patient (Family) Choices and Treatment Goals

All health-care decisions should be guided by the patient's choices. Choices range from decisions about activity level and medication use to more complex issues including advance directives.

Decisions regarding life-sustaining treatment are often influenced by quality of life considerations balanced by the potential length of life. For family members acting in the best interests of patients who can no longer participate in decision-making, this can be a complicated dilemma. Life-sustaining treatments are often employed with very old

patients who die in the course of hospitalization although most prefer comfort care. Geriatric models are meant to address this lack of congruence by supporting efforts to provide care that is more consistent with patients' preferences [50]. For this reason, many geriatric models work collaboratively or in conjunction with palliative care programs.

Employ Evidence-Based Interventions

Given that most physicians, nurses, and other health providers have received minimal content in their training regarding geriatrics, it is not surprising that there is a higher complication rate for older hospitalized patients. Advances in geriatric science, similar to other research-based approaches, are not readily employed in hospital care. Problems with polypharmacy, inappropriate medications (e.g., overuse of psychoactive), overuse of restraints, inadequate detection of delirium, depression, and undermanagement of pain are some of the many hospital factors that can contribute to poor outcomes. Thus, geriatric models promote the use of standardized evidence-based protocols.

Promote Interdisciplinary Communication

Since geriatric syndromes are not just medical problems but represent a complex interaction of medical, functional, psychological, and social issues, other disciplines such as nursing, pharmacy, social work, physical and occupational therapy are needed. Geriatric care models all include interdisciplinary teams, i.e., an approach that facilitates communication among disciplines.

Emphasize Discharge Planning (or Transitional Care)

Many older patients will require rehabilitation or skilled nursing services following hospitalization. Almost a quarter of older hospital patients are discharged to another institution such as a rehabilitation hospital or nursing home and more than 10% are discharged with home care [51]. Older adults are more likely to experience problems associated with discharge planning that can lead to delays in discharge and greater use of emergency service use and hospital readmission. Hospital readmission for older patients is most likely associated with medical errors in medication continuity [52, 53], diagnostic workup, or test follow-up [54]. These

poor outcomes are attributed to a lack of coordination among health-care providers that can result in unresolved medical issues [55] and deficient preparation of patients and their caregivers to carry out discharge instructions [56]. One study found wide variations among providers in discharge planning effectiveness; the providers cited their lack of knowledge and experience when not making appropriate home-care referrals [57]. Thus, geriatric models not only focus on the inpatient experience but also the post-hospital care environment and the care transition following hospital discharge. Two of the six models consider the care transition a primary focus of their programs.

Geriatric Models

There are several types of geriatric models that are currently employed in hospitals throughout the USA. In addition to incorporating the original tenets central to comprehensive geriatric assessment (screen for those at high risk for geriatric-specific problems, assess for modifiable risk factors, and implement strategies consistent with the patients' treatment goals), all strive to deliver quality care for older adults in a cost-effective manner. Comprehensive geriatric assessment assumes that the systematic evaluation of a frail older person by a multidisciplinary health-care team will uncover actual or potential health problems. The considerable advances in geriatric health-care science over the last 30 years can then be applied to treating or preventing these conditions and thus result in better health outcomes.

Although the specific mode of intervening may differ among the models, they all address both common health problems and care delivery issues. The geriatric model may consider all geriatric syndromes or target specific ones such as delirium or functional decline. Similarly, the geriatric model may be employed as a hospital-wide approach, unit-based intervention, or focus on specific processes of hospitalization such as admission screening or discharge planning. Regardless of the structure of the geriatric model, all facilitate the general objectives listed in Table 21.3. Table 21.4 provides a summary of the clinical foci, unique features, coordination, and interventions for each of the six most commonly employed geriatric models of care.

Geriatric Consultation Service

Geriatric Consultation Service provides a geriatrician, a gero-psychiatrist, a geriatric clinical nurse specialist or an interdisciplinary team of geriatric health-care providers to conduct a comprehensive geriatric assessment or evaluate a

specific condition (delirium), symptom (patient dislodges or removes treatment), or situation (adequacy of family support for discharge back to community setting). The consultation may be requested by another primary service for an individual patient or may be initiated by a hospital policy for all patients that are screened at high risk for geriatric-related complications or are admitted from a home-bound program or a nursing home [58].

Outside of academic medical centers, few hospitals have geriatric departments that can provide geriatricians or a geriatric consultation team. Although geriatric nurse specialists may be more prevalent in hospitals than geriatricians, many function without the benefit of a geriatric team or a geriatrician. Similar to geriatricians, it is difficult to evaluate their effectiveness when their practice is limited to a consultative role in which recommendations may not be followed or institutional resources are not adequately available for staff to implement [59].

Acute Care for the Elderly Units

Acute Care for the Elderly (ACE) Units are discrete geriatric care-focused units. Originally developed in the 1970s within Veterans Administration Hospitals, Geriatric Evaluation and Management (GEM) Units were meant to provide comprehensive geriatric assessment delivered by a multidisciplinary team with a focus on the rehabilitative needs of older patients. Multidisciplinary team rounds and patient-centered team conferences are considered the hallmarks of care. The core team includes a geriatrician, clinical nurse specialist, social worker as well as specialists from other disciplines providing consultation: occupational and physical therapy, nutrition, pharmacy, audiology, and psychology. GEM units usually have been redesigned to facilitate care of the older patient, which, in contrast to geriatric consultation services, have direct control over the implementation of team recommendations. Research conducted in the 1980s and 1990s have documented significant reductions in functional decline and suboptimal medication use as well as return to home postdischarge and, more recently, decreased rate of nursing home placement [60] among hospitalized veterans on GEMUs compared to general medical units.

Beginning in the 1990s, Acute Care of Elders (ACE) Units have been implemented in non-VA hospitals although they generally focus on more acutely ill patients than GEM units. These units utilize staff with geriatric expertise working collaboratively in an interdisciplinary team (fostered by care processes such as team rounds and family conferences) in a physical environment with adaptations to address age-related changes (e.g., flooring to reduce glare and low-height

TABLE 21.4 Core components of six geriatric care models

Model type	Clinical outcome focus ^a	Unique features	Program/team coordination	Interventions ^b
Geriatric Consultation	<ul style="list-style-type: none"> Primary focus can vary depending on composition of consult team & may be specific to a surgical specialty or procedure 	<ul style="list-style-type: none"> Employed by primary provider request 	<ul style="list-style-type: none"> Individual consultant (geriatrician, geropsychiatrist or geriatric nurse specialist) <i>or</i> Interdisciplinary team that is coordinated by geriatric medicine or psychiatry fellow, geriatric nurse specialist or an administrative director 	<ul style="list-style-type: none"> Comprehensive geriatric assessment: medical, psychiatric, functional, and social Recommends interventions based on consultant discipline (medicine, psychiatry, or team that includes nurses, social workers, and others) Primary provider chooses which recommendation to employ
Acute Care for the Elderly (ACE)	<ul style="list-style-type: none"> Functional decline 	<ul style="list-style-type: none"> Dedicated unit with explicit admission criteria Requires interdisciplinary team Redesign of physical environment to accommodate physical and cognitive needs 	<ul style="list-style-type: none"> Unit directed and/or team coordinated by geriatrician, geriatric nurse specialist, administrator or co-managed by clinician-manager 	<ul style="list-style-type: none"> Physical environment to promote patient mobility, orientation and staff observation Interdisciplinary rounds facilitate care coordination and thus: <ul style="list-style-type: none"> Identify modifiable risk factors for geriatric syndromes and complications Prevent avoidable discharge delay Promote timely referrals to disciplines or specialists
NICHE: GRN/ACE	<ul style="list-style-type: none"> Nursing processes related to all geriatric syndromes and potential complications, such as avoiding restraint use, initiating urinary catheter removal 	<ul style="list-style-type: none"> Focus on improving nursing care of all geriatric syndromes Prepares staff nurses to take active part in geriatric care management including coordinating or facilitating other geriatric models of care 	<ul style="list-style-type: none"> Program implementation by NICHE Coordinator (usually a geriatric nurse specialist) Geriatric Resources Nurses (staff nurses with additional training) implement protocols Depending on availability, other clinicians (geriatrician, hospitalist, social worker, etc.) work as interdisciplinary team 	<ul style="list-style-type: none"> Nurse-initiated protocols: <ul style="list-style-type: none"> Restraint and psychoactive drug reduction Functional mobility Fall/injury prevention Pressure ulcer assessment/treatment Prevention of UTI – early catheter removal Delirium assessment/treatment Organizational strategies including measurement schema, performance improvement techniques, and management tools to promote implementation of above protocols

^aAll programs are meant to address geriatric syndromes and potential complications. Geriatric syndromes refer to “clinical conditions in older persons that do not fit into discrete disease categories.” This may also include other conditions highly associated with aging such as frailty, sleep disorders, self-neglect. For the purpose of this review, these syndromes and potential complications are more narrowly defined to 6 of the most common complications

^bInterventions are guided by the use of standardized assessment tools known to be valid and reliable for older adults. See the Hartford Institute's Try This and How to Try This series for examples of assessment instruments (<http://www.hartfordinstitute.org/trythis>)

beds to reduce fall-related injury), promote orientation (clocks and calendars) and facilitate staff observation (e.g., alarmed exit doors, windows inserted in walls and communal space for meals). The interdisciplinary team (led by geriatricians and/or geriatric nurse specialists) aims to facilitate care coordination and thus identify modifiable risk factors for geriatric syndromes and complications, prevent avoidable discharge delay, and promote timely referrals to disciplines/specialist.

Palmer et al. designed the first ACE unit at the University Hospitals of Cleveland [61]. A randomized controlled trial of Acute Care for Elders in an academic medical center reported improved functional status (ADL or activities of daily living, instrumental ADLs and ambulation) at discharge of patients hospitalized on the ACE unit compared to those on other units. Fewer patients from the ACE group were discharged to nursing homes. These beneficial effects were achieved without increasing in-hospital or postdischarge costs. There were no significant differences in mortality, length of stay, readmission, or hospital costs between the two groups [62]. In another randomized trial conducted in a community hospital, patients were randomly assigned to either ACE care or a regular care unit. Positive outcomes of the ACE intervention was demonstrated in several processes of care including a reduction in restraint use, days to discharge planning and use of high-risk medications. They also found benefit in a composite outcome of ADL improvement and nursing home placement but not in discharge ADL levels alone. There was no significant reduction in length of stay, hospital costs, or mortality in the ACE unit subjects compared to the regular unit subjects [63]. These savings are recognized in integrated health-care delivery systems such as the VA, Kaiser, and PACE (Program of All Inclusive Care of the Elderly); however, our current “silo-based” reimbursement system to individual hospitals does not provide incentives for postdischarge reductions in health services usage [64].

Since one unit cannot provide care for all older patients within a hospital, many hospitals use this unit for patients at highest risk for age-related complications. The unit is an excellent environment for training of all disciplines. ACE staff may also provide consultation throughout the hospital to export ACE principles throughout the health system.

Nurses Improving the Care of Health System Elders

Nurses Improving the Care of Health System Elders (NICHE; <http://www.nicheprogram.org>) is a national program aimed at system improvement to achieve positive outcomes for hospitalized older adults. NICHE has two main goals: improving the quality of care to patients and improving nurse competence. This is accomplished by “modifying the nurse practice environment with the infusion of geriatric-

specific: (a) core values into the mission statement of the institution; (b) special equipment, supplies, and other resources; and (c) protocols and techniques that promote interdisciplinary collaboration.” [65] NICHE includes several approaches, each of which facilitates transfusion of evidence-based geriatric best practices into hospital care. A geriatric nurse specialist as the NICHE Coordinator functions in both a “primary care” role (evaluating and managing patients directly) and in a leadership role (teaching and mentoring others and changing systems of care).” [66] Foundational to NICHE is the Geriatric Resource Nurse Model (GRN) which is an educational intervention model that prepares staff nurses as the clinical resource person on geriatric issues to other nurses on their unit. The GRN model provides staff nurses, via education and modeling by a NICHE coordinator, with specific content for improved knowledge of care management for geriatric syndromes. Clinical protocols and organizational strategies provide necessary tools to apply evidence-based practice. For example, in one NICHE orthopedic unit, GRNs received intensive education on the prevention and detection of delirium in a unit where the primary diagnoses were joint replacement and hip fracture repair. Utilizing a combination of standardized assessment of cognition and focused interventions to prevent post-op delirium, the unit realized a significant reduction in the incidence of delirium. Other systemic interventions utilized by the GRNs include a revised nursing database and delirium-specific order sets [67]. An evaluation of responses of 9,802 direct-care registered nurses from 75 acute care hospitals participating in NICHE found that a positive geriatric nurse practice environment was associated with positive geriatric care delivery. The independent contribution of all three aspects of the geriatric nurse practice environment (resource availability, institutional values, and capacity for collaboration) influences care delivery for hospitalized older adult patients. The study findings demonstrate that a nurse practice environment that provides adequate geriatric-specific resources (continuing education, education, specialty services), promotes interdisciplinary collaboration, and fosters patient, family, and nurse involvement in treatment-related decision-making is associated with quality geriatric care [64]. In single site studies, NICHE hospitals demonstrate improved clinical outcomes, rate of compliance with geriatric institutional protocols; cost-related outcomes; and nurse knowledge. In a study of eight hospitals, nurses reported higher quality of geriatric care following NICHE implementation [68].

NICHE also promotes a unit-based ACE model. The ACE model within NICHE emphasizes: (1) implementation of nurse-driven protocols, (2) geriatric training of all nursing staff, and (3) utilization of geriatric-specific units within a health system’s overall geriatric care programming. Similar to other ACE studies, a NICHE-ACE unit in which the majority of the staff nurses were nationally certified in geriatric

nursing reported lower fall and pressure ulcer rates, and lower length of stay when compared to overall hospital [69].

Since NICHE is a system-level approach it provides a structure for nurses to collaborate with other disciplines and to actively participate or coordinate other geriatric care models. For example, in hospitals with a geriatric department or consultation service, GRNs screen for appropriate referrals to these services and can effectively implement geriatric service recommendations with support from the NICHE coordinator. The models enhance NICHE program effectiveness by expanding the scope of geriatric programming within a health system.

The Hospital Elder Life Program

The Hospital Elder Life Program (HELP; <http://elderlife.med.yale.edu/public/public-main.php>) is a program designed to implement protocols that target six delirium risk factors: mental orientation, therapeutic activities, early mobilization, vision and hearing adaptations, hydration and feeding assistance, and sleep enhancement. These protocols were tested in several well-designed clinical trials and demonstrated significant reduction in the incidence of new delirium. Further, among those who did develop delirium, these protocols are associated with a significant reduction of total number of episodes and days with delirium, functional decline, costs of hospital services, and reduction in use of long-term nursing home services [70, 71].

HELP employs geriatric specialists of various disciplines (geriatrician, geriatric nurse specialist, recreation therapy, and physical therapy) working together as an interdisciplinary team with trained volunteers. The program is coordinated by Elder Life Specialists, typically an Elder Life Nurse Specialist who has advanced geriatric nursing education and is responsible for implementing nursing-related assessments and tracking of delirium risk factor protocol adherence. The latter depends on the involvement of well-trained and supervised volunteers in patient-care interventions [72]. The research-tested protocol was made available to hospitals in 2000. Implementation in many hospitals has been adapted based on hospital resources. This has led to wide variations in adherence to the intervention protocol. Although higher levels of adherence have been associated with lower rates of delirium, these adapted protocols continue to provide positive results [73].

Transitional Care Models

An American Geriatric Society Position Statement defines transitional care as a set of actions designed to ensure the

coordination and continuity of health care as patients transfer between different locations or different levels of care within the same location [74]. Older adult patients with complex medical and social needs and their caregivers require assistance to effectively navigate the health-care system, including recovery from surgery and return to pre-morbid health and living arrangements. Two models have emerged that have demonstrated improved outcomes for older adults hospitalized for both medical and surgical interventions.

APN transitional care model utilizes advanced practice nurses (APNs) whose primary responsibility is to optimize the health of high-risk, cognitively intact older adults with a variety of medical and surgical conditions during hospitalization and for designing and overseeing the plan for follow-up care following discharge [75]. The APN work collaboratively with the older adult, family caregiver, physician, and other health team members and are guided by evidence-based protocols. The same nurse implements this plan after discharge by providing traditional home-care services and by phone availability 7 days a week. Three federally funded, randomized, controlled trials consistently demonstrated that this model of care improves older adults' satisfaction, reduces rehospitalizations, and decreases health-care costs [76–78].

Care transitions coaching or *care transitions intervention* (see <http://www.caretransitions.org/index.asp>) employs a nurse or “transitions coach” to encourage older patients and their family caregivers to assume more active roles during care transitions by facilitating self-management and direct communication between the patient/caregiver and primary care provider. The four content areas or “pillars” of the patient/caregiver intervention are as follows: (1) medication self-management, (2) a patient-centered record, (3) primary care and specialist follow-up, and (4) knowledge of “red flags” warning symptom or sign indicative of a worsening condition [79]. The Personal Health Record includes data elements essential to promote productive patient–provider encounters across settings such as an active health problem list; medications and allergies; a list of warning symptoms or signs that correspond to the patient's chronic illnesses; a checklist of activities that need to take place before and following discharge. This record is maintained by the patient and caregiver with assistance from the transition coach. The 4-week intervention begins in the hospital and continues through home visits and/or phone follow-up after discharge.

Several studies, including a randomized, controlled trial, found that patients who received this intervention had lower all-cause rehospitalization rates 30 and 90 days after discharge compared with control patients. Intervention patients also had lower rehospitalization rates for the same condition that they were admitted for in the index hospitalization at 90 and at 180 days than controls. Mean hospital costs were approximately \$500 less for patients in the intervention group compared with controls [80].

New Specialty Models

In some hospitals, multiple geriatric models are employed. For example, a hospital may begin with NICHE. The NICHE coordinator, a geriatric nurse specialist, will then become an Elder Life Specialist to implement HELP hospital wide or within a discrete ACE unit. Often the core geriatric interdisciplinary team of any geriatric program screens patients for other related services such as palliative care, rehabilitative services, or pain management programs. Some have developed dual-function units such as merging an ACE unit with a palliative care unit [66]. Others have developed programs that merge geriatrics with other specialties. Examples include hip fracture, trauma, and oncology.

The American Academy of Orthopedic Surgeons recommends coordination of care and communication by providers as important aspects of quality care for hip fracture patients [81]. In response, several hospital programs that incorporate geriatric co-management of hip fracture patients have been developed. The expectation is that involvement of geriatricians in care management will avoid iatrogenic problems. For example, one program focuses on minimizing time to surgery and employment of standardized orders and protocols [82]. These programs have been shown to reduce delirium by over one-third, reduce severe delirium by over one-half, decrease predicted length of stay, readmission rates, complication rates, and mortality [83]. Others have developed a geriatric trauma team that include a geriatrician and geriatric advanced practice nurse who evaluate older trauma patients and share recommendations in weekly multidisciplinary rounds and performance improvement meetings of the trauma service. Most (91%) geriatric recommendations were followed and included: advanced care planning, disposition decisions to promote function, decreased inappropriate medications, and pain management [84].

Similarly, oncology programs have either developed geriatric – oncology consultation team or have developed geriatric – oncology units, some of which are part of an existing ACE unit [85, 86]. These programs report that older oncology patients have more complex medical and social needs than adult oncology patients and thus require input from both perspectives [87].

Conclusion

Although these models use different strategies, all share common goals of treatment. Each hospital or health system chooses a model based on the unique needs of that hospital's patient population, the resources available (geriatric specialists, bed capacity to support separate unit, volunteers, etc.) and especially senior administrator's commitment to geriatric

programming. Since there is no direct reimbursement for many components of these models (interdisciplinary rounds, geriatric nurse specialist, volunteers, etc.) administrators seek external (grants, donor gifts) and internal funding (hospital foundation grants). They are motivated by the model's alignment to the hospital's strategic plan (e.g., excellence in senior care), the institution's mission, patient/family satisfaction, relationship with the community, and costs savings (i.e., reduction of complications). All of the models have demonstrated positive outcomes and each have been implemented in at least 50 hospitals; however, this still only represents a small proportion of American hospitals. Each model was originally developed with government and/or foundation support. Future survival of these models may depend on advancing the unique contributions of each within an integrated model that will enhance the hospital experience of the older patient.

Another problem influencing geriatric model implementation is availability of geriatric clinicians. Since significant geriatric medicine input is needed for many of these models, they generally are limited to academic medical centers, which only represent a small proportion of US hospitals. All of these models require providers with knowledge of core concepts in geriatrics; however, there is a significant shortage of fellowship-trained geriatricians, geriatric psychiatrists, master's prepared geriatric nurse specialists, as well as other disciplines [88]. In addition to efforts to increase the training of geriatric specialists, several initiatives are underway that involve specialty organizations, medical schools [89], and resident training programs [90, 91] to integrate principles of geriatric care into curriculums and practice. As more geriatrics is being integrated into undergraduate medical training and surgical resident training, knowledge of geriatric care principles and collaboration with geriatric models will enhance outcomes of the older surgical patients. The Council of the Section for Surgical and Related Medical Specialties in the American Geriatrics Society program provides the Geriatrics Syllabus for Specialists; a useful guide (lectures, PowerPoint presentations, etc.) geared toward providing vital information for surgeons caring for older patients as well as faculty leadership training to promote geriatric training and research within their disciplines. The initiative also enables surgical professional certifying bodies and societies to build the capacity of their members to provide better care of older adults [92].

Financial and administrative barriers deter the implementation of geriatric models. Medicare payment system focuses on provider-specific reimbursement and thus limits payment for organizational redesign, multidisciplinary teams or nurse-coordinators. The new CMS financial incentives that will not reimburse for nosocomial "never" events such as pressure ulcers, catheter-associated infections, and fall-related injury, may eventually encourage the use of these models [15]. A recent IOM report recommended that "payers should promote and reward the dissemination of those models of

care for older adults that have been shown to be effective and efficient.” [87] Incentives suggested included elimination of Medicare’s co-payment disparity for mental health and enhanced payments for services under these models.

Finally, most of the research documenting complications of the older patient are based on studies combining both medical and surgical patients, thus future research should address the risk factors of these complications specific to surgical patients. Further, with the exception of hip fracture and cardiac surgery, additional studies should also identify complications within specific types of surgical procedures. This may provide important data to tailor models to specific surgical populations.

Introduction

Aging Epidemiology

Beginning in 2012, nearly 10,000 Americans will reach age 65, each day [1]. The number of older Americans is expected to increase from 35 million (12.4% of the total population) in 2000 to 71 million (19.6% of the total population) in 2030 [2]. As demonstrated in Fig. 22.1 [3], the proportion of adults who are ≥ 65 years of age is increasing, while the proportion of persons < 65 is decreasing. In fact, individuals over age 85, dubbed the “oldest old,” are the most rapidly growing segment of the population, and their number is expected to increase fivefold to almost 19 million by the year 2050 [2].

The aging of the American population has created the need to provide surgical care to an ever-increasing number of

older persons. At present, 35% of all surgical procedures performed in the USA are on persons 65 years of age or older; the rate of surgical procedures performed per 10,000 is 4.4 in older patients compared with 1.5 in younger adults [4]. Approximately half of individuals over age 65 will have at least one major surgical procedure in the remainder of their lifetime [4]. Overall, workload varies considerably by specialty; persons of age 65 years and older represent 60% of the cases in general surgery and almost 90% of the cases in ophthalmology [5].

Over the past several decades, advances in surgical and anesthetic techniques have led to an overall decline in operative mortality in older patients [6]. The “risk” of surgery therefore has become somewhat less of a concern, whereas the need and ability to provide maximal disease management has increased. While age cannot be completely ignored, functional status and/or comorbid conditions usually contribute more to operative outcomes than age alone. However, there are physiological changes that occur with aging that warrant recognition in order to maximize perioperative outcomes. As the number of older surgical candidates continues to grow, it will become increasingly important for all surgeons to understand the special issues involved in the selection and evaluation of older patients for surgical care.

Pattern of Surgical Disease in the Elderly

Before discussing the process of selecting and evaluating geriatric patients, it is important to note that the pattern of surgical disease in older patients is not always superimposable on the pattern seen in younger patients. The indication for surgery therefore may not be apparent until a complication has occurred. The absence of the classic signs and symptoms often leads to delays in treatment and errors in diagnosis. As a result, emergency surgical intervention is frequently necessary.

For example, older adults are twice as likely (33 vs. 16%) to have a right-sided colon cancer compared with younger adults [7]. As a result of this anatomical difference older adults may present more often with symptoms that are not initially associated with colorectal cancer, such as syncope and fatigue. Older adults with left-sided colon cancer often delay seeking medical care because they do not consider symptoms such as constipation to be abnormal. Thus, it is not surprising that up to 40% of older patients with colorectal cancer present for surgical intervention secondary to obstruction and/or perforation [7]. Further evidence of altered symptomatology in older persons is found in the pattern of presentation of biliary tract disease. The classic pattern of worsening biliary symptoms preceding the development of a complication is often absent in older adults. Consequently, up to two-thirds of the cholecystectomies in patients over the age of 65 are performed urgently or emergently compared with less than one-fifth in younger patients [8].

The high rate of emergency surgery in older adults is important because emergency surgery is associated with at least a threefold increase in mortality and morbidity. In one series of patients over the age of 70 years, emergency operations carried a mortality rate ten times greater than that for elective procedures [9]. Emergency surgery is also associated with a higher rate of long-term hospital stay (>30 days), more need for postoperative intensive care, larger decline in functional status, and increased need for postoperative nursing home placement [10].

Eliciting Patients' Preferences

Before the decision is made to proceed with elective surgery, a thorough discussion of the patient's goals of care and preferences is warranted. Items for consideration include the following:

- How clear is the indication for surgery, including the likelihood of progression of the disease?
- What is the likelihood of achieving equal or improved functional status?
- What degree of symptom improvement can be expected after the procedure?
- What quality of life can be expected with or without the surgery?
- Does the patient, and his or her family, understand the problem and the proposed solution?
- What is the risk of a negative outcome as determined by the nature of the procedure and the presence of comorbid conditions?

Fried et al. have shown that for older persons, the burden of treatment, the possible treatment outcomes (desirable vs. undesirable), and the likelihood of a particular outcome each influence treatment preferences [11]. Given various hypothetical situations, the majority of older patients (>70%) stated they would not want even a low-burden treatment if severe functional impairment or cognitive impairment was the expected outcome. As the likelihood of an adverse outcome increased, the number of patients who stated they would want treatment decreased. Thus, advance care planning that includes elucidation of patients' treatment preferences and designation of surrogate decision makers is one of the most important components of preoperative assessment for older surgical patients.

Objectives of Preoperative Assessment

Once these issues are addressed; the main thrust of the preoperative evaluation is to identify, and optimize, any coexisting disease processes or decline in physiologic reserve. With this

information, an accurate risk/benefit determination can be made for each surgical intervention in each elderly patient. Although we refer to risk primarily as the chance of postoperative mortality and morbidity, risk in the elderly should also be assessed in terms of restoration of preoperative functional status and quality of life. For older patients, maintenance of independence, quality of life, and symptom resolution may be as important as, if not more so, than survival.

Efforts are currently underway to develop process-based quality indicators to improve perioperative care and subsequent outcomes for older patients undergoing ambulatory, major elective, or nonelective inpatient surgery [12]. Additional work is needed both to determine the feasibility of implementing quality indicators into routine care and to demonstrate improved patient outcomes secondary to their use.

General Evaluation

Affect of Age on Perioperative Outcomes

The general approach to the preoperative assessment is directed toward identifying those factors that place the patient at increased risk for postoperative complications or death. Although some of these factors are related to the surgical disease itself and to the type of operation required, the most important factors in the determination of risk are related to the overall health, function level, cognitive abilities, and nutritional status of the patient.

Many studies have demonstrated comparable outcomes among older and younger adult surgical patients. A retrospective analysis of cardiac surgery among octogenarians in Germany demonstrated that mortality was associated with comorbid conditions (e.g., chronic obstructive pulmonary disease or heart failure), nonelective surgery, and male gender, but not with age [13]. Follow-up with these patients 3–5 years after surgery revealed that approximately 85% were clinically better than they were prior to surgery. Another German study examined outcomes for colorectal cancer patients who underwent surgery. While mortality rates were higher for patients ≥ 80 years than for patients < 80 years (8.0 vs. 2.6%), specific morbidity related to the operation was not significantly different (20.5 vs. 19.9%) [14].

Yet, some evidence suggests that even after adjusting for comorbid conditions, age itself is associated with higher risk for adverse outcomes among patients undergoing noncardiac surgery [15, 16]. The reason for this increased risk is presently unclear. It is possible that confounders associated with aging exist but are unrecognized, and thus unadjusted for, in multivariate analyses. If true, the increased risk observed with increasing age would in fact be due to the confounders, not age itself. Nonetheless, many older adults tolerate surgery if it is well conducted and free of complications. However,

if complications arise, the additional stress associated with the complications exceeds the physiological reserves of many older adults.

Comorbidity

ASK the question	<i>Do a thorough history including review of systems 2</i>
DO the test	<i>Do a complete physical exam</i>

Over 80% of Americans aged ≥ 65 have at least one chronic condition and 50% have at least two [17]. The prevalence of comorbid diseases clearly rises with increasing age. The age-related increase in cardiac, pulmonary, renal, and hepatic comorbid conditions in a cohort of colon cancer patients over age 50 has previously been demonstrated [18]. The prevalence rates for some common chronic conditions experienced by older adults are depicted in Fig. 22.2 [1].

In a larger, more detailed review of comorbidity in elderly patients with colon cancer, Yancik et al. explored the increase in the number of additional conditions with age [19]. By age 75, patients with colon cancer had a mean of five disorders in addition to the primary cancer. For all adults, the influence of comorbid conditions on activity level increases substantially with age as demonstrated in Fig. 22.3 [3]. In addition, comorbid conditions more frequently contribute to the cancellation of surgery after hospital admission in older adults compared with younger adults [4].

FIGURE 22.2 Prevalence of selected chronic conditions among adults age 65 and over, 2000–2001. *Asterisk* indicates a respondent was considered to have “arthritic symptoms” if s/he answered “yes” to the following questions: “During the past 12 months, have you had pain, aching, stiffness, or swelling in or around a joint?” and “Were these symptoms present on most days for at least one month?” (from Centers for Disease Control and Prevention, National Center for Health Statistics, National Health Interview Survey, 2000–2001).

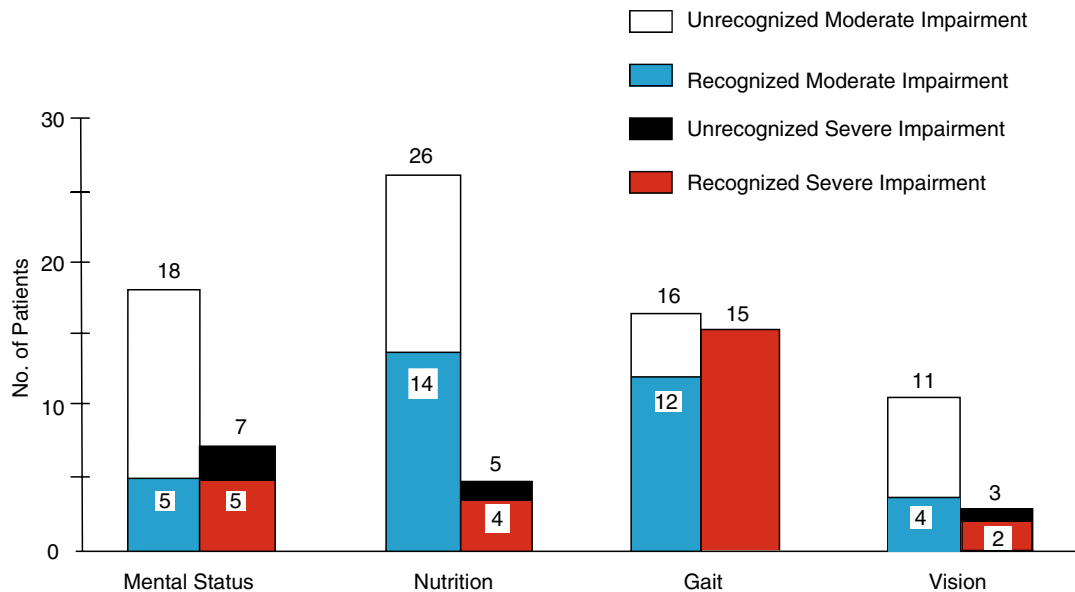

FIGURE 22.3 Limitation of activity caused by selected chronic health conditions among older adults, by age: United States, 2005–2006 (from [13]).

As the number of associated illnesses increases, so does the rate of perioperative complications. In a study on the effect of increasing comorbidity on outcome, Tiret and colleagues demonstrated a strong correlation between the number of conditions and the rate of perioperative complications. This effect was seen in all age groups but was most pronounced in the youngest and oldest patients [20]. Only a

minimal increase in mortality and morbidity was seen in old patients who lacked coexisting disease. Such minimal increases were insignificant when compared with the three-fold increase associated with as few as two additional comorbidities. Other studies of outcome for both surgical and medical treatment demonstrate a similar correlation between comorbidity and poor treatment outcome [19, 21].

As is true for surgical disease itself, older adults often do not present with the “classical” signs and symptoms typically attributed to comorbid conditions. The search for comorbid conditions must therefore be diligent. In the Framingham heart study for example, myocardial infarction was unrecognized or silent in more than 40% of persons of age 75–84 compared with fewer than 20% of those of age 45–54 [22]. Thyroid dysfunction (either hyper or hypo), cognitive impairment, and malnutrition are among the many other coexisting disorders that may not be recognized during the initial history and physical examination. For example, one study of hospitalized medical patients over age of 75 years revealed that 63% of patients meeting criteria for cognitive impairment were not identified as impaired on their discharge summary [23]. Earlier studies demonstrate that 46% of moderate to severe nutritional deficits identified among patients during hospital admission had not been recognized by the primary caregiver in the community (Fig. 22.4) [24].

Frailty is another comorbid condition that is frequently not recognized by providers. But recent evidence suggests that frailty may be an important predictor of postoperative mortality in one study, patients who had four of the following

Prevalence and recognition by primary caregivers of functional impairment in 79 medical inpatients. Number at top of each bar represents total number of patients impaired in that functional area.

FIGURE 22.4 Patients found to have nutritional and mental status deficits during formal geriatric assessment at admission to the hospital compared to those identified by the primary caregiver in the community. *Lighter bars* indicate the results of formal assessment. It is seen that most of the nutritional deficits and a large percentage of mental

status deficits were not recognized prior to admission to the hospital, indicating that these deficits are subtle and may not be appreciated without purposeful attempts to identify them (from Pinholt [24] with permission, Copyright © 1987 American Medical Association. All rights reserved).

TABLE 22.1 Herbal medicines and recommendations for discontinuation of use before surgery

Herb: common name(s)	Uses	Perioperative concerns	Preoperative discontinuation
Echinacea: purple coneflower root	Prophylaxis, treatment of viral, bacterial, fungal infections	Decreased effectiveness of immunosuppressants	No data
Ephedra: ma huang	Weight loss, increase energy	Tachycardia, hypertension	At least 24 h before surgery
Garlic: ajo	Lowers blood pressure, serum lipid and cholesterol level	May potentially increase risk of bleeding	At least 7 days before surgery
Ginkgo: duck foot tree, maidenhair tree, silver apricot	Cognitive disorders	Potential to increase risk of bleeding	At least 36 h before surgery
Ginseng: American ginseng, Asian ginseng, Chinese ginseng, Korean ginseng	Prevention of stress, restore homeostasis	Potential to increase risk of bleeding, hypoglycemia	At least 7 days before surgery
Kava: awa, intoxicating pepper, kawa	Anxiolytic sedative	Potential to increase sedative effect of anesthetics	At least 24 h before surgery
St. John's wort: amber, goat weed, hardhay, Hypericum, klamathweed	Depression	Induction of cytochrome P450 enzymes, decreased serum digoxin levels	At least 5 days before surgery
Valerian: all heal, garden heliotrope, vandal root	Insomnia	Potential to increase sedative effect of anesthetics	No data

Extensive testing for comorbidity in every organ system is neither cost-effective nor necessary for every patient. A thorough history and physical examination provide information that can direct further workup, if necessary. It is important, however, to adjust the history and physical examination to look for risk factors and signs and symptoms of the more common comorbid disorders. The addition of simple questions and simple tools for assessing functional, cognitive, and nutritional status significantly enhances understanding the individual elderly patient's true operative risk. When initial evaluation identifies specific disease or risk factors for disease, further workup may be indicated. Evaluation of specific organ systems is described later in the chapter.

Medication Assessment

ASK the question *Can you tell me all the prescription, herbal, and over-the-counter pills you take on a regular or as-needed basis*

DO the test *Check medication lists or bottles*

The vast majority of medications taken on a daily basis are consumed by adults over the age of 65 years. Thus, a

comprehensive medication review is warranted for all older preoperative patients. Patients should specifically be queried regarding the use of herbal medications, given the potential for drug–herbal interaction and the low likelihood of self-report among patients. Education (≥12 years) and annual income (>\$20,000) were found to be associated with herbal medication use in the multivariate logistic regression of one study [26]. A list of the most commonly taken herbal medicines, their uses, perioperative concerns, and recommended preoperative discontinuation time is found in Table 22.1 [27].

Geriatrics-Specific Evaluation

Functional Status Evaluation

ASK the question *“Can you carry a bag of groceries up a flight of steps without getting short of breath?”*

DO the test *Timed Get Up and Go*

Functional status can be measured in many different ways. Regardless of the methods, preoperative functional deficits have been shown to contribute to postoperative immobility, with associated complications such as atelectasis and pneumonia, multisystem deconditioning, increased length of stay, and increased mortality and morbidity. Individuals with poor preoperative function have longer hospitalizations, more surgical complications, and are more likely to die within 30 days of surgery when compared with individuals with good preoperative functional fitness [28]. Deconditioning is an important clinical entity that leads to further functional decline despite improvement in the acute illness [29]. The recovery period from deconditioning can be three or more times as

long as the period of immobilization that led to the decline. Methods of measuring functional status are described below.

Measures of Functional Status

American Society of Anesthesiologists Classification

For decades, the American Society of Anesthesiologists (ASA) Physical Status Classification has been one of the most reliable and accurate predictors of surgical mortality. This simple classification ranks patients according to the functional limitations imposed by coexisting disease (see Table 25.4). Despite its subjective nature, ASA classification has repeatedly been shown to accurately predict postoperative outcomes. Curves for mortality versus ASA class in older patients are superimposable on those of younger patients, thus demonstrating that coexisting disease, rather than chronologic age, has the most profound impact on surgical outcome [30]. Even for patients over age 80, ASA classification has been shown to predict postoperative mortality accurately [31].

The value of the ASA classification is further demonstrated by the results of a large, multicenter Department of Veterans Affairs (VA) study begun in 1991, later referred to as the National Surgical Quality Improvement Project (NSQIP), in which surgical patients were assessed prospectively for operative risk. Risk-adjusted models were then created to allow comparison of the quality of surgical care among institutions [32]. Sixty-eight preoperative and intraoperative variables were collected, and nine models for mortality and morbidity (one for each subspecialty and one overall) were created [33, 34]. Serum albumin and ASA class were the top two risk factors for both mortality and morbidity. Disseminated cancer was ranked third for mortality while operation complexity was ranked for morbidity [35]. The ASA functional classification was the second most predictive factor for mortality and the most predictive for morbidity after serum albumin. A discussion of the predictive value of serum albumin is found below under “Nutritional Assessment.”

Activities of Daily Living

Activities of daily living (ADLs) are physical tasks performed routinely, namely bathing, dressing, personal grooming, toileting, transferring, walking, and eating [36]. Instrumental activities of daily living (IADLs) are higher order tasks performed regularly such as telephone use, transportation, meal preparation, shopping, housework, medication management, and managing finances. Studies have demonstrated an association between ADLs or IADLs and operative outcomes. For example, the Preoperative Assessment of Cancer in the Elderly (PACE) study conducted

in the UK demonstrated that among older patients electively scheduled for cancer surgery, individuals with IADL dependence (RR 1.43), poor performance status (RR 1.52), and moderate/severe fatigue (RR 1.64) all had higher rates of postoperative complications [37]. Similar findings have also been demonstrated in less specific patient populations [38].

Exercise Capacity (in Metabolic Equivalents)

Exercise tolerance, as an indication of functional reserve, is the single most important predictor of cardiac and pulmonary complications following noncardiac surgery. In a study comparing Dripps Criteria (ASA), Goldman Clinical Criteria, pulmonary function tests, exercise tolerance, and several other variables, Gerson et al. demonstrated that the inability to raise the heart rate to 99 beats/min while doing 2 min of supine bicycle exercise was the most sensitive predictor of postoperative cardiac and pulmonary complications, and death [39, 40].

The physiologic basis for this finding has been further clarified by a study in which older patients performed supine ergometry while connected by mouthpiece to a metabolic cart [41]. The authors identified an anaerobic threshold – defined as the level of oxygen consumption above which circulatory supply could not meet metabolic demand – and correlated this threshold with surgical outcome. For those patients able to reach an anaerobic threshold of 11 ml/kg/min or more, the mortality was 0.8% compared with 18% for those unable to reach this threshold. Even in patients who experienced ischemia at the time of exercise testing, threshold levels were highly predictive of postoperative mortality (Table 22.2).

Formal exercise testing is neither readily available nor practical in a routine preoperative clinic. However, the metabolic requirements for many routine activities have already been determined and are quantified as metabolic equivalents (METs). The Duke’s Activity Status Index is an example of a standardized self-assessment tool that quantifies METs [42]. One MET, defined as 3.5 ml/kg/min, represents the basal oxygen consumption of a 70-kg, 40-year-old man at rest. Estimated energy requirements for various activities are shown in Table 22.3 [43]. The inability to function above four METs has been associated with increased perioperative cardiac events and long-term risk. Functional capacity of the individual can be estimated by inquiring about the ability to perform these routine physical activities.

TABLE 22.2 Mortality in relation to anaerobic threshold

Anaerobic Threshold (ml/min/kg)	All patients		Patients with ischemia	
	No.	% Mortality	No.	% Mortality

Tests of Functional Ability

Preoperative gait speed, balance, and upper extremity strength have been shown to correlate with postoperative recovery. Utilizing the Timed Get Up and Go, Hand Grip Strength, and Functional Reach Test as measures of physical status, Lawrence et al. have shown that older adults with intact preoperative physical status recover more quickly than persons with preoperative physical limitations [44]. Results from a study by Moriello et al. support the use of gait speed as a measure of postoperative recovery [45].

In addition, Lawrence et al. [44] demonstrated that recovery of various functions may not occur concurrently. While cognitive status recovery was relatively quick (3 weeks), gait speed (6 weeks), balance (6 weeks–3 months), and IADL abilities (3–6 months) took longer to return to preoperative levels [44]. Upper extremity strength measured by grip strength took the longest to recover and had not returned to baseline levels even after 6 months for some individuals. A description of the Timed Get Up and Go, Hand Grip Strength, and Functional Reach Tests is included below.

Timed Get Up and Go: For this test, participants are seated in a straight back chair. They are instructed to rise from the chair without using the armrests, ambulate 10 ft, turn around, walk back to the chair, and sit down. Completing the test in 10 s or less is a normal result.

Hand Grip Strength: This measure is calculated as the kilograms of pressure applied to a handheld dynamometer. Preoperative mean grip strength for the population of older patients examined by Lawrence et al. was 27 ± 11 kg [44].

Functional Reach Test: For this test, participants are asked to lean against the wall with their arm outstretched and their hand clenched in a fist. They are instructed to lean forward as far as possible without losing their balance. Persons who can reach 10 in. or more are at lowest risk for falling in the future.

Prehabilitation

It seems intuitive that improving exercise capacity preoperatively would result in better postoperative outcomes. However, to date, little data exist about the effectiveness of prehabilitation – exercise therapy conducted before surgery. However, what data do exist have shown postoperative benefits for some, but not all, patient groups. Orthopedic surgery patients engaged in prehabilitation did not show improvements in their health-related quality of life (HR-QOL) or recovery [28]. As reported by Carli, one study demonstrated that 275 elderly patients electively scheduled for abdominal or cardiac surgery, who participated in prehabilitation, had improved HR-QOL, fewer postoperative complications, shorter hospitalization, and lower levels of functional disability compared with a control group of sedentary patients [28]. More research in the area is clearly needed.

Nutritional Assessment

ASK the question “Have you lost 10 pounds or more in the last 6 months without trying to do so?”

DO the test Height & weight (BMI), serum albumin

Poor nutrition has been long recognized as a risk factor for pneumonia, poor wound healing, and other postoperative complications. Malnutrition, defined as a decrease in nutrient reserves, occurs in approximately 0–15% of community dwelling elderly persons, 35–65% of older patients in acute care hospitals, and 25–60% of institutionalized elderly [46] (see Chap. 6). Physiological changes that occur with aging, such as increased total body fat, loss of lean body mass, decreased bone density, and decreased total body water, may all affect nutritional requirements [47].

The assessment of nutritional status begins by understanding the risk factors for nutritional deficiency in older adults.

Factors that may lead to inadequate intake and utilization of nutrients include inability to access food (e.g., financial constraints, availability of food, limited mobility), lack of the desire to eat food (e.g., living alone, impaired mental status, chronic illness), inability to eat and/or absorb food (e.g., poor dentition, chronic gastrointestinal problems such as gastroesophageal reflux disease or diarrhea), and medications that interfere with appetite or nutrient metabolism.

Preoperative Serum Albumin

Serum albumin is a strong predictor of outcome in both non-surgical and surgical patients. Evidence demonstrates that low serum albumin in hospitalized elderly patients correlates with increased length of stay, increased rates of readmission, decreased rates of discharge to home, and increased all-cause mortality [48]. In surgical patients, low preoperative serum albumin has also been shown to correlate with postoperative morbidity and mortality [49]. Data from the NSQIP demonstrate an inverse relationship between serum albumin and 30-day morbidity and mortality (Fig. 22.5) [50].

Nutrition Screening Tests

Complicated markers of malnutrition exist [46] but are not necessary in the routine surgical setting. Subjective assessment by history and physical examination, in which risk factors and physical evidence of malnutrition are assessed, has been shown to be as effective as objective measures of nutritional status [51]. Additionally, there is evidence to support the use of a simple screening question “Have you lost 10 pounds or more in the last 6 months without trying to do so?” to diagnose malnutrition in older adults [52].

FIGURE 22.5 Relationship between albumin and 30 day mortality. Data from the National Surgical Quality Improvement Program showing 30-day operative mortality as a function of serum albumin for several different surgical specialties and for all specialties combined (reprinted with permission from [49]. Copyright © 1999 American Medical Association. All rights reserved).

Body Mass Index (BMI) measured by weight in kilograms divided by height in meters squared, has been shown to correlate with surgical outcomes. Underweight and overweight persons have both been shown to have worse surgical outcomes compared with persons with normal weight [53, 54].

The Subjective Global Assessment (SGA) is one relatively simple reproducible tool for assessing nutritional status from the history and physical exam [55]. SGA ratings are most strongly influenced by loss of subcutaneous tissue, muscle wasting, and weight loss. In a study of patients undergoing elective gastrointestinal surgery, both SGA and serum albumin were predictive of postoperative nutrition-related complications [56].

The Mini Nutritional Assessment (MNA) is another instrument that is designed to identify older adults at risk for malnutrition [57]. A short form of the MNA has been developed and used preoperatively (Table 22.4) [58].

Preoperative Nutritional Supplementation

Data confirming that the reversal of nutritional defects, by using enteral or parenteral supplementation prior to surgery, improves outcomes are few and inconclusive. However, some initial studies suggest that improving preoperative nutrition may positively impact perioperative outcomes. In one such study, cardiac surgery patients who received a preoperative oral immune-enhancing nutritional supplement had lower rates of pneumonia compared with individuals who did not receive supplementation; rates of urinary tract and wound infections did not differ [59].

Information obtained during the preoperative nutritional assessment will be particularly useful for perioperative decisions regarding nutritional support. A flow diagram regarding which patients should be considered for nutritional support perioperatively is illustrated in Fig. 22.6 [47].

Cognitive Assessment

ASK the questions	“Do you have problems with your memory?” “Do you drink alcohol during the day or before going to bed at night?”
DO the test	Mini-Cog

The perioperative cognitive assessment tends to be undervalued and underapplied as a predictor of postoperative outcome. However, cognitive dysfunction as either a presurgical condition or postoperative complication can interfere with surgical treatment and postsurgical recovery. Patients with dementia and/or delirium have worse perioperative outcomes. Dementia, the clinical manifestation of chronic cognitive impairment, is the major risk factor for delirium, an acute

TABLE 22.4 Mini-nutritional assessment-short form

Question	Score
A. Has food intake declined over the past three months due to loss of appetite, digestive problems, chewing or swallowing difficulties? 0=severe loss of appetite 1=moderate loss of appetite 2=no loss of appetite	
B. Weight loss during last 3 months 0=weight loss greater than 3 kg (6.6 lbs) 1=does not know 2=weight loss between 1 and 3 kg (2.2 and 6.6 lbs) 3=no weight loss	
C. Mobility 0=bed or chair bound 1=able to get out of bed/chair but does not go out 2=goes out	
D. Has suffered psychological stress or acute disease in the past 3 months 0=yes 2=no	
E. Neuropsychological problems 0=severe dementia or depression 1=mild dementia 2=no psychological problems

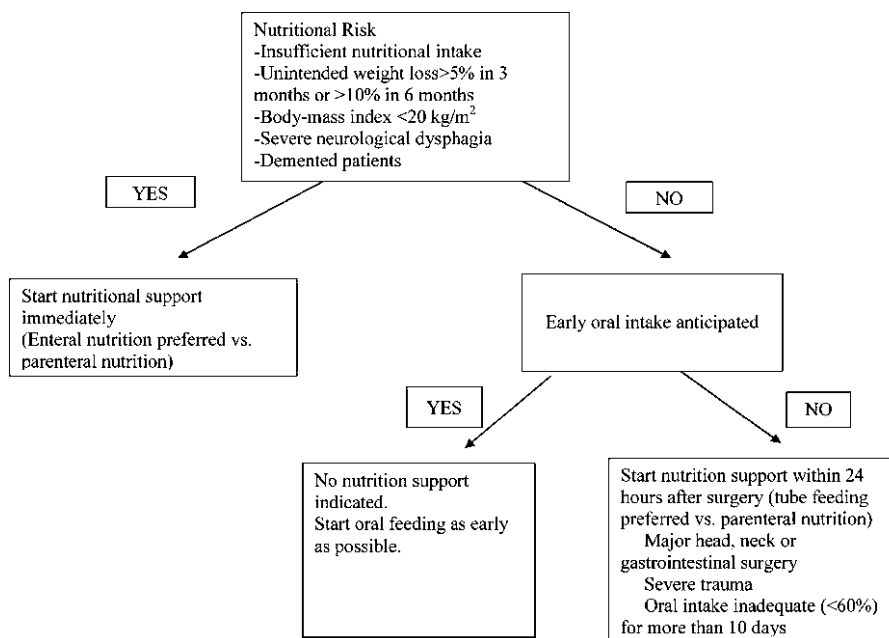

FIGURE 22.6 Decision flow chart for implementing perioperative nutrition support in geriatric patients (modified from Lugli [47], with permission from Elsevier).

reversible state of confusion, during hospitalization. As such, it is important to identify patients who have baseline cognitive impairment, even at mild levels, in the preoperative period.

Screening Tools for Dementia

There are several methods for evaluating baseline cognitive function in the elderly. Each of these instruments, although extremely informative, may take 5–10 min to administer which may not be practical in a busy preoperative clinic. The exception is the Mini-Cog, a quick and practical screening tool for dementia that can be completed in 2–4 min.

The Mini-Cog has sensitivity and specificity rates similar to the Folstein Mini Mental Status Examination (MMSE) and a standardized neuropsychological battery [60]. Participants are asked to recall three words and to draw a clock indicating an abstract time such as one forty five (1:45) or ten after 11 (11:10). The three item word recall assesses short-term memory, while the clock drawing task assesses for key features of executive function such as initiation, planning, and multistep processing. The instructions for the administration and scoring of the Mini-Cog can be found in Appendix 22.1.

The Folstein Mini Mental Status Examination (MMSE) has become widely accepted for its ease of administration and reliability [61]. The MMSE allocates a total of 30 points to five areas (1) orientation, (2) registration, (3) attention/calculation, (4) recall, and (5) language. MMSE scores are influenced by several factors including age and educational attainment. As such, MMSE scores should be interpreted according to population-based norms for age and educational level as shown in Table 22.5 [62].

The Telephone Interview for Cognitive Status (TICS) is a validated, reliable modification of the MMSE, which can be

easily administered over the telephone [63]. The TICS has a maximum score of 38.

The St. Louis University Mental Status (SLUMS) Examination is a dementia screening instrument that allocates 30 points to four areas (1) orientation, (2) memory, (3) attention, and (4) executive function (Appendix 22.2) [64]. The sensitivity and specificity of the SLUMS has been shown to be similar to the MMSE; the SLUMS may be better able to detect mild cognitive impairment.

Delirium

Estimates of postoperative delirium rates vary significantly depending upon the type of surgery performed. Delirium is reported in <5% of older patients after cataract surgery, 35% of patients after vascular surgery, and 40–60% of older patients after hip fracture repair [65]. Delirious surgical patients have more major complications, longer hospitalizations, costlier hospital stays, higher rates of discharge to long-term care facilities, and higher rates of death compared with nondelirious patients [66]. In addition, postoperative delirium has been shown to persist for several months after surgery, up to three, in a significant percentage of older patients [67]. Thus, identifying preoperative patients at highest risk for delirium has the potential to significantly improve perioperative outcomes. Marcantonio et al. developed a clinical prediction rule for postoperative delirium from a large prospective study of major elective noncardiac surgery patients over age 50 years [66]. The independent correlates for postoperative delirium and the point system devised to quantify the risk of delirium are illustrated in Table 22.6. For additional information on delirium, please refer to Chap. 16.

Unrecognized alcohol abuse should always be included on the list of potential causes of delirium. Older adults may not report their intake of alcohol with meals or prior to bedtime. Forced abstinence as a result of hospitalization may present in a mild form such as evening agitation or

“sundowning” or in a more severe form such as delirium tremors (DTs). Older patients should be specifically asked about mealtime and/or bedtime alcohol use. More comprehensive alcohol screening tools specifically designed for older adults, such as the Michigan Alcohol Screening Test-Geriatric Version [68] (see Appendix 22.3), are available.

Mental status changes in older surgical patients are often the earliest signs of a postoperative complication. If an older patient presents with an altered mental status in the perioperative period, knowledge of his or her preoperative cognitive status provides critical information for determining the extent and aggressiveness of intervention warranted.

Depressive Symptoms

Not all patients who perform poorly on screening examinations will have cognitive impairment. Patients with depressive symptoms may appear to have cognitive impairment as a result of providing little effort during testing. In addition, patients with depressed mood may exhibit less desire to participate in rehabilitation activities. Interestingly, one study [69] demonstrated an association between number of depressive symptoms reported by older adults on the Geriatric Depression Scale (GDS) and delirium. Persons who reported more depressive symptoms preoperatively had higher incidence rates, and more days, of delirium postoperatively.

The GDS [70] is a 15-item questionnaire that can be administered in person or over the telephone. Respondents provide a yes or no response to the questions posed. A score ≥ 5 indicates depression is a possibility. The GDS is reprinted in Appendix 22.4.

Specific Organ System Evaluations

Although cardiac and pulmonary complications are the most common postoperative events for older patients, physiological changes in the renal and hepatic systems also place older adults at risk. Complications due to specific organ system problems may prolong hospitalization and contribute to functional decline, necessitating the addition of rehabilitation services upon discharge. Thus, preoperative history or physical examination findings consistent with clinically significant cardiac, pulmonary, renal or hepatic disease warrant investigation, monitoring, and/or intervention.

Pulmonary Assessment

Comparatively much more attention has been paid to the preoperative evaluation and optimization of cardiac risk factors

than pulmonary risk factors. However, there is evidence to support the assertion that pulmonary complications are equal determinants of postoperative morbidity, mortality, and length of stay for older surgical patients [71]. This assertion is supported by the findings of a large study in which the 30-day mortality rate for persons with postoperative pneumonia was 21 versus 2% for persons without postoperative pneumonia [72]. In the literature, pulmonary complications refer to a variety of conditions including pneumonia, respiratory insufficiency, respiratory failure, atelectasis, acute respiratory distress syndrome, and pleural effusions. It is important to remember that aspiration is one of the leading causes of these complications. While aspiration is possible in any age group, monitoring for aspiration is especially important in the elderly. As with all adverse surgical outcomes, pulmonary complications are more common following emergency operations. Given the high prevalence of emergency surgery in persons over the age of 65, this is of particular significance for older adults.

Risk Factors

Patient, procedure, and laboratory factors have all been implicated as increasing the odds of developing postoperative pulmonary complications. A recent systematic review examined the literature regarding risk factors and subsequent pulmonary complications [71]. The patient and procedure-related factors for which there was good or at least fair evidence to support the association between the risk factor and postoperative pulmonary complications are presented in Tables 22.7 and 22.8.

Patient-Related Risk Factors

Subtle nasopharyngeal dysfunction is frequently unrecognized in the elderly but is known to be a factor predisposing to aspiration pneumonia. Devices that traverse the oropharynx may further disrupt the normal swallowing process and

further increase the risk of aspiration. In one multivariate analysis, postoperative nasogastric intubation was the single most important variable associated with postoperative pulmonary complications [73]. In another study of cardiac surgery patients, the use of transesophageal echocardiography probes intraoperatively was significantly associated with the development of postoperative aspiration [74].

Several conditions, commonly found in older adults, increase the risk of aspiration. These include cognitive impairment, prior stroke, xerostomia (dry mouth), poor dentition, gastroesophageal reflux disease (GERD), and diabetes. Thus, aspiration precautions are particularly important in this population.

Several studies have examined the impact of age on postoperative pulmonary complications with equivocal results. Studies that were not controlled for the presence of comorbid conditions indicate 4–45% of persons over the age of 70 develop postoperative pulmonary complications. More recent reviews of the literature suggest that older age remains an independent predictor of postoperative pulmonary complications even after adjusting for comorbid conditions [71].

The ASA classification, a subjective assessment of overall functional and physical well-being (see above), has been shown to be an accurate predictor of postoperative cardiac and pulmonary status [75]. Similarly, functional dependence is an important determinant of postoperative pulmonary complications. Individuals who are either unable to complete any ADLs or require assistance from another person or device have been shown to have worse pulmonary outcomes compared with functionally independent persons [76].

The most commonly identified risk factor for postoperative pulmonary complications is chronic obstructive pulmonary disease. In multivariate analyses [72], the degree of obstructive disease (none to mild vs. moderate to severe) contributed to the degree of risk. Unintentional weight loss $\geq 10\%$ in the prior 6 months, acute cognitive changes secondary to

delirium, cigarette smoking within the past 1 year, and consumption of >2 drinks/day in the past 2 weeks have all been shown to increase the risk of postoperative pulmonary complications [72]. Of note, individuals who discontinue smoking ≤ 8 weeks prior to surgery have higher rates of complications compared with individuals who were still actively smoking at the time of their operation.

Although obesity is widely thought to be associated with postoperative pulmonary complications, the incidence of pulmonary complications following surgery even for patients with morbid obesity is no higher than would be expected in a group of procedure-matched nonobese patients. In addition, there is little evidence that diabetes or well-controlled asthma affect postoperative pulmonary complication rates [71].

Procedure-Related Risk Factors

Procedure-related risk factors implicated in the development of postoperative pulmonary complications include the site of incision, type of anesthesia, duration of the procedure, amount of blood loss, type of repair (e.g., open vs. endovascular), and urgency of the operation (e.g., emergency vs. elective) [71].

The proximity of the surgical incision to the diaphragm has been long known to influence the rate of postoperative pulmonary complications. Upper abdominal incisions are accompanied by a 13–33% [77, 78] pulmonary complication rate, compared with a 0–16% [78, 79] rate for incisions in the lower abdomen. Rates as high as 40% are reported with thoracic incisions [79, 80]. Minimally invasive procedures, such as laparoscopic cholecystectomy, are associated with little risk of pulmonary complications. In several large series rates as low as 0.3–0.4% were reported [81, 82].

The importance of the type of anesthesia and the length of operation in terms of the incidence of postoperative pulmonary complications is less clear. Although most studies support the lower complication rate following regional anesthesia compared with general anesthesia, these results are not uniform. Duration of anesthesia of more than 3 h has been shown to be significant [73, 83].

In one retrospective analysis, intraoperative blood loss of more than 1,200 ml was an independent predictor of postoperative pneumonia [84]. This may be an indication of the complexity of the procedure or of underlying comorbidity. Although multiple transfusions are known to be immunosuppressive, the relation of transfusion to postoperative infection is not clear [85]. However, when combined with the declining immunologic competence associated with aging, a transfusion-related alteration in host defenses may facilitate the development of pneumonia in the elderly.

Pulmonary Assessment Tools

Tests for Aspiration Risk

Evaluation for aspiration is important for all older adults with conditions that place them at higher risk for aspiration, such as persons with a history of stroke, poor dentition, or GERD. The 3-ounce water swallow test is a time-efficient method to clinically screen individuals who are at risk for aspiration [86]. Individuals are asked to swallow 3 ounces (90 cc) of water without pausing. Persons who choke, cough, are unable to complete the task, or have a wet quality to their voice after completing the task are typically referred for fiberoptic endoscopic evaluation. One study of 3,000 individuals, 20% of whom were surgical patients, demonstrated that the water swallow test has high sensitivity and negative predictive value [86]. Thus, individuals who pass the swallow test have a high likelihood of passing a fiberoptic endoscopic evaluation. However, the swallow test had a high false positive rate such that half of the individuals who failed the swallow test did not demonstrate aspiration on a fiberoptic evaluation. Fiberoptic evaluation should, therefore, be reserved for those persons with known risk factors for aspiration. Aspiration precautions, however, should be observed for any patient with either a failed water swallow test or has a known risk factor for aspiration.

Laboratory/Radiology Tests

There is good evidence that an albumin level <35 g/L increases the odds of postoperative pulmonary complications by 2.53 [71]. The evidence that other laboratory tests, such as chest radiography, contribute to the predictions of postoperative risk, is less convincing. Even though chest radiographs are routinely ordered as part of a preoperative evaluation, it is rare that the radiograph illustrates issues that were not discovered during the history and physical examination [71]. Preoperative chest radiographs are arguably only beneficial for patients with established cardiopulmonary disease and/or adults over the age of 50 who will likely receive an incision close to the diaphragm [71].

Pulmonary Function Evaluation

Although previous guidelines for preoperative pulmonary function testing suggested that spirometry was indicated for every patient over the age of 70 years [87], more recent data refute that claim. The few studies that have compared clinical findings with spirometric measures do not uniformly support the use of spirometry over a comprehensive history and physical examination [71]. Abnormal chest findings on physical examination and chest radiography have been shown

TABLE 22.9 ACP guidelines for preoperative spirometry

Source: Data from Quaseem et al. [76]

to be highly associated with postoperative pulmonary complications; the data for spirometry is equivocal.

Present guidelines from the American College of Physicians for the use of preoperative pulmonary function tests are shown in Table 22.9 [76]. There is consensus that all patients undergoing lung resection should have pulmonary function tests. Individuals with uncharacterized pulmonary disease, known COPD or asthma, and questionable CABG candidacy should also be tested. However, those patients with normal physical examinations and good exercise tolerance do not benefit from additional studies.

A risk index has been developed to identify the patients at highest risk for developing postoperative pneumonia [72]. Points are assigned depending upon the presence of various risk factors (Table 22.10); the maximum point value is 164. Individuals are classified into five risk classes: class I (0–15 points), class II (16–25 points), class III (26–40 points), class IV (41–55 points), or class V (>55 points). Persons in the lowest risk class have an average predicted probability of postoperative pneumonia of 0.24%; those in the highest class have a probability of 15.3%.

Cardiovascular Assessment

With the aging of America it is estimated that the annual number of noncardiac surgical procedures performed in older adults will increase from the present level of six million to approximately 12 million over the next 30 years [43]. Four procedures that constitute one-fourth of the surgeries performed in older adults, namely major intraabdominal, thoracic, vascular, and orthopedic procedures, have been associated with significant cardiovascular morbidity and mortality. Because cardiovascular events are a leading cause of perioperative complications and death, preoperative evaluation of cardiac risk has been studied extensively. The American College of Cardiology (ACC)/American Heart Association (AHA) Task Force on Practice Guidelines routinely publish guideline on perioperative cardiovascular evaluation and care for noncardiac surgery patients [43]. The recommendations provided in the guidelines are based upon the available scientific evidence as well as expert opinion; the objective is to improve patient care. Use of the guidelines is intended to clarify which patients would benefit from additional cardiac evaluation and what evaluation should be pursued, if any.

TABLE 22.10 Postoperative pneumonia risk index

Preoperative risk factor	Point value
Type of surgery	
Abdominal aortic aneurysm repair	15
Thoracic	14
Upper abdominal	10
Neck	8
Neurosurgery	8
Vascular	3
Age

Clinical Risk Factors

The previous terminology of major and intermediate risk factors has been replaced, respectively, with active cardiac conditions and Revised Cardiac Risk Index clinical risk factors. The terminology of minor clinical predictors remains the same. The clinical risk factors are listed in Table 22.11.

Perioperative Algorithm (Appendix 22.5)

Step 1: Determine the Urgency of Noncardiac Surgery

Preoperative cardiac evaluation is not necessary for emergency surgery. Patients should proceed directly to surgery; risk stratification and management can be performed perioperatively.

Step 2: Determine If Any Active Cardiac Conditions Exist

The presence of ≥1 active cardiac conditions warrants intervention and, unless deemed emergent, may result in a delay

TABLE 22.11 Clinical predictors of increased perioperative cardiovascular risk

Active cardiac conditions

Unstable coronary syndromes
 Recent myocardial infarction (>7 days but <30 days) with evidence of important risk based on clinical symptoms or noninvasive study
 Unstable or severe angina (Canadian class III or IV) [58]
 Decompensated heart failure
 Significant arrhythmias
 High-grade atrioventricular block
 Symptomatic ventricular arrhythmias in the presence of underlying heart disease
 Supraventricular arrhythmias with uncontrolled ventricular rate
 Severe valvular disease

Revised cardiac risk index

History of ischemic heart disease
 History of cerebrovascular disease
 History of compensated or prior heart failure
 Diabetes mellitus
 Renal insufficiency

Minor predictors

Advanced age (greater than 70 years)
 Abnormal electrocardiographic findings
 Left ventricular hypertrophy
 Left bundle branch block
 ST-T abnormalities
 Rhythm other than sinus
 Atrial fibrillation, for example
 Uncontrolled systemic hypertension

Source: Reprinted from Fleisher et al. [43], with permission from Elsevier

or cancelation of surgery. If no active cardiac conditions are present, proceed to the next step. Evidence suggests that cardiovascular intervention does not influence surgical outcomes in asymptomatic patients without active cardiac conditions. Therefore, preoperative cardiovascular screening is not necessary.

Step 3: Consider the Risk of the Planned Surgery

Cardiac risk stratification according to surgical procedure is listed in Table 22.12. If the proposed surgery is a low-risk procedure, stable patients may proceed to surgery without cardiovascular evaluation since the results of testing are unlikely to warrant a change of plans.

Step 4: Consider the Functional Capacity and Symptom Status of the Patient

Highly functional asymptomatic patients may proceed to surgery without cardiovascular evaluation, since the results of testing are unlikely to warrant a change of plans. As mentioned

TABLE 22.12 Cardiac risk stratification for noncardiac surgical procedures**Vascular (reported cardiac risk often more than 5%)**

Aortic or other major vascular surgery
Peripheral vascular surgery

Intermediate (reported cardiac risk generally 1–5%)

Carotid endarterectomy
Head and neck surgery
Intraperitoneal and intrathoracic surgery
Orthopedic surgery
Prostate surgery

Low (reported cardiac risk generally less than 1%)

Endoscopic procedures
Superficial procedures
Cataract surgery
Breast surgery
Ambulatory surgery

Risk denotes combined incidence of cardiac death and nonfatal myocardial infarctions

above, questioning patients on their ability to perform certain activities for which the estimated MET values are known provides individual scoring of functional capacity (Table 22.3). Utilizing METs, functional capacity can be classified as excellent (>10), good (7–10), moderate (4–6), or poor (<4). Patients unable to meet a four-MET demand during most normal daily activities are at increased risk for perioperative cardiopulmonary and long-term complications.

Step 5: Determine If Clinical Risk Factors Are Present For Patients with Poor Functional Capacity or Symptoms

If no clinical risk factors are present, the patient may proceed to surgery without further evaluation. If ≥ 3 clinical risk factors are present, cardiac risk stratification (Table 22.12) must be considered.

Renal Assessment

Physiological Changes of the Aging Kidney

Renal insufficiency is often asymptomatic in older adults. Preoperative renal insufficiency is a strong predictor of perioperative cardiac and pulmonary morbidity [88]. Moreover, impaired preoperative kidney function increases the likelihood of perioperative kidney failure. Physiological changes that occur with aging, namely decreases in renal plasma flow and glomerular filtration rate (GFR), contribute to the increased rates of renal insufficiency among older adults.

Muscle mass also decreases with age. As a result, serum creatinine level may not accurately estimate renal function in older adults. (A complete discussion of changes in renal physiology can be found in Chap. 76.)

Glomerular Filtration Rate

Accurately assessing GFR is an essential component of the preoperative renal evaluation for older adults. GFR can be estimated via the Cockcroft–Gault equation for creatinine clearance (CrCl):

$$\text{CrCl} = (140 - \text{age}) \times \text{Ideal body weight} / (\text{Serum creatinine} \times 72) (\times 0.85 \text{ for women})$$

$$\text{Ideal body weight} = 2.3 \text{ kg for every inch over 5 ft} + [50 \text{ kg (men) or } 45.5 \text{ kg (women)}]$$

More recent formulas, such as the Modification of Diet in Renal Disease (MDRD) equation, may also be used to calculate GFR and stage chronic kidney disease [89]. The MDRD equation takes into account serum creatinine level, age, race, and gender. A free online MDRD calculator can be accessed at <http://www.mdrd.com>.

In addition to calculating GFR, identifying patient medications that are cleared by the kidneys is warranted during a preoperative assessment. Medications that are cleared by the kidney may need to be administered at a lower dose, with a longer dosing interval, or avoided altogether in individuals with impaired GFR (<30 mg/dL). Avoiding dehydration preoperatively and perioperatively is a vitally important management issue. Older adults are predisposed to dehydration due to impairments with the thirst drive with increasing age. Thus, monitoring for appropriate hydration, especially in patients recently restarted on a diet after a period of nothing-by-mouth (NPO) status is warranted.

Hepatic Assessment

Liver failure is an important predictor of poor perioperative outcomes [88]. Physiological changes that occur with aging may increase the risk of hepatic dysfunction. Liver blood flow, size, and mass all decrease with increasing age, as does cytochrome P450 content. As a result, medications that undergo a first pass effect, such as nitrates, may have a higher serum concentration or higher bioavailability in older adults. Additionally, the metabolism of medications, in particular anesthetic agents, can be impaired in adults over the age of 65. Obtaining an accurate history of current and previous alcohol use should be incorporated into the preoperative hepatic assessment. Laboratory evaluation of liver function tests including albumin, and the coagulant profile are also recommended.

Processes of Care to Improve Outcomes

Preoperative Evaluation of Postoperative Needs

Once the decision to proceed with surgery has been made, planning for the postoperative period should begin. In particular, knowledge of the geriatric surgical patient's social support structure will help guide postoperative discharge decisions. A functionally independent individual living with involved family members, for example, requires far less ancillary support than a frail individual living alone. Preoperative patients who do not receive adequate support from family, friends, or paid professionals are unlikely to be discharged home postoperatively, when their needs are likely to be greater, unless additional support can be arranged. If a patient's needs exceed the level of assistance home services can provide, then short-term rehabilitation or long-term care placement may be indicated. Assistance with housework, laundry, and driving are just a few examples of needs that may originate during the postoperative period. If possible, patients should be encouraged to make arrangements for additional home support, prior to surgery. If informal assistance is not available, involving care coordination as early as possible may smooth the transition from hospital to home. Determining the level of additional support required and preparing for this support prior to surgery allows the patient to prepare for their entire recovery period and may positively affect compliance with follow-up care.

Surgery–Geriatrics Comanagement Models

As previously discussed, older adults have an increased risk of postoperative adverse outcomes including mortality, longer hospitalization, and new discharge to a long-term care facility. A combined surgery–geriatrics comanagement care model has been utilized in various hospitals outside of the USA for several years; some US hospitals have recently implemented similar models. Comprehensive Geriatric Assessment (CGA) is a common component of comanagement models instituted for patients scheduled for elective surgery. CGA typically includes preoperative cognitive, functional, and nutritional assessments; mood evaluation; and medication review. In one study, older patients who had CGA as part of a comanagement model had shorter hospitalizations (11.5 vs. 15.8 days) and fewer delayed discharges (24.1 vs. 70.4%) [90]. In another study, older hip fracture patients who were assessed by the geriatrics service within 24 h of admission and subsequently comanaged by geriatrics

and orthopedic surgery throughout the remainder of their hospitalization had lower rates of delirium (RR=0.64) and severe delirium (RR=0.4) compared with patients who received usual care [91]. A collaboration of surgeons and geriatricians in Japan has used the functional and cognitive components of CGA to predict which thoracic surgery patients are at highest risk for postoperative complications [92]. Additional studies are necessary in order to fully understand all the benefits afforded to older surgical patients who receive care via combined surgery–geriatrics comanagement programs. Perhaps comanagement programs will emerge as a low risk, cost-effective means to improve perioperative and postoperative outcomes for older surgical patients. Given the expected increase in the number of older adults in the next few decades, any intervention or model of care that improves outcomes for geriatric surgical patients would likely make a significant contribution to the overall US healthcare system.

Summary

Successful surgical care of the older patient requires a full understanding of the factors that will influence the postoperative recovery of each individual. Determining these factors need not take an excessive amount of time or require elaborate testing. A thorough history and physical examination will identify serious comorbidity that may direct additional specific testing. Assessment of the factors specific to the older patient can be done by asking these simple questions:

1. "Can you carry a bag of groceries up a flight of steps without getting short of breath?"
2. "Have you lost 10 pounds or more in the last 6 months without trying to do so?"
3. "Do you have problems with your memory?"
4. "Do you drink alcohol occasionally, with meals, or before going to bed?"

...and doing these three tests:

1. Timed Get Up and Go
2. Height, weight, BMI, serum albumin
3. Mini-Cog

The need for further testing or preoperative preparation will be guided by the results of these simple assessments.

Improving the care of the older surgical patient presents special challenges. However, these challenges may be overcome by developing patient-centered treatment plans that recognize individual preferences, geriatric-specific issues, and the physiological changes that occur with aging.

Appendix 22.1 Mini-Cog Screen for Dementia**Administration**

1. Make sure you have the patient's attention. Instruct the patient to listen carefully to and remember three unrelated words and then to repeat the words back to you (to be sure the patient heard them)
2. Instruct the patient to draw the face of a clock, either on a blank sheet of paper, or on a sheet with the clock circle already drawn on the page. After the patient puts the numbers on the clock face, ask him or her to draw the hands of the clock to read a specific time (1:45 or 11:10 are commonly used). These instructions can be repeated, but no additional instructions should be given. If the patient cannot complete the clock-drawing test (CDT) in 3 min or less, move on to the next step
3. Ask the patient to repeat the three previously presented words

Scoring

Give 1 point for each recalled word after the CDT distractor. Score 0–3 for recall

Give 2 points for a normal CDT, and 0 points for an abnormal CDT. The CDT is considered normal if all numbers are depicted, once each, in the correct sequence and position, and the hands readably display the requested time. Add the recall and CDT scores together to get the Mini-Cog score

0–2 positive screen for dementia

3–5 negative screen for dementia

Appendix 22.3 Michigan Alcoholism Screening Test: Geriatric Version (MAST-G)

1. After drinking have you ever noticed an increase in your heart rate or beating in your chest?	Yes	No
2. When talking with others, do you ever underestimate how much you actually drink?	Yes	No
3. Does alcohol make you sleepy so that you often fall asleep in your chair?	Yes	No
4. After a few drinks, have you sometimes not eaten or been able to skip a meal because you didn't feel hungry?	Yes	No
5. Does having a few drinks help decrease your shakiness or tremors?	Yes	No
6. Does alcohol sometimes make it hard for you to remember parts of the day or night?	Yes	No
7. Do you have rules for yourself that you won't drink before a certain time of the day?	Yes	No
8. Have you lost interest in hobbies or activities you used to enjoy?	Yes	No
9. When you wake up in the morning, do you ever have trouble remembering part of the night before?	Yes	No
10. Does having a drink help you sleep?	Yes	No
11. Do you hide your alcohol bottles from family members?	Yes	No
12. After a social gathering, have you ever felt embarrassed because you drank too much?	Yes	No
13. Have you ever been concerned that drinking might be harmful to your health?	Yes	No
14. Do you like to end an evening with a nightcap?	Yes	No
15. Did you find your drinking increased after someone close to you died?	Yes	No
16. In general, would you prefer to have a few drinks at home rather than go out to social events?	Yes	No
17. Are you drinking more now than in the past?	Yes	No
18. Do you usually take a drink to relax or calm your nerves?	Yes	No
19. Do you drink to take your mind off your problems?	Yes	No
20. Have you ever increased your drinking after experiencing a loss in your life?	Yes	No
21. Do you sometimes drive when you have had too much to drink?	Yes	No
22. Has a doctor or nurse ever said they were worried or concerned about your drinking?	Yes	No
23. Have you ever made rules to manage your drinking?	Yes	No
24. When you feel lonely, does having a drink help?	Yes	No

Scoring: Five or more "Yes" responses are indicative of an alcohol problem

Appendix 22.4 The Geriatric Depression Scale (Short Form)

Choose the best answer for how you felt over the past week.

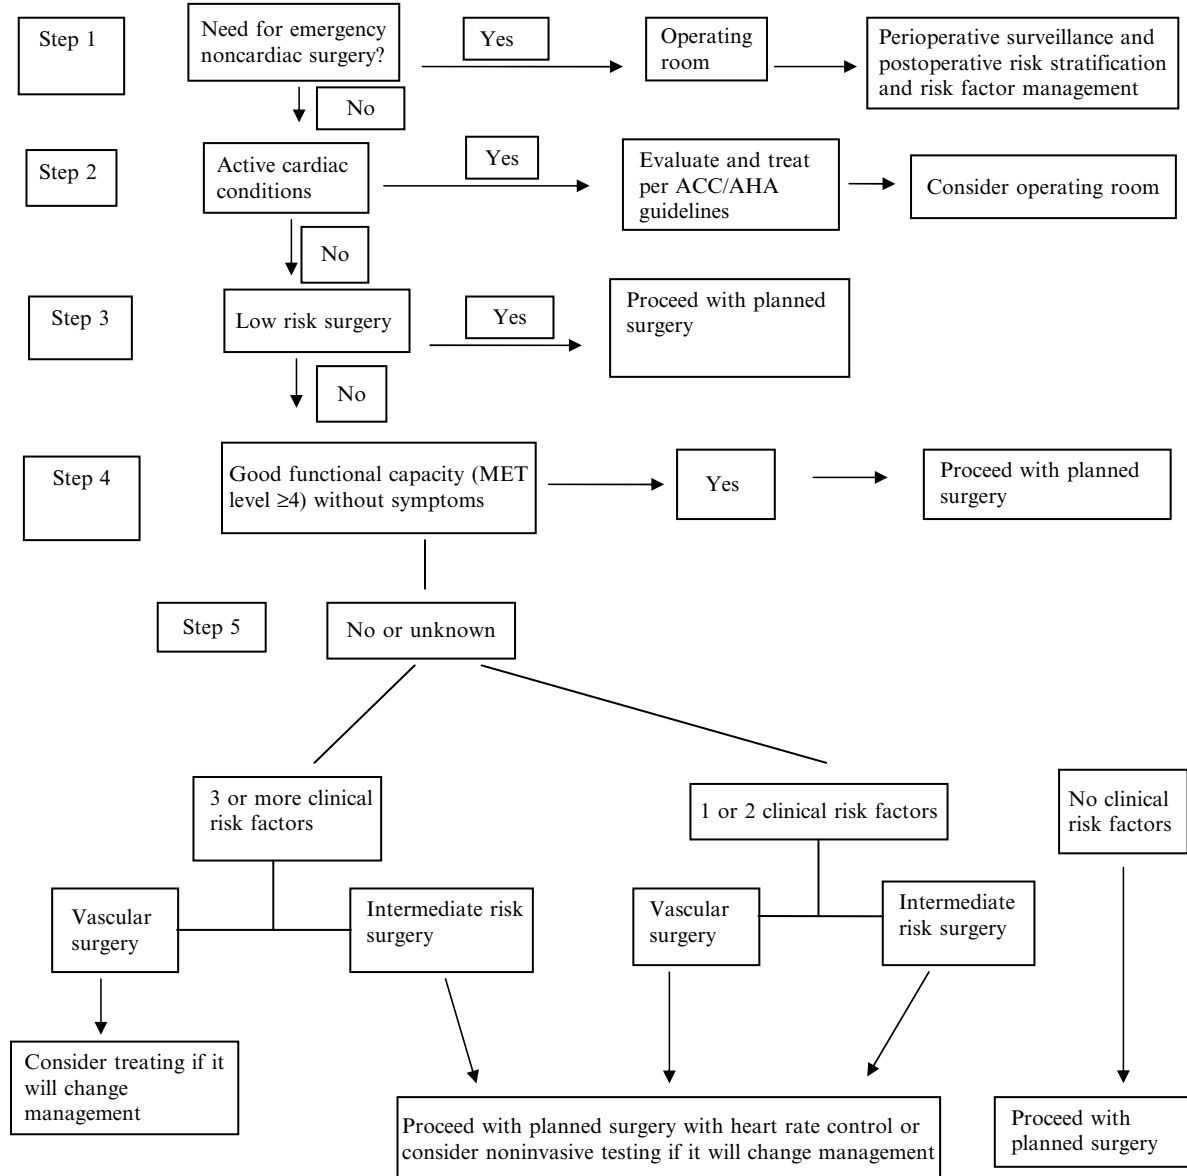

Date / /	Please tick ✓	
1. Are you basically satisfied with your life?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
2. Have you dropped many of your activities and interests?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
3. Do you feel that your life is empty?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
4. Do you often get bored?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
5. Are you in good spirits most of the time?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
6. Are you afraid that something bad is going to happen to you?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
7. Do you feel happy most of the time?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
8. Do you often feel helpless?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
9. Do you prefer to stay at home, rather than going out and doing things?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
10. Do you feel you have more problems with memory than most?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
11. Do you think it is wonderful to be alive now?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
12. Do you feel pretty worthless the way you are now?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
13. Do you feel full of energy?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
14. Do you feel that your situation is hopeless?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
15. Do you think that most people are better off than you?	Yes <input type="checkbox"/>	No <input type="checkbox"/>
TOTAL SCORE		

Answers in **bold** indicate depression and receive one point. Scores greater than five suggest the presence of depression.

Chapter 23

Invited Commentary

Jerry G. Reves

Practice of surgery and anesthesiology has changed immensely over time. I can best comment on the field of anesthesiology from my vantage point as a cardiac anesthesiologist, but obviously, I have admired the progress and development of all anesthesiology during my professional time in the field since 1969.

I became a cardiac anesthesiologist because of my interest in the cardiovascular system and the ability to rapidly alter it with acute pharmacologic intervention during surgery. This preoccupation with cardiac surgery and anesthesia began in 1965 with my pharmacology research as a medical student and continues till today. Over this near half-century, we have witnessed great changes and improvements in the operative care of patients which merit commentary.

Of the many things that have changed over time, none is greater than patient selection and operative procedure. In early cardiac anesthesiology practice, virtually all patients had congenital heart disease or acquired valvular disease. The most morbid cardiovascular disease, coronary artery disease, was not amenable to the surgical approach until the latter half of the past century. At the same time, the age of the adult population with the disease has been steadily increasing. I recall the days when we were doing our initial investigations into the anesthetic effects of patients undergoing coronary bypass surgery and the average age was almost always 55 years. Today, the average age is much higher for patients undergoing coronary artery bypass surgery than in the past. Reasons for this include less smoking among patients, multiple available drugs such as statins that prevent cardiac events, and greater variety of nonsurgical medical interventions that delay surgery.

Older patients present a variety of problems to cardiac anesthesiologists. For example, as patients age, there is increased sensitivity to the central nervous system drugs that

anesthesiologists use for sedation, sleep, analgesia, and anesthesia. Awareness of this is critical in prevention of “overdosing” the patients that results in unwanted hemodynamic problems and prolonged somnolence after surgery. There is no question that the tissue of older patients is not the same as younger patients, and this leads to surgical hemostasis issues that can be challenging for the anesthesiologist as well as surgeon. The entire coagulation system is also less functional as patients age, again raising management problems around coagulation for the anesthesiologist and surgeon. Although no organs function in the very old as they do in the young patient, the lungs and liver seem to be resilient to the aging process, and this is important in the all important areas of oxygenation and drug metabolism, respectively. However, renal function tends to decline, and some of the drugs administered by the anesthesiologist depend on good renal clearance including some muscle relaxants and some of the antiarrhythmic medications. Awareness of these potential problems can avoid postoperative complications.

The greatest organ of concern to the cardiac anesthesiologist caring for elderly patient is the brain. All central nervous system complications are increased with age. These complications vary in severity from temporary confusion to proven susceptibility to cognitive impairment that can prohibit patients from returning to preoperative functional levels. Stroke is the most profound and dreaded of the neurologic consequences of cardiac surgery. The causes of neurologic adverse events are still largely unknown but probably are a combination of compromised cerebral vascular perfusion, emboli from the aorta, air and other debris when the heart or aorta are opened, thrombi from the atria in patients with atrial fibrillation, and many other possible causes. It is devastating to anesthesiologist, surgeon, family, and patient when a surgery patient is never quite the same after the procedure, especially when the heart or aorta has been “fixed.”

Despite the risks with cardiac surgery and the additional risk that age confers on these patients, the results over the years have steadily improved even as we have cared for older and more complicated patients. This is a result of many innovations and improvements. The first of these is the education

J.G. Reves (✉)

Cell and Molecular Pharmacology & Experimental Therapeutic,
Medical University of South Carolina, Charleston, SC, USA
e-mail: revesj@muscc.edu

of the cardiac anesthesiologist. Many of the anesthesiologists today who practice cardiac anesthesia have had formal education and a fellowship. There are journals, textbooks, and a whole new field of cardiac anesthesiology that has emerged over the past 30 years. Evidence-based knowledge guides the cardiac anesthesiologist today. The many drugs used today by anesthesiologists are better than years ago, and the anesthesiologist has an array of compounds to tailor to the needs of the patient. Technology is vastly improved as well. Monitoring allows the anesthesiologist to assess the patient on virtually a beat-to-beat basis and to look at the heart's function with echocardiography. The anesthesiologist now is diagnostician of the heart's anatomy and physiology, as well as pharmacology. The development of better pump oxygenators and many other life-assist devices has made it

possible to get through surgery for patients who would not have been able to in the past. Finally, a major development, in my experience, was the introduction of myocardial protection with cardioplegia in the 1970s. This permitted prolonged periods of safe heart stoppage to allow the surgeon to perform a more perfect operation. We are still searching for other organ protective strategies.

Cardiac surgery has vastly improved as has cardiac anesthesiology over the past half-century. The two disciplines are complementary approaches to improve patient outcomes even in the very old. The same is true for all of our many surgical fields. Neither the surgeon nor the anesthesiologist can justifiably claim to have improved surgery for the patient alone; it has been a marvelous team effort unmatched in all medicine.

Chapter 24 Physiologic Response to Anesthesia in the Elderly

Aaron N. LacKamp and Frederick E. Sieber

Cardiovascular physiology: effects of anesthesia and aging

	Physiologic effects of anesthesia	Physiologic effects of aging	Combined effects of anesthesia and aging	Clinical implications
Venous	Slight dilation	Less compliant venous system	Decrease in preload	Greater fluctuation in preload for a given volume challenge
Arterial	Dilation	Decreased sympathetic response, stiffening of arterial system	Decreased systemic vascular resistance	Possible hypotension, increased vasopressor requirements
Heart	Decreased contractility	Diastolic dysfunction Left ventricular hypertrophy	Higher filling pressures needed to maintain cardiac output	Possible hypotension Susceptible to volume overload, dependant on late ventricular filling from atrial contribution
Baroreceptor	Response impaired	Response impaired	Response greatly impaired	Greater susceptibility to hypotension

Pulmonary physiology: effects of anesthesia and aging

	Physiologic effects of anesthesia	Physiologic effects of aging	Combined effects of anesthesia and aging and their clinical implications
Shunt	Hypoxic pulmonary vasoconstriction inhibited, atelectasis, V/Q mismatching	V/Q mismatching, increased closing capacity, increased PA pressures	Increased A-a gradient
Neuromodulation	Decreased response to hypoxia and hypercarbia	Decreased response to hypoxia and hypercarbia	Susceptible to hypercapnea Susceptible to hypoxemia Susceptible to residual anesthetic respiratory depressant effects
Mechanics	Decreased TV, \dot{V}_E , FRC (anesthetized and supine)	Decreased muscle mass, Loss of lung elasticity Decreased chest wall compliance	Increased work of breathing Increased dead space ventilation Susceptible to residual muscle relaxant
Protection	Impaired cough Impaired mucociliary clearance	Dysphagia, decreased cough reflex, decreased esophageal motility	Greater aspiration risk

Organ specific effects of anesthesia and aging

	Physiologic effects of anesthesia	Physiologic effects of aging	Clinical implications
Neurologic	Inhibition of neurotransmitter function	Decrease in neurotransmitters	Increased postoperative delirium and cognitive dysfunction
Renal	Decreased blood flow and glomerular filtration rate	Decreased renal mass	Decreased drug clearance; Susceptible to acute renal failure
Hepatic	Decreased blood flow		Decreased clearance of drugs with high hepatic extraction ratios
Endocrine	Impaired glucose tolerance	Impaired glucose tolerance	Hyperglycemia: Infection
Thermoregulation	Vasodilatation; decreased shivering threshold	Decreased muscle mass	Hypothermia: Infection Coagulopathy Intraoperative arrhythmia Postoperative myocardial infarction

Introduction

This chapter focuses on the physiologic components of aging and anesthesia that are likely to increase perioperative complications. The approach entails a separate description of anesthetic and aging physiology, followed by a discussion of how the two interact. Only the physiologic changes invoked by aging that provide important interactions with anesthesia are discussed. The reader is encouraged to consult relevant chapters contained in this textbook on preoperative assessment and specific organ systems for a more comprehensive discussion of the physiologic changes with aging.

Cardiovascular Implications of Anesthesia in the Elderly

Cardiovascular Effects of Anesthesia

Anesthetics decrease blood pressure by decreasing left ventricular contractility, decreasing systemic vascular resistance, and inhibiting baroreceptor function (Fig. 24.1).

Decreased ventricular contractility occurs with intravenous anesthetic agents. Propofol is the most common induction agent used today and is generally thought to be a direct

myocardial depressant. The negative inotropic effect of propofol is mediated by a decrease in intracellular Ca^{++} [1]. In fact, propofol is a greater myocardial depressant than the inhalational anesthetics [2]. Even ketamine, which produces a sympathetically mediated increased heart rate and blood pressure, causes some direct myocardial depressant effect [3, 4]. It appears that opioids have minimal effects on contractility [3]. It has been suggested that etomidate is the induction agent of choice in elderly patients with limited cardiovascular reserve [5]. In fact, hemodynamic stability after induction with this agent in severely compromised patients can be remarkable. Etomidate can cause transient adrenal depression [6,7], although the effect is of questionable significance.

In comparison to the intravenous agents, inhaled anesthetic agents are associated with less myocardial depression. Volatile anesthetics decrease inotropy by means of their effects on the L-type Ca^{++} channels, the sarcoplasmic reticulum, and the contractile apparatus [8]. Older drugs, such as halothane and enflurane, cause greater decreases in myocardial contractility than the modern agents isoflurane, sevoflurane, and desflurane [9–12]. Cardiac output is generally maintained under the modern agents because the myocardial depression is accompanied by afterload reduction [10, 13, 14].

Most anesthetic agents reduce afterload by decreasing arteriolar tone (Fig. 24.2). Propofol is a potent vasodilator [15]. Opioids are also vasodilators, though this effect is small when compared to propofol or the inhalational agents [16].

FIGURE 24.1 The effects of increasing concentrations (MAC) of halothane, isoflurane, desflurane, and sevoflurane on mean arterial pressure (mmHg) when administered to healthy volunteers. MAC is a means of defining dose of inhaled volatile anesthetics, higher MAC values representing higher anesthetic dose. One MAC equals the minimum alveolar concentration at which 50% of subjects aged 40 would not move in response to a surgical stimulus (used with permission from Calahan [121]).

FIGURE 24.2 The effects of increasing concentrations (MAC) of halothane, isoflurane, desflurane, and sevoflurane on systemic vascular resistance (dynes/cm²) when administered to healthy volunteers. MAC is a means of defining dose of inhaled volatile anesthetics, higher MAC values representing higher anesthetic dose. One MAC equals the minimum alveolar concentration at which 50% of subjects aged 40 would not move in response to a surgical stimulus (used with permission from Calahan [121]).

Anesthetic agents blunt baroreceptor function. The degree of inhibition depends on the anesthetic agents administered. As a result, tachycardia may not be observed in response to hypotension. Inhalational agents blunt baroreceptor function in a dose-dependent manner [17]. Although both opioids and propofol alter baroreceptor function, the effect is much less than observed with the inhalational agents [2]. Significant bradycardia can occur, however, because of the direct vagotonic effect of the opioids, especially fentanyl.

Anesthetic effects on venous pooling have been an area of intense investigation because of the possible causal relationship to deep vein thrombosis. However, the impact of general anesthetics on venous blood flow of the lower extremities is insignificant. Rather it seems that surgical stress is the primary mediator of perioperative decreases in venous blood flow [18].

Cardiovascular Changes with Aging That Affect Anesthetic Physiology

Cardiovascular aging is characterized by increased sympathetic tone, diminished β -adrenergic response, and stiffening of the left ventricle and venous and arterial systems. The increased sympathetic tone and arterial stiffening have several important long-term effects. Arterial stiffening causes hypertension late in systole, and this in turn causes an increased vascular load by means of increased pulse wave velocity and wave reflection [19]. This elevated vascular load is thought to be associated with the development of left ventricular hypertrophy [20].

With ventricular hypertrophy comes delayed relaxation and myocardial stiffening. Delayed relaxation impairs early diastolic filling [21]. This enhances the importance of late diastolic filling in maintaining cardiac output [22]. Late diastolic filling, however, must now overcome ventricular stiffness and that requires higher preload. The contribution of the atrial contraction to ventricular filling becomes critical and creates greater susceptibility to hypotension should atrial fibrillation occur. Thus, the combination of chronic hypertension and left ventricular hypertrophy contribute to a higher incidence of diastolic dysfunction in the elderly. To boost cardiac output in the setting of increased ventricular stiffness, elderly patients may depend on higher diastolic filling pressures. This impaired diastolic filling increases preload requirements. Elderly patients may be thereby predisposed to volume overload as they become increasingly reliant on preload to maintain cardiac output.

Another factor that affects diastolic filling of the ventricle is the relative time the heart spends in systole versus diastole. In the aging heart, length of diastole is shortened and systole is lengthened as a compensatory mechanism to maintain ejection fraction [23, 24]. Increased left ventricular filling does increase inotropy by means of the Starling forces, but the compensation

for the systolic function is at the expense of higher diastolic pressures and greater time in systole [25–28]. Shortened diastolic time also affects coronary perfusion [27, 28].

Stiffening of the vessel walls occurs in the venous system with aging. Rigid veins fail to function as a preload buffer. The venous system normally contains 80% of blood volume, so low venous capacitance means that the aging venous system cannot accommodate excess volume or adapt to low volume states without a comparatively large change in filling pressure [29]. This loss of venous compliance may be associated with impairment in diastolic filling.

Conduction abnormalities occur in the elderly. Dilation and fibrotic change in the atria predispose the elderly to atrial fibrillation. Bradycardia is the second most common initiating rhythm after premature atrial contractions [30] and may increase the incidence of new onset atrial fibrillation. The high incidence of sinus bradycardia may be related to drop-out of sinus node pacemaker cells to as little as 10% of levels seen in young adults [23]. New onset atrial fibrillation during the perioperative period in the elderly frequently results in significant blood pressure changes. The cell populations in the aging AV node are maintained. AV conduction slows with aging, however, resulting in lengthened P - R interval [31, 32].

Cardiovascular responsiveness in the elderly is impaired. For instance, maximal heart rate decreases with aging, and can be estimated by the formula: maximum predicted heart rate = $220 - \text{age}$ [33]. As a consequence, the ability to increase cardiac output by means of an increase in heart rate is limited [20]. There is reduced adrenergic responsiveness [34], affecting both the β -adrenergic [5, 35] absolute heart rate [36] response and inotropy [37] and α -adrenergic mediated arteriolar tone [38].

Rapid response to hypotension is mediated by baroreceptor function. The stiffening of arterial walls in the elderly may contribute to the well-documented decrease in baroreceptor response. There is a decrease in baseline vagal tone [39] and consequently diminished carotid sinus baroreceptor response to hypotension in the elderly [40, 41].

The aging of the autonomic nervous system is characterized by progressively limited capacity to adapt to stress. A main concern of the anesthesia provider in evaluating the elderly patient is the response to acute hemodynamic challenges in which the autonomic nervous system and its effectors may play an important role. The preoperative history can provide some indication of the competence of the autonomic nervous system. The patient should be specifically questioned concerning signs and symptoms of exercise intolerance, orthostatic hypotension, temperature intolerance, and unusual patterns of sweating (especially increased upper body sweating). If the history suggests that autonomic nervous system responses are attenuated, one has good reason to suspect that blood pressure lability will occur perioperatively.

The Interplay of the Aging Cardiovascular System and the Effects of Anesthesia

Cardiovascular compensation occurs even in the healthy aging patient, and the significance of age-related change varies greatly on an individual basis. Physiologic limitations, however, may be unmasked by anesthesia.

The most frequent cardiovascular problem that occurs with anesthesia in the elderly is hemodynamic instability, which manifests itself primarily as hypotension. This effect is mediated through interactions with myocardium, preload, and afterload. Anesthesia causes sympatholysis which results in decreased afterload because the primary resistance vessels are sympathetic sensitive. However, the ability to augment cardiac output to maintain blood pressure in the face of decreased systemic vascular resistance is lessened. Anesthesia decreases contractility and inhibits baroreceptor responses. This makes the aging heart with diastolic dysfunction more dependent on adequate preload to maintain cardiac output. The margin of safety in administering an anesthetic decreases as the aging heart with diastolic dysfunction becomes increasingly preload dependant. Important clinical situations in which hypotension frequently occurs in the elderly in the setting of relative perioperative hypovolemia include causes such as chronic hypertension, prolonged NPO status, impaired renal salt conservation, and use of diuretics [5].

Most anesthetic drugs can be used safely without hemodynamic compromise in the elderly population if several principles are kept in mind. Anesthetic dose requirements of both intravenous induction agents and inhalational agents decrease with age. In addition, slower titration of medication as opposed to bolus administration may be warranted because changes in body composition alter the pharmacokinetics of intravenous agents. The loss of lean body mass, increase in percent body fat, and 20–30% decrease in blood volume observed with aging cause the initial drug bolus to be dispersed in a reduced volume of distribution. The so-called greater “sensitivity” of aged patients to the bolus administration of certain drugs has been related to a reduction in either the initial volume of distribution or the initial distribution clearance. In elderly patients compared to younger ones, the same bolus dose will generate a markedly higher plasma concentration and thus a greater pharmacologic effect.

The elderly are at increased risk of fluid overload during management of hypotension and correction of fluid deficits. The balance of euvolemia is more delicate in the elderly than in the younger patient, as the clinical range between hypovolemia and fluid overload is narrowed. Perioperative congestive heart failure in the elderly occurs in a bimodal type of time frame. It may first appear in the immediate recovery phase after anesthetic emergence. It is most likely to occur when sympathetic tone reappears and may be the result of

pain or fluid shifts from the peripheral vasculature to the heart. It may next appear on postoperative day 2–3, and likely occurs with mobilization of extravascular fluid. Late postoperative congestive heart failure is exacerbated by underlying renal dysfunction, and its prevention requires physician attentiveness and diuresis.

Mode of ventilation during anesthesia can have significant cardiovascular effects in the elderly. Positive pressure ventilation decreases venous return via an increase in intrathoracic pressure. Similarly, hyperventilation can cause hypotension via impairment of venous return. An additional mechanism of hypotension is the decrease in sympathetic tone associated with hypocapnea [42–44]. Spontaneous ventilation is associated with less hypotension in the elderly patient with diminished cardiovascular reserve, because venous return is augmented during inspiration.

The prone position can be associated with a significant reduction in the cardiac index secondary to vena caval compression [45]. Both the sitting position and reverse Trendelenberg position decrease venous return and can worsen hypotension in severely preload-dependant elderly patients. Trendelenberg augments venous return. Lateral position is generally not associated with significant hemodynamic effects. Although right lateral decubitus has improved venous return over the supine and left lateral decubitus positions, the effect is probably minimal except in patients with congestive heart failure [46].

Laparoscopic insufflation causes decreased venous return. This, coupled with the depressant effect of anesthetic drugs, can result in hypotension. It is typical for PaCO₂ to slowly rise after 30 min of laparoscopy. This results from the increased CO₂ load and the decreased ability to eliminate CO₂ secondary to pneumoperitoneum. The hypercapnea and its associated increase in sympathetic tone [47] may cause hypertension and ectopy. Correction of hypercapnea requires ventilatory changes such as increased respiratory rate, tidal volume, and peak airway pressures, which may further impair venous return.

Elderly patients frequently take cardiovascular medications, which interact with anesthetics. For instance, bradycardias are apt to occur in anesthetized patients being treated with β -blockers and calcium channel blockers. Bradycardia may also be associated with anesthesia-specific medications such as high-dose narcotics, acetylcholinesterase inhibitors for reversal of neuromuscular junction blockade, and with a rare acetylcholine-like effect of succinylcholine (a short-acting neuromuscular relaxant). Under rare instances, heart block can occur; the risk increases with preexisting bundle branch block. Preoperative use of ACE inhibitors [48] and angiotensin receptor blockers [49] has been closely associated with increased risk of hypotension in anesthetized patients. It is controversial, however, whether discontinuing these medications preoperatively will decrease the incidence of perioperative hypotension.

Regional Anesthesia: Spinal and Epidural

Spinal and epidural anesthesia cause significant afterload reduction due to blockade of sympathetic fibers. Because the sympathetic fibers are small in diameter, they are highly susceptible to local anesthetic blockade. The sympathectomy associated with regional anesthesia has greater effects in the elderly because of limited ability to mount a compensatory response and possibly greater propensity to obtain a higher spinal anesthetic level [50]. With epidural anesthetics, the decreased compliance of the epidural space in the elderly is associated with achievement of a higher dermatome level of anesthesia with the same dose of local anesthetic in comparison to younger patients. A decrease in blood pressure with neuraxial blockade is nearly universal and often heralds the onset of motor and sensory blockade (Fig. 24.3). Preload reduction contributes to hypotension as well as afterload reduction. Tachycardia is the normal compensatory response but may be impaired in the elderly. With a very high sensory level (T1–T4), the cardioaccelerator fibers may be blocked, thus precluding the tachycardia response and predisposing the patient to severe hypotension and reduction in cardiac output. When hypotension occurs after administration of spinal anesthesia in the elderly, volume loading is generally insufficient to correct the hypotension, and vasopressors are generally required [51]. Furthermore, excessive volume loading can be associated with ventricular dysfunction [52].

It should be noted that the careless use of spinal anesthesia in a hypovolemic patient with limited cardiac reserve will likely result in cardiovascular collapse. These events are asso-

FIGURE 24.3 The effect of spinal anesthesia on mean arterial pressure is shown in 15 elderly men with cardiac disease. The thoracic block level is noted on the “during spinal” side of the graph. The four patients with a baseline ejection fraction (EF) less than 50% were no more or less likely to demonstrate significant decreases in mean arterial pressure than those with normal baseline ejection fraction (used with permission from Rooke et al. [122]).

ciated with profound bradycardia resulting from activation of the Bezold–Jarisch reflex. When patients are hypovolemic and spinal anesthesia is to be used, it may be best to use a continuous catheter technique. This allows slow titration of drug so that hemodynamic changes have a slower onset and can be treated in a timely manner. Epidural anesthesia also can be administered slowly via a catheter so that the hemodynamic response can be gradual and controlled. Even with gradual administration, there is a risk of rapid hemodynamic changes if the patient is not closely monitored.

Spinal and epidural anesthesia can be desirable modes of anesthesia in the elderly in order to attenuate the stress response to surgery, avoid central nervous system depressants, avoid airway manipulation and its associated pulmonary complications, and to assist in postoperative pain management.

Pulmonary Implications of Anesthesia in the Elderly

Pulmonary Effects of Anesthesia

During spontaneous ventilation, the inhalational agents decrease tidal volume and minute ventilation [53–55]. This is associated with an increase in PaCO₂ and respiratory rate (Fig. 24.4). In the absence of opioids or other respiratory depressants, profound tachypnea can occur. Despite the increase in respiratory rate, however, the net effect on the alveoli is a decrease in ventilation. In the anesthetized state, spontaneous ventilation in the supine position results in decreased functional residual capacity due to cephalad displacement of the diaphragm and inward displacement of the ribcage [56]. The work of breathing [57] is increased because the weight of the abdominal contents must be displaced with inspiration. Decreased functional residual capacity means less oxygen reserve prior to any apneic interval.

Normal ventilatory drive depends on central and peripheral chemoreceptor response to hypercapnea, hydrogen ion concentration, and pH. The response to hypercapnea is independent and synergistic with the response to hypoxia. The carbon dioxide response curve is shifted to the right under anesthesia requiring higher CO₂ [58] for a given minute ventilation. Likewise, there is impaired response to hypoxia with even minimal residual inhalational anesthetic levels [59].

Ventilation–perfusion (V/Q) mismatching occurs during anesthesia and is caused largely by atelectasis [60] and impaired hypoxic pulmonary vasoconstriction. Atelectasis commonly forms in dependent regions of the lung shortly after induction of anesthesia and progresses as gas is absorbed from poorly ventilated regions [61]. Positive end-expiratory

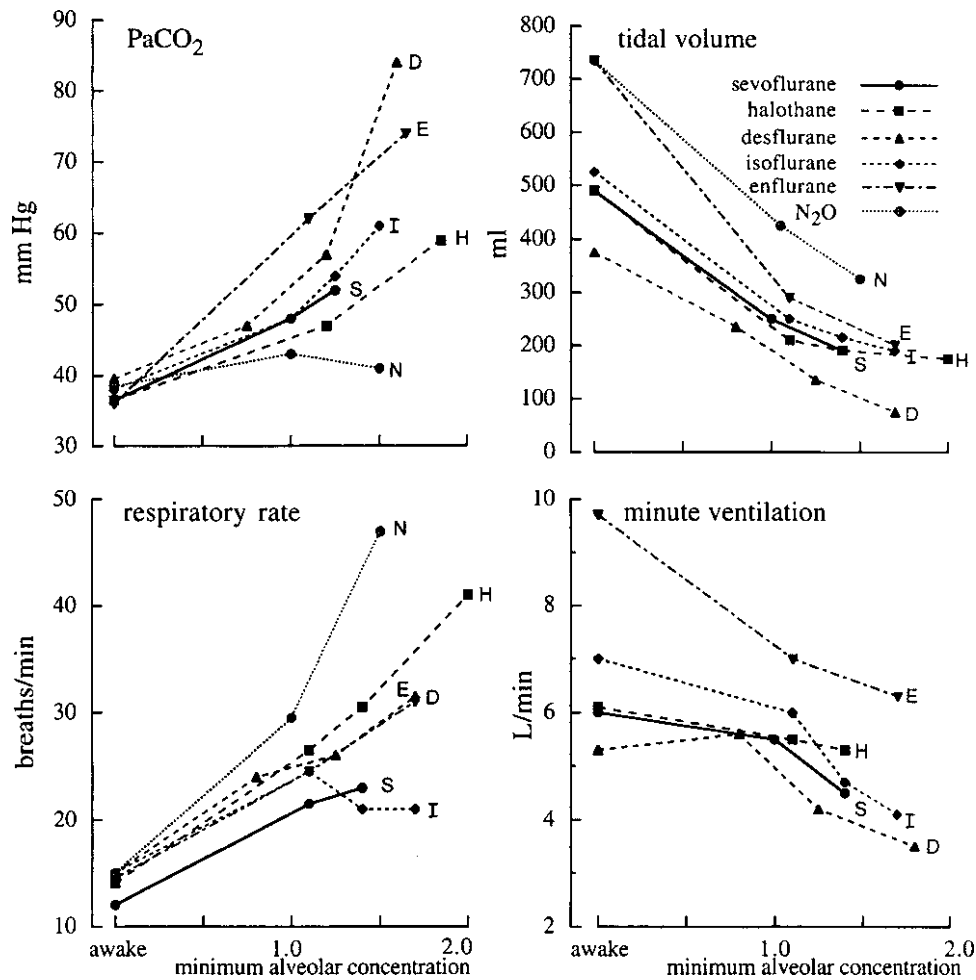

FIGURE 24.4 Comparison of mean changes in resting PaCO₂, tidal volume, respiratory rate, and minute ventilation in patients anesthetized with either halothane, isoflurane, enflurane, sevoflurane, desflurane, or nitrous oxide. Anesthetic-induced tachypnea compensates in part for the ventilatory depression caused by all volatile anesthetics (decrease in minute ventilation and tidal volume and concomitant increase in PaCO₂). Desflurane results in the greatest increase in PaCO₂ with corresponding

reductions in tidal volume and minute ventilation. Isoflurane, like all other inhaled agents, increases respiratory rate, but does not result in dose-dependent tachypnea. MAC is a means of defining dose of inhaled volatile anesthetics, higher MAC values representing higher anesthetic dose. One MAC equals the minimum alveolar concentration at which 50% of subjects age 40d would not move in response to a surgical stimulus (used with permission from Barash et al. [123]).

pressure can reduce atelectasis formation, but large tidal volume recruitment maneuvers are generally necessary to reverse shunt [62]. Hypoxic pulmonary vasoconstriction reduces blood flow to underventilated regions, but this mechanism is partially inhibited by anesthetic agents [63].

Other anesthetic effects on the pulmonary system include impairment of bronchial mucociliary clearance in intubated patients [64, 65] and impairment of swallowing reflex from pharyngeal dysfunction and risk of aspiration at subhypnotic concentrations of anesthetic [66]. Decreased pharyngeal tone results in upper airway obstruction. The incidence of apnea due to upper airway obstruction is increased in obese individuals. Inhalational anesthetics are potent bronchial dilators in the face of bronchoconstriction [67], although bronchoconstriction can be induced during anesthesia by the stimulus of tracheal intubation [68] and by the inhalational agent desflurane [69].

Pulmonary Changes with Aging That Affect Anesthetic Physiology

The loss of muscle mass with aging does not spare the muscles of respiration. Decreased muscle strength in the intercostals and accessory muscles of respiration impairs the ability to perform maximal ventilatory maneuvers and impairs the ability to mount a strong cough. Clearance of secretions is in part dependent on the patient having sufficient strength to perform the maneuver. Elderly patients are less able to maintain adequate tidal volume and generate sufficient inspiratory or expiratory force. If the weakness is severe enough, it may interfere with extubation and weaning efforts.

Less efficient gas exchange is inherent in the aging lung. The incidence of overt chronic lung disease increases with

age, a problem compounded by smoking. Normal structural changes account for some of the increased risk of respiratory compromise in the elderly. There is a loss of elasticity of the lung tissue, and the chest wall becomes less compliant. The result is increased residual volume of the lung. Total lung capacity remains unchanged or slightly decreases, but the increase in residual volume causes a decrease in vital capacity [70]. The effect is increased work of breathing for given level of gas exchange, and increased shunt and dead space. Functional residual capacity also increases along with residual volume, yet the geriatric patient is more susceptible to hypoxia stemming from the increased closing capacity of the small airways. As the aging lung loses elasticity, the smallest airways are no longer stented open by elastic tissue but instead rely on some minimal amount of lung inflation, or closing capacity, to maintain small airway patency. As lung volumes decrease with active expiration, there comes a point when the summation of intra-airway pressure and elastic forces stenting open distal air passages become insufficient to overcome the tendency of these distal airways to collapse. There is a general trend toward increased closing capacity with aging. By age 66, closing capacity exceeds FRC in the sitting position [71]. When closing capacity exceeds FRC, some portion of the lung will be ineffective in gas exchange during part of the respiratory cycle. This mechanism leads to increasing V/Q mismatch in the elderly and a gradual decrease in blood oxygenation. On average, the PaO₂ decreases 0.31 mmHg per year of age [70].

Other changes in the elderly that are of importance to anesthetic physiology include a blunting of the response to hypoxia and hypercarbia [72, 73]. In addition, aging leads to dysphagia, decreased esophageal motility, and decreased cough reflex.

The Interplay of the Aging Pulmonary System and the Effects of Anesthesia

Pulmonary complications are a major cause of postoperative morbidity in the elderly. Postoperative respiratory complications are associated with 40% of the perioperative deaths in patients older than 65 years of age [74]. The aging of the pulmonary system and anesthesia interact to increase the likelihood of these events. Increased A–a gradient is likely to occur under anesthesia. Impaired oxygenation is secondary to the anesthetic effects of decreased minute ventilation, increased atelectasis, and the aging effect of increased closing capacity. In addition, hypoxic pulmonary vasoconstriction is impeded by the aging effect on pulmonary vascular rigidity and by anesthetic inhibition. Ventilatory failure may occur secondary to the combined effects of anesthesia and aging to decrease minute

ventilation, depress hypoxic and hypercarbic respiratory drive, and increase the work of breathing in the face of decreased muscle mass. Many of the changes outlined act in concert with a less effective cough and impaired airway protective mechanisms to increase the risk of aspiration and pneumonia.

The pulmonary implications of residual anesthetic effects after emergence is a serious issue in the elderly. Of primary importance are the effects of muscle relaxants. Age-related pharmacokinetic and pharmacodynamic changes interact with the decrease in muscle mass to potentiate the effects of these drugs, thus increasing the risk of respiratory compromise in the early postoperative period [75–77]. The respiratory depressant effects of sedative agents, narcotics, and inhalational anesthetics are prolonged. As a special case, the inhaled anesthetics are eliminated primarily by the lung. Decreases in minute ventilation and cardiac output, as well as V/Q mismatch, will prolong the elimination of inhaled anesthetic agents [78, 79].

The insufflation pressure during laparoscopy displaces the diaphragm cephalad; this reduces tidal volumes toward that of the dead space volume. In this case, adequate ventilation is maintained either by increasing the airway pressure to maintain adequate tidal volume or by decreasing insufflation pressures. Under these conditions, atelectasis develops at an accelerated rate. Low levels of PEEP may be used in this setting as long as intrathoracic pressures do not impair venous return so as to cause hemodynamic compromise.

Regional Anesthesia and Pulmonary Implications

With spinal or epidural blockade of sufficient dermatomal height for abdominal procedures, the musculature of the thoracic cage will be anesthetized, eliminating the contribution of the intercostal muscles to respiration. Spontaneous ventilation is still possible, however, because the diaphragm is the major muscle of respiration. In these circumstances, loss of accessory muscle function may be an issue in patients with limited pulmonary reserve. Protective airway reflexes are maintained although cough may be impaired.

Spinal and epidural anesthesia have been advocated as a means of decreasing postoperative pulmonary complications, although there is little data to support this contention. Epidural anesthesia continued into the postoperative period may help in promoting early mobilization, cough, and deep breathing by relieving postoperative pain. In theory, spinal or epidural anesthesia helps to minimize the administration of central nervous system depressants during the perioperative period, thereby maintaining protective airway reflexes. It is common practice, however, for sedation to be administered during spinal and epidural anesthetics. Therefore, it is important to identify at

risk patients, and verify recovery of protective reflexes in the elderly after an anesthetic, including sedation for spinal.

Physiologic Response to Anesthesia in the Aging Nervous System

Age-related decreases in central nervous system functional reserve lead to alterations in pharmacodynamics, and increased susceptibility to postoperative cognitive dysfunction and delirium.

Altered Pharmacodynamics

Brain sensitivity to most anesthetic agents increases with age. This necessitates decreasing the drug dose in the elderly (Fig. 24.5). Some components of the elderly drug response can be explained by pharmacokinetic changes associated with aging; these are specific to each drug. The underlying mechanism to explain altered brain pharmacodynamics is unclear at present. Altered brain pharmacodynamics may

FIGURE 24.5 Aging influences MAC in humans for desflurane, isoflurane, halothane, and sevoflurane. MAC is at its peak in humans less than 1 year of age, decreasing by approximately 40% in older adults. MAC is a means of defining dose of inhaled volatile anesthetics, higher MAC values representing higher anesthetic dose. One MAC equals the minimum alveolar concentration at which 50% of subjects aged 40 would not move in response to a surgical stimulus (used with permission from Eger et al. [124]).

result from age-related changes in the receptors, signal transduction, or homeostatic mechanisms. Within the central nervous system, aging is associated with decreases in dopaminergic and cholinergic neurons and receptors as well as a decrease in the number of synapses. There are also alterations in brain phospholipid chemistry associated with changes in second messengers such as diacylglycerol [80]. A definitive association between these changes and age-related brain pharmacodynamics has yet to be established.

Increased Susceptibility to Postoperative Delirium and Cognitive Dysfunction

The incidence of postoperative delirium and postoperative cognitive dysfunction may exceed 50% in certain surgical populations [81]. The incidence of cognitive dysfunction in elderly patients after major surgery seems to be highest after cardiac surgery and hip fracture repair [82, 83]. Thus, postoperative delirium and postoperative cognitive dysfunction are two of the most common postoperative complications in the elderly, and their incidence may be higher than that of myocardial infarction or respiratory failure [81, 84, 85].

A wide variety of drugs are associated with delirium, many of which are used frequently in the perioperative period. These include benzodiazepines, anticholinergics, opioids, corticosteroids, anticonvulsants, antidopaminergic antiemetics, and H₂ antagonists [86]. Although a recent critical review of the literature concerning the relationship of psychoactive medications and delirium found that the evidence for an association is weak, the authors attributed this to methodological issues in the studies and concluded that a relationship may indeed exist [87].

The hypothesis that postoperative delirium is the result of age-associated central cholinergic deficiency has been the driving force behind studies examining the role of intraoperative management as it relates to postoperative delirium. Arguably, the most important decision concerning anesthetic management is whether patients should have a regional or general anesthetic. In theory, regional anesthetic techniques should be associated with a reduced incidence of postoperative delirium because these techniques minimize exposure to agents that influence central cholinergic activity and drugs that are associated with delirium in medical patients, such as opiates and benzodiazepines. Furthermore, regional anesthesia deeply suppresses the neuroendocrine stress response to surgery [88–90]. Unfortunately, studies to date have not demonstrated that regional anesthetic techniques reduce the incidence of postoperative delirium [91].

Postoperative pain increases the risk of postoperative delirium. Interestingly, maximum pain and pain with movement are not predictive of delirium. Only high levels of rest pain are associated with postoperative delirium [92]. As a class,

opiates are not associated with postoperative delirium, except for meperidine [93]. This may be because of its atropine-like structure and influence on brain cholinergic activity. Postoperative use of benzodiazepines has also been associated with postoperative delirium [94].

It is important to recognize that postoperative delirium may be the presenting symptom of a number of complications, including sepsis, urinary tract infections, myocardial infarction, stroke, pneumonia, etc [95]. Thus, the first step in managing postoperative delirium is to identify and treat underlying medical and/or surgical causes.

Many surgeons are aware of patients who complain after surgery of difficulties performing cognitive tasks that they were previously able to do without difficulty. Postoperative cognitive dysfunction is the term used to describe this condition. It can consist of a variety of cognitive deficits. Unlike patients with postoperative delirium, however, those with postoperative cognitive dysfunction are generally alert and oriented.

In vitro and animal studies suggest that inhalational and intravenous anesthetic agents alter neuronal function after exposure [96–98]. Neurons exposed to volatile anesthetics in vitro have increased oligomerization and cytotoxicity of β -amyloid, the protein associated with Alzheimer disease [98]. In aged rats, exposure to anesthetic agents causes long-term declines in cognitive function [99–101]. The clinical relevance of these findings is unclear because studies examining the influence of regional versus general anesthesia on the incidence of postoperative cognitive dysfunction in humans have not found a difference between the two techniques [91, 102]. One reason may be that patients who received regional anesthesia in those studies also received intravenous sedatives. Another may be that postoperative management was not controlled. Stress plays a role in cognitive function [103]. Although regional anesthetic techniques attenuate the surgical stress response [88, 104], if these techniques were not continued into the postoperative period, any benefit may have been negated. Also, by not continuing regional analgesic techniques into the postoperative period, patients were exposed to higher doses of opiates, which may have influenced their cognitive outcomes. Interestingly, unlike the case with postoperative delirium, perioperative use of benzodiazepines is not associated with postoperative cognitive dysfunction [105, 106].

Though the exact mechanisms by which postoperative delirium and postoperative cognitive dysfunction occur are not well understood, the likely cause is an acute insult in a vulnerable patient. The degree of surgical or physiological insult required to precipitate postoperative delirium or postoperative cognitive dysfunction varies from patient to patient. In patients with a high degree of preoperative cognitive reserve, a substantial insult is required for postoperative delirium and/or postoperative cognitive dysfunction to occur. Conversely, in patients with a lower degree of cognitive reserve, a relatively minor stress is all that is necessary for

postoperative delirium and/or postoperative cognitive dysfunction to develop [107].

Renal Implications of Anesthesia in the Elderly

Anesthesia decreases renal perfusion and glomerular filtration rate. When a patient receives an anesthetic, glomerular filtration rate may be acutely decreased by hypotension, redistribution of blood flow away from body core, or a specific pressure effect of laparoscopy. The potential for postoperative acute renal injury is greater with preexisting renal disease.

Drug excretion and metabolism by the kidney is proportionately decreased with aging. Many anesthetic drugs depend on renal elimination. Dose adjustment of most medications should be anticipated in the elderly. Of special note, many of the commonly used opioids and muscle relaxants have some component of renal elimination, and their effects are prolonged in the elderly. Fortunately, there are alternate drugs, with little or no dependence on renal elimination. Inhaled anesthetics are eliminated primarily by the respiratory route. Serum enzymes degrade certain drugs such as cisatracurium, remifentanyl, and chloroprocaine. Due to the blood stream degradation of cisatracurium, this agent may be of special value in the elderly patient with renal impairment who requires muscle relaxation.

Hepatic Implications of Anesthesia in the Elderly

Hepatic functional reserve is fairly well maintained with healthy aging. As a result, anesthetic drug binding to serum proteins produced by the liver is not significantly affected. One potential effect of anesthesia is decreased hepatic blood flow. Hepatic blood flow parallels cardiac output and correlates with the rate of elimination of drugs with high hepatic extraction ratio [108, 109]. Commonly administered anesthetic agents with high hepatic extraction ratios include fentanyl, sufentanyl, lidocaine, meperidine, ketamine, and propofol. Drugs with lower hepatic extraction ratios are less impacted by hepatic blood flow.

Endocrine Implications of Anesthesia in the Elderly

Hyperglycemia is a frequent issue during surgery in the elderly patient. Inhalational anesthetics impair glucose tolerance. The mechanism is unclear but may be secondary to direct inhibition of insulin secretion [110]. Thus, hyperglycemia

occurs in the anesthetized state with or without surgery. Insulin resistance and prevalence of diabetes is increased in the elderly. This effect is compounded in the face of obesity.

Thermoregulation

Normal human thermoregulation allows only small fluctuations in core temperature within the narrow interthreshold range of 0.2°C; this range can be extended to 2–4°C under the effects of anesthesia [111]. Multiple inputs from the core and periphery contribute to the detection of temperature variation. Peripheral sensation tends to contribute largely to behavioral aversion to unpleasant environments, while core sensing mechanisms have a relatively larger impact on autonomic responses [111]. The response to decreased temperature begins when the threshold of vasoconstriction is reached. Beyond the vasoconstriction threshold lays the threshold for the energy intensive shivering mechanism. Non-shivering thermogenesis, although important in neonates, is negligible in adults. The response to elevation in core temperature begins when the threshold for sweating is reached. With extremes of temperature elevation, active vasodilation can also occur [111].

During anesthesia, hypothermia is a common challenge as a consequence of several colluding factors. Preparations for surgery entail exposing large surfaces of the patient's skin. Operating rooms are traditionally kept very cool. Under anesthesia, vasodilation occurs as a direct anesthetic effect. This results in an immediate decrease in core body temperature from a redistribution of body heat from the core to the periphery, and eventually results in greater dissipation of heat to the environment. By central mechanisms, anesthesia decreases the threshold temperature for vasoconstriction and shivering, allowing drift of the core temperature.

The elderly are predisposed to hypothermia [70, 112] as a result of decreased muscle mass and neural and hormonal mechanisms. Thyroid function and overall metabolic rate decrease with aging. Decreased muscle mass leads to greater heat loss and less heat generation. The neural thermoregulatory mechanisms [112] are altered with a lowered threshold for vasoconstriction, decreased maximum vasoconstriction response, decreased α -adrenergic response [113, 114], and decreased thermal perception.

These changes with aging compound the tendency, present among all patients, to develop hypothermia during both general and spinal anesthesia. The effects occur across a wide spectrum of anesthetic techniques and agents [115].

Complications of hypothermia include possible coagulopathy [116, 117], increased risk of surgical wound infection [118], and increased cardiac risk [119, 120] secondary to

hypermetabolism if shivering occurs after emergence from anesthesia. See the physiology table at the beginning of this chapter, which summarizes the interactions of anesthesia and aging in the brain, kidney, liver, endocrine system, and with thermoregulation.

Summary

Aging affects every body system, so the interplay between anesthesia and aging is necessarily complex. Because of decreases in hepatic and renal reserve, pharmacodynamic/pharmacokinetic changes must be taken into account when administering anesthetics. Other important considerations include the cardiopulmonary and neurologic systems. Labile hemodynamics and potential for diastolic heart failure are the important cardiovascular issues as compared to younger adults. The risks of postoperative ventilatory failure and pneumonia are increased in the elderly. Postoperative cognitive dysfunction is a common entity after all types of major surgery. At this time, it is difficult to define the optimal anesthetic for the elderly because both regional and general anesthesia affect many of these organ systems, and definitive data concerning the advantage of one anesthetic technique over another has yet to be established.

Chapter 25

Choosing the Best Anesthetic Regimen

Sheila R. Barnett

Introduction

Why Is Anesthesia a Particular Concern in Elderly Patients?

The administration of anesthesia to a geriatric patient requires meticulous attention to detail and a clear understanding of the impact of aging on organ reserve and function. Older surgical patients present for surgery with complicated medical histories, limited physiologic reserve, and frequently unpredictable responses to anesthetic agents [1, 2]. In general, elderly frail patients with underlying chronic disease can be less tolerant of brief episodes of hemodynamic instability such as hypotension or desaturation that may not be preventable during the course of a surgery. While these events may be insignificant in a young patient and in the frail elder, they may lead to serious consequences, such as cardiac ischemia and arrhythmias [3, 4]. This chapter reviews the basic anesthetic concepts and discusses the impact of aging on the choice of anesthesia.

Choosing the Anesthetic Regimen

Regardless of the age of the patient, the choice of anesthesia is influenced by several factors: the patient's medical and psychological condition, the type and duration of the procedure or surgery, and the requirements of the surgery itself. The anesthesiologist is ultimately responsible to

choose the regimen that is most appropriate for the patient and the surgeon. In many instances, the choice of the anesthesia is limited, for example, the elderly patient presenting with a perforated bowel and evidence of hemodynamic instability will require a general anesthesia with endotracheal intubation. In this example, there are no viable alternatives for the anesthetic type. However, even in this case and other similar cases in which the choice of anesthetic type is limited, the risks and benefits of the individual medications administered, the monitoring requirements, the positioning during the surgery, the duration of the surgery, and the post operative recovery plan will require thorough consideration [5]. For the older patient, the anesthesiologist must be prepared to tailor the anesthetic carefully to provide age appropriate care.

Using the case below, the challenges encountered by a "geriatric" anesthesiologist will be illustrated through a discussion of the case of Mr. Smith.

General Considerations for the Elderly Patient

Mortality and risk of an adverse event associated with surgery increase with advanced age [4, 6–9]. This is due to multiple factors including age related reductions in physiologic reserve, the increase in comorbid conditions, and the magnitude and type of the surgery itself. Complex emergency cases in the elderly carry the highest mortality with a suggested threefold increase in mortality. The risk of cardiac complications in geriatric patients following emergency surgery increases three to five times, and the chance of postoperative intubation and ventilation is five times that of a young patient undergoing a major emergency surgery. The magnitude and size of surgery are relevant: thoracotomy mortality in patients over the age of 70 years has been reported as high as 17% and emergency abdominal surgery in patients over the age of 80 years carries a mortality rate of 10–25%.

CASE STUDY: PART 1

Mr. Smith is a 85-year-old male presenting with new right upper quadrant pain. He is scheduled for an upper endoscopy and ERCP with a possible biliary dilation. Past medical history includes known gallstones, chronic lower back pain, Parkinson's disease, and hypertension. Prior surgery includes brain surgery for his tremor 5 years ago, and a lumbar discectomy 15 years ago. He consults his primary care doctor regularly and a neurologist for his Parkinson's every 3 months. In the past 12 months, he has had an EKG, which showed left ventricular hypertrophy and nonspecific ST changes; he has not had any further cardiac testing. His medications include a beta blocker, levodopa, intermittent ibuprofen and he has a prescription for acetaminophen with codeine but as per his wife he rarely takes any pain medication. Mr. Smith lives with his wife, in the past 12 months he has had increasingly difficulty with ambulation and has fallen several times. His appearance and speech are consistent with severe Parkinson's. Depending on the results of the ERCP, he may or may not require either a laparoscopic cholecystectomy or a more extensive biliary surgery.

Mr. Smith has several medical issues that will challenge the anesthesiologist during each of the procedures proposed.

For the ERCP, sedation is routinely recommended. However, Mr. Smith's medical conditions will make sedation challenging and it is possible that a general anesthesia will ultimately be a safer choice.

For the potential follow-up procedures, either a laparoscopic cholecystectomy or an exploratory laparotomy, Mr. Smith will need a general anesthesia. Mr. Smith has a significant increased risk from delirium post operatively, and may need adjustment on his Parkinson's medication. Although a laparoscopic cholecystectomy is generally an ambulatory procedure, serious consideration will need to be given to admit Mr. Smith until it is clear that he is stable. A major exploratory laparotomy and biliary dissection carry a very high risk of mortality in his age group, especially in view of his overall apparent frailty. For the more extensive surgery, Mr. Smith will need a general anesthesia and invasive monitoring including an arterial line at a minimum and possibly a central venous line. Although he has no history of congestive heart failure, if significant blood loss is encountered, he may benefit from cardiac output monitoring to assist with volume resuscitation. Postoperatively recovery should include intensive care unit, possible ventilation, and appropriate pain control. Depending on his hemodynamic status, he could benefit from a postoperative thoracic epidural for the treatment of postoperative pain.

The occurrence of any complications appears to be a major factor influencing outcomes in the elderly surgical patient. Several studies have shown a significant increase in 30-day mortality in patients who experienced complications following noncardiac surgery. In addition, patients experiencing a cardiac or noncardiac complication had a threefold increase in length of stay. Thus avoiding complications, even minor ones, and conducting a careful review of the patients' physical and medical status prior to anesthesia must be a primary focus for all anesthesiologists taking care of older patients.

The increased morbidity experienced by older patients largely reflects the burden of disease encountered in this age group. In a study examining preoperative health status in elderly patients, over 84% of 544 patients had at least one comorbid condition [1]. Thirty percent of patients had three or more preoperative health conditions, 27% had two, and 28% had one preexisting disease. Hypertension (HTN) was the most commonly encountered comorbidity. Other common conditions included: diabetes mellitus, dysrhythmias, pulmonary

disease, neurologic disease, arthritis, and ischemic heart disease including congestive failure. Despite a long list of diseases, functional status and clinical evidence of congestive heart failure [1, 8] were the two most important predictors of adverse events postoperatively in this study. Functional status is particularly important and frequently impacted by the presence of a physical disability. In the oldest patients, over the age of 80 years, 74% have a disability and 35% of this group requires assistance with daily activities.

Anesthetic Choices

Aspiration

Regardless of the anesthetic regimen, protection of the airway is paramount. The geriatric patient is at increased risk of aspirating because of physiologic changes and common

disease conditions [10]. A reduction in pharyngeal sensitivity has been demonstrated and common comorbidities such as a previous cerebrovascular accident, swallowing disorders, and diseases such as Parkinson lead to the increased possibility of aspiration. The development of aspiration pneumonia can be devastating in the older patient with reduced functional reserve. Thus, sedation should be administered cautiously in patients with an unprotected airway [11,12]. Pulmonary complications were among the most common in a study comparing young and elderly patients undergoing noncardiac surgery leading to both an increased length of stay and subsequent mortality [8].

General Anesthesia

The decision to use a general anesthesia is driven by the extent of the surgery, and the patient and surgeon preference [5]. A general endotracheal anesthesia with paralysis allows maximal exposure for abdominal surgery and is necessary for abdominal and laparoscopic surgeries. When paralysis is not required, provided the patient is fasting, not significantly obese with a low risk of aspiration and the surgery site, and positioning is appropriate, the laryngeal mask airway (LMA) has largely replaced the traditional mask anesthetic. For certain very brief surgeries a mask anesthetic is still desirable. Advantages of intubation compared with the LMA include the ability to protect the airway from aspiration, and possible reduction in the risk of development of intraoperative atelectasis through the use of positive pressure volume ventilation with or without additional positive pressure end-expiratory pressure. Mucociliary dysfunction occurs after using an LMA or an endotracheal tube, but it is worse following intubation.

In some instances, a patient will request to be asleep for a procedure and provided there is no additional risk, patient preferences should be followed. Dementia increases with age: in patients of 60–70 years old, the incidence ranges from 5 to 7%, while in those between 80 and 90 years old, the incidence ranges from 15 to 20%. Depending on the ability to cooperate, these patients may require a general anesthesia or deeper sedation than would normally be indicated by the procedure itself.

Regional Anesthesia

Regional anesthesia includes both neuraxial techniques such as spinal and epidural anesthesia and peripheral nerve blocks. Regional anesthesia may be administered as the primary anesthetic or as an adjuvant for pain relief during or after the surgery [13]. When utilized to treat

postoperative pain, epidural analgesia and peripheral nerve blocks improve pain relief, functional outcomes, and have been shown to reduce hospital stay in selected patient groups. Advantages of a pure regional anesthesia include a reduction in the requirement for sedatives, preservation of spontaneous ventilation, the absence of airway instrumentation, and potential decrease the incidence of postoperative thrombosis and blood loss following orthopedic surgery [14].

The choice for a regional anesthesia vs. general anesthesia remains the subject of significant debate [14–17]. Despite increasing popularity of regional blocks such as intrascapular and femoral nerve blocks, there is no consistent data supporting a reduction in morbidity or mortality after general surgery.

Neuraxial Anesthesia

The spine undergoes significant age-related changes, including a gradual deterioration of the intervertebral disks, fibrosis of the intervertebral foramina, and a reduction in fat in the epidural space. In addition to making the placement of a spinal or epidural more challenging, these changes also result in a less compliant epidural space. When dosing the geriatric patient, enhanced local anesthetic spread can occur in the spinal column, and the dose of epidural medications should be reduced and given more slowly [18]. Similarly, local anesthetic administered through the spinal needle into the subarachnoid space can result in a variable and higher level of analgesia and sympathetic block in an older patient due to a decrease in the CSF and age-related changes in the pain fibers themselves [19, 20]. In addition to changes in the spread of local anesthetic agents, metabolism and clearance of these drugs are also delayed with advanced age. Lidocaine and other local anesthetic doses should be reduced for both neuraxial and peripheral nerve blocks. The enhanced cephalad spread of epidural and spinal local anesthetic agents also contributes to the increased hypotension observed in older patients from the consequent sympathectomy. Older patients are also more sensitive to the central effects of opioids and are at increased risk of apnea following neuraxial opioid administration.

Epidural analgesia can be employed postoperatively to improve pain control from large abdominal and thoracic incisions. Epidural analgesia includes several advantages over systemic narcotics including improved pain relief, less sedation, and improved respiratory mechanics. However, epidural anesthetics usually include low dose local anesthetic agents and this can be associated with a sympathetic blockade and subsequent potential vasodilatation and hypotension. The effects of the sympathectomy are often

exaggerated in the elderly patient due to a combination of existing age-related declines in autonomic function and increased decline in vascular resistance. The increase in hypotension in older vs. younger patients can be a significant factor limiting the use of an epidural for postoperative analgesia or even a spinal for a procedure [3, 13, 20]. In general, fluid administration alone will not offset the impact of the sympathectomy and carries the risk of inducing congestive heart failure once the sympathectomy wears off and the fluid is returned to the central volume. Epidural- (or spinal) induced hypotension usually requires treatment with an alpha agonist such as phenylephrine [3, 13], and this may be undesirable in patients with tenuous blood supply or new vascular grafts. In general, if phenylephrine will be deemed unacceptable in the postoperative course then alternative postoperative pain management strategies to epidural anesthetics should be considered. Pure opioid analgesia through the epidural may be useful but significant complications with postoperative apnea have occurred and limited the use in elderly frail patients [21].

Absolute contraindications to neuraxial anesthesia include anticoagulation and antiplatelet medications. Other contraindications to neuraxial anesthetic include sepsis, bacteremia, and hypovolemia. Current recommendations suggest discontinuing warfarin for 3–5 days and allowing normalization of the INR to 1.5 or less prior to placing an epidural or spinal. Antiplatelet medications take several days or weeks to wear off and it is recommended that ticlopidine be stopped for 14 days and clopidogrel for 7 days at a minimum prior to a neuraxial anesthetic. Nonsteroidal anti-inflammatory drugs (NSAIDs) and aspirin can be continued. Twice daily low molecular heparin should be discontinued for 24 h, if only once per day then 12 h is sufficient [22].

In all patients in whom anticoagulation or antiplatelet medication is an issue, a serious discussion is needed regarding risks and benefits of discontinuing the medication and the plans for reinstating the medications postoperatively. It is important that any plans to change a patient's anticoagulation medication involve a discussion with the patient's cardiologist or primary care physician.

Monitored Anesthesia Care

This is the most common type of anesthesia administered. A monitored anesthesia care (MAC) can range from the administration of minimal anxiolysis to deep sedation. In older patients, continuous supplemental oxygen is recommended in all cases as physiological changes with aging result in a lower arterial oxygen tension on room air, even before the administration of sedation. In general, the medication administered by the anesthesia provider is supplemented by local anesthesia through infiltration or a field block administered by the surgeon. Patients undergoing an MAC need to be at least partially cooperative and able to lie still without significant pain; in the older patient with agitation, dementia, or chronic pain, this can be difficult and a lower threshold for recommending a general anesthesia may be needed. Similarly, an MAC may be unreasonable in patients with chronic cough or intractable tremors.

Minimum Requirements for Anesthesia

Regardless of the anesthetic technique chosen, there are certain minimum requirements that must be met for all patients undergoing an anesthesia. Patients must have a preoperative anesthetic evaluation, appropriate laboratory testing, pertinent consultations, and should receive instructions regarding NPO status and general information on “what to expect following their surgery and anesthesia.” There are several options for the completion of the preanesthetic evaluation; the choice will depend on the patient, the surgeon, and the facility guidelines (Table 25.1).

When a preoperative testing clinic is utilized, the patient may meet with an anesthesiologist for a full discussion of anesthetic options. It is recommended that patients are not promised any particular anesthetic type in advance, the anesthesiologist assigned to the case should be free to make that decision. In general, older patients with complex medical

CASE STUDY: PART 2

Considering Mr. Smith, he has a high risk of aspiration due to his Parkinson's disease. In addition, it is not clear how cooperative he will be with only sedation. The plan

for his ERCP should include the strong possibility of a general anesthesia with intubation. A general anesthesia will definitely be required for either his subsequent laparoscopic cholecystectomy or exploratory laparotomy and biliary dissection.

TABLE 25.1 Preoperative assessment alternatives and the elderly patient

	Advantages	Disadvantages
Preoperative assessment clinic	Reduction lab testing Reduction consultations Improved OR efficiency Decrease in OR cancelations and delays Anesthesiology input Specific NPO instructions	Expensive Cost of administrative clerical staff Requires allocated hospital space and support Primary MD maybe unaware of surgery Second trip to hospital
Primary physician visit “clearance”	Patient known to MD Primary MD involved for postoperative care No second hospital visit Good for simple surgeries	More laboratory testing No anesthesia discussion – especially detrimental in complex high risk cases No instructions for surgery Scheduling dependent on MD office availability Paperwork/clearance at remote site
Telephone interview	Convenient for patient Preoperative instructions including NPO	No anesthesia input Difficult to reach patients at work Language barriers Advanced age usually an exclusion factor

Surveys

May be added to above visits/calls

Preoperative health survey	Simple No extra visits	No instructions No anesthesia input No time to optimize medical conditions identified Mail return unreliable
Internet health quiz	Simple Remote access to information Algorithm for laboratory testing	No instructions No anesthesia input

histories are best seen prior to surgery to ensure that an appropriate work-up to optimize the patient’s condition has been completed [23, 24].

Preoperative Assessment

The aims of the preoperative assessment are to prepare the patient for anesthesia, obtain consent for the anesthesia, and ensure that the patient is adequately prepared for their procedure. Chronological age may not accurately reflect a patient’s physiological age, and a significant goal of the preoperative assessment is to estimate the patient’s physiologic reserve function. The physiologic age reflects the combined impact of aging and comorbid conditions, and is more likely to be predictive of outcome than age in years alone (Table 25.2).

The assessment can begin with a general assessment of the geriatric patient: Does the patient look their age? Is there evidence of cognitive dysfunction or significant disability? Does the patient’s caregiver answer all the questions? Patients with preexisting cognitive dysfunction are at higher risk from postoperative delirium and the anesthetic plan may need to

TABLE 25.2 The goals of the preoperative assessment

Obtain a thorough history and physical examination
Provide a risk assessment
Recognize high risk patients
Implement risk reduction strategies
Perform selected laboratory and cardiac testing
Improve control of perioperative diseases
Formulate and discuss the anesthetic plan
Obtain informed consent
Formulate a post operative plan
Reduce anxiety through education

be altered to accommodate the patient with cognitive or other disabilities.

Functional status should be assessed during the preoperative interview, and this is easily achieved using a simple scale as outlined in Table 25.3. Patients with reduced functional status (<4 METS) have an increased risk of cardiac morbidity and poor outcome following noncardiac surgery [25]. The anesthesiologist’s physical examination should be focused including an airway examination and examination of the cardiopulmonary system and other relevant organs.

TABLE 25.3 Functional assessment scale

1 MET	Can you take care of yourself? Eat, dress, use the toilet? Walk indoors around the house Walk 1–2 blocks on level ground at 2–3 mph? Do light housework? Can you take care of yourself?
4 METS	Climb a flight of stairs? Carry groceries? Walk on level ground at 4 mph? Run a short distance Do heavy housework? Do moderate sports – golf, dance, doubles tennis? Climb a flight of stairs? Carry groceries?
10 METS	Play competitive sports? Singles tennis? Ski?

Laboratory and Other Testing

Large-scale preoperative laboratory testing in healthy individuals leads to an increase in false positive results and inappropriate work-ups [26, 27]. Several studies have demonstrated that preoperative screening laboratory testing rarely provides new information that would not otherwise have been obtained from a thorough history and physical examination [26, 28]. Anesthesiologists tend to order fewer laboratory tests compared with outside referral physicians and some have found financial benefit derived from anesthesiology-directed laboratory testing vs. other providers. Except for concurrence on the complete blood count, anesthesiologists generally order fewer tests compared with surgeons [29–31]. The data refers to laboratory testing that is being performed to allow safe administration of anesthesia, in all patients, there may be other reasons why additional laboratory testing is requested by a surgeon or primary care physician in the general course of a patient's disease work-up.

A Hemoglobin or hematocrit. It is indicated when the surgery is associated with significant blood loss potential or the patient has systemic disease and may be anemic. The American Society of Anesthesiologists (ASA) practice advisory on preoperative evaluation concluded that age alone was not an indication for a routine blood count before surgery [32]. However, anemia is more common in the elderly and may be poorly tolerated in patients with cardiac disease. In elderly patients undergoing significant surgery, it is not unreasonable to request a baseline hematocrit.

Coagulation studies. These studies are indicated in symptomatic patients with significant liver disease or known coagulopathic conditions. Baseline studies may also be valuable in patients who are undergoing major surgery with a high risk of blood loss that are likely to need blood products during the case. Patients on anticoagulants or those for whom

postoperative anticoagulation is planned generally should have baseline studies. The other group of patients for whom coagulation profiles should be considered is those who will have an epidural or spinal placed [22].

Electrolytes and blood chemistry. Healthy elderly ambulatory patients or those with mild-to-moderate systemic disease such as hypertension do not need routine electrolyte levels drawn [29]. Patients scheduled for extensive procedures such as an exploratory laparotomy or a major vascular procedure should have baseline blood chemistries, as renal insufficiency occurs in advanced and hyponatremia is more common in geriatric patients. Although not routinely ordered, reduced albumin in frail older patients is a marker of increased risk of mortality and morbidity [33].

Electrocardiograms. An ECG should be done in patients with cardiac risk factors and a history of cardiac disease. Occult cardiac disease is extremely common in older patients and most institutions recommend age-related screening with ECGs. A common requirement is a preoperative ECG in males over the age of 45 years and females over 55 years. A prior ECG within 6 months of the surgery in the absence of ongoing symptoms or changes in cardiac status is frequently acceptable [32, 34, 35].

Consultations

Elderly patients have a very high incidence of cardiac conditions. Ischemic heart disease increases almost exponentially with age and is frequently under diagnosed. It is not surprising that cardiac complications are the most significant following surgery and anesthesia. However, the decision to obtain a cardiology work-up or consultation prior to surgery will depend on the severity of the patient's disease and the onset of symptoms. Scheduled surgery per se is not an indication for a cardiac work-up [24, 36].

Chest radiographs. These are not recommended preoperatively unless indicated by the history or dictated by the underlying diagnosis. Widespread routine chest X-rays led to significant morbidity in larger studies secondary to unnecessary follow-up on false positive examinations and unexpected findings were rare [27, 32, 37].

Institutionalized Patients

The preoperative assessment of institutionalized elderly patients can be especially challenging. It may be difficult or impractical to require these patients to come to a hospital or

CASE STUDY: PART 3

The preoperative assessment of Mr. Smith will provide critical information for the anesthesiologist. A visit to a preoperative clinic is advisable, and in addition to a general assessment for his Parkinson's disease, a brief cognitive assessment will be valuable to establish a baseline prior to any surgery. Mr. Smith has a very high risk of developing postoperative delirium and he and his family should be warned. In view of his potential for a more significant surgery following his ERCP, Mr. Smith should have baseline laboratory testing done including a blood count, electrolytes, and an ECG. From the current history, which does not indicate any new chest pain or shortness of breath, further cardiac testing is not warranted and a chest X-ray is not needed unless his chest exam reveals abnormalities. Mr. Smith's overall poor functional status is a significant concern if he is

required to ultimately undergo a major surgery. A baseline albumin may provide an indication of his nutritional status and if reduced, it may be associated with increased risk of mortality (see physical classification Table 25.4).

TABLE 25.4 ASA physical status classes

Class 1.	A healthy patient (no physiologic, physical or psychological abnormalities)
Class 2.	A patient with a mild systemic disease without limitation of daily activities
Class 3.	A patient with severe systemic disease that limits activity but is not incapacitating
Class 4.	A patient with incapacitating systemic disease that is a constant threat to life
Class 5.	A moribund patient not expected to survive 24 h with or without the operation
Class 6.	A brain dead patient whose organs are being removed for donor purposes

Add "E" to denote emergency surgery

faculty for a special preoperative visit. Frequently, a remote preoperative screen can be conducted. The facility physician can be asked to provide a brief history and physical and the results of any laboratory testing done recently. The preoperative examination can be completed the day of the surgery. Arrangements for consent from a legal guardian or family member should be made in advance to prevent delays on the day of surgery.

After the completion of the preoperative assessment the anesthesiologist assigns a physical status classification (ASA 1–6). The physical status classification reflects the patient's condition and underlying disease complexity, it is independent of the patient's age. A higher ASA classification carries independent diagnoses that lead to increased risk from surgery. In general, risk for anesthesia increases in patients with more advanced ASA classification. An E is added to the physical classification to designate a patient for whom a surgery is emergent. The ASA physical classification system is a useful way to communicate about patients and is used by many health care providers outside of anesthesia.

NPO Status (Table 25.5)

The ASA has published guidelines for liquid and solid foods prior to the administration of an anesthetic. For the older patient, it is important that these instructions are written and provided to both the caretaker and the patient when relevant.

TABLE 25.5 ASA guidelines for NPO status preoperatively

Substance	Minimum fasting period (h)
Clear liquids ^a	2
Breast milk	4
Infant formula	6
Non human milk	6
Light meal	6
Fried or fatty foods, meat	8

^aClear liquids include: water, fruit juices without pulp, clear tea, carbonated beverages, and black coffee

Medications

Elderly patients are on average taking three medications and patients must receive clear instructions on which medications should be held or continued on the day of surgery. In many instances, it is recommended that patients bring all their medications on the day of preoperative visit and/or provide a complete list of all medications in advance of the procedure.

As a general rule, most medications should be continued until the morning of surgery, especially cardiac and antihypertensive medications. Angiotension converting enzyme inhibitors (ACEIs) and angiotension receptor blockers (ARBs) have been associated with profound and prolonged hypotension following the induction of anesthesia and provided they are not being administered for congestive heart failure and these should be held prior to surgery. Similarly, diuretics can be continued in the presence of significant fluid

CASE STUDY: PART 4

Mr. Smith is an ASA 3 patient, his Parkinson's disease is significantly altering his daily life and appears progressive. His medication situation is particularly challenging to prevent acute worsening of his Parkinson's symptoms and he should be instructed to continue his Levo dopa until 3 h prior to surgery. He can take his other usual medications on the morning of surgery. He should be instructed to bring his medications with him to the holding area if his surgery is delayed; he should

continue his scheduled anti-Parkinson's medication. Given his complex medications, all instructions should be clearly written for him (Table 25.6).

TABLE 25.6 Preoperative instructions

Instructions should be clearly written in simple language
Instructions should be specific avoiding vague or ambiguous terms such as "maybe"
Directions to exact location in the hospital
Recommendations on clothing and belongings
NPO recommendations – written down
Number to call with change in health

overload; however, for the most part thiazide diuretics can be held for patient convenience. As discussed above, anticoagulation and antiplatelet medications will restrict the anesthesia choices and the decision to hold anticoagulant and antiplatelet medications should be made by the surgeon. Whenever a change in these medications is planned, the patient's primary care physician should be informed and included in the decision. One-third of older patients have chronic pain and in these instances it is important to encourage patients to continue their analgesics until the day of surgery. The patient's tolerance to pain medication may require intraoperative adjustment of the anesthetic itself [38].

Special Considerations

Cardiac Adverse Events

In general, the risk of a cardiac event following a noncardiac surgery is 1–2%, and advanced age (over 65 years) is associated with an almost 2½-fold increase in risk of a significant event. Other risk factors described recently are consistent with those mentioned above: the presence of congestive heart failure (fourfold increase), emergency surgery (twofold), the need for a blood transfusion (almost threefold), and longer surgery (twofold increase). Past history of cardiac intervention, cerebrovascular, and hypertension disease was also significant (almost twofold increase) risk factors for an adverse event. The intraoperative hemodynamic course is probably relevant and this study suggested that episodes of hypotension and tachycardia increased chance of a postoperative event in high risk patients [3, 4, 6].

Pulmonary Disease

Five to fifteen percent of elderly patients undergoing surgery develop a postoperative pulmonary complication. The presence of chronic obstructive pulmonary disease (COPD) can increase the postoperative mortality rate by tenfold. Risk factors for postoperative pulmonary complications include severe COPD, advanced age, and undergoing high risk procedures, such as upper abdominal or intrathoracic surgery [8, 39]. The increased risk during surgery in the presence of COPD relates to a combination of factors related to the patient, the surgery, and the anesthesia. Patients may exhibit increased sensitivity to medications through alterations in central respiratory control and changes in sensitivity to hypoxemia and hypercapnia; in addition, changes in respiratory mechanics that occur during mechanical ventilation can persist postoperatively. These detrimental effects may be exaggerated by residual muscle paralysis and the development of atelectasis and consequent hypoxemia. The trauma induced by surgical incision can further limit optimal respiration and pulmonary mechanics. In these older patients, full reversal of muscle relaxant and adequate analgesia is particularly important to overcome the increased work of breathing associated with advanced age from stiffening of the chest wall and reduced elasticity of the lung tissues.

Elderly patient's exhibit reduced threshold for apnea following narcotic administration and a blunting of the responsiveness to rising carbon dioxide levels. These changes leave the geriatric patient susceptible to periods of apnea, desaturation, and respiratory arrest. Opioid sparing techniques using peripheral nerve blockade or alternate analgesic such as NSAIDs can be useful if they are compatible with the surgery [40].

Regional anesthesia may obviate the need to manipulate the airway and this may offer advantages in patients with severely reactive airways disease. However, caution is needed as COPD patients with significant disease may not tolerate the associated reduction in respiratory muscle function with a spinal or epidural anesthetic, especially if they are dependent on active expiration or have excessive secretions requiring frequent coughing [41]. These compromised patients may experience a significant respiratory depression with a neuraxial block. Intrascapular nerve blocks may be associated with diaphragmatic paralysis secondary to phrenic nerve paresis and should not be used in patients with significant lung disease.

Renal and Metabolic

Normal aging is associated with a steady decline in baseline renal function and the choice of anesthesia administered to a geriatric patient should take into account the potential reduction in baseline renal function. Postoperative renal failure is rare but associated with a high mortality rate, accounting for one-fifth of postoperative deaths in elderly patients [42]. Associated risk factors for acute postoperative renal failure include advanced age over 65 years, type 1 diabetes mellitus, preexisting renal insufficiency, major vascular surgery, and recent exposure to nephrotoxins including NSAIDs, radio contrast dye, and amino glycoside antibiotics. The postoperative renal failure is usually secondary to an ATN developing as a result of hypotension, hypovolemia, and/or dehydration.

Nervous System Assessment

In addition to predictable anatomical changes in the central nervous system, there is an increase in disorders of cognitive function with an increase in dementia, memory loss, and degenerative diseases such as Parkinson's disease. Anatomical changes include gradual atrophy of the brain, reduction in gray cells, and widening of the ventricles. Alterations in neurotransmitter levels and neuronal circuits lead to changes in memory and pharmacodynamic changes resulting in an increased sensitivity to certain medications such as midazolam and some of the opioids [43]. Alterations in pain perception result from age-related changes in the peripheral nervous system, such as a reduction in myelinated fibers. In general, elderly patient's exhibit increased pain thresholds, and this may contribute to the delay in presentation of painful conditions such as peritonitis.

Neurodegenerative disorders increase with age and may influence the administration of anesthesia. One of the most common is Parkinson's disease, which afflicts 3% of elderly persons over 65 years of age. Parkinson's disease results from a loss of dopaminergic cells in the ventrolateral aspect of the substantia nigra of the basal ganglia. Characteristic symptoms include resting tremor, bradykinesia, cogwheel rigidity, postural instability, and a shuffling gait. The disease is also associated with autonomic dysfunction and orthostatic hypotension is common and frequently exacerbated by medication such as L-DOPA and other treatments. Patients with Parkinson's disease have increased oral secretions and are at increased risk of aspiration and laryngospasm during anesthesia. Orthostatic hypotension may be profound and medications that induce vasodilatation such as propofol should be administered cautiously. Parkinson's medications should be continued until the time of surgery. L-DOPA (sinemet), the mainstay of treatment is only available orally with a relatively short half life of approximately 3 h. Unfortunately, Parkinson's patients have a very high incidence of postoperative confusion and delirium that may be difficult to treat. When possible, a regional anesthesia can be advantageous or a combined general regional technique that can lead to improved postoperative pain control. When treating Parkinson's patients, it is important to avoid agents that may exacerbate the symptoms such as the phenothiazines and metoclopramide.

Postoperative Cognitive Disorders

Postoperative delirium and postoperative cognitive dysfunction (POCD) are common complications in the elderly population [43–45]. Delirium is an acute confusional state, usually appearing 1–3 days after surgery; it may persist for weeks to months in afflicted patients. The etiology is multifactorial including acute medical conditions such as sepsis, hypoxemia, urinary tract infections, and alcohol withdrawal. Certain medications including meperidine and medications with anticholinergic effects such as diphenhydramine and scopolamine are highly associated with delirium, and should be avoided in the elderly patient [46]. Patients with preexisting dementia, baseline cognitive difficulties and depression carry a high risk of developing delirium postoperatively. Delirium is associated with an increase in morbidity and mortality and also an increase in the length of stay and dependent living situations. When pharmacological intervention is required, low dose haloperidol starting at 0.25–0.5 mg intravenously may be administered for treatment for agitation. Midazolam has been associated with a paradoxical excitation in elderly patients with delirium and, in general, it is not

recommended; similarly long acting benzodiazepines can accumulate in the older patient and should be avoided.

In contrast to delirium, POCD refers to a specific cognitive disorder generally recognized in the postoperative period and is ultimately diagnosed through neuropsychological testing. Studies have demonstrated that almost 10% of elderly patients receiving a general anesthesia had some cognitive dysfunction 3 months after surgery. The cause of POCD is unknown, and multiple studies have looked at the difference in prevalence between general and regional techniques [44, 47, 48]. To date there is no convincing evidence that regional anesthesia offers any cognitive advantages over general anesthesia.

The Intraoperative Course

Monitoring

Basic monitoring standards for all patients, including the elderly, undergoing anesthesia have been established by the ASA. The first standard requires the continuous presence of qualified anesthesia personnel in the operating room. The second standard requires a continuous assessment of the patient's oxygenation, ventilation, circulation, and temperature. Although these standards are not different for older patients, aging patients may have associated comorbid conditions that influence monitoring choices.

In most instances, oxygenation is continuously assessed using variable pitch pulse tone pulse oximetry. As a fall in oxygenation may actually be a late indicator of hypoventilation, ventilation should be monitored using end tidal carbon dioxide to provide early identification of hypoventilation and possible hypercapnia. In addition to continuous ECG monitoring, the ASA requires BP assessment at least every 5 min. The decision to use additional invasive monitoring depends on the patient and the procedure. In the older patient labile blood pressure is commonly encountered [49], and a low threshold for continuous arterial blood pressure monitoring should be maintained. An arterial line can assist in both the precise titration of medications and access for blood sampling during the case.

Aging cardiac changes render the older patient more susceptible to congestive heart failure in the event of excessive fluid administration or significant shifts in volume [3, 50]. Central monitoring of the central venous pressure or pulmonary artery catheter may be useful to manage the fluid administration during a case. Interpretation of the central pressure requires a careful consideration of the aging patients underlying physiologic condition. For instance, an older hypertensive patient with a "normal" CVP may actually be

modestly hypovolemic. In general, elderly patients benefit from higher preloads and are very dependent on the atrial contraction during diastole. There is significant controversy over the utility of the PA catheter as a tool to measure volume status and guide fluid resuscitation and the role of the transesophageal echocardiogram is yet to be established.

The Surgery

Laparoscopic surgery carries significant advantages in the elderly patient including a more rapid recovery, less pain following surgery, and reduced fluid requirements [51–53]. Laparoscopic cholecystectomy has been associated with improved postoperative pulmonary function vs. open cholecystectomy, and that may be advantageous for the frail elder with reduced pulmonary reserve. General anesthesia with controlled ventilation is preferred to allow adequate abdominal insufflation. During the surgery absorption of CO₂ can result in hypercapnia and acidosis. The rise in intra-abdominal pressure accompanying the insufflation can lead to reduced venous return, increased peripheral resistance, and intrathoracic pressure leading to a diminished cardiac output and hypotension. In the frail elderly patient with reduced cardiac function these cardiovascular challenges can be significant, requiring increased monitoring, and adjustment of the anesthetic medications to optimize cardiac function.

Medications

A decrease in total body water and increase in adipose can lead to a change in distribution of medications. Specifically, the water soluble agents such as most induction agents are distributed in a smaller initial compartment, resulting in increased exposure of receptors and potentially augmented impact. In contrast, lipid soluble medications may be deposited in larger fat stores leading to prolonged and unpredictable recovery. Age-related hepatic changes and reduction in hepatic blood flow can result in a delay in the metabolism of certain drugs such as lidocaine [54]. Although albumin levels are usually preserved in health, they may be diminished in older patients with chronic disease, in general, the quality of protein binding may be reduced and these combined changes can lead to increased free fractions of tightly bound medication such as warfarin. For certain drugs such as the benzodiazepines and opioids, [55–57] age related increased sensitivity seems more related to changes in the pharmacodynamic and sensitivity of the receptors as opposed to an alteration in the distribution or clearance of the medications. In the next section, the impact of aging on individual agents will be considered [40].

Anxiolytics

Benzodiazepines provide anxiolysis and amnesia. *Diazepam* and *lorazepam* are long acting anxiolytics compared with midazolam, and their administration has been associated with postoperative delirium. In general, these longer acting drugs should be avoided in frail geriatric patients, although lorazepam may be indicated in certain circumstances such as alcohol withdrawal [56, 58].

Midazolam is a water soluble benzodiazepine generally given intravenously as an anxiolytic prior to the induction of anesthesia or as an adjunct to sedation; it may even be used as the sole anesthetic agent for very brief procedures. It is metabolized via hepatic hydroxylation to its major metabolite 1-hydroxymidazolam that is subsequently conjugated and excreted. Pharmacodynamic changes with aging result in increased sensitivity to midazolam and the starting dose should be reduced to 0.5–1 mg, and increased slowly if needed [56]. There are very limited hemodynamic effects, although hypotension has been observed when midazolam is combined with fentanyl. In general, in older patients, it is advantageous to avoid midazolam altogether, and if needed in anxious patients the initial and subsequent doses should be reduced.

Induction Agents

Propofol or 2,6 di-isopropyl phenol is now the most commonly used intravenous anesthesia agent inside the operating room and also for procedures in remote locations. Propofol provides excellent hypnosis, a rapid recovery, and some protection against nausea and vomiting. Propofol also causes significant vasodilatation and potential hypotension that is exaggerated in older patients especially in the presence of hypovolemia. In general, older patients require less drug (20–60% reduction) to achieve the same level of anesthesia. The initial propofol dose in the older patient is distributed in a smaller central volume of distribution, and the peak concentration may be more pronounced and prolonged compared with a young patient in whom the redistribution occurs rapidly after the bolus dose. This translates to an increased sensitivity of older patients to smaller bolus doses and a delay to peak effect, including delayed peripheral vasodilatation. Thus in the elderly patients, it is important to reduce the bolus and increase the interval between repeated doses. Administration of even a small dose of propofol may result in respiratory arrest and for that reason it has been recommended that its use is limited to anesthesiologists or providers trained in basic airway management and resuscitation [40, 59].

Etomidate is another induction agent frequently used to induce anesthesia, especially in elderly patients, trauma victims, or emergency circumstances. In contrast to propofol, etomidate has almost no cardiovascular side effects and is preferred in the patient with unstable hemodynamics and poor cardiac reserve. In older patients with significant cardiac disease or unknown physiological reserve etomidate can be advantageous. In general, the induction dose should be reduced 25–50% in elderly patients.

Ketamine is a phencyclidine derivative, NMDA blocker that can produce dissociative anesthesia. Advantages of ketamine include absence of respiratory depression and analgesic properties. In the elderly patient, small doses of ketamine can reduce opioid requirements and offset the hypotensive effects of higher propofol doses during an MAC anesthetic. Its use has been associated with bad dreams and agitation in younger patients, but this may be less of a problem in the older patient when administered with low dose benzodiazepines or propofol. Preemptive low dose ketamine infusions in the postoperative period have been used to treat patients with significant pain that is resistant to traditional medications. The opioid sparing effects of ketamine can be very useful in the older compromised patient. At these lower doses, there has been no evidence of any increase in cognitive problems.

Opioids

Elderly patient's exhibit increased sensitivity to central respiratory effects of opioid medications, and this may lead to an increase in the risk of unrecognized postoperative hypoventilation and apnea. In general, all initial opioid doses should be reduced in older patients and careful monitoring of both oxygenation and ventilation is required [60, 61].

Fentanyl is a synthetic opioid, about 50–100 times as potent as morphine but not associated with histamine release. It is lipid soluble and has a rapid onset with little effect hemodynamically and relatively short duration. During induction of anesthesia, fentanyl has been shown to block the adverse hemodynamic effects of intubation [55, 62].

Remifentanyl is another highly potent synthetic opioid that is becoming increasingly popular for short stimulating procedures and sedation, especially in elderly patients in whom significant perturbations of the cardiovascular system can be deleterious. Remifentanyl is metabolized by rapid hydrolysis through esterases in blood and tissue, and is suitable for infusions. In older patients, the initial dose and infusion should be reduced by about 33%. When larger doses are administered bradycardia (that can be profound) and respiratory depression may occur and limit remifentanyl's use [57].

Morphine is a popular opioid for postoperative pain [38, 61], frequently administered via a PCA [63]. Older patients show an increased sensitivity, decreased clearance, and in the presence of renal failure, the accumulation of metabolites can occur. Several studies have suggested that the initial postoperative requirements of morphine are similar in old and young patients but the maintenance doses should be reduced [64].

Meperidine is a short acting analgesic, which is *not* recommended in elderly patients. It has been associated with delirium and the accumulation of the metabolite normeperidine that can be neuroexcitatory and lead to seizures.

Neuromuscular Blocking Agents

Muscle relaxation during surgery is critical for exposure and to prevent patient movement, and is generally achieved through the administration of nondepolarizing drugs such as vecuronium and cisatracurium. These drugs are competitive antagonists of acetylcholine at the nicotinic receptor and act at the postjunctional membrane of the neuromuscular junction. The most important anesthetic concern for the elderly patients is the complete reversal of these agents at the end of the surgery. Even a small amount of residual drug effect could result in significant respiratory impairment in the recovery room. For this reason, the longer acting muscle relaxant pancuronium should be avoided altogether in older patients.

Inhalational Agents

General anesthesia usually includes the addition of a volatile anesthetic agent; the most popular agents include sevoflurane, desflurane, and isoflurane. It is well documented that older patients require less volatile anesthetic to attain a suitable depth of anesthesia. The amount of inhalational agent decreases linearly with aging so by age of 80 years a patient requires only about one-third that needed in a 20-year-old patient [65].

Other

Dexmetomidine is an alpha 2 agonist, similar to clonidine, that is approved for sedation and has gained popularity as a sedative and anesthetic adjunct. Dexmetomidine has powerful analgesic properties and can be used in small bolus or as a continuous infusion. In addition to providing sedation

and analgesia, dexmetomidine is also a hemodynamic depressant and its administration can cause significant hypotension and bradycardia. In general, the cardiovascular side effects limits the use in older patients with cardiac disease, but in certain cases such as plastics, the hypotensive effect may be valuable; offsetting the hypertensive effects of infiltration of local anesthesia that includes epinephrine [59]. The full extent of dexmetomidine's role in postoperative analgesia has yet to be established.

Acetaminophen is frequently overlooked as a useful opioid sparing analgesic in the immediate post-recovery phase. For the older patient without liver impairment, scheduled dosing is recommended and frequently combined with a multimodal approach that includes low doses of NSAIDs or opioids [66].

Ketorolac is a potent NSAID available for intravenous administration. It can be a useful adjunct for pain relief and result in significant opioid sparing. Ketorolac, like all NSAIDs, must be used cautiously in elderly patients, especially in patients with dehydration or renal failure, a history of gastrointestinal bleeding, or anticoagulant or antiplatelet therapy. Postoperatively ketorolac should be administered for a short duration less than 5 days, and in older patients the dose should be reduced 50% starting at 15 mg and not exceeding total 60 mg/24 h.

Gabapentin is an anticonvulsant that has strong analgesic effects [67]. The mechanism of action of gabapentin is not fully known, but probably involves the neurotransmitter gamma amino butyric acid (GABA) system. Single preoperative doses of gabapentin have been found to reduce pain intensity and opioid use in the first 24 h postoperatively. In addition, gabapentin administration is associated with a reduced incidence of postoperative nausea and vomiting, constipation, and urinary retention, although an increase in sedation has been noted, especially at higher doses.

Ambulatory Surgery

Older age is not a contraindication to ambulatory surgery. Indeed some studies have suggested elderly patients may be more able to be fast tracked through the recovery area and discharged, possibly due to a reduction in medications and a lighter level of sedation administered compared with young healthy patients [51]. In general, there is limited data on outcomes in older patients following surgery, however, there is the suggestion that intraoperative arrhythmias and hypertension are more common in older patients vs. younger and that the incidence of postoperative nausea may be diminished with age [7, 9]. Postoperative urinary retention

CASE STUDY: PART 5

After discussion among the anesthesiologist, the endoscopist, and the patient, a general anesthesia is agreed upon. Due to his high risk from aspiration and increased risk of significant complications in the event of an aspiration, the anesthesiologist proceeds with a general anesthesia and endotracheal intubation. The endoscopist is able to dilate his biliary duct at the time of the ERCP. During the procedure, Mr. Smith receives several boluses of phenylephrine for low blood pressure, but overall is hemodynamically stable and extubated at the end of the

case. Mr. Smith's Parkinson symptoms worsen temporarily and mobility is a significant problem. After reinstating his Parkinson medications, Mr. Smith is hospitalized for 4 days following the procedure. He is ultimately discharged home and his family notes that his memory appears slightly worse, for instance, he has more trouble with word finding, names, and dates than he did prior to the surgery, but he does not appear delirious. This appears to resolve over the next few months. His abdominal pain is better following the dilation and the patient and the family decline a laparoscopic cholecystectomy to remove remaining gall stones.

can lead to significant morbidity, for instance in older males following hernia repair. In general, urinary retention has been associated with the administration of opioids, regional anesthesia (spinal or epidural anesthetics), male sex, older age, and anticholinergic medications.

Temperature Control

In general, exposure of a nonanesthetized patient to a cold environment such as the operating room will result in activation of receptors peripherally and centrally that lead to vasoconstriction and an increase in heat production and basal metabolic rate. Usually the core temperature is maintained a few degrees higher than the peripheral tissues through tonic vasoconstriction. Unfortunately, normal aging results in the deterioration in thermoregulation both peripherally and centrally leading to an increased risk of hypothermia. The age-related physiologic changes blunt vasoconstriction and heat production, shivering is less effective and induced at lower temperatures compared with younger subjects. Furthermore, older patients have less lean body mass and lower basal metabolic rates at the outset, and they lose heat more quickly compared with younger patients.

The issues with temperature regulation are further exacerbated in the anesthetized elderly patient and the ability to withstand cold temperatures is inhibited in the presence of all anesthetic agents. Disordered temperature regulation has been observed following both general and regional anesthetics. The risks of hypothermia to an older patient are substantial and include myocardial ischemia, surgical infection, coagulopathy, bleeding, delayed drug metabolism, and arousal [68].

Since older patients may not respond appropriately to a drop in core temperature, the anesthetic plan should include the ability to actively warm older patients in and outside

of the operating room. Intraoperative heat loss may be minimized by prewarming surfaces and maintain room temperatures high until the patient is fully draped. Warmed forced air blankets have been associated with improved maintenance of temperature.

Summary

In summary, "choosing the best anesthetic" for the geriatric patient requires meticulous attention to detail, knowledge of the physiologic changes that can be expected to occur during aging and an understanding of common comorbidities found in the elderly population. The risk of anesthesia and surgery is increased in frail older patients and anesthetics should be designed to avoid side effects and eliminate the occurrence of even small complications.

Chapter 26

Acute Postoperative Pain Management in Elderly Patients

Jack M. Berger

In their review article, Brennan, Carr, and Cousins conclude that “because pain management is the subject of many initiatives within the disciplines of medicine, ethics, and law, we are at an ‘inflection point’ in which unreasonable failure to treat pain is viewed worldwide as poor medicine, unethical practice, and an abrogation of a fundamental human right” [1]. In coming to this conclusion these authors review much of the medical ethics literature which taken together is summarized in their statement that “...a virtue ethics approach to bioethics would also yield a clear response to patient’s pain. A virtuous doctor would place the recognition, monitoring, and treatment of pain as a high priority. To this end, a virtuous doctor would inquire regularly about pain, respond appropriately, and refer wisely if unable to control it” [1]. This of course became mandated by the Joint Commission for the Accreditation of Healthcare Organizations (JCAHO) in 2000–2002, and the declaration by the US Congress calling 2001–2010 the “Decade of Pain Control and Research” [1].

Brennan, Carr, and Cousins go on to state that “if there is a clear ethical duty to relieve suffering or to act virtuously by doing so, then one may argue that from that duty springs a *right*. The moral right to pain management emerges from, and is directly founded upon, the duty of the doctor to act ethically. Classically, the holder of a *right* has the capacity to enforce a duty in a person or institution. That ‘other’ has a duty to fulfill that *right*. Indeed, a basic tenet of the *philosophy of rights* is that a *right* can only exist if there is a preexisting obligation. If one accepts that a health professional has an obligation, where appropriate, *to manage pain*, then the patient has a concomitant *right*, where appropriate, to receive such care” [1].

It is clear that this right to receive adequate pain management is not more evident than in the postoperative surgical patient (of any age). Yet fear of uncontrolled postsurgical pain continues to be among the primary concerns of many patients about to undergo surgery [2]. This fear is not

unfounded since, despite increasing research and clinical attention, many adult surgical patients continue to experience moderate to severe pain [3, 4]. Some improvement has been the result of the Joint Commission for the Accreditation of Healthcare Organizations (JAHCO) initiative for better pain management assessment and treatment as reported by Frasco et al., who demonstrated that there has been an increased use of morphine and prophylactic antiemetics in postanesthesia recovery rooms without a concomitant increase in length of stay in the recovery rooms [5].

The ill effects of inadequately treated pain in the acute postoperative period are summarized by Sinatra [6]. Acute pain leads to increased sympathetic activity which in turn leads to tachycardia and hypertension [6]. In elderly patients with coronary artery disease, the risk of myocardial infarction is therefore increased. Regional blood flow can be impaired which may increase the risk of postoperative infection. Fear and anxiety resulting from inadequate pain control can impair sleep and rehabilitation. Splinting and shallow breathing can lead to hypoxemia, atelectasis, and pneumonia [6] (Fig. 26.1).

Less well recognized is the fact that inadequate acute postsurgical pain management can lead to chronic pain syndromes [7, 8]. Without belaboring the point further, it is clear that these pathological effects of acute pain can lead to life threatening consequences and can also lead to chronic neuropathic pain states that can affect the future quality of the patient’s life through a constellation of maladaptive physical, psychological, family, and social consequences. These chronic neuropathic pain states can be regarded as true disease entities leading to dependence on medication, reduced mobility, loss of strength, disturbances of sleep, and social consequences that can result in dissolution of family relations [9].

Ginsberg writing in *Anesthesiology News*, February 2002 commenting on a Canadian study of postoperative pain management states “Pain interferes with out-patients’ activities, work, sleep, appetite, and concentration...Pain on the first day after surgery can be expected. But in the Canadian study, 7 days after surgery, 50% of patients had pain that interfered with activity or work, and 25% could not sleep because of

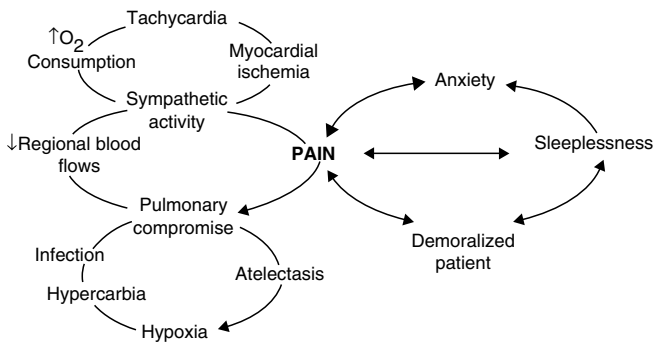

FIGURE 26.1 Harmful effects of unrelieved acute pain (reprinted from Sinatra [6], with permission from Elsevier).

pain” [10]. Ginsberg goes on to state that “Physicians as caregivers must take blame for inadequate pain treatment... in the Canadian study on day 1, 60% were given a mild opioid...by day 7, they only received tender loving care and chicken soup” [10].

These pathological consequences of uncontrolled pain may have greater consequences in the elderly population [11]. As the population ages, and surgical and anesthetic protocols become safer, the number of older patients undergoing surgery will grow [12]. By the year 2050, there will be a fourfold increase in the elderly population compared with only a 50% global population increase, and at that time 25% of the elderly will be over the age of 80 [13]. Elderly patients have surgery four times more frequently than the younger population [14].

However, there is little merit in considering the treatment of acute pain in the elderly population unless it differs from that provided to younger patients [13]. This begs the questions of whether elderly patients perceive pain differently from younger patients; are there changes in nociception that occur with aging, and do elderly patients process and respond to nociception differently?

Issues in treating pain in the elderly can therefore be broken down to:

- Sensitivity to painful stimuli – nociception
- Sensitivity of the central nervous system (CNS) (cognitive impairment)
- Pharmacodynamics/pharmacokinetics, organ function, and aging
 - Metabolism of drugs (liver function)
 - Excretion of drugs (renal function)
- Social concerns – addiction, pseudoaddiction, dependence, and tolerance
- Principles of titration of medications
- Role of interventional techniques and regional anesthetics

These issues will be addressed below.

Nociception Is Not Pain

Activity induced in the nociceptor and nociceptive pathways by a noxious stimulus is not “pain,” which is always a psychological state. Although we appreciate that pain most often has a proximate physical cause, especially acute pain, activity in nociceptor systems is not equivalent to the “experience of pain” [15]. The recognition that pain serves an important biological function related to survival raises the important question: to what extent do age-related changes in nociception impact on the capacity of the pain experience to fulfill an “interoceptive” function such as thirst, hunger, and thermoception that constitute sensory indexes of the health of the body? [16]

Assessment and intervention for pain in the elderly should therefore begin with the assumption that all neurophysiologic processes subserving nociception are intact [17]. In fact Gagliese and Melzack demonstrated that age did not affect the rating of pain by postsurgical patients [18]. That is to say, tissue injury produces the same intensity of stimulus in an elderly person as in a young person.

There are data to suggest, however, that some impairment of A δ fibers occurs with aging, and therefore impedes the early warning of tissue injury [16]. There are also data that suggest that widespread and substantial changes in structure, neurochemistry, and function occur in the dorsal horn of the spinal cord and CNS with aging [16].

Multiple studies report reductions in the descending inhibitory modulating systems for nociception in the elderly [16, 19]. Gibson and Ferrell conclude that the reduced efficacy of endogenous analgesic systems might be expected to result in a more severe pain experience following prolonged noxious stimulation [16]. It is also possible that the documented decline in afferent transmission pathways could be offset by a commensurate reduction in the endogenous inhibitory mechanisms of older persons, with a net result of little or no change in the perceptual pain experience [16]. They further conclude that any deficit in endogenous analgesic response (which is stimulus intensity dependent) will become critical, thereby making it more difficult for persons of advanced age to cope with severe or persistent clinical pain conditions [16].

Gibson reviewed the literature on pain threshold and tolerance in elderly patients [20]. Evidence suggests that as age advances, pain threshold increases, but pain tolerance decreases. The net effect may be that elderly patients experience acute surgical pain in the same way as younger patients. It is clear that if a surgeon was to make a skin incision with a scalpel in an elderly unanesthetized patient, then the patient would most certainly scream with pain. Yet silent myocardial infarctions are more common in the elderly, and the bowel must be more distended before the elderly sense pain, often delaying the diagnosis of such conditions as a bowel obstruction [20, 21].

With respect to the heart, the complete absence of “the perception of pain” that can occur in the presence of myocardial ischemia, arteriolar occlusion, myocarditis, early acute endocarditis, valvular ulceration, etc. makes it difficult and yet extremely important to assess for pain in elderly patients recovering from surgery [22].

But while there is controversy over whether the number and integrity of nociceptors decreases with age, *the clinical position that age dulls the “sense of pain” is untenable* [16]. It is the processing of the nociceptive information that may be altered in the elderly, and the elderly may be more sensitive to the side effects of medications that are used to treat pain. These observations thereby give the impression that the elderly are less sensitive to pain. But no physiologic changes in pain perception in the elderly have been demonstrated according to a five-state study by Cleeland [21]. This is supported by the observation that age does not affect the success of traditional interventions for the treatment of pain [17].

Again one would not assume that a surgical incision in an elderly patient will “hurt” less and therefore does not need to be treated. Likewise, anyone who has observed an elderly patient with acute herpes zoster certainly can attest to the excruciating pain that these unfortunate patients report. If given adequate preoperative teaching, assessed preoperatively for any impediments to the use of patient-controlled analgesia (PCA), e.g., dementia, elderly patients were successfully started on PCA in the postanesthesia care unit after general anesthesia once they were awake and responsive enough to receive a loading dose of opioids titrated to comfort [17].

Postoperative Central Nervous System Dysfunction

Postoperative CNS dysfunction is a common complication in elderly surgical patients. Rohan and his associates reported that the incidence of postoperative cognitive dysfunction (POCD) in elderly patients on the first postoperative day after minor surgery performed under general anesthesia (either propofol or sevoflurane) was 47% compared with 7% for matched nonsurgical hospitalized patients [23]. The acute confusional state, postoperative delirium (POD), is also common and can occur in as many as 60% of patients depending on preoperative risk factors and the type of surgery [16]. Preoperative confusion has been found to be a predictor of POD [23]. Pain can lead to delirium which can complicate pain assessment [24]. At the same time, the effect of pain in patients who already have preexisting cognitive deficits or dementia with loss of communication skills, or even loss of basic reflexes (e.g., gag), may disturb the assessment of critical functions for the expression of pain [13].

Little is known of the neurophysiological relationships between pain- and age-related degenerative brain diseases. It has been reported that beginning at the age of 40 and continuing into late old age, there is reduced expression in the human brain of genes involved in learning and memory and neuronal survival [25]. But the ability for plasticity and new dendritic synapses (i.e., memory) is preserved even into old age [26].

It would appear that elderly patients are more susceptible to confusion and cognitive impairment, but retain some capacity to recover. It is not uncommon for elderly patients to go through a period of delirium postoperatively, and although recovery from the acute confusional state may be complete, POCD may persist for far longer. This is manifested by the complaint from the family that the elderly patient just never seemed “quite the same” again after the operation.

Pharmacodynamics/Pharmacokinetics, Organ Function, and Aging

Fine recently reviewed the issues of pharmacological management of persistent pain in older patients [27]. In general, the *pharmacodynamic* actions of drugs (what the drug does to the patient) are unaffected in the normal aging process. The molecular action of morphine is the same in all animals, although dose requirements to produce the same effect may change with age, and the therapeutic window between intended effect and side or adverse effects may be narrowed in the elderly [28, 29]. However, since centrally acting drugs may interact with a preexisting disease state, care must be taken when treating pain in patients with CNS disease such as Parkinsonism, Alzheimer dementia, or stroke.

The pharmacokinetic actions of drugs (what the patient does to the drug), on the other hand, are frequently affected by aging processes and disease states. Pharmacokinetic changes due to physical aging may complicate medication management [30]. Woodhouse and Mathur studied the 24-h cumulative PCA opioid administration as a function of age, and found that morphine and fentanyl both showed the expected reduction in dose by 50% in the elderly, but meperidine was more variable due to a more complex pharmacology [31]. This 50% reduction in PCA opioid analgesia requirement in elderly surgical patients compared with younger patients was confirmed by other investigators [17]. The patients in this study showed comparable levels of pain relief and satisfaction with this technology. Opioids have been shown to produce a greater incidence of respiratory depression in the elderly, but the elderly seem to be less sensitive with respect to nausea and vomiting [32].

The most important generalization from physiologic studies of aging is that although the basal function of the

various organ systems may decline with aging *that the impact of this decline may not be functionally important at rest*. However, functional reserve and the ability to compensate for physiologic stress are reduced with aging [33]. With aging there is a decreased lean body mass and total body water and an increased proportion of body fat; these alter the volume of distribution and redistribution of drugs and alter their rates of clearance and elimination [33]. There is decreased liver mass and blood flow, which prolongs drug metabolism [34]. There is an age-related decrease in basal metabolic rate of the liver and a decline in albumin production of about 10% [35]. However, overall age-related changes in protein binding do not produce clinical difference in drug transport [36].

Drug biotransformation reactions can either lead to the inactivation of the parent compound, the conversion of an inactive compound to an active one, or result in metabolites that are even more active than the parent active drug [37]. Toxic metabolites are also produced that depend on rapid excretion to avoid harm to the organism. Drug biotransformation is usually an enzymatic process. Although most tissues have some enzymatic metabolism, most occurs in the liver. Patients with impaired liver function will therefore have altered metabolic capacity for drug elimination [37].

Renal blood flow is also compromised by aging; approximately 10% per decade of life after the age of 50 with a loss of renal parenchyma also [38]. Perioperative metabolic acidosis is relatively common in elderly patients who are less efficient in the renal excretion of acid [33]. Anesthetics, surgical stress, pain, sympathetic stimulation, and renal vasoconstrictive drugs may all compound subclinical renal insufficiency [33]. Cook and Rooke conclude that what is clear from a review of the physiologic changes with aging is that even the fit elderly patient's ability to compensate for perioperative stress is compromised. The cardiac, pulmonary, neurologic, and neuroendocrine changes that occur with aging make hypotension, low cardiac output, hypoxia, hypercarbia, and disordered fluid regulation more commonplace in the perioperative period. Furthermore, because baseline cardiac, pulmonary, renal, and neurologic function is typically adequate in the absence of acute challenges, it can be very difficult to predict the effect of perioperative stress on the older patient [33].

The kidney, lungs, GI tract, and skin all have some capacity to metabolize drugs. One of the major enzymatic systems for drug elimination with respect to analgesics and adjuvant analgesics is the cytochrome P450 system of enzymes. Drugs that are administered simultaneously and that are metabolized by the same enzyme system will compete for binding sites leading to altered blood levels [37].

The elderly have decreased renal function which increases the risk of nonsteroidal anti-inflammatory drug (NSAID) nephrotoxicity and accumulation of metabolites of drugs like meperidine. There is decreased plasma binding which

increases blood levels of active drugs, opioids, and NSAIDs [even the specific cyclooxygenase 2 (COX-2) inhibitors, such as celecoxib (Celebrex®)]. [39]

To understand the cascade of renal effects of NSAIDs, it is necessary to look at the beneficial effects of the enzyme cyclooxygenase 1 (COX-1) on converting arachidonic acid to various prostaglandins. These prostaglandins are necessary for maintaining good renal blood flow, adequate glomerular filtration rate, and homeostasis of potassium and sodium retention through appropriate secretions of renin, aldosterone, and antidiuretic hormone (ADH). When the conversion of arachidonic acid to prostaglandins is inhibited by NSAID inhibition of COX-1, then the kidney comes under risk and loses its ability to regulate salt and water balance. This detrimental effect of NSAIDs on the kidney is potentiated by renal hypoperfusion states [40]. All NSAIDs can result in renal insufficiency; and with the exception of salicylic acid and choline magnesium trisalicylate, for which the risk is less, they can inhibit platelet aggregation and cause dyspepsia and gastric ulceration [41].

In a Canadian study of nearly 650,000 elderly patients being prescribed either traditional NSAIDs with or without a PPI, acetaminophen with or without a PPI, or NSAID and acetaminophen together with or without a PPI, it was found that when given together, an NSAID plus acetaminophen increased the risk of GI bleeding even with the addition of a PPI [42]. *Elderly patients must therefore be warned about the combined use of NSAIDs and acetaminophen that can be purchased over-the-counter.*

NSAIDs have peripheral and central effects [43]. The "Constitutive" effects of the prostaglandins resulting from the actions of COX-1 also include protection of the stomach and intestinal lining, and preservation of platelet function [44]. The "Inducible" effects of COX-2 on conversion of arachidonic acid to prostaglandin E₂ leads to inflammation and pain. Blockade of the action of COX-2 reduces inflammation and pain without affecting the good effects of the prostaglandins that are COX-1 dependent [44, 45]. In the presence of inflammation, COX-2 can be found elevated in the CNS. This elevation is primarily due to upregulation of interleukin-1 β . The action of COX-2 leads to increased levels of prostaglandin E₂. *Antagonists of interleukin-1 β or blocking COX-2 both lead to antinociception* [46]. The common NSAIDs are nonspecific because they have variable effects on blockade of COX-1 and COX-2. The most common oral NSAIDs used in clinical practice are shown in Table 26.1.

There is a ceiling dose effect to all of the NSAIDs, above which no further analgesia is obtained; and although the dose may vary it usually falls below the maximal recommended dose of the manufacturer [47]. In general, for elderly patients, agents with short half-lives (e.g., ibuprofen) are most appropriate; for patients with a history of dyspepsia, ulcer disease,

TABLE 26.1 Common oral NSAIDs by chemical class

Propionic acids	Salicylates	Fenamates	Oxicams	Acidic acids	Benzene-acidic acid
Ibuprofen (Motrin®)	Aspirin	Meclofenamate sodium (Meclomen®)	Piroxicam (Feldene®)	Tolmetin sodium (Tolectin®/DS)	Diclofenac sodium (Voltaren®) (Voltaren® XR)
Naproxen (Naprosyn®)	Diflunisal (Dolobid®)			Indomethacin (Indocin®) (Indocin® SR)	
Fenoprofen calcium (Nalfon®)	Salicylsalicylic acid (Disalcid®)			Sulindac (Clinoril®)	
Ketoprofen (Orudis®)	Choline magnesium trisalicylate (Trilisate®)				

Source: Data from Insel [60]

or bleeding diatheses, either salicylsalicylic acid or choline magnesium trisalicylate should be used if a traditional NSAID is indicated [41]. NSAIDs can be combined with opioids to enhance analgesia.

Parenteral NSAIDs

Parenteral NSAIDs (e.g., ketorolac) are being used increasingly for postoperative pain as sole analgesic agents and in conjunction with opioids as opioid-sparing agents [48]. The efficacy of ketorolac, currently the only available parenteral NSAID in the USA, has been well established with 30 mg being equianalgesic with 10 mg of parenteral morphine [48]. When used together, there was a significant reduction of adverse side effects of opioids due to a significant reduction in morphine requirements. Intravenous ketorolac has been shown to reduce opioid requirements for knee and hip replacement surgery by 35–44%, and by 50–75% for thoracotomy and upper abdominal surgery [49, 50]. While ketorolac can reduce opioid requirements, it is not potent enough to be used as a sole analgesic after major surgery such as intra-abdominal surgery [51].

Peak analgesia from ketorolac is typically seen 1–2 h after administration, and the half-life is approximately 6 h, although it may be prolonged in patients with reduced renal function or in the elderly. The manufacturer's recommended dose for elderly individuals or those with renal insufficiency is 15 mg every 6 h following a 30 mg loading dose, and doses as low as 7.5 mg q6h have been found to significantly reduce opioid requirements in such painful surgeries as spinal fusion [52].

Ketorolac has a side-effect profile similar to those of other NSAIDs. There appears to be a significantly increased risk of gastrointestinal bleeding in the elderly, particularly with high doses and with the duration of use of more than 5 days [53–55]. But when used in doses of 15 mg or less q6h for less than 3 days, toxicity seems to be minimal.

Parecoxib is a specific COX-2 inhibitor that is available in Europe for intravenous administration. In a study of parecoxib 40 mg IV administered on induction of general anesthesia, and then q12h for 24 h; improved postoperative analgesia without increased bleeding for total hip arthroplasty was observed. It is well known that COX-2 is responsible for the synthesis of prostaglandins, which sensitizes the nociceptor and acts as excitatory neuromediators in the CNS and in the periphery [45, 56].

In another study, parecoxib was found to be an effective analgesic in acute postoperative pain at 20 or 40 mg over placebo given either intravenously or intramuscularly. The number needed to treat (NNT) for parecoxib 20 mg IV for at least 50% pain relief over 6 h was 3.0 and for 40 mg was 2.2 [57]. This compares favorably with other analgesics, e.g., morphine 10 mg where the NNT was 3, ibuprofen 400 mg where the NNT was 2.7, and acetaminophen 1,000 mg where the NNT was 4.6 [58]. Ibuprofen was actually more effective than morphine at these doses. In direct comparison of 4 mg of intravenous morphine with 30 mg of intravenous ketorolac or 20 mg of intravenous parecoxib, the times to re-medication were 3 h for morphine versus 5.5 h for both the ketorolac and parecoxib at the specified doses [59].

Symptomatic hepatic effects attributable to therapeutic use of most NSAIDs are extremely rare and usually mild except in over dosage of acetaminophen (not a true NSAID but used as a nonopioid analgesic) where fatal hepatic necrosis can occur. There is no clearly established explanation for why some compounds are more hepatotoxic than others. It is possible that some compounds undergo oxidation, probably to the phenylic ring structure, yielding highly reactive metabolites. Compounds that cause mild hepatic damage, such as diclofenac and bromfenac, may produce some reactive epoxides during biotransformation [60].

Impairment of wound healing has been attributed to the use of NSAIDs in the postoperative period. Studies have shown that there was no effect on epidermal wound healing with selective COX-2 and nonselective COX inhibitors in a

mouse model. The authors propose that this was probably due to redundant mechanisms for wound repair, most of which are not influenced by the COX-2 inhibitors [61].

Power indicates in his review article that the data is conflicting with respect to bone healing and nonunion when these agents are used in orthopedic procedures [62]; but much of the adverse data come from animal studies which may not have clinical significance in humans [63, 64]. Short-term use of COX-2-specific inhibitors may play an important role in preventive analgesia for postoperative pain management [56, 65].

It is important to remember that COX-2-specific inhibitors do not affect platelet aggregation [45, 56] and therefore may pose a risk for myocardial infarction (MI) if the patient is taken off aspirin therapy. Since low-dose aspirin is increasingly being used for cardioprotection, it is important to note that coadministration of selective COX-2 inhibitors does not alter this protective effect [66]. It has recently been shown that celecoxib (Celebrex™) does not appear to be associated with an increased risk of serious cardiovascular thromboembolic events and it is the only remaining oral COX-2 inhibitor available in the USA [67]. It could therefore be used as a preoperative medication and continued postoperatively through healing (e.g., <10 days) as part of a multimodal preventive analgesic regimen, if the patient is able to take oral medications and does not have an allergy to sulfa-containing medications.

Opioids

Opioids are the closest drugs we currently have to an ideal analgesic. They exhibit no ceiling effect and can produce profound analgesia by progressive dose escalation. They are the most effective agents for the relief of any type of acute pain because of their predictable dose-dependent response.

Opioids have no significant long-term organ toxicity and can be used for years [68]. Addiction is negligible when opioids are used in the context of medical care [69].

It is clinically useful to classify opioids as weak or strong depending on their relative efficacy. Weak opioids are used for moderate or less severe pain, and their efficacy is limited by an increased incidence of side effects at higher doses (e.g., nausea and constipation with codeine, CNS with propoxyphene) [41].

Morley introduced a concept of “Broad Spectrum Opioids” versus “Narrow Spectrum Opioids” [70]. The narrow spectrum opioids have analgesic actions limited to the Mu, Kappa, and Delta opioid receptors. For purposes of acute postoperative pain management, we are primarily dealing with Mu opioid agonists. The broad spectrum opioids find more usefulness in chronic pain and neuropathic pain with their Mu opioid action enhanced by actions also as *N-methyl d-aspartate (NMDA)* receptor antagonists. In addition, some have central neuromodulating effects through inhibition of reuptake of serotonin and norepinephrine similar to many antidepressants. Some broad spectrum opioids have all three properties (e.g., methadone). These actions of the different opioids in common use are summarized in Table 26.2.

When opioids are used in a fixed oral dose mixed with a nonopioid analgesic, their efficacy is limited by the maximal safe dose for the acetaminophen, aspirin, or NSAID component. A list of the common combination oral opioids is shown in Table 26.3.

Strong opioids are used for more severe pain. They have a wide therapeutic window and no ceiling effect, with higher doses producing an increasing level of analgesia. They are the agents of choice for parenteral administration. Patients experiencing moderate pain should be started on a weak opioid. Patients whose pain is severe or whose pain persists, despite the use of a weak opioid, should be administered a strong opioid [41].

TABLE 26.2 Broad spectrum versus narrow spectrum opioid analgesics

Broad spectrum opioids with NMDA receptor blocking action	Broad spectrum opioids which inhibit reuptake of serotonin and norepinephrine	Narrow spectrum opioids with analgesic action limited as Mu opioid agonist
Methadone	Methadone	Morphine
Ketobemidone	Levorphanol	Hydromorphone
Dextropropoxyphene	Dextromethorphan	Codeine
Dextromethorphan	D-Propoxyphene	Etorphine
Meperidine (pethidine)	Tramadol	Fentanyl
	Meperidine (Pethidine)	Sufentanil
		Oxycodone
		Hydrocodone
		Buprenorphine

TABLE 26.3 Combination opioids available for oral administration

Trade name [®]	Opioid component	Dose of opioid (mg)	Adjuvant drug	Dose of adjuvant (mg)	Tabs/caps/day
Advil			Ibuprofen	200	12
E.S. Tylenol			Acetaminophen	500	8
Tylenol-3	Codeine	30	Acetaminophen	300	13
Tylenol-4	Codeine	60	Acetaminophen	300	13
Darvon	Propoxyphene	65			NL
Darvocet	Propoxyphene	65	Acetaminophen	325	13
Darvocet N-100	Propoxyphene	100	Acetaminophen	325	13
Vicodin	Hydrocodone	5	Acetaminophen	500	8
Vicodin ES	Hydrocodone	7.5	Acetaminophen	750	5
Lortab Elix	Hydrocodone	7.5	Acetaminophen	500	8
Lorcet 10/650	Hydrocodone	10	Acetaminophen	650	6
Norco	Hydrocodone	10	Acetaminophen	325	13
Vicoprofen	Hydrocodone	7.5	Ibuprofen	200	12
Percodan	Oxycodone	5	Aspirin	325	6
Percocet	Oxycodone	5	Acetaminophen	325	13
		10			
Tylox	Oxycodone	5	Acetaminophen	500	8
Oxycodone	Oxycodone	5			NL

The dose is limited by the adjuvant not by the opioid component. The maximum doses should be reduced in the elderly or in the presence of liver and renal insufficiency

Weak Opioid Agents

These are the most commonly prescribed opioids particularly in the elderly. They are available in various strengths and should be started in low doses in the elderly. Most are even scored so that half doses can be given.

Codeine, an alkaloid of opium, is the prototype “weak” analgesic. Although a parenteral preparation is available, it is nearly always given orally and often in a fixed mixture with a nonopioid analgesic. A 200 mg dose is equipotent to 30 mg of morphine. The half-life of codeine is 2.5–3.0 h [41]. Codeine is often combined with acetaminophen with or without caffeine in doses of 300 mg acetaminophen, 30 mg codeine, and 15 mg caffeine (e.g., Tylenol 3TM).

Hydrocodone is a codeine derivative, available in the USA only in combination with acetaminophen, aspirin, or ibuprofen. It is more potent than codeine, although good data are lacking [41].

It should be remembered, however, that codeine (TylenolTM 3 or 4), dihydrocodeine (SynalgosTM DC), and hydrocodone (VicodinTM, LortabTM, NorcoTM, etc.) do not have opioid action until they undergo metabolic conversion to morphine or hydromorphone by the action of the enzyme CYP2D6, one of the P450 group of enzymes [71]. Twenty percent of the population is reported to be deficient in this enzyme and therefore will have a poor response to these medications. In addition, there are a number of drugs which

will depress the action of CYP2D6, such as: amiodarone (Cordarone[®]), fluoxetine (Prozac[®]), haloperidol (Haldol[®]), paroxetine (Paxil[®]), propafenone (Rythmol[®]), propoxyphene (Darvon[®]), quinidine, ritonavir (Norvir[®]), terbinafine (Lamisil[®]), thioridazine (Mellaril[®]), etc. [71].

Oxycodone is a semisynthetic derivative of the baine, an opium alkaloid. Because of its high bioavailability (>50%), it is suitable for oral administration and is 1.5 times more potent than morphine by this route and ten times more potent than codeine [72, 73]. When administered parenterally, its intensity and duration of analgesia are 25% less than those of morphine [73]. However, in the USA, oxycodone is exclusively an oral medication. Oxycodone given orally has a half-life of 2–3 h and duration of action of 4–5 h. It is metabolized like codeine: demethylated and conjugated in the liver and excreted in the urine [73]. Oxycodone has been considered a “weak” analgesic because of its use in a fixed combination with acetaminophen and aspirin, e.g., Percocet[®] (oxycodone 2.5, 5, or 10 mg with acetaminophen 325 mg) or Percodan[®] (oxycodone 5 mg with aspirinTM 325 mg) which limits its dose. When oxycodone is used alone, it has no ceiling effect for analgesia. It is more potent than morphine, and there are reports suggesting that it might have fewer side effects [74, 75]. Its availability in 5 mg tablets permits careful titration in patients with a narrow therapeutic margin. It is also available in extended-release preparations with doses of 10, 20, 40, and 80 mg without acetaminophen, which can be used for q12h dosing or occasionally q8h dosing.

Oxycodone is therefore a versatile and flexible oral medication that can be used to treat pain of any intensity requiring an opioid analgesic [41]. It is also interesting that patients who report poor analgesic effect from codeine- and hydrocodone-based opioids will report excellent analgesia from oxycodone-based analgesics. This is a result of enzymatic metabolism of oxycodone by CYP2D6. Therefore, the patients who are deficient in this enzyme cannot convert codeine or hydrocodone to morphine, but also will not metabolize oxycodone quickly and therefore have a prolonged effect from oxycodone [71]. The reverse would also be true in that those patients who genetically have high levels of CYP2D6 will get excellent analgesia from codeine or hydrocodone, but oxycodone although effective, will have a shortened duration and require more frequent dosing.

Propoxyphene (Darvon™ or Darvocet™, propoxyphene/acetaminophen) is a synthetic analgesic structurally related to methadone. It is approximately equipotent to codeine as an analgesic but lacks its antitussive properties. Its analgesic activity lasts 3–5 h, its half-life is 6–12 h, and its major metabolite is norpropoxyphene, which has a half-life of 30–36 h and may be responsible for some of the observed toxicity, particularly in the elderly [76]. Norpropoxyphene has local anesthetic effects similar to those of lidocaine, and high doses may cause arrhythmias. Seizures occur more often with propoxyphene intoxication than with other opioids. It is more difficult to manage and offers no advantage over other opioids, and therefore it is a poor choice of mild analgesic in the elderly [41].

Tramadol (Ultram®) is a weak opioid analgesic that also inhibits the reuptake of serotonin and norepinephrine. A tramadol dose of 50 mg appears to be equianalgesic with 60 mg of codeine [77]. Unlike other opioids, tramadol exhibits an analgesic ceiling, which limits its use for severe pain syndromes. Tramadol appears not to be associated with physical dependence but does have a relatively high incidence of associated nausea compared with that of other opioids [78]. Tramadol is also available as a combination drug with acetaminophen (Ultracet® 37.5 mg tramadol/325 mg acetaminophen) or as a sustained-release tramadol of 100 or 200 mg (Ultram® ER).

Strong Opioid Agents

As described by Morrison et al., *morphine* is the prototype strong opioid agonist [41, 79]. In the past, all other opioids were compared with morphine when determining their relative analgesic potency. But Shafer and Flood describe several concepts that must be considered when treating the elderly with opioids by bolus intravenous administration or by continuous infusions as is commonplace in the postoperative period [30].

They state that “the calculation of the equianalgesic dose is complicated by the relative intrinsic potency of the opioids, the different pharmacokinetic profiles, and the large differences in the rate of blood–brain equilibration.” Further, because of these stated differences in the properties of the opioids, the equianalgesic dose also becomes a function of the time after the injection was made; and they give an example of fentanyl (50 µg), which has a rapid onset, will have the same effect at 10 min as 5 mg of morphine which has a slow onset time. However, at 60 min postinjection, 50 µg of fentanyl will have the same effect as 1 mg of morphine [30]. Thus, one must be careful in titrating morphine with frequent bolus doses since it may result in stacking the effect which may not become evident until 60 min later. It may be better to load a patient to comfort with fentanyl while starting a PCA with morphine or hydromorphone, in order to allow enough time for the longer acting and slower onset opioids to reach peak effect and steady state.

Like other “strong” opioids, there is no ceiling to the analgesic effect, although side effects, particularly sedation and confusion, may intervene before optimal analgesia. Morphine is metabolized in the liver, where it undergoes glucuronidation at the 3- and 6-positions. Morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G) accumulate with chronic morphine administration [80]. M6G binds to Mu receptors with affinity similar to morphine but also binds to delta receptors, which may account for its higher analgesic potency [69, 81].

M6G appears to be 20 times more analgesic than morphine when administered directly in the periaqueductal gray, but only 0.077% of this metabolite crosses the intact blood–brain barrier following oral or parenteral administration [81, 82].

With single-dose morphine studies, the relative parenteral/oral potency ratio is 1:6 [83]. After chronic use, the ratio changes to 1:3 as a result of the accumulation of active metabolites [84]. There is experimental [85] and clinical [86] evidence that M3G, which has negligible affinity for opioid receptors and does not produce analgesia, has excitatory effects on neurons and can cause myoclonus and rarely a hyperalgesic state [81]. It is thought that the myoclonus and hyperalgesia precipitated by M3G are mediated by different receptor mechanisms [87].

The half-life of morphine is about 2 h but the onset time for analgesia from a bolus dose can be as long as 90 min [88]. Shafer and Flood comment that this slow onset of analgesia should make it difficult to titrate morphine [30] even though Auburn showed that titration of small morphine doses every 5 min was safe and effective in the elderly [28, 88].

Extended-release oral preparations of morphine have been available for many years in many different doses permitting q8h, q12h (MS Contin™), and once daily dosing (Kadian™ and Avinza™). Slow-release preparations should be used only after dose titration with morphine sulfate and only if the pain is expected to continue [41]. Morphine

metabolites are eliminated by glomerular filtration and can accumulate in patients with renal insufficiency, leading to an increased incidence of side effects [89]. Morphine should be used with caution in the presence of renal failure; and if utilized, the dosing interval should be increased.

Hydromorphone (Dilaudid®) is a potent semisynthetic phenanthrene-derivative opioid agonist [22]. When single doses are administered parenterally, 2 mg of hydromorphone is equipotent to 10 mg of morphine. Hydromorphone is somewhat shorter acting than morphine but has a higher peak effect. Its bioavailability is 30–40% with an oral to parenteral ratio of 5:1 [90]. It has a half-life of 1.5–2.0 h, and active metabolites may accumulate during renal failure [91]. Because hydromorphone is highly water soluble, continuous subcutaneous infusion and intravenous infusions of hydromorphone result in similar analgesia and side effects [92].

Fentanyl is a synthetic phenylpiperidine-derivative opioid agonist that interacts primarily with Mu receptors [93]. It is 80–100 times more potent than morphine and highly lipophilic [30]. The onset time for analgesia when administered intravenously is 2–3 min making it an ideal agent for analgesic titration.

Fentanyl is also available in both a transdermal (Duragesic™) form and oral transmucosal (Actiq™) form. The transdermal form is not recommended, however, for the treatment of postoperative pain because the titration is lengthy and it lacks the flexibility, which is the cornerstone of treatment for acute and evolving pain. Oral transmucosal fentanyl is being used for severe breakthrough pain requiring rapid onset without intravenous access (e.g., at home). Its inherent safety is that the patient can discontinue administration with the onset of analgesia without having to use the entire dose.

Levorphanol (Levo-Dromoran™) is a synthetic opioid agonist structurally related to the phenanthrene-derivative opiates. It is a potent Mu agonist but also binds delta and kappa receptors [94]. When administered parenterally, 2 mg of levorphanol is equianalgesic to 10 mg of morphine [95]. Because it has a half-life of 12–30 h and duration of analgesia of 4–6 h, dose reduction may be required 2–4 days after starting the drug to avoid side effects resulting from drug accumulation. Levorphanol should not be used in patients with impaired renal function or encephalopathy because of the dangers of drug accumulation and the development of toxic serum levels. It should be used only for patients who cannot tolerate other opioids because of the combination of inadequate analgesia and intolerable side effects [96].

Because Levo-Dromoran™ is four to eight times as potent as morphine and has a longer half-life, the dosage in elderly patients with cancer or with other conditions for which chronic opioid therapy is indicated must be individualized. Because there is incomplete cross-tolerance among opioids, when converting a patient from morphine to Levo-Dromoran™, the total daily dose of oral Levo-Dromoran™ should begin at

approximately 1/15 to 1/12 of the total daily dose of oral morphine that such patients had previously required and then the dose should be adjusted to the patient's clinical response not more frequently than every 72 h.

Methadone is a synthetic diphenylheptane-derivative opiate mu agonist. It is an inexpensive and effective analgesic, but its use is limited by the need for a carefully individualized dose and interval titration. When administered to opioid-naïve patients, especially the elderly, the risk of overdose is high. It should therefore be used only for selected patients and only by individuals experienced with its use [97]. The oral bioavailability is high, ranging up to 100%, and it is rapidly absorbed from the gastrointestinal tract with measurable plasma concentrations within 30 min after oral administration [97, 98]. It has no active metabolites and its clearance is not affected by hepatic or renal disease [98].

When administered in single parenteral doses to opioid naïve patients, methadone is equipotent to morphine, with duration of analgesia of 4–6 h [99]. Its plasma level declines in a biexponential manner with a half-life of 2–3 h during the initial phase and 15–60 h during the terminal phase [100]. This biexponential decline accounts for the relatively short analgesic action and the tendency for drug accumulation with repeated dosing. A reduction in dose and interval frequency is often needed during the first few days of treatment to prevent side effects from overdosage [101]. The rare patient allergic to morphine and intolerant to fentanyl might benefit from methadone because of its different chemical structure. Furthermore, *since methadone is cleared almost exclusively by the liver, it can be a useful medication in patients with renal failure* [102].

Patients with neuropathic pain or opioid tolerance can often obtain relief when changed to methadone. However, methadone must be started at a much lower dose and increased slowly, with a frequency of not less than every 3 days. Breakthrough doses of the present opioid must be maintained during this transition period [103]. Another interesting recent finding concerning methadone is the report that it is a potent inducer of cell death in leukemia cells and inhibited proliferation of these cancer cells [104].

As stated previously, methadone also has antagonist action at the NMDA receptor site thus being effective in neuropathic pain states of tolerance, and has action on inhibiting reuptake of serotonin and norepinephrine effectively increasing the concentration of these antinociceptive hormones at the level of the spinal cord [103].

Meperidine (Demerol®), a synthetic phenylpiperidine-derivative mu agonist with anticholinergic properties, used to be the most commonly prescribed analgesic for acute pain and was widely used for chronic pain [41]. The reasons for this enthusiasm are unclear and irrational. Meperidine is reported to cause less biliary spasm than morphine [105].

This property, however, has not been shown to be clinically advantageous. The *CNS excitatory effects* that appear after chronic use, *particularly in the elderly*, and in patients with renal insufficiency are well substantiated, and the accumulation of its metabolite normeperidine causes multifocal myoclonus and grand mal seizure that are not reversed by naloxone [106, 107]. The half-life of meperidine is 3 h. Short-term treatment with meperidine has been associated with mild negative alterations in various elements of mood [107]. *Therefore, the physician order for 25 mg of Demerol® q4h i.m. PRN for pain in the elderly hip fracture patient should be discouraged.*

When administered to patients' receiving monoamine oxidase (MAO) inhibitors, severe respiratory depression or excitation, delirium, hyperpyrexia, and convulsions can occur [108]. The equianalgesic dose to 10 mg of parenteral morphine is 75–100 mg of meperidine. The oral/parenteral ratio is 1:4. Its use as an oral agent for long-term use is rare if ever justified because of its poor oral bioavailability and toxic metabolite (normeperidine); however, it still can be a useful agent for acute pain crisis in the emergency room or postanesthesia recovery room when patients have known neuropathic pain or acute opioid tolerance, or shivering [109, 110].

Principles of Dosing and Delivery Methods

Onset, peak, and duration of analgesia vary with the drug, route of administration, and individual patient. The recognition of this variability allows the appropriate choice of drug, route, and scheduling. The elderly exhibit a more pronounced pharmacologic effect after any weight-adjusted opioid dose. The analgesia is more intense, but the cognitive and respiratory effects and perhaps constipation are more severe. This enhanced effect is likely due to a lesser volume of distribution (approximately half that of younger patients), decreased clearance, and diminished target organ reserve (CNS, pulmonary function, and bowel function) [111, 112].

Other factors that influence opioid effects, but to a lesser degree than that of age, are body weight, severity of pain, abnormal renal function, nausea/vomiting, and cardiopulmonary insufficiency. After the initial dose determination, drugs are titrated based on the analgesic effect. For patients with severe acute pain, such as postoperative pain, parenteral morphine was usually the opioid of choice [41]. Today, at least in the well-monitored site of the postanesthesia recovery room, hydromorphone and fentanyl have become more common. Opioids should be titrated until one of the two endpoints is reached: adequate analgesia or the development of intolerable side effects [113].

Dose titration to comfort must be accomplished before beginning PCA. In this author's experience, one can utilize

the total dose required to obtain comfort as a measure of the 3-h patient requirement in setting up a PCA. Basal infusion rates are not recommended for the elderly as accumulation of dose can occur during periods of sleep. But the lockout period must also be adjusted so that the patient has adequate time to experience the effect of the analgesic but short enough that the patient can "catch up" with his/her pain (see below).

PCA and Intravenous Infusions

PCA is a safe, effective modality for the delivery of opioids for pain that is expected to resolve (e.g., postoperative pain). The patient self-delivers fixed doses of an opioid by pressing a button. An overdose is infrequent because the patient must be alert to press the button and there is a lockout time between delivered doses during which pressing the button does not result in the delivery of medication. Family members must be cautioned not to press the button for their loved ones while the patient is sleeping in response to a groan or grimace. The usual PCA starting dose for morphine is 1 mg and for hydromorphone is 0.2 mg. The usual lockout time is 8, 10, or 15 min, although this should be adjusted for the individual patient depending on the severity of pain, the age of the patient, and whether there is a basal rate. Some advocate a low-dose basal infusion of opioid at night (e.g., morphine 0.5 mg/h or hydromorphone 0.1 mg/h) to avoid frequent awakenings because of pain, especially for the first 2–3 nights after surgery, although this may increase the daily morphine consumption [114]. Others feel that in the elderly it is better that the patients be allowed to awaken and press the PCA button on their own [115]. However, when PCA was compared with the more traditional "as-needed" administration of intramuscular opioids in a randomized trial involving postoperative pain control in elderly men, PCA using morphine without a basal rate was clearly found to result in better analgesia, fewer complications, less sedation, and higher patient satisfaction than intramuscular opioids [116].

For patients unable to operate PCA or in situations where PCA is not available, a continuous opioid infusion (e.g., morphine 0.5–1.0 mg/h or hydromorphone 0.10–0.25 mg/h) could be started and the patient observed for excessive sedation (reduce dose) or behavioral cues of pain (increase dose). This may be necessary for intubated patients or patients treated in end-of-life care. Frequent assessments focusing on face and body language that may indicate pain are essential, particularly during the first 24 h following surgery [41]. However, most hospitals might require an intensive care setting in order to provide a continuous infusion of opioid analgesia which the patient's condition may not warrant. It has also been shown that round the clock bolus dosing of intravenous opioids can provide good pain control if the patient is

unable to use the PCA machine. This could be in the mode of “nurse-controlled analgesia,” and would probably be safer than the continuous infusion.

For patients in whom pain is difficult to control, it has been shown that optimum pain control with minimal side effects could be obtained using PCA with a combination solution of 1 mg/ml morphine and 1 mg/ml ketamine, with a lockout period of 8 min [117]. This takes advantage of the ability of ketamine to block NMDA receptors and enhance the opioid analgesic effect of morphine.

When venous access is problematic, the subcutaneous route can be used. The infraclavicular area is generally the best site when a continuous infusion, PCA, or both are used. A 27-gauge butterfly needle is well tolerated and can be maintained for 3–5 days, after which the site must be rotated. When intermittent dosing is required, an insulin syringe is used to minimize trauma. Doses for subcutaneous administration are equal to intravenous doses, and hydromorphone is the agent of choice because of its high potency and lipid insolubility. It is best to avoid the intramuscular route because of erratic absorption and pain from the injection [41]. One must remember, however, that the subcutaneous tissue site can only accommodate <2 ml volume per hour and so solutions must be concentrated. Hydromorphone being more soluble and more potent than morphine is suitable for concentrating.

Initial opioid doses are much higher for patients on chronic opioid therapy. For these patients, the presurgical opioid dose must be converted to a continuous infusion, and the as-needed PCA dose should be set equal to the hourly infusion dose. When converting oral opioids to parenteral opioids refer to an opioid conversion chart (Table 26.4). A patient receiving 180 mg of oral morphine every 24 h prior to surgery, for example, should be started postoperatively on 60 mg of morphine intravenously in 24 h (2.5 mg/h) and a PCA dose of 2.5 mg every 15 min. If the pain is severe, the continuous infusion rate should be increased. Patients on chronic opioid therapy have almost always developed tolerance to the respiratory suppressant and cognitive side effects of opioids, and so it is rare for these patients to develop these symptoms, even after receiving doses substantially higher than their baseline [41].

Oxycodone is not available for intravenous administration and so the oral dose must be converted to a morphine or hydromorphone equivalent to convert to an intravenous dose. Since oxycodone is about 1.5 times more potent than morphine, 120 mg/day of oxycodone (extended-release oxycodone) would be equivalent to 180 mg/day of oral morphine or 60 mg/day of intravenous morphine [41]. This equivalency can then be used to set up a PCA of morphine or hydromorphone (15 mg/day hydromorphone = 60 mg/day morphine).

When patients are being prepared for discharge from the hospital after surgery, it will usually be necessary to convert from their current pain control regimen to an oral medication

TABLE 26.4 Equianalgesic doses of common intravenous and oral opioids

Drug	IV (mg)	Oral (mg)
Morphine	10	30
Hydromorphone (Dilaudid®)	1.5	7.5
Methadone ^a	10	12
Fentanyl	0.1 (100 µg)	N/A ^b
Meperidine (Demerol®)	100	300
Codeine	N/A	200
Oxycodone (Percodan®) (Percocet®)	N/A	20
Hydrocodone (Vicodin®) (Lorcet®)	N/A	30 (5 mg/tab Vicodin® with 500 mg acetaminophen)

Notice that the oral equivalent for 10 mg of intravenous morphine is 30 mg of oral hydrocodone. But when hydrocodone is combined with acetaminophen, the ratio is such that a toxic dose of acetaminophen would be taken with the hydrocodone. It is better to convert to a pure opioid agonist until such time that a reasonable dose of a combination medication can be given safely as shown in Table 26.3

^aNot recommended for acute titration, ratio depends on the presence of prior opioid tolerance

^bOral transmucosal fentanyl is available in 200, 400, 800, and 1600 µg doses, and the transmucosal absorption depends on the duration of contact with the mucosa but will maximize at about 25% of the total dose with the remainder being swallowed and subject to a small degree of gastric absorption. An effervescent lozenge is also available in similar doses with a reported absorption of about 50%

regimen. This conversion should be made prior to discharge and it is recommended that at least 24 h of observation be allowed so that an adequate oral regimen can be established and tested prior to discharge.

For example, for conversion from intravenous or oral morphine to a fentanyl transdermal patch, one only needs to remember that 60 mg/day of intravenous morphine or 180 mg/day of oral morphine will equal a 100 µg/h transdermal fentanyl patch. As with all sustained-release opioids, this is for continuous pain that is opioid responsive. One still needs to consider breakthrough pain medications, fast onset, and short duration, for activity based pain. Since hydromorphone is about 4–5 times as potent as morphine, a similar conversion can be made from intravenous hydromorphone of 15 mg/day to a 100 µg/h transdermal fentanyl patch. Once patients have been receiving intravenous opioid medication for several days, the equianalgesic relationship between intravenous and oral doses changes from 1–6 (IV to oral) to closer to 1–3.

In the elderly, although there is increased CNS sensitivity to opioids leading to enhanced sedation, analgesia, and side effects including delirium, the experience of pain tends to counteract the sedative and respiratory effects of opioids as evidenced by the low rate of respiratory depression noted in postoperative patients receiving parenteral, PCA, or epidural opioids [118]. As stated earlier, pain itself can aggravate delirium.

Intraspinal Administration

Discovery of opioid receptors in the spinal cord provided a rationale for the administration of opioids into the epidural and subarachnoid spaces for the treatment of postoperative pain [119]. Reports have documented the efficacy and safety of this approach in a variety of patient populations [120–125]. The subarachnoid route is useful intraoperatively as part of a spinal anesthetic providing up to 24 h of postoperative analgesia after a single dose of morphine [126, 127]. For postoperative pain and acute pain in general, the epidural route is highly effective, especially if a combination of opioid plus local anesthetic is used [128]. When epidural analgesia was compared with parenteral opioid analgesia in a randomized study of high-risk surgical patients, epidural anesthesia was associated with significantly less postsurgical mortality and morbidity [128]. The epidural route is used for continuous infusion with or without patient-controlled epidural analgesia (PCEA). PCEA reduces analgesic requirements compared with continuous epidural infusion after major abdominal surgery [129].

When choosing the opioid for epidural infusion, it is important to consider the lipid solubility of the drug. Lipid-soluble drugs (fentanyl and sufentanil) are absorbed rapidly, resulting in a fast onset of analgesia [126, 127]. In addition, lipid-soluble agents concentrate at the spinal level where the tip of the epidural catheter is positioned. Thus, the tip of the catheter should be positioned, if possible, at the segmental level of the surgery.

Hydrophilic drugs (e.g., morphine) have a slower absorption rate and, upon entering the cerebrospinal fluid (CSF), have more rostral distribution. Morphine can cause more sedation and respiratory depression than fentanyl because of its ability to reach brain stem centers after penetrating the dura into the CSF [126, 127]. Fentanyl, on the other hand, tends to be sequestered in the fat tissue of the epidural space and absorbed rapidly by the vascular structures in the epidural space and reaches systemic plasma levels within 2 h of commencing an epidural infusion that would equal the same infusion rate given intravenously [130, 131]. Care must therefore be taken with fentanyl during the initial phases of the infusion, whereas the respiratory depressive effects of morphine or hydromorphone tend to be more delayed if they are to occur, and are the result of rostral spread of the opioid once it has diffused into the CSF rather than systemic absorption [126, 127].

For example, an epidural infusion of a solution containing 0.1 mg/ml of morphine at a rate of 10 ml/h would infuse a total of 2.4 mg of morphine in 24 h. Systemic absorption of this amount of morphine over 24 h would hardly produce respiratory depression in a postsurgical patient. Fentanyl on the other hand with a solution of 5 µg/ml infused epidurally

at a rate of 10 ml/h, would provide 50 µg/h epidurally to be potentially absorbed systemically. Since fentanyl is 100 times more potent than morphine, this would be equivalent to 5 mg/h of intravenous morphine. This is a significant dose of morphine if given intravenously.

Various combinations of opioid and local anesthetic can be used to meet the needs of individual patients. Local anesthetic side effects include orthostatic hypotension, numbness/weakness, and urinary retention. Opioid side effects include sedation, urinary retention, and pruritis [132].

The local anesthetic/opioid ratio is adjusted based on the type and severity of side effects that develop. Complications of epidural infusions include accidental subarachnoid puncture with postdural puncture headache (generally benign and self-limiting), epidural hematoma, and epidural abscess. Side effects and complications are minimal if the catheters are inserted and monitored by those experienced with the technique [41].

For frail, elderly patients undergoing painful procedures (thoracotomy, extensive abdominal and pelvic surgery) and particularly for those with cognitive impairment, the epidural route is probably the best option for pain management because of its better analgesic efficacy/side effect profile (sedation/delirium, constipation, and postoperative complications) [133, 134].

Elderly patients undergo a high number of surgical interventions. The importance of adequate postoperative analgesia for reducing morbidity and mortality in the elderly is undisputed [33]. Epidural analgesia and I.V. PCA are both excellent postoperative techniques. Physicians are often reluctant to use PCA in older patients [135, 136]. However PCA was found to be effective in this population with the caveat that the patient is physically and mentally able to operate the machine [17].

Regional anesthetic techniques are excellent for the elderly. Although a fair amount of research has been published, data proving long-term benefit are lacking [33]. In a study of elderly patients following abdominal surgery, I.V. PCA versus PCEA, the I.V. PCA group had general anesthesia with sufentanil, isoflurane, nitrous oxide, and atracurium for muscle relaxation. Postoperative analgesic loading with 5 mg morphine intravenously was followed by morphine PCA of 1.5 mg, with a lockout of 8 min. The epidural group had a T7–T11 catheter placed, depending on surgery level, which was activated with 2% lidocaine with epinephrine 5 µg/ml, dosed to a T4 sensory level prior to the induction of general anesthesia. A solution of 0.25% bupivacaine plus 1 µg/ml sufentanil was infused continuously throughout the surgery and continued postoperatively with a solution of 0.125% bupivacaine plus 0.5 µg/ml sufenta at 3–5 ml/h with 2–3 ml PCEA bolus and a lockout of 12 min [133]. The authors concluded that PCEA with local anesthetic and opioid provided better pain control, improved mental status, and

better bowel function return than did traditional IV PCA morphine after general anesthesia. Orthostatic and mobility deficits were not a problem with the PCEA adjustments.

Carli et al. in a study of 64 patients for elective colon surgery randomized to an IV PCA group or epidural group found that epidural analgesia enhanced functional exercise capacity and health-related quality of life indicators after colonic surgery [134]. In this study, the PCA group had anesthetics consisting of 250 µg fentanyl, adjusted isoflurane, nitrous oxide, oxygen, and followed postoperatively with a PCA of morphine with no basal rate but a dose of 1–2 mg q5min. It was discontinued on day 3–4 if the verbal analog score was less than 3/10. The epidural group had T8–T9 catheters placed preoperatively and activated with 15–20 ml 0.5% bupivacaine to a sensory level of T4. General anesthesia was then induced and maintained with 100 µg fentanyl, maintenance 0.4% end tidal isoflurane, nitrous oxide, oxygen, and bolus doses of 5 ml 0.5% bupivacaine epidurally. Postoperatively, the epidural infusion was 4–15 ml/h of 0.1% bupivacaine and 2 µg/ml fentanyl and continued for 4 days.

The results indicated that the epidural group had improved outcomes for pain control, mobilization, gastrointestinal motility, and intake of protein and calories. This may be a function more of the local anesthetic, facilitating bowel function, thereby causing less nausea, and more willingness to eat. Decreased pain can also result in the same benefits, not just at rest but also with mobility, and less pain may ameliorate insulin sensitivity, hypercatabolism, and maintain muscle protein better. These benefits seemed to carry out to 6 weeks in the study of health-related quality of life indicators, leaving little doubt that epidural analgesia is even better than systemic opioids in the elderly [134].

Concomitant use of the epidural and parenteral routes is not recommended because (1) it makes titration of drugs overly complicated and (2) it becomes difficult to determine the origin of side effects if they develop. Generally, it is not advisable to maintain an epidural catheter for more than 8 days even if the site of insertion is without evidence of inflammation or infection. The source of epidural infection from continuous catheters is not well known but skin flora is considered the primary source [137]. If the epidural route is still needed, the catheter can be replaced with a new one at the segmental level above or below the insertion of the old catheter.

Pruritis is a common side effect of morphine administered either parenterally (intravenous or intramuscular) or spinally (intrathecal or epidural) [138]. However, the mechanisms and therefore effective treatments are different. Parenteral morphine results in histamine release in a dose-dependent manner and can be treated with antihistamines such as promethazine or dyhenhydramine. This pruritis is not ameliorated by naloxone and so is not Mu opioid receptor mediated [138].

Epidural or intrathecal morphine also produces pruritis which is through a central stimulating effect mediated

through the mu opioid receptor. It is treated most effectively not with antihistamines but with a naloxone infusion at a low enough dose to ameliorate the pruritis without reversing the analgesic effect [138].

An additional benefit of spinal anesthesia has been suggested, although not yet proven. The perioperative period is characterized by a state of immunosuppression, which was shown in animal studies to underlie the promotion of tumor metastasis by surgery [139]. Bar-Yosef and his associates demonstrated that spinal anesthesia when added to general anesthesia reduced tumor recurrence in an animal model. They propose that as the immunosuppression of surgery is partly ascribed to the neuroendocrine stress response, it is hypothesized that spinal blockade, known to attenuate this response, may reduce the tumor-promoting effect of surgery. They therefore conclude that the addition of spinal block in their model had an advantage over the use of general anesthesia alone, and they suggest that it acts by reducing the neuroendocrine response to surgery [139].

These authors further state that since in clinical practice, an epidural block can be carried over into the postoperative period, it is reasonable to assume, but certainly proof is needed, that the favorable effect of prolonged epidural block on immune function and tumor metastasis will exceed the effect they found using short-term spinal block. This study provides the first experimental evidence that regional anesthesia may reduce postoperative metastatic development [139]. Controlled clinical studies are necessary to confirm this result in humans

Peripheral Nerve Block Analgesia

While epidural analgesia has been the gold standard for post-surgical analgesia for many years, the disadvantages of bilateral blockade when local anesthetics are employed, pruritis and nausea from spinal opioids, hypotension from local anesthetics, and the necessity for a Foley catheter have spurred interest and utilization of peripheral nerve blocks including continuous catheter techniques. With these techniques, unilateral blockade is possible using local anesthetic infusions without the addition of opioids to the infusions. However, patients will still need reduced doses of supplemental opioids as explained below.

With the interscalene technique, blockade of the shoulder is possible. The upper extremities below the shoulder are easily blocked with supraclavicular or infraclavicular techniques. And the lower extremities including the hips can be blocked with a combination of sciatic with lumbar plexus or the so-called 3-in-1 femoral block. The use of ultrasound needle guidance in addition to nerve stimulation techniques has made these procedures more accurate and less risky [140].

Thoracotomy pain can be blocked with paravertebral catheters, as can the pain from mastectomy surgery. Of significance is that in a recent report woman undergoing mastectomy for tumor removal had one-fourth the risk of metastatic recurrence when surgery was performed with a continuous paravertebral catheter. The catheter was placed at T2-3 through which a bolus of local anesthetic was given followed by a continuous infusion of local anesthetic. These patients also received general anesthesia with intravenous propofol. This group of patients was compared with a group that received general anesthesia alone [141]. The general anesthesia group had sevoflurane, fentanyl, and morphine with a postoperative morphine PCA. The paravertebral catheters were removed after 2 days.

Surgery and tissue injury cause the release of prostaglandins, histamine, potassium, hydrogen, oxygen radicals, bradykinins, substance P, and multiple cytokines involved in chemotaxis [141]. Vallejo also states that some opioids such as heroin inhibit the induction of nitric oxide, a molecule with a critical role in the regulation of immune response and resistance to infection challenges. Therefore, the above study supports that regional anesthesia may not only reduce the stress response associated with surgery, but also avoid anesthetic agents that may directly affect the immune response during the perioperative period, creating a friendlier cytokine environment. It is therefore important that regional anesthetic techniques be employed in a preemptive manner in tumor surgery instead of solely for postoperative pain management.

These blocks allow for unilateral analgesia, facilitating movement, and rehabilitation without the necessity of a Foley catheter. In addition, patients can safely be sent home with continuous catheters and infusions of local anesthetic, pulling the catheters out themselves when the disposable pumps are empty [142].

Just as postoperative epidural analgesia requires the participation of the anesthesiology department of the hospital, so does a peripheral nerve block service. Such a service is predicated upon the anesthesiology department having the expertise and personnel to oversee such a service.

Unfortunately, unlike epidural analgesia which can in fact provide complete analgesia without the need for supplemental intravenous or oral opioid analgesia (since opioids are administered spinally), peripheral nerve blockade cannot be used to completely eliminate the need for supplement opioid analgesics. In order to have complete analgesia, the local anesthetic dose would have to be high enough for a complete sensory blockade which is undesirable. The technique is designed instead to provide adequate analgesia that patients can be discharged from the same day of surgery to home, or remain in the hospital with the need for only oral opioid and anti-inflammatory analgesic supplementation. Decreasing the opioid analgesic requirements can result in reduced side

effects such as nausea and constipation. Patient satisfaction is high with these techniques, and the incidence of complications is relatively low [143, 144].

In some orthopedic surgeries, bone graft may be harvested from the iliac crest. This can cause severe pain, which extends far out from the surgical procedure, and can become a chronic problem. It has been shown that the injection of morphine percutaneously into the prospective donor site can produce both immediate postoperative pain relief and long-term benefit [145, 146].

Although the mechanism of the long-term benefit of this technique is not known, there are at least three nerves that can be injured or entrapped in scar tissue at the donor site, the lateral femoral cutaneous nerve, the ilioinguinal nerve (retraction), or the superior cluneal nerves. It is possible that morphine inhibits sensitization of the nerve fibers. This author uses 10 ml of 1% ropivacaine with 2.5–3 mg of morphine injected by the surgeon along the iliac crest percutaneously prior to skin incision for the bone graft harvest.

Multimodal Techniques for Acute Postoperative Pain Management in the Elderly

Because patients rarely present with pure nociceptive pain (i.e., pain caused by activity in the neural pathways in response to damaging or potentially damaging stimuli) or neuropathic pain (i.e., pain initiated by a primary lesion or dysfunction in the nervous system), but rather, have a mixed pain syndrome (i.e., pain caused by a combination of both the primary injury and secondary effects), a rational polypharmacy approach that targets key peripheral and central pain mechanisms and modulating pathways may yield the best outcomes [147].

Oral Administration

Once pain is controlled and bowel function restored, analgesics should be changed to the oral route. Depending on individual variability and the type of surgery, this transition should occur 3–8 days after the surgery. Occasionally patients require parenteral or epidural opioids for a more prolonged period, usually because of intervening complications. Typically, patients require oral opioids for 5–10 days after parenteral or epidural opioids are discontinued. A certain percentage of patients, especially after more painful surgeries, require oral opioids for 2 weeks or longer [41].

Oral analgesics such as oxycodone or codeine are appropriate choices for a patient with mild-to-moderate pain [148].

Fixed combinations with nonopioid analgesics can be useful, but they sometimes limit the careful individualized titration that is the basis of therapeutic success. The oral transmucosal route may prove effective for rescue doses, but absorption is probably inadequate for more sustained relief. This latter statement also holds for the rectal route, which, additionally, is often uncomfortable for the patient and the caregiver.

One example of the difficulty with combination medications is conversion from intravenous PCA to oral. As seen in Table 26.4, the oral equivalent of hydrocodone to 10 mg of intravenous morphine is 30 mg. The usual combination of hydrocodone with acetaminophen is 5 and 500 mg, respectively. Therefore, six tablets of this combination drug would be necessary to equal 10 mg of intravenous morphine.

In patients suffering from continuous cancer pain, Foley recommended that the opioid analgesic should be administered regularly, including waking the patient from sleep at intervals based on the duration of analgesia for the given drug. This approach keeps the patient's pain at tolerable levels and often results in a reduction in the total amount of medication taken during a 24-h period [149]. In elderly patients with acute postsurgical pain, disrupting sleep to provide pain medication on a time contingent basis may be more detrimental than helpful. When the pain is present only during particular activities (e.g., physical therapy) or at particular times of the day, the opioid should be administered on an as-needed basis. It must be remembered that it takes approximately 1 h to reach peak serum levels after oral administration.

Special Circumstances

Some surgical procedures are associated with a higher risk of postoperative pain syndromes such as phantom limb pain syndrome after amputation. Regional anesthetic techniques offer the greatest protection; however, some patients either decline to have a regional blockade or the blocks are contraindicated for various reasons, and general anesthesia must be administered. General anesthetics alone do not protect the spinal cord from undergoing central sensitization leading to chronic neuropathic pain [150, 151]. But a polypharmaceutical approach, although not proven yet, seems to offer an advantage over traditional anesthetic and postoperative management techniques.

The following recommendations for the example of phantom limb pain prevention with amputation surgery are based on this author's experience, supported by the available evidenced-based medicine, which although limited in this regard, aims to target polypharmacy in such a way to help the brain modulate neuropathic pain [152]. The recommendations given below for this presented scenario of an amputation

without the benefit of regional anesthesia is similar to the multimodal polypharmaceutical therapeutic recommendations of power, in which he reviews the uses of both opioid and nonopioid analgesics, anticonvulsants, and antidepressants in postoperative pain management [62].

As indicated above, in this author's experience, agents that have NMDA receptor blocking action like ketamine [153, 154], drugs with Mu opioid agonist action, tetrodotoxin resistance (TTXr) sodium channel blockers such as the local anesthetics, serotonin and norepinephrine reuptake inhibitors such as antidepressants [155–157], and neuronal calcium channel blockers such as the anticonvulsants gabapentin or pregabalin [158–163], and anti-inflammatory drugs if not contraindicated (see above), can all contribute to CNS protection. In such a case, preoperative oral gabapentin (Neurontin®) 300–1,200 mg [158–167] or pregabalin (Lyrica®) 75–150 mg, and if available a COX-2 inhibitor celecoxib (Celebrex®) 200 mg, can also be given orally which would alleviate the need for intraoperative ketorolac. It is true that COX-2 inhibitors are controversial with respect to patients at risk for stroke or myocardial infarction which makes up a large percentage of the elderly population. But there does not seem to be evidence that a single preoperative dose of 200 mg of celecoxib would pose a significant risk versus the benefit of preemptive analgesia [168].

Glucocorticoids given both preoperatively or postoperatively have been shown to reduce postoperative nausea and vomiting, and to decrease pain [169, 170]. Less than 8 mg of dexamethasone or 150 mg of methylprednisolone intravenously seem to be adequate.

Preoperative oral administration of clonidine, an α_2 -agonist, reduces postoperative analgesic requirement as determined by IV morphine utilization via PCA after knee surgery [171], but not after major abdominal surgery [172]; whereas analgesia from intrathecally administered morphine was enhanced by oral clonidine premedication after total abdominal hysterectomy [173].

The recommended dose of gabapentin should be reduced from that given in the above references when dealing with the elderly population. Again this is an empiric decision of the author since the preoperative dose that would be appropriate in elderly patients has not been determined. But gabapentin and pregabalin have both been used in patients of all ages for the treatment of such conditions as postherpetic neuralgia [174]. Gabapentin in a dose of 600 mg preoperatively has also been found to decrease the incidence of nausea and vomiting and reduce the postoperative opioid requirements in a study of laparoscopic cholecystectomy patients [175].

Intraoperatively, the anesthesiologist (*again in this author's experience*) can administer several adjuvants that will also assist in protecting the spinal cord from excessive nociceptive input. Methadone would be a good choice for an opioid because of its NMDA receptor antagonist effect but it is often

TABLE 26.5 Antidepressants in clinical practice (Tricyclic antidepressants)

	Anticholinergic effects (sedation)	Dose range	Tolerability
Tricyclics			
Amitriptyline (Elavil®)	Least effect	10–25 mg qhs	
Desipramine (Norpramin®)	Least effect	10–25 mg qhs	Best
Doxipin (Sinequan®)	Most effect		Most sedating
Imipramine (Tofranil®)	Intermediate	10–25 mg/day	Best
Nortriptyline (Pamelor®)	Intermediate	10–25 mg/day	Best
Non-Tricyclics			
Venlafaxine (Effexor®)		≥150 mg/day	
Duloxetine (Cymbalta®)		30–120 mg/day	Best
Bupropion (Wellbutrin®SR)		150–300 mg/day	
Trazadone (Deseryl®)	Sleep aid in women	50–300 mg/day	Risk of priapism in men

Note: Dosages are low adjusted for the elderly patient. The antidepressants that are effective in pain management are those that have both serotonin and norepinephrine reuptake inhibition effects. The Tricyclic antidepressants all have these effects but their side effect profiles determine the tolerability of these drugs particularly by elderly patients, e.g., anticholinergic effects, sedation. The non-Tricyclic antidepressants that are effective in

unavailable and its slow onset of action is not suitable for intraoperative administration. Fentanyl would therefore be a logical choice since it is potent and more easily titrated due to its rapid onset of action when administered intravenously.

Although the data are not conclusive there is data to show that magnesium amplifies the analgesic effects of low-dose morphine in conditions of sustained pain [176]. Lysakowski et al., in a meta-analysis study of magnesium, concluded that the trials reviewed did not provide “convincing” evidence that perioperative magnesium has a favorable effect on postoperative pain intensity and analgesic requirements. Nevertheless, it may be worthwhile to further study the role of magnesium as a supplement to postoperative analgesia, since this molecule is inexpensive, relatively harmless, and the biological basis for its potential antinociceptive effect is promising [177]. There is a possibility that magnesium might have an additive or even synergistic effect with other NMDA antagonists, specifically ketamine although the optimum dose is not established [178, 179].

Considering the good tolerability of magnesium, these findings may have clinical application in neuropathic and persistent pain. Again the appropriate dose of magnesium is not known, but 30 mg/kg IV intraoperative administered prior to skin incision seems to be safe even in the elderly population. In combination with low-dose gabapentin, significant improvement in the effectiveness of morphine is observed in a rat model of nerve ligation neuropathic pain [166]. Referring to the above-stated preoperative dosing of gabapentin, the two should enhance the protective analgesic effect of the opioid used.

Low subanesthetic doses of ketamine (0.10–0.2 mg/kg IV intraoperative preincision) can be used for as part of the intravenous induction, and repeat doses q2h intraoperative can provide additional inhibition of activation of spinal cord

NMDA receptors. Midazolam preinduction can reduce anxiety and also has an antagonist site on the NMDA receptor. As previously stated, if the patient is unable to take a COX-2 inhibitor (celecoxib), then ketorolac 7.5–15 mg should be given prior to amputation intraoperatively and continued q6h intravenously for 48 h. Lidocaine 1.5 mg/kg IV at the time of skin incision and repeated during the amputation as a general sodium channel blocker can all be helpful.

Postoperatively, the antineuropathic regimen should be continued until the wound (stump) has healed in terms of continued gabapentin or pregabalin (100–300 mg tid or 50 mg tid, respectively) along with an appropriate opioid, anti-inflammatory, and antidepressant (for serotonin and norepinephrine reuptake inhibition action).

Antidepressants that have been used in pain management are listed below (Table 26.5) along with starting doses and tolerability [147]. In summary, amitriptyline is probably the most studied in pain management and its efficacy is well established. Of the newest antidepressants that have been studied in pain management, duloxetine (a non-Tricyclic) is well tolerated with a fast onset of effect after the initiation of treatment [147].

Addiction, Dependence, Tolerance, and Pseudoaddiction

The fear of addiction or psychological dependence is one of the major barriers to the appropriate management of pain in the USA. Psychological dependence is the development of drug-seeking behavior that persists despite harm to the patient or others. Such drug-seeking behavior includes the hoarding of medication, use of medication for purposes other

TABLE 26.6 Choosing the best option for postoperative pain control in the elderly

Cognitively intact	Cognitively impaired
More painful procedures (e.g., thoracotomy, complex abdominal/pelvic surgery)	
<i>Epidural:</i> lipophilic opioid (e.g., fentanyl) plus local anesthetic as a continuous infusion with or without epidural PCA <i>or</i>	<i>Epidural:</i> opioid plus local anesthetic as a continuous infusion without PCA <i>or</i>
<i>Intravenous:</i> strong opioid as an intravenous infusion with intravenous PCA	<i>Intravenous:</i> strong opioid as a continuous infusion without PCA, or nurse administered “PCA” without a basal rate based on patient assessment
Less painful procedures (e.g., lower abdominal surgery, hip/knee replacement)	
<i>Intravenous:</i> strong opioid via PCA or given intravenously every 4–6 h	<i>Epidural:</i> opioid plus local anesthetic as a continuous infusion without PCA <i>or</i>
If appropriate for the surgery, continuous peripheral nerve blocks with supplemental oral medications	<i>Intravenous:</i> strong opioid as a continuous infusion without PCA If appropriate for the surgery, continuous peripheral nerve blocks with supplemental oral medications

Continuous epidural or peripheral nerve block techniques offer the best control of postoperative pain in the elderly patient but if not appropriate or contraindicated, then intravenous administration must be utilized. Transition to oral medications must be adequate to control pain prior to discharge. When intravenous access is not available and the oral route cannot be used, the subcutaneous route is better than the intramuscular route. When the subcutaneous route is used, the absorption is less erratic with hydromorphone (more lipid soluble) than with morphine. For intermittent dosing, it is best to use an insulin syringe. For continuous infusion, a 27-gauge butterfly needle can be used. Postoperative orders for pain medication should be standing rather than PRN. The remarks “hold for excessive sedation” and “patient may refuse” add a safety valve to the order PCA patient-controlled analgesia

Source: Data from Morrison et al. [41]

than control of pain, and obtaining opioids from multiple sources. It is important to distinguish true psychological dependence from “pseudoaddiction” [180], which can develop in patients who are undermedicated for their level of pain. Pseudoaddiction is drug-seeking behavior motivated by a need to obtain enough analgesia to control pain. When pain is appropriately managed and adequate analgesia provided, the behavior disappears. Although further research is needed, it appears that the incidence of psychological addiction in patients without a history of substance abuse and treated with opioids for control of pain is rare [69]. Fear of addiction should never limit the use of opioids for pain control in the elderly patient who has no history of substance abuse [41].

Conclusion

As aptly stated by Morrison, Carney, and Manfredi, in the first edition of this book, “good pain management in the elderly surgical patient is a complex, challenging undertaking of critical importance. Ensuring adequate analgesia requires an understanding of age-related changes in pharmacokinetics and pharmacodynamics, pain physiology, the appropriate use of analgesic agents, and knowledge of these agents’ limitations and side effects. Unfortunately, few studies have focused on the assessment and treatment of pain in elderly individuals, and guidelines for analgesic therapy are often based on the experiences of young and middle-aged adults. Further research involving pain in the elderly is critically needed given the evolving changes in population demographics (persons over

65 represent the most rapidly growing segment of the US population) and the increasing rates of surgery in this population. Until such research is completed, clinicians must continue to interpret the available data in the context of their knowledge of age-related physiologic changes, medication effects, side effect profiles, and clinical experience. This approach is summarized in Table 26.6 and results in appropriate pain management for most elderly surgical patients” [41]. The increased use of regional and peripheral nerve block techniques holds much promise for acute postsurgical pain management in the elderly population, as does our increasing knowledge of the pathophysiological mechanisms of pain translating into advances in the polypharmaceutical multimodal approach to pain management.

Chapter 27

Drug Usage in Surgical Patients: Preventing Medication-Related Problems

Richard A. Marottoli, Sean M. Jeffery, and Roshini C. Pinto-Powell

Examples of age-related physiologic changes affecting drug pharmacokinetics

Physiologic change	Direction of change	Drugs affected by this change	Result of change
Serum albumin	↓	Phenytoin, naproxen, valproate, and warfarin	Increased free (active) fraction of drug; increased effects
α_1 -Acid glycoprotein	↑	Propranolol, antidepressants, lidocaine, methadone, and quinidine	Decreased free (active) fraction of drug; decreased effects
Body fat	↑	Fat-soluble drugs (e.g., benzodiazepines)	Increased volume of distribution; increased half-life and potential for accumulation
Lean muscle mass	↓	Digoxin	Decreased volume of distribution; increased concentration; lower loading dose is needed
Body water	↓	Water-soluble drugs (e.g., lithium)	Decreased volume of distribution; increased concentration and effects
Hepatic blood flow	↓	High-hepatic extraction ratio drugs (e.g., morphine, meperidine, lidocaine, and isosorbide)	Decreased first-pass metabolism; increased effects
Hepatic metabolism (phase 1: reduction, oxidation, hydroxylation, and demethylation)	↓	Diazepam, alprazolam, triazolam, theophylline, quinidine, propranolol, phenytoin, and imipramine	Decreased metabolism; increased half-life and concentration
Renal function	↓	Aminoglycosides, digoxin, ciprofloxacin, and allopurinol	Decreased clearance; increased effects, toxicity, or both

On January 1, 2011, the first of the Baby Boomers will turn 65 years old. And so will begin the largest increase in the number of older adults ever seen. To put this in perspective, in the entire history of mankind, two-thirds of all people who have ever lived to the age of 65 are alive today [1]. Advances in pharmacotherapy are partially responsible for this unprecedented increase in longevity and will play a central role in reducing morbidity and mortality in this aging cohort. However, when it comes to older adults, medications are often improperly dosed, overprescribed, and poorly monitored for signs of toxicity. Furthermore, changes in pharmacokinetics associated with aging leave little room for error. Surgeons operating on elderly patients should preoperatively

identify potential medication-related problems (MRPs) that can result in postoperative complications. This chapter reviews some of the factors that contribute to MRPs in the elderly, general approaches to prescribing, signs and symptoms to monitor, and highlights of certain drug categories that are commonly used or have substantial potential to cause side effects in older adults.

Biology of Aging

After the age of 30, it is all downhill (Table 27.1). All organ systems decline in function to some extent with advancing age, but they decline at varying rates, and independent of each other. In the absence of disease, these declines are not sufficient to impair daily function [2, 3]. However, the overall reserve capacity of an organ system diminishes with age. Thus, the ability to withstand even a minor insult is decreased, and

TABLE 27.1 Pharmacokinetic changes with aging

Absorption	Extent not affected
	Rate is reduced or unaltered
	Increased gastric pH
	Unchanged passive diffusion
	Decreased active transport
	Decreased first-pass effect
Distribution	Decreased GI blood flow with certain diseases (e.g., HF)
	Decreased total body water
	Decreased lean body mass
	Decreased serum albumin
	Increased body fat
Metabolism	Increased or decreased free fraction of highly plasma protein-bound drugs
	Higher concentration of water-soluble drugs
	Decreased liver blood flow
	Decreased liver size
	Decreased enzymatic activity
Excretion	Variable decreased and increased $t_{1/2}$ for phase I oxidation drugs
	Decreased clearance and increased $t_{1/2}$ of drugs with high-extraction ratio
	Decreased GFR
	Decreased renal blood flow
	Decreased tubular function
	Decreased clearance and increased $t_{1/2}$ for drugs eliminated primarily by the kidneys

recovery may be delayed. Appreciating medication-related factors that affect an organ system's reserve capacity is an imperfect science. The principles of pharmacokinetics help frame an understanding of how physiologic changes with aging affect medications [4]. Understanding pharmacokinetic changes associated with aging can help surgeons better anticipate MRPs. Pharmacokinetics is defined as the delivery of a drug to its site of action. This includes drug absorption, distribution, metabolism, and excretion. These changes are reviewed here in general terms to provide a background for the discussion of individual drug classes [5].

Drug Absorption

The amount of oral drug absorption (bioavailability) is dependent on many factors not related to age, including the presence of food, drug ionization, and dosage formulation [6]. Absorption can occur anywhere along the gastrointestinal tract. Oral drug absorption can also include buccal absorption of orally disintegrating tablets (ODT) specifically designed for patients unable to swallow. Some formulations are specifically designed to release medication in response to changes in intestinal pH or osmolality. In general, older adults tend to have a slight increase in gastric pH. This increase is unlikely to result in altered drug absorption [6,7]. Achlorhydria was once thought to be a consequence of aging. However, the

identification and treatment of indolent *Helicobacter pylori* infections has diminished achlorhydria as a concern.

Older adults tend to experience two alterations that can lead to clinically significant changes in the rate of oral drug absorption. First, changes in gastrointestinal blood flow may reduce portal circulation and delay gastric absorption. For example, these changes can be seen in some heart failure or cirrhosis patients with substantial hepatic congestion. And second, decreased gastric emptying, resulting from conditions such as Parkinson's disease or diabetes, may also delay the rate of absorption, but not the extent of drug absorbed [7, 8]. Unless therapeutic failure is observed, no changes in dosing are required to overcome delays in gastric absorption.

Oral bioavailability can be substantially altered in the presence of food, so called drug–food interactions. For example, patients who receive calcium supplementation while taking quinolones have a 50% reduction in the absorption of the quinolone due to chelation with calcium. The authors recommend discontinuing most calcium supplementation during the postoperative period to prevent potential chelation interactions with antibiotics. Bisphosphonate bioavailability is exceedingly low when taken with anything other than water. Levodopa absorption is substantially decreased when consumed with a high-protein meal [9]. In addition, certain foods can substantially alter drug levels and actions. Patients on warfarin who alter their intake of vitamin K-containing foods risk changes in their international normalized ratio (INR). Consumption of grapefruit irreversibly inhibits intestinal CYP-450 3A4 isoenzyme activity. This results in presystemic decreases in metabolism leading to increases in therapeutic concentrations that can last for up to 72 h. In summary, the rate of absorption may be delayed with aging, but the overall extent of absorption is unlikely to be altered.

Limited information is available about topical drug absorption changes as a result of aging. Topical administration is gaining popularity as a way to minimize first-pass metabolism, improve medication adherence, and provide more continuous therapeutic drug concentrations. For example, postoperative pain control may include the use of fentanyl or lidocaine patches. In general, decreases in skin thickness and integrity may alter drug absorption and subsequently peak concentrations. When comparing healthy young volunteers with healthy elderly volunteers receiving transdermal fentanyl patches, the older patients demonstrated higher systemic concentrations of fentanyl and correspondingly greater adverse effects resulting in drug discontinuation [10]. An additional concern when administering medications in patch form is the ability to safely remove the patch without damaging the underlying skin. Finally, all patches utilize adhesives that can cause localized skin irritation. The use of presurgical skin disinfectants and body preparations may contribute to heightened skin sensitivity to patch adhesives.

Distribution

The distribution of drugs is altered by the aging process. Total body and intracellular water decrease, as does muscle mass, whereas body fat increases [2, 3]. These changes have important implications for drug distribution that can affect both the half-life of a compound and the concentration of the drug in various tissues (e.g., lipophilic versus hydrophilic saturation). Water-soluble drugs tend to have an increased level per unit dose because of the decreased total body and intracellular water described above. Similarly, the volume of distribution for lipid-soluble drugs tends to be higher because of increased fat stores, resulting in prolonged and less predictable half-lives. Changes in protein binding can also alter receptor site activity. When medications exhibit substantial protein binding (generally >90%), the potential for protein-binding interactions due to changes in serum albumin becomes more pronounced. For example, in the case of low albumin levels, the relative proportion of free or unbound drug may be increased, enhancing the pharmacologic and toxic properties of the drug. To further illustrate this point, consider the highly protein bound drug phenytoin. By convention, when ordering phenytoin levels what is typically reported is the total drug level [11]. In the setting of low albumin, however, the free drug concentration may be high, resulting in toxicity despite a total level in the therapeutic range. In contrast, the carrier protein α_1 -acid glycoprotein may increase with age, as it does with illness, so drugs that bind to this protein may have a lower proportion unbound; an example is propranolol [12]. Another caveat with drug levels is that normal ranges are often established on young persons, therefore targeting lower therapeutic drug levels may minimize the risk of toxicity. The important exception to this approach is for antibiotic therapy where specific minimum inhibitory concentrations (MIC) are specified. Finally, some evidence suggests that conformational changes in the ability of albumin to bind drugs increase as one ages [11]. Therefore, despite a normal albumin level, the affinity of albumin to bind to medications may be reduced.

Metabolism

First-pass metabolism and high-hepatic extraction ratio drugs, liver size, and blood flow tend to decrease with age by 20–30%. Drugs that depend on extensive first-pass metabolism may have higher therapeutic levels resulting from decreased hepatic metabolism [9, 13, 14]. Pertinent to a surgeon, it is estimated that morphine exhibits a 33% reduction in clearance in the elderly as a result of decreased first-pass metabolism [14]. Therefore, the effects of morphine may last longer in the elderly. However, this does not constitute a reason to avoid morphine in older patients. Drugs that have high-hepatic

extraction ratios also exhibit decreased metabolism and potentially increased therapeutic concentrations. Atorvastatin is a high-hepatic extraction ratio drug with increased serum concentration (40%) and area under the concentration curve (30%) [14]. Therefore, closer attention to liver function tests and potential dose reduction may be warranted. Similar findings occur with simvastatin and lovastatin.

Pharmacogenomics and the Cytochrome P450 Enzymes

Drug metabolism can be affected by diet, smoking, enzyme induction or inhibition, and alcohol intake [4, 14, 15]. Polymorphisms in the drug-metabolizing enzymes influence drug safety and efficacy. Pharmacogenomics refers to the influence of genes in determining drug metabolism, safety, and efficacy. As most drugs are metabolized by the liver and involve one or more enzymatic pathways, the ability to prescreen a patient for potential genetic variants that affect drug response has clinical utility. Individualizing medication therapy based on a patient's specific metabolic genotype now exists for some medications. For example, the FDA approved genetic testing for warfarin in 2007. Completion of the Human Genome Project has helped accelerate the discovery of genetic variations affecting treatment response.

Appreciating potential changes in drug metabolism with aging and the influence of genetic factors that alter metabolic functions is central to the field of pharmacogenomics. For example, genetic polymorphism and changes in hepatic blood flow can explain interpatient variability to medications commonly used in the surgical intensive care unit [15]. The use of codeine in patients deficient in CYP2D6 results in poor conversion of codeine to morphine (the active metabolite) [14, 15]. Therefore, switching to an equianalgesic dose of morphine based on the failed codeine regimen can result in drug toxicity.

Conventional wisdom was that metabolism through the cytochrome (CYP) P450 system was impaired with aging. While some drugs metabolized via pathways involving microsomal oxidation are slowed with aging and may have active metabolites, broader probes for hepatic microsomal activity have shown inconsistent results [14–17]. For example, early studies of diazepam and chlorthalidone in the elderly demonstrated longer and less predictable half-lives. However, both these drugs are highly lipophilic and therefore have a larger volume of distribution given the increase in adipose tissue common in aging. Changes in drug distribution are now thought to account more for the prolonged and erratic half-life than decreases in metabolism [18, 19]. Regardless, neither agent is recommended for elderly patients.

Metabolism via glucuronide conjugation is minimally changed with advancing age, and metabolites tend to be

TABLE 27.2 Half-life of common benzodiazepines

inactive [14, 15]. Thus, drugs metabolized through these pathways, including benzodiazepines such as lorazepam, oxazepam, and temazepam, have shorter, more predictable half-lives and are therefore preferred for elderly patients (Table 27.2) [8, 18, 19]. Drug inhibition of enzymatic pathways typically occurs at a faster rate than induction of the same pathways. The ability to induce hepatic enzymes to the same extent as in younger individuals is unclear. Some agents commonly associated with enzyme induction include phenytoin, carbamazepine, phenobarbital, and chronic alcohol use. One potent inhibitor frequently used to control behavior in dementia patients is valproic acid.

Renal Elimination

The kidney is the main route of excretion for most drugs. On average, there are declines in glomerular filtration rate and renal blood flow with advancing age, although up to one-third of elderly persons have no substantial changes in renal function [20, 21]. Because of decreases in muscle mass and therefore creatinine production, serum creatinine levels may not accurately reflect renal function. Therefore, it is strongly recommended that creatinine clearance be calculated for every elderly patient. Even patients with seemingly normal serum creatinine levels may have a decreased creatinine clearance [22, 23]. Many formulas exist to estimate renal function [24–26]. It is important to recognize that all the available methods have limitations [27, 28]. The most widely used method is the Cockcroft and Gault equation:

$$\frac{[(140 - \text{Age}) \times (\text{Lean body weight in kilograms})]}{(72 \times \text{serum creatinine})} [\times 0.85 \text{ for women}]$$

This equation is valid when serum creatinine is at steady state. It is the authors' approach to use the resulting creatinine clearance to determine a range of possible renal function by adding and subtracting five points to the calculation. Many medications have specific dosing guidance based on creatinine clearance. Therefore, knowing the range of a patient's creatinine clearance allows for more conservative dosing if necessary and compensates for patient variability in

serum creatinine. When renal dose adjustments are necessary, surgeons should reduce the dosage or extend the dosing interval of primarily renally excreted drugs. This also applies to drugs with active metabolites that may have prolonged durations of action during renal insufficiency. One example of a medication commonly used in older adults is glyburide for type 2 diabetes. The dosing guidelines for glyburide recommend against using this product if the patient's creatinine clearance is <50 mL/min. The reason is an increased incidence of hypoglycemia secondary to reduced elimination of a renally active metabolite. Glipizide is the preferred sulfonylurea. To further emphasize the potential for hypoglycemia, the Veterans Health Administration (VHA) Pharmacy Benefits Management Services (PBM), Medical Advisory Panel (MAP), and Center for Medication Safety (VA Medsafe) issued a national bulletin advising providers to switch all patients with a calculated creatinine clearance of <50 mL/min to glipizide [29].

Medication-Related Problems in the Elderly

Polypharmacy and the Surgeon

Increases in the number of chronic conditions in the elderly generally result in increased medication use. Comorbidity is also associated with poor quality of life, physical disability, high health care use, and increased risk for adverse drug events and mortality [30–32]. Approximately 82% of older adults are treated for one or more conditions with 88% receiving a medication [33]. Prescription drug use is greatest in the elderly, with over one-third of all medications used annually [34]. Unfortunately, polypharmacy remains a significant problem for many older adults. Underuse, overuse, duplicate medication use, and ineffective medication use are by definition inappropriate medication use. Polypharmacy includes not only the number of medications a patient receives, but also potentially inappropriate medications that can lead to MRPs in older adults. In a nationally representative probability sample of community-dwelling adults aged 57–84 years old, Qato et al. found that more than half of older adults used five or more prescription medications, over-the-counter medications, or dietary supplements [35]. Almost one-third of this study population used five or more prescription medications and the prevalence of the use of five or more prescription medications increased steadily with age. Data from the Center for Medicare & Medicaid Services (CMS) estimate that 58% of community-dwelling elderly are taking three or more different acute and chronic medications in a year. CMS rates of medication use in long-term care are staggering with 67% of residents receiving nine or more different medications.

The increased emphasis on guideline-based medicine often results in patients receiving multiple agents for a condition in

order to conform to “best practices.” Patients with heart failure, hypertension, and diabetes can easily exceed six or more medications based on current clinical practice guidelines [36]. Medication management in elderly patients is more complex than in younger patients and each added medication increases the potential for interactions and adverse events. Medication errors and safety concerns in the elderly increase with each new prescription. For example, clinically significant drug interactions are more likely to occur when a patient takes five or more medications, and the likelihood for falls increases when an older adult takes four or more medications. Adding to the medication diaspora is the lack of coordination of prescribing in the elderly. Primary care physicians are unable to coordinate the multitude of specialists prescribing medications. Competitive pricing among major pharmacies often leads to patients filling prescriptions from multiple locations with no pharmacy holding a complete record of the patient’s current medications. Collectively, there is a loss of control over ensuring medication safety and appropriateness.

It is unrealistic to expect surgeons to make substantive changes to a patient’s chronic medications. Therefore, the issue of polypharmacy is more often a burden to the surgeon given the number of medications they must coordinate. While the absolute number of medications a geriatric surgery patient might receive may not change, the appropriateness of the prescribing should be optimized. When prescribing a new medication, attention to published lists of medications not to be used in the elderly (Beers criteria), avoidance of medications with known effects on cognition (anticholinergics and sedatives/hypnotics), and the judicious use of pain medication will help minimize the potential for polypharmacy-related complications [37–39]. In addition, particular attention should be given to any drugs with known narrow therapeutic windows to ensure proper monitoring for signs of toxicity. For example, warfarin is associated with five out of the top ten drug interactions in older adults (Table 27.3) [40]. Finally, any new symptom in an elderly patient should be considered a drug side effect until proven otherwise. During

the course of treatment, the patient should be monitored closely and regularly for adverse effects. Regardless of age, 95% of all adverse drug reactions (ADRs) are predictable extensions of the pharmacology of the drug. Proper dosage adjustment based on renal and hepatic function can reduce the likelihood of experiencing an ADR. Once the desired effect is achieved and maintained, or the inciting event has passed, taper and discontinue the medication.

General Principles of Prescribing

The maxim of geriatric prescribing is to “start low, go slow, and sometimes say no.” While perhaps overly simplistic and not applicable to all medications (i.e., antibiotics), the message is clear – medications are potentially dangerous in the elderly and should be used with caution [37–39]. Furthering the maxim, if starting low, it follows that you should also discontinue slow. Many drugs can be discontinued directly, but others (e.g., benzodiazepines and β -blockers) should be tapered to avoid adverse drug-withdrawal effects. With this background in mind, several underlying principles can help minimize the occurrence of MRPs and maximize adherence to prescribed drug regimens. Although they may seem rudimentary, they are nonetheless helpful to review (Table 27.4).

It is now required by the Joint Commission that all patients have their medications reconciled upon admission, discharge, or transfer within the hospital. Medication reconciliation can prevent MRPs resulting from forced adherence, a common occurrence resulting from a medication being restarted in a patient who stopped or changed their medication without notifying their primary provider. Elderly patients are often reluctant to admit they have stopped a medication or altered the dose. When reviewing medications, it is not enough to have the patient to recall their list of medications given the prevalence of cognitive impairment in older adults. The provider must also determine the dose and frequency of administration to assure accuracy when prescribing.

TABLE 27.3 Top ten drug interactions in the elderly

Warfarin – NSAIDs ^a
Warfarin – sulfa drugs
Warfarin – macrolides
Warfarin – quinolones ^b
Warfarin – phenytoin
ACE inhibitors – potassium supplements
ACE inhibitors – spironolactone
Digoxin – amiodarone
Digoxin – verapamil
Theophylline – quinolones ^b

^bQuinolones that interact include: ciprofloxacin, enoxacin, norfloxacin, and ofloxacin

TABLE 27.4 Principles of safe geriatric prescribing

Take a detailed medication history (including over-the-counter and herbal/alternative preparations)
Establish clear, feasible therapeutic endpoints
Know the clinical pharmacology of drugs prescribed; use a few drugs well; balance safety with efficacy
Begin with a low dose of a drug and titrate up to achieve the desired response
Keep the regimen as simple as possible
Review medications regularly and discontinue those no longer needed
Remember that new symptoms (and illness) can be caused by a drug as well as by a new illness
Select the least costly alternative whenever possible
Encourage compliance. Utilize available pharmacy resources for counseling, written information, special packaging, and other reminder devices

When obtaining a full medication history, it is ideal to have the patient or a family member to bring all medications with them. The authors recommend instructing patients to bring all prescription and active nonprescription bottles to their presurgical screening visit. Actually examining the pill bottles can provide valuable information about the individual's medication management abilities. For example, you might be able to determine the number of providers following the patient, if they use only one pharmacy (important for drug interaction screening), if there is duplication of medications from multiple providers, the physical appearance of the

bottles (recently filled prescription bottles that are filthy may be indicative of the individual's home environment), if the refills are on time, the pills are in the right bottles, pills are mixed together, and if the pill counts are accurate. Additional questions should probe for any new side effects or possible allergic reactions.

When assessing nonprescription medication usage, the authors advocate prompting patients with names of commonly used agents versus simply asking if they take any additional medications. The flow sheet in Table 27.5 is used by the authors to screen patients for OTC MRPs [41].

Given that many drugs with potential toxicity and interactions are available without a prescription, every patient should also be asked about the use of OTC, herbal, or alternative medications. The pharmacist is a valuable resource for conducting the medication history/review. Pharmacist interventions with in-patients may decrease subsequent hospital and emergency visits and medication-related re-admissions [42, 43]. Inclusion of pharmacists on daily rounds in the intensive care units is encouraged to help improve overall prescribing [44]. Utilization of computerized provider order entry can further reduce medication errors [45]. When preparing discharge prescriptions, keep medication regimens simple. Once-daily dosing substantially improves adherence! If a complicated regimen is necessary, the hospital pharmacist may be able to arrange for the patient's community pharmacy to dispense the medication in a pill box or have them blister packed. These approaches may enhance adherence to the regimen. Providing the patients with a *legible* list of their medications with directions written in lay-terms is perhaps the single most important strategy to prevent MRPs. Many hospitals have pharmacists available for comprehensive medication counseling and to assist in streamlining regimens.

Specific Prescribing Issues

Delirium

Although seemingly a deviation from the topic, a discussion of delirium is warranted at this point because it is prevalent, potentially serious, potentially reversible, and because medications are leading contributors. This point is of particular importance in the hospital and during the perioperative period because a number of factors may contribute to the onset and propagation of delirium, including underlying cognitive impairment, change in environment, comorbid illnesses, the underlying illness prompting hospitalization or surgery, complications of that illness or procedures, anesthesia, the surgery itself, and a variety of medications, many of which are described below. The central focus in delirium is looking for and recognizing its appearance and then moving quickly to identify and correct the inciting factors.

Delirium is the acute or subacute development of an alteration in mental state that fluctuates during the course of the day. Standardized assessment instruments such as the confusion assessment method can be helpful for its detection [46]. Risk factors can be thought of as "predisposing factors," making one vulnerable to developing delirium, and "precipitating factors," which directly or indirectly lead to it. Among the predisposing factors are cognitive impairment, visual impairment, severe illness, and renal insufficiency [47]. Precipitating factors include the use of physical restraints,

malnutrition, bladder catheterization, iatrogenic events, and the number and type of medications [48]. Certain medications have been linked to a particular risk of postoperative delirium (e.g., meperidine and benzodiazepines) [49]. However, one study noted that the simultaneous addition of three or more medications to a drug regimen in the hospital was a significant contributing factor to delirium, suggesting that the sheer volume of new medications in certain hospitalized patients may be sufficient to overwhelm their reserve capacity (it should be noted that as the number of prescribed medications increased there was a greater likelihood of at least one of the medications being psychoactive) [48].

A number of strategies may be employed to try to decrease the risk of delirium, including attention to underlying illness and complications. The general prescribing principles outlined above may also be helpful along with specific examples detailed below when discussing individual drug categories. Another factor that is particularly problematic in the hospital setting is the scheduling of medications or treatments at night that require patients to be awakened, sometimes repeatedly. Although it may be necessary for acutely or severely ill patients or during the immediate postoperative period, it is helpful to attempt to minimize the occurrence later in the hospital course. Multifactorial interventions have been shown to reduce the incidence of delirium by 35–40% in medical and posthip fracture patients [50, 51].

Antipsychotics

Antipsychotics are used to treat hallucinations, delusions, paranoia, and extreme agitation or physical violence [52]. They tend to not be useful for pacing or wandering. Because of potential serious side effects, they should not be used to treat insomnia. It is important to look for delirium as the potential cause of a new-onset behavioral disturbance or thought disorder, so the underlying etiology can be determined and treatment of the primary process initiated.

Once a target sign or symptom is identified to gauge the effectiveness of treatment, the choice of agent largely depends on the desired side effect. For the most part, neuroleptics are essentially equally effective, so the choice of agent depends on which side-effect profile fits the characteristics of the patient or is best tolerated by the patient. "Typical" agents, such as haloperidol (starting dose 0.25–0.5 mg, maximum daily dose 2.0 mg), are inexpensive and are available in oral, intramuscular, and intravenous preparations. The latter parenteral preparations may be particularly helpful in the setting of acute agitation or if the patient is unable to take oral medications. Haloperidol is more likely to produce extrapyramidal side effects, but less likely to cause sedation, orthostasis, and anticholinergic effects than lower potency agents. Among the extrapyramidal effects are parkinsonian

features including tremor, bradykinesia, and masked fascies. Although these symptoms may fade over time, they have in the past also been treated with anticholinergic agents such as benztropine and trihexyphenidyl. This approach should be avoided because of the increased potential for delirium with concomitant therapy. A wiser approach might be to decrease the dose or switch to a different agent. Akathisia is manifested as motor restlessness, pacing, or disturbed sleep and may be reported as discomfort or anxiety. A danger is that these features may be misinterpreted as increasing psychosis, with the neuroleptic dose then being increased, resulting in worsened symptoms. As a result, it is often better to decrease the dose as an initial response to such symptoms to see if they are alleviated.

Tardive dyskinesia is a potential serious side effect of neuroleptic use and one of the reasons their use should be limited to the indications described above. Tardive dyskinesia starts as fine movement of the tongue, a facial tic, or lip smacking but may progress in the extreme to affect speech, eating, and breathing. Furthermore, it may be irreversible. Older adults and women are most likely to develop tardive dyskinesia, and it is more likely to be severe and less likely to be reversible in the older adults. It is less clear that treatment duration and type of agent are important contributors to risk [53, 54]. The primary treatment is to taper and discontinue the drug.

“Atypical” agents, such as risperidone (starting dose 0.25–0.5 mg, maximum daily dose 2.5 mg), have been touted as having fewer extrapyramidal side effects, although the risk does increase with increasing dosage. Olanzapine (starting dose 2.5–5 mg, maximum daily dose 20 mg) may be helpful in individuals who have insomnia or poor oral intake in addition to psychosis, although these effects may be problematic with longer-term use.

A number of precautions can be taken to minimize the risk or extent of side effects. Once the desired effect is achieved and the target symptom is alleviated, or the inciting event is resolved, the drug should be tapered and discontinued. Many of the problems with neuroleptic use result from patients being left on the drug long after the inciting event has resolved and after discharge from the hospital. If patients are discharged to a rehabilitation or long-term care facility, it is helpful to indicate a time limit to treatment with these agents, much as one would do with a course of antibiotics. If agents are prescribed on an as-needed, or pro re nata (PRN), basis, the indication for use and maximum daily dose should be clearly stated in the orders. The maximum daily doses provided for agents outlined above are guidelines; while they may be exceeded, this should be done cautiously and under close supervision because of the increased risk of side effects.

Of note, recent evidence has raised concern about the limited effectiveness of these agents in controlling behavioral symptoms and the potential risk of other serious adverse effects, such as cardiac and cerebrovascular events and death

[55–57]. These effects have been noted in patients with dementia and with long-term use and higher doses, but they may affect the risk-benefit equation in a given patient. They also add to the importance of judiciously using these medications only for the appropriate indications (psychosis and agitation where the health and safety of the patient or caregivers is threatened) and at as low a dose and for as short a duration as is clinically necessary.

Antidepressants

The cardinal features of depression are the “vegetative” or depressive signs and symptoms, including increased or decreased sleep, decreased activity level, fatigue, decreased concentration, increased or decreased appetite or weight, motor slowing or agitation, guilt, suicidality, chronic somatic complaints, and pain [58]. Although standardized instruments, such as the Geriatric Depression Scale, can be useful adjuncts, diagnosis still often relies on the recognition of depressive signs and symptoms [59]. It is important to rule out underlying medical illnesses contributing to depression, such as stroke, myocardial infarction, congestive heart failure, thyroid disorders, uremia, and certain cancers. Medications may contribute as well, including central-acting antihypertensives and β -blockers, narcotics, neuroleptics, benzodiazepines, antihistamines, and sedative/hypnotics [60].

Once these contributing factors have been ruled out and target signs or symptoms identified, the choice of agent again depends in part on the characteristics or features of the patient and the desired side-effect profile [58, 61, 62]. There is currently a wide range of therapeutic options to treat depression. While early agents such as tricyclics can be effective, their side-effect profiles require much more caution when used in older patients. Tertiary amine tricyclics (e.g., amitriptyline, imipramine, and doxepin) were among the early agents used. Although still effective, their side effects are very poorly tolerated by elderly persons and they should be avoided. Their metabolites (secondary amine tricyclics such as nortriptyline and desipramine) are available and are preferred if a tricyclic is to be used. Like the low-potency neuroleptics, tricyclics also have potential side effects such as sedation, orthostasis, and anticholinergic effects. In addition, they have the potential to contribute to arrhythmias. While nortriptyline and desipramine have relatively low arrhythmogenicity, they should be used cautiously in persons with underlying conduction disorders, and PR and QRS intervals should be monitored periodically while on treatment. Desipramine is an activating agent and is preferable for persons who are apathetic, withdrawn, and anhedonic. Nortriptyline is a sedating agent and is preferred in individuals who are anxious or have sleep difficulties as well as depression. Blood levels are

available for both agents and can be used to adjust doses depending on effect and side effects (nortriptyline has a therapeutic window – a level beyond the upper limit may lead to less effectiveness and more side effects) [63].

Because of their enhanced safety and tolerability profiles, selective serotonin and norepinephrine reuptake inhibitors (SSRI and SNRI) are the current preferred agents for treating depression in older patients [62, 64]. In general, citalopram/escitalopram, sertraline, and venlafaxine are safe, effective, and well-tolerated by older patients and are reasonable initial choices. For patients with certain associated features, other agents may be considered. For patients with poor sleep, poor intake, and anxiety as features of their depression, mirtazapine would be an option. For patients with pain and depression, duloxetine is an alternative. The latter options may minimize the number of medications by treating multiple symptoms with a single agent. Most agents take several weeks to have an effect on mood, but beneficial effects on sleep or appetite may be seen sooner. Potential side effects include gastrointestinal upset, change in sleep, headaches, dizziness, and sexual dysfunction.

Methylphenidate (starting dose 5 mg daily, maximum dose 10 mg twice a day, dosed early), which often exhibits an effect within 24–48 h, may be used as a bridging activating agent for particularly anhedonic or apathetic patients until other agents exert their effect, with its primary side effects being excessive arousal, gastrointestinal upset, and tachycardia [65]. Monoamine oxidase (MAO) inhibitors are used infrequently because of their potential serious interactions with certain medications and tyramine-containing foods. For life-threatening depression or patients refractory to medications, electroconvulsive therapy can be used safely and effectively in elderly persons [60].

Anxiolytics

Pharmacologic intervention for anxiety is warranted if symptoms are sufficiently severe to interfere with daily coping or enjoyment of life. In general, treatment should be short term: for a grief reaction or as an adjunct to supportive therapy to develop coping strategies. It is again important to rule out contributing disorders such as congestive heart failure and chronic obstructive pulmonary disease.

The mainstays of anxiolytic therapy are the benzodiazepines [52, 66]. Given the metabolic changes that occur with aging described above, short-acting agents such as lorazepam (starting dose 0.5 mg/day) and oxazepam (starting dose 7.5 mg/day) are preferred because of their more predictable half-lives and duration of action. All benzodiazepines share potential side effects, including sedation, dizziness, depression, confusion, agitation, and disinhibition. Dependence

can develop, and tolerance to their effects often occurs after 2–4 weeks of continuous use. Consequently, it is best to use these agents short term. Because a withdrawal reaction or “rebound” characterized by tremor and agitation can occur after abrupt withdrawal, benzodiazepines should be tapered prior to discontinuing. Buspirone (starting dose 5 mg twice a day) is a nonbenzodiazepine anxiolytic that is less likely to cause dependence, sedation, or psychomotor retardation. However, it has a delayed onset of action (several weeks) and lacks the soporific and muscle relaxant effects of benzodiazepines. Its primary side effects are dizziness and nausea. Barbiturates should be avoided because they are less effective and have greater addictive potential than other available agents [66, 67].

Sedative/Hypnotics

Disturbed sleep is a common complaint among older persons, particularly in the hospital [52, 68]. Part of this is due to changes that occur in sleep patterns with aging, including a phase shift (falling asleep and waking up earlier than in prior years) and more disruptions to sleep. Disturbed sleep may manifest as difficulty falling asleep, difficulty staying asleep, or early morning awakening. A variety of medical factors contribute to sleep difficulties, including anxiety, depression, pain, itching, nocturia, and congestive heart failure. Medications that may contribute include amphetamines, steroids, decongestants, caffeine, and alcohol. A number of other factors may play a role among hospitalized patients, including daytime naps, intravenous lines, catheters, traction, and frequent wakings for medications or treatments. After establishing by history if sleep is disturbed, the mainstay of treatment should be nonpharmacologic interventions directed at potential contributing factors.

If drug treatment is indicated, there are several potential choices that can be used safely and effectively short term (suggested maximum duration of use is 7–10 days). Among the benzodiazepines, short-acting agents are preferred because they are less likely to cause carryover sedation the following day. Temazepam (starting dose 7.5 mg) has a reasonable duration of action but a delayed onset of action and so must be given approximately 1–2 h before bedtime. Nonbenzodiazepine hypnotics, such as zolpidem, zaleplon, and eszopiclone, also appear relatively safe in older persons [69]. If the primary problem is difficulty falling asleep, ramelteon is another option. If persons are depressed and have sleep difficulties, treatment with a sedating antidepressant is preferable to separate treatment with two different medications. Similarly, if someone has a thought disorder and disturbed sleep, a sedating neuroleptic is preferred, but neuroleptics should not be used for sleep alone.

Pain Management

Pain is a common complaint among elderly persons and can have a substantial impact on affect and physical functioning. Adequate treatment is thus important, but caution must be exercised because of the strong potential for adverse effects with many of these agents. As such, it is helpful to follow the stepwise approach defined above for assessing the nature and extent of pain, determining its etiology, and starting with lower doses of less potent agents. A variety of instruments are available to help gauge the current severity of pain and the effectiveness of treatment [70, 71].

The first line of therapy often consists of acetaminophen, aspirin, or nonsteroidal anti-inflammatory agents (NSAIDs) [71–73]. Although all three possess analgesic and antipyretic properties, acetaminophen lacks the anti-inflammatory properties of the other two classes. Acetaminophen is safe, effective, inexpensive, and well-tolerated by older persons. Caution should be exercised in the setting of liver disease or alcohol use, and there may be an increased risk of end-stage renal disease with high-dose long-term use [71, 74]. Caution must also be taken to ensure that patients avoid compound medications that include acetaminophen, which may contribute to their unknowingly exceeding recommended daily limits. Aspirin and the nonsteroidals can cause gastrointestinal bleeding or renal insufficiency and can interfere with platelet function. A variety of central nervous system (CNS) side effects may also be seen with nonsteroidals. Given that these three classes provide roughly equipotent analgesic effects, acetaminophen is a safer initial choice in the absence of inflammation. Of note, the most recent guidelines of the American Geriatrics Society recommend acetaminophen rather than nonsteroidals for the first line treatment of pain because of their side-effect profiles in older adults [73].

If pain is not controlled with these agents, opioid analgesics are the next line of treatment [71–73]. They are often characterized as mild or strong. Mild opioids, such as codeine and oxycodone, may provide relief alone or in conjunction with the nonopioid analgesics described above. Strong opioids, such as morphine, are used if pain remains unrelieved. All opioids have similar potential side effects, among which are respiratory depression, constipation, urinary retention, nausea and vomiting, delirium, and myoclonus. The patient should be monitored closely and appropriate dose adjustments made when these side effects appear. Prophylactic bowel regimens are often necessary and should be initiated when the narcotic is started. Tolerance to some of the effects may appear and may be facilitated by continuous, rather than as-needed, administration schedules. For respiratory depression, the opiate antagonist naloxone may be helpful. Meperidine should be avoided in the elderly, as it must be used with caution in patients with renal insufficiency and its metabolite, normeperidine, may cause seizures. Topical

analgesics such as capsaicin may be helpful for conditions such as herpes zoster. Nonpharmacologic modalities such as heat, cold, massage, biofeedback, and transcutaneous electrical nerve stimulation (TENS) help in certain situations. Nerve blocks are another potential option for certain types of refractory pain. A recent trial of an interdisciplinary analgesic program in orthopedic patients found that intervention participants had less pain postoperatively and at 6 months and better physical performance [75].

Antihistamines

Histamine H₁ receptor blockers are commonly used for the treatment of allergies and allergic reactions; occasionally they are used as sedative/hypnotics. Because of their prominent anticholinergic properties, they should be used cautiously in the elderly. Newer agents with relatively low anticholinergic properties, such as loratadine, are preferred to treat allergy symptoms. Antihistamines such as diphenhydramine should not be used as sleep medications given the availability of safer agents.

Histamine H₂ receptor blockers, used to inhibit gastric acid secretion, can be safely used in elderly persons. All of these agents can cause alterations in mental status [76]. In general, the dose and duration of use should be kept to a minimum and always adjusted for renal function. If used prophylactically during the perioperative period, the dose should be decreased and ultimately discontinued as soon as possible.

Antibiotics

There are two major clinical categories of antibiotic usage among surgical inpatients: perioperative prophylaxis and the treatment of postoperative infections. Although this chapter does not deal with specific antibiotic recommendations, it addresses the general principles of antibiotic choice, dosing, and specific side effects in the geriatric patient.

As the population ages and as individuals live longer and productive lives through the benefits of advances in pharmacotherapy and medical technology, it has become important to consider technologic devices (grafts, stents, pacemakers, transplanted organs, and dialysis catheters) as important factors in the selection of antibiotics in the elderly surgical patient. Both the devices themselves, as well as the medications (immunosuppressive drugs and anticoagulants) that patients may be on as a result, need to be taken into consideration when choosing an antibiotic regimen. With the expansive antibiotic armamentarium currently available and new drugs being released with regular frequency, it is imperative that the proper choice of antibiotic be made by taking

TABLE 27.6 Selected antibiotics and their drug interactions

Antibiotic	Other drugs	Effect
Ampicillin	Anticoagulants	↑ Anticoagulation
Aminoglycosides	Amphotericin B	↑ Nephrotoxicity
	Cyclosporine	↑ Nephrotoxicity
	Loop diuretics	↑ Ototoxicity
	Neuromuscular blockers	↑ Respiratory paralysis
	NSAIDs	↑ Nephrotoxicity
Cefoperazone, cefotetan	Vancomycin	↑ Nephrotoxicity
	Anticoagulants	↑ Anticoagulation
Clindamycin	Muscle relaxants	↑ Frequency of respiratory paralysis
Ciprofloxacin	Antacids/sucralfate/cations (vitamins and calcium supplements)	↓ Absorption of ciprofloxacin if taken within 2 h
	NSAIDs	↑ CNS stimulation/seizures
	Anticoagulants	↑ Anticoagulation
	Tacrolimus	↑ Tacrolimus level with toxicity
Fluconazole	Cyclosporine	↑ Cyclosporine level, nephrotoxicity
	Ca channel blockers	↑ Ca channel blocker level
	Anticoagulants	↑ Anticoagulation
	Theophylline	↑ Theophylline level
	Alcohol	Disulfiram-like reaction
Metronidazole	Oral anticoagulants	↑ Anticoagulation
Imipenem cilastatin	Cyclosporine	↑ Cyclosporine level
Trimethoprim-sulfamethoxazole	Anticoagulants	↑ Anticoagulation

Source: Data from [77]

into account possible drug interactions (Table 27.6), the side-effect profile of a particular drug, and the appropriate dose in a given patient [77].

The increasing antibiotic resistance noted in several strains of gram-positive bacteria has led to the development of new classes of antibiotics in an effort to combat this problem. All this has improved our ability to successfully care for and treat patients, but has also increased the risk of potential side effects and drug interactions to which patients are exposed. The advent of the electronic medical record, electronic prescribing systems, and electronic prescribing data bases have made the life of a busy clinician easier and have been shown to prevent adverse events [78].

While the maxim of geriatric prescribing, “start low, go slow” is true for most classes of drugs, this practice is not advisable with antibiotic use. This is especially true in the critically ill surgical patient and may in fact contribute to the problem of antimicrobial resistance. Understanding when pharmacokinetic changes in the elderly are important and

call for dose adjustments is imperative [79]. Proper dosing of antibiotics and other drugs in older adults reduces the incidence of ADRs. This point is especially important in light of the fact that the incidence of ADRs increases with advancing age and the effects are more serious in frail elderly patients than in their younger counterparts [80]. In general, improper dosing is a more frequent cause of error in therapy than is the use of an inappropriate drug [81].

Judicious clinical practice requires the prescribing physician to be aware of age-related changes in drug absorption, distribution, metabolism, and elimination. These have been described earlier in this chapter. Of these factors, the one with the most direct clinical relevance to antibiotic dosing is the decline in renal function. Many disease processes in the elderly, including most notably hypertension and diabetes, contribute to and accelerate this decline [80].

Most clinicians are aware of the need to decrease the dose of certain nephrotoxic antibiotics, such as aminoglycosides in the setting of frank renal insufficiency or decreased creatinine clearance. However, other commonly used drugs such as quinolones and most cephalosporins need to be dose-adjusted for a creatinine clearance of less than 30 ml/min [82]. Table 27.7 lists selected antibiotics whose dosages need to be adjusted [83, 84].

Although aminoglycosides remain important drugs for treating serious infections, alone or in combination with other drugs, the availability of newer agents (quinolones, monobactams, and carbapenems) with broad-spectrum coverage and less nephrotoxicity make the use of aminoglycosides less attractive in elderly persons. Risk factors for the development of aminoglycoside-induced nephrotoxicity include diabetes mellitus, dehydration, advanced age, and duration of treatment [85]. In addition to nephrotoxicity, aminoglycosides may also cause ototoxicity. This is more likely to occur in elderly patients especially if given in high dose or for prolonged periods because ototoxicity is cumulative. Furthermore, the risk of ototoxicity is greater in patients concomitantly taking a loop diuretic [86–88].

Evidence suggests that once-daily dosing of an aminoglycoside is at least as effective as, and less toxic than, conventional dosing regimens of multiple daily dosages as long as trough levels are monitored closely. Several analyses of pooled data from randomized controlled studies in adults found that once-daily aminoglycoside dosing may be associated with less nephrotoxicity and no greater ototoxicity than with conventional dosing [89–92]. Keep in mind, however, that once-daily aminoglycoside dosing is not appropriate for, or recommended in, any patient with a creatinine clearance <30 ml/min.

As mentioned above, although liver size and blood flow tend to decrease with age, in the absence of serious liver disease and subsequent hepatic dysfunction, antibiotic dosages do not need to be adjusted. Drug-induced hepatitis in patients treated with antituberculous agents, especially isoniazid,

TABLE 27.7 Selected antibiotics requiring dose adjustment during renal insufficiency

Antibiotic	Usual dose	Dose for CrCl 10–50 ml/min	Dose for CrCl <10 ml/min
Cefazolin	1–2 g q8 h	1–2 g q12 h	1–2 g q24–48 h
Cefuroxime	0.75–1.50 g q8 h	0.75–1.50 g q12 h	0.75–1.50 g q24 h
Ceftazidime	2 g q8 h	2 g q12–24 h	2 g q24–48 h
Cefotaxime	2 g q8 h	2 g q12–24 h	2 g q24 h
Penicillin G	0.5–4.0 million units q4 h	75% of dose	20–50% of dose
Ampicillin	1–2 g q6 h	1–2 g q6–12 h	1–2 g q12–24 h
Piperacillin tazobactam	3.375–4.5 g q6–8 h	2.25 g q6 h	2.25 g q8 h
Piperacillin	3–4 g q4–6 h	3–4 g q6–8 h	3–4 g q8 h
Ticarcillin clavulanate	3.1 g q4 h	3.1 g q8–12 h	2 g q12 h
Aztreonam	2 g q8 h	50–75% of dose	25% of dose
Ertapenem	1 g q24 h	0.5 g q24 h	0.5 g q24 h
Imipenem cilastatin	0.5 g q6 h	0.25 g q6–12 h	0.125–0.25 g q12 h
Metronidazole	7.5 mg/kg q6 h	7.5 mg/kg q6 h	50% of dose
Vancomycin	1 g q12 h	1 g q24–96 h	1 g q4–7 days
Gentamicin	1.7 mg/kg q8 h	1.7 mg/kg q12–24 h	1.7 mg/kg q48 h
Amikacin	7.5 mg/kg q12 h	7.5 mg/kg q24 h	7.5 mg/kg q48 h
Amphotericin B	0.4–1 mg/kg q24 h	0.4–1 mg/kg q24 h	0.4–1 mg/kg q24 h
Fluconazole	100–400 mg q24 h	50% of dose	50% of dose
Ciprofloxacin (IV)	400 mg q12 h	400 mg q12–24 h	400 mg q18–24 h

CrCl creatinine clearance

TABLE 27.8 Selected antibiotics requiring dose adjustment in the presence of severe hepatic dysfunction

Nafcillin
Cefoperazone
Clindamycin
Erythromycin
Ketoconazole
Isoniazid
Rifampin

increases in incidence from 2.8/1,000 in patients <35 years old to 7.7/1,000 in patients ≥55 years old [86, 93]. Therefore, liver function tests must be performed frequently prior to and during the course of antituberculous therapy. Antibiotics that require dose adjustments in patients with hepatic dysfunction include cefoperazone, clindamycin, erythromycin, isoniazid, ketoconazole, nafcillin, and rifampin (Table 27.8).

β-Lactam antibiotics (penicillins, cephalosporins, cephamycins, carbapenems, and monobactams) have varying characteristics of absorption, peak concentration, bioavailability, and metabolism. These topics are described in detail in standard texts and are not covered here. In general, bioavailability is relatively poor after oral administration, which has implications for the switch from intravenous to oral preparations, and pharmacokinetics are similar after intramuscular or intravenous administration [83].

Cephalosporins are relatively safe drugs to use in older persons. Dosages for certain cephalosporins need adjustment for renal insufficiency (Table 27.7). The broad spectrum of activity of ceftriaxone together with its convenient once-daily dosing make it an ideal drug for empiric use in a variety

of clinical infections in the older adults [94, 95]. In addition, it has both renal and biliary excretion and as a result needs little adjustment for renal insufficiency. A lesser known side effect of ceftriaxone is the formation of biliary sludge with prolonged use [96].

Cefoperazone, a third-generation cephalosporin still in use especially for the treatment of intra-abdominal infections, has primarily biliary excretion and needs no adjustment for renal insufficiency; however, it can cause elevation of the prothrombin time [97]. This side effect is particularly important in the surgical patient. There are three proposed mechanisms of cephalosporin-associated hypoprothrombinemia, two of which involve the *N*-methylthiotetrazole (NMTT) moiety. The most plausible mechanism is NMTT inhibition of vitamin K epoxide reductase in the liver. Patients at increased risk for this adverse event include those with low vitamin K stores, specifically patients who are malnourished with low albumin concentrations and poor food intake. The elderly and patients with liver or renal dysfunction are examples of populations at potential risk. The manufacturer therefore recommends concomitant use of vitamin K once a week during cefoperazone administration, although epidemiologic studies suggest that bleeding complications with antibiotics in general may have more to do with other risk factors than the specific antibiotic [98–101]. It should also be noted that cefoperazone causes a mild disulfiram-like reaction when given within 72 h of alcohol ingestion.

Carbapenems (imipenem cilastatin, meropenem, and ertapenem) are a widely used class of drugs especially in the post-operative patient because of their broad spectrum of activity. Their pharmacokinetics are similar to that of cephalosporins, and they require dose adjustment for renal insufficiency

because they are excreted renally. The cilastatin component of imipenem cilastatin has no antibacterial activity, but is used to inhibit renal tubular metabolism of imipenem, thereby increasing the urinary concentration of the active drug. Major adverse effects of the carbapenems, especially imipenem cilastatin, are related to the CNS, including seizures, somnolence, and confusion [102]. This is more likely to occur in the elderly with a history of a CNS lesion, prior seizure disorder, or renal failure.

Aztreonam is a monobactam that has only aerobic gram-negative bacterial coverage. Its pharmacokinetics are similar to that of the cephalosporins. It is frequently used in patients with renal insufficiency as a substitute for aminoglycosides, although it too needs dose adjustment in such patients. Its use in combination with β -lactam antibiotics for synergy (as with aminoglycosides for enterococcal or pseudomonal infections), however, has not been validated. It lacks cross-reactivity with other β -lactam antibiotics and can be used safely in patients with severe allergy to penicillin or cephalosporins [103, 104].

The fluorinated quinolones have gained wide usage during the past few decades. Compared with the older quinolones (norfloxacin and ciprofloxacin), the third- and fourth-generation quinolones (ofloxacin, levofloxacin, and moxifloxacin) have a broad spectrum of aerobic gram-positive and gram-negative bacterial activity along with the same excellent pharmacokinetic profile. The gram-positive coverage, especially in vitro activity against *Streptococcus pneumoniae*, of the earlier quinolones (ciprofloxacin) is not as good as that of the new generation of quinolones. In addition, they are active against intracellular organisms such as *Legionella*, *Mycoplasma*, *Chlamydia*, and *Mycobacteria*. They are well absorbed orally, with a high degree of bioavailability that makes them especially useful drugs in the transition from intravenous to oral dosing. They also have excellent tissue penetration. Care should be taken with the oral administration of these drugs to ensure that they are administered 2 h before or after antacids, sucralfate, or other multivalent metallic cations as their absorption can be severely impaired [105, 106]. Renally eliminated fluoroquinolones (ofloxacin and levofloxacin) need to be dose-adjusted when the creatinine clearance is <50 ml/min.

Along with the increased usage of this class of antibiotics, there have been reports of specific side effects when prescribing these drugs in older adults. Certain quinolones can cause QT interval prolongation. They should be avoided in patients with known prolongation of the QT interval, patients with uncorrected hypokalemia or hypomagnesemia, and patients receiving Class I or Class II antiarrhythmic drugs [107]. Elderly patients on corticosteroids, especially in the setting of chronic renal insufficiency, are also at risk for Achilles tendon rupture [108]. An important and well-documented drug interaction of quinolones with warfarin is particularly noteworthy in the postsurgical patient. The

prothrombin time (PT) and INR need to be closely monitored to prevent bleeding complications [109, 110].

With the current escalating problem of antibiotic resistance and the increase in the numbers of resistant gram-positive infections (methicillin resistant *Staphylococcus aureus* and vancomycin resistant enterococci), several new antibiotics have been introduced in the past decade as an alternative to vancomycin. Linezolid and quinupristin dalbapristin are two such antibiotics. Linezolid, a fluorinated oxazolidinone active against gram-positive organisms, is a nonselective inhibitor of monoamine oxidase (MAOI). In the elderly patient with the potential for polypharmacy as discussed above, drug interactions need to be kept in mind when using this antibiotic. Linezolid is on the list of drugs with serotonergic activity that may cause serotonin syndrome – a potentially preventable complex of symptoms that may be fatal if not recognized early. The most common drug combinations associated with serotonin syndrome are MAOIs with selective serotonin reuptake inhibitors (SSRIs). Since SSRIs are frequently used for the treatment of depression, this is an important drug interaction to keep in mind [111–113].

No discussion of antibiotic use is complete without mention of *Clostridium difficile*-associated diarrhea (CDAD) – a challenge in the care of all hospitalized patients, particularly older ones. Surgical patients comprise 55–75% of all patients with CDAD [114]. Initial treatment regimens remain the same in this population and include oral metronidazole (cheap and effective) or oral vancomycin (expensive and concern for antibiotic resistance); however, there is an increased frequency of treatment failure and CDAD recurrence among elderly persons. Prolonged, tapering course of antibiotics, treatment with anion exchange resins, oral lactobacillus, or nonpathogenic yeast such as *Saccharomyces boulardii* and fecal transplants (enema with feces from healthy donors) or combinations of the above may need to be considered. None of these regimens has been proven superior to the others [115].

Summary

A number of factors can potentially influence the risk-benefit equation for drug use in an older population, including age-related physiologic changes in organ system function; increased likelihood of comorbid diseases affecting organ systems that are the intended site of drug action or are responsible for the metabolism or clearance of a drug; and increased likelihood of multiple chronic medications, which may increase the possibility of drug interactions. However, the vast majority of drugs can be used safely and effectively in older surgical patients if appropriate precautions are taken in the selection, dosing, and timing of drugs and in the active monitoring of effects and side effects.

Chapter 28

Invited Commentary

Donald D. Trunkey

Injury in the elderly is increasing, and we now see a bimodal distribution of injury deaths. The first peak in death rates is in the 16 to 24 age group, and the second is after the age of 60. This increase in the number of elderly patients is due in no small part to the fact that they are more active, continue to drive, and remain involved in some risk-taking sports, such as skiing and driving motorcycles. One can ask, "When does 'old age' begin?" If one reviews the National Trauma Data Bank maintained by the American College of Surgeons, there appears to be an increase in deaths after the age of 45. I wish to emphasize the variability in the physiologic changes that occur in the aged. The most common comorbidities that I see are cirrhosis, smoking, heart disease, and chronic obstructive pulmonary disease.

There have been many recent changes in the management of shock and hemotherapy. One has to be careful in analyzing and applying some of these changes to the elderly. Data from Iraq and Afghanistan have confirmed what Cannon observed in World War I. It is important *not* to over-resuscitate the patient prior to surgical control of bleeding. The military studies show that minimal pre-hospital fluid should be given, corroborating Cannon's data in that keeping the blood pressure above 85 mm/Hg is optimal. However, this may not be applicable or should be modified in the case of elderly patients who have arterial sclerosis or congestive heart failure. One of the more dramatic changes shown recently by our military is in hemotherapy. During World War I, Cannon used whole blood. The component therapy data from Operation Enduring Freedom and Operation Iraqi Freedom have been modified to reflect a 1:1:1 ratio of packed red blood cells, fresh frozen plasma, and platelets and provide a statistically better outcome when compared to the earlier management of components. An even better outcome can be achieved with whole blood, which most surgeons believe to be the appropriate fluid to give for hypovolemic shock.

Another concept that is gaining credibility is the prevention and treatment of compartment syndromes. Compartment syndromes can occur in the cranial vault, hemithoraces, abdomen, pelvis, and the extremities. Neurosurgery has rightly pointed out the ravages of compartment syndrome within the cranial vault, and there has been aggressive management in the form of evacuation of hematomas, and even craniectomy. These problems are aggravated in the elderly because many of them come into the emergency room after major injury and are on Warfarin, Plavix, or aspirin. Although rapid reversal of these compounds is desirable, it is fraught with difficulties, particularly if one uses vitamin K, fresh frozen plasma, or platelets. These all take time to reverse. Some centers have used low-dose Factor VII with promising results, but there is the downside of increased thrombosis. Compartment syndromes, including air and blood within either hemithorax can usually be addressed once the patient arrives at the emergency department, but in some instances, can be relieved (tension) in the pre-hospital care. The compartment syndromes that develop in the abdomen and pelvis are partly preventable by prudent limitation of over-resuscitation, but in some instances will require leaving the abdomen open, packing the pelvis temporarily to gain hemostasis, and repeated damage control until the abdomen can be closed either primarily or at a later date after temporary closure with synthetic material.

A related issue is the triad of coagulopathy, hypothermia, and acidosis, which is often a complication of resuscitation. Oftentimes, this is preventable. Warming the patient should start in the prehospital setting, and acidosis can be partially ameliorated by use of balanced salt solutions. In the emergency room, this triad *must* be recognized early and aggressively addressed.

A particularly contentious issue in the elderly is futility of care in the emergency room and the ICU. This includes both quantitative and qualitative futility. Examples of quantitatively futile care would include full ventilatory support of a patient with documented brain death or an instance where there is no precedent for survival. Qualitative futility describes the nature of function following survival of a devastating insult. The descriptors of qualitative futility are dependent on

personal preferences and are value-laden. For geriatric trauma patients, substantial erosion in the capability for independent living defines qualitative futility, with the range of individual preferences defining the specifics of the loss of function. For some elderly patients, becoming permanently dependent on the assistance of others for management of bodily function constitutes a qualitative futile outcome; while for others, coma and a requirement for mechanical ventilation would be the threshold for qualitative futility. Futilities are tough ethical issues that the surgeon and intensivist face almost on a daily basis. Unfortunately, when we studied this at our institution, our outcomes were mixed. Patients who were discharged to nursing homes, skilled nursing facilities,

and rehabilitation centers had a higher death rate at 1 year than those discharged to their homes. Furthermore, those who had significant injury (ISS >15) were able to return immediately to independent living status in only 25% of instances. When discharged to secondary care institutions, many did not return to independent living status.

The elderly represent a heterogeneous group in the physiologic changes that occur during latter years. Comorbid factors described above also influence the elderly patient's response to injury and surgery. There are no simple rules in preventing futility, but the surgeon has to be aggressive in making decisions, working with the families, and trying to do what is best for the patient.

Chapter 29

Common Perioperative Complications in Older Patients

Sandhya A. Lagoo-Deenadayalan, Mark A. Newell, and Walter E. Pofahl

Introduction

As one of the fastest growing segments of the population, elderly patients account for an increasing percentage of operations in most practices. On the basis of the 2006 National Hospital Discharge Survey, patients aged 65 and older accounted for 35% of all procedures [1]. Elderly patients have a higher rate of postoperative complications. Two large studies found complication rates of 20–50% in patients aged 80 years and older [2, 3]. In contrast, younger patients had complication rates approximately half of that in the elderly patients. Table 29.1 outlines the relative frequency of specific complications in elderly patients undergoing a variety of noncardiac surgical procedures.

Elderly patients are similar to other patients in terms of the “typical” postoperative complications that can occur with an operation such as bleeding, infection, or technical errors. However, elderly patients are at risk for a group of unique complications owing to the physiologic changes of aging and the stress of the perioperative period. The underlying mechanisms for recognition, treatment, and prevention of these complications are the focus of this chapter.

There are some general principles for identifying, preventing, and treating postoperative complications in elderly patients. First and foremost, many postoperative complications in elderly patients have “atypical” presentations, making the recognition of postoperative complications difficult in this age group. For example, infectious complications do not necessarily present with fever and leukocytosis; delirium can be the sole clinical manifestation of an infectious complication.

The second principle is to actively search for and avoid complications. Every surgeon caring for elderly patients has

had a case where a single, seemingly minor, postoperative complication spiraled into something more significant. This is because although elderly patients tolerate most elective operations, they have limited physiologic reserves to tolerate the increased physiologic stress of postoperative complications. After emergency operations, much of physiologic reserve is spent maintaining homeostasis, leaving even less reserve for complications. Therefore, it is imperative to avoid preventable complications such as those that result from a poor choice of medications.

The third principle is to perform an adequate preoperative risk assessment including functional status and cognitive assessment. In the elective setting, there is adequate time to fully evaluate the elderly patient for occult comorbidities and determine functional and cognitive status. Unfortunately, the same time is usually not available in the case of urgent or emergency operations. However, this information can often be obtained from caregivers and family. This has a direct impact on expected postoperative course, especially after emergency operations, and can help set expectations and goals of therapy.

Age-Related Complications

Delirium

Delirium is a relatively frequent complication following surgery in elderly patients. Table 29.2 outlines the rates of postoperative delirium for selected common procedures. The reported rates of postoperative delirium range from 15 to >50%. [4] The rate varies from <5% following cataract surgery to as high as 60% after hip replacement [5]. Elderly patients who develop delirium have longer postoperative hospital stays, are more likely to be discharged to a nursing home, less likely to regain full function, and have higher death rates at 30 days, 6 months, and 1 year [5–8].

Impact on Outcome

The development of postoperative delirium has a deleterious effect on postoperative outcomes. Specifically, postoperative delirium is associated with longer length of stay [6, 9], higher

postoperative complication rates [9], higher probability of discharge to nursing home [6], poorer functional outcome [7, 10], and higher death rates at 6 [6] and 12 months [7]. This results in a greater financial burden of care for these patients. Robinson documented an average cost of hospitalization of \$50,100 in patients who developed postoperative delirium [6]. In contrast, the average cost of hospitalization in patients who did not develop delirium was \$31,600. Two studies of patients undergoing nonorthopedic operations documented a doubling of length of stay in patients with postoperative delirium when compared to patients who do not develop delirium [6, 9].

The development of delirium is also associated with higher rates of overall postoperative complications [9]. This is not unexpected as delirium is often the initial sign of a postoperative complication. However, a large study of patients who developed delirium after surgical treatment of hip fracture did not show an increased length of stay or increased postoperative complication rate when compared to patients who did not develop postoperative delirium [7].

There are also conflicting data on increased rates of discharge to nursing homes in patients who developed postoperative delirium. Robinson et al. [6] showed a significantly higher rate (33%) of postdischarge institutionalization in patients who developed delirium as compared to patients who did not (1%) following nonorthopedic procedures. In contrast, Edelstein et al. [7] did not find a significant increase in the rate of discharge to a skilled nursing facility for patients who developed delirium after hip fracture repair.

There is general agreement, however, that postoperative delirium is associated with worse functional recovery, as demonstrated by decline in basic activities of daily living at 1 [10] and 12 months [7] after treatment of hip fracture, and with a higher risk of death in the 6–12 months following operation [6, 7].

Etiology, Risk Factors, and Precipitating Factors

The underlying mechanisms of delirium are uncertain. However, it appears to represent an imbalance between central nervous system cholinergic and dopaminergic activity. The predominant theory is that underactivity of cholinergic system coupled with excessive dopaminergic activity can lead to delirium. This is supported by precipitation of delirium through use of anticholinergic or dopaminergic medications [11].

Delirium is the end result of a complex interaction between risk factors and precipitating events. Furthermore, in similar situations, similar patients may not necessarily develop delirium. A key component in preventing postoperative delirium is recognition of at-risk patients. The preoperative evaluation should include a detailed cataloging of the common risk factors noted in Table 29.3. The risk factor with the strongest association with development of postoperative delirium is preoperative cognitive impairment [12].

TABLE 29.3 Risk factors for and precipitating factors of delirium

Risk factors	Precipitating factors
Advanced age	Infection
Underlying cognitive impairment	Medications
Functional impairment	Hypoxemia
Coexisting medical comorbidities	Dehydration
Psychotropic medications	Sensory deprivation
Alcohol abuse	Electrolyte abnormalities
Sensory impairment	Unfamiliar environment
Immobility	Surgery
	Neurologic events
	Sleep deprivation/disruption
	Use of physical restraints
	Malnutrition
	Use of a bladder catheter

Unfortunately, this and many of the other risk factors cannot be modified in the preoperative setting prior to elective operation. However, reduction in the severity of individual risk factors, such as visual and hearing impairment and immobility, has been shown to reduce the incidence of delirium [13]. In addition to risk factors noted in the table, the presence of preoperative pain is a risk factor for postoperative delirium [14]. This is a factor that can be mitigated prior to operation using an appropriate clinical strategy. Specifically, use of oral instead of intravenous analgesia is associated with lower rates of postoperative delirium in elderly patients.

During the perioperative period, the most important strategy to prevent delirium is to actively monitor, treat, and avoid the precipitating factors. Each precipitating factor is a marker for a risk factor, has the potential to increase the severity of risk factors, or can lead to development of complications for which delirium may be a sign. Use of physical restraints and bladder catheters both lead to immobilization. In addition, indwelling bladder catheters predispose to urinary tract infection, which can precipitate delirium. Factors that alter sensorium, such as sleep deprivation or disruption, medications, or neurologic events, can also precipitate delirium. It should be noted that neurologic events are an unusual, but often sought, cause of postoperative delirium.

Diagnosis

Delirium is distinguished from dementia by its acute onset and fluctuating course. Other components include inattention with the inability to focus, disorganized thinking, and altered level of consciousness. Although most clinicians are familiar with the agitated or hyperactive state of delirium, the condition can also present as somnolence. This can lead to misdiagnosis and attribution to other causes. The Confusion Assessment Method as proposed by Inouye [15] is a validated method to diagnose delirium. It requires the presence of acute onset with a fluctuating course and inattention. Either disorganized thinking or altered level of consciousness must

TABLE 29.4 Etiology of acute confusion in surgical patients

<i>I</i>	Infection
<i>M</i>	Metabolic
<i>C</i>	Cognitive, sensory
<i>O</i>	Oxygenation
<i>N</i>	Nutrition, swallowing
<i>F</i>	Function, pharmacy, Foley catheter
<i>U</i>	Unfamiliar environment
<i>S</i>	Stress, pain
<i>E</i>	Electrolytes/fluids
<i>D</i>	Dysfunction lung, liver, kidney, brain

also be present to confirm the diagnosis. The presence or absence of each component is obtained by history or testing. Acute onset and fluctuating course are confirmed by direct observation or in the case of patients presenting with delirium through history from family and/or care providers. Inattention can be tested using simple tests such as counting backward (by threes or sevens) or naming months in reverse order. Disorganized thinking is noted on interviewing the patient. The patient will have rambling speech and/or illogical flow of ideas. He or she may switch between subjects of conversation unpredictably. Altered level of consciousness is defined as reduced clarity of surroundings – either lethargy/somnolence or hyperactivity/mania.

Evaluation and Treatment

Initial evaluation of patients with postoperative delirium is focused on assessing etiology and stabilizing the patient. Review of the preoperative history, including functional assessment and medications, is critical. The presence of risk factors as outlined should be determined. Possible precipitating factors should also be sought. A mnemonic for etiologies of acute confusion in surgical patients is shown in Table 29.4.

In those instances when postoperative delirium occurs, treatment is directed at identifying the underlying cause, providing supportive care and controlling symptoms (Fig. 29.1). Delirium is often a manifestation of other postoperative complications such as occult infection, anastomotic leak, hypoxia, hypovolemia, or electrolyte imbalance. A thorough investigation is indicated to evaluate and treat these possible etiologies. Unfortunately, a single, specific etiology is not identified in a significant number of cases. Supportive care includes many of the strategies used to prevent delirium and also includes measures to ensure airway protection, maintain adequate oxygenation, maintain fluid and electrolyte balance, and provide nutritional support. If possible, physical restraints should be avoided. Control of the patient's symptoms includes the prevention strategies previously discussed. Pharmacologic intervention should be reserved

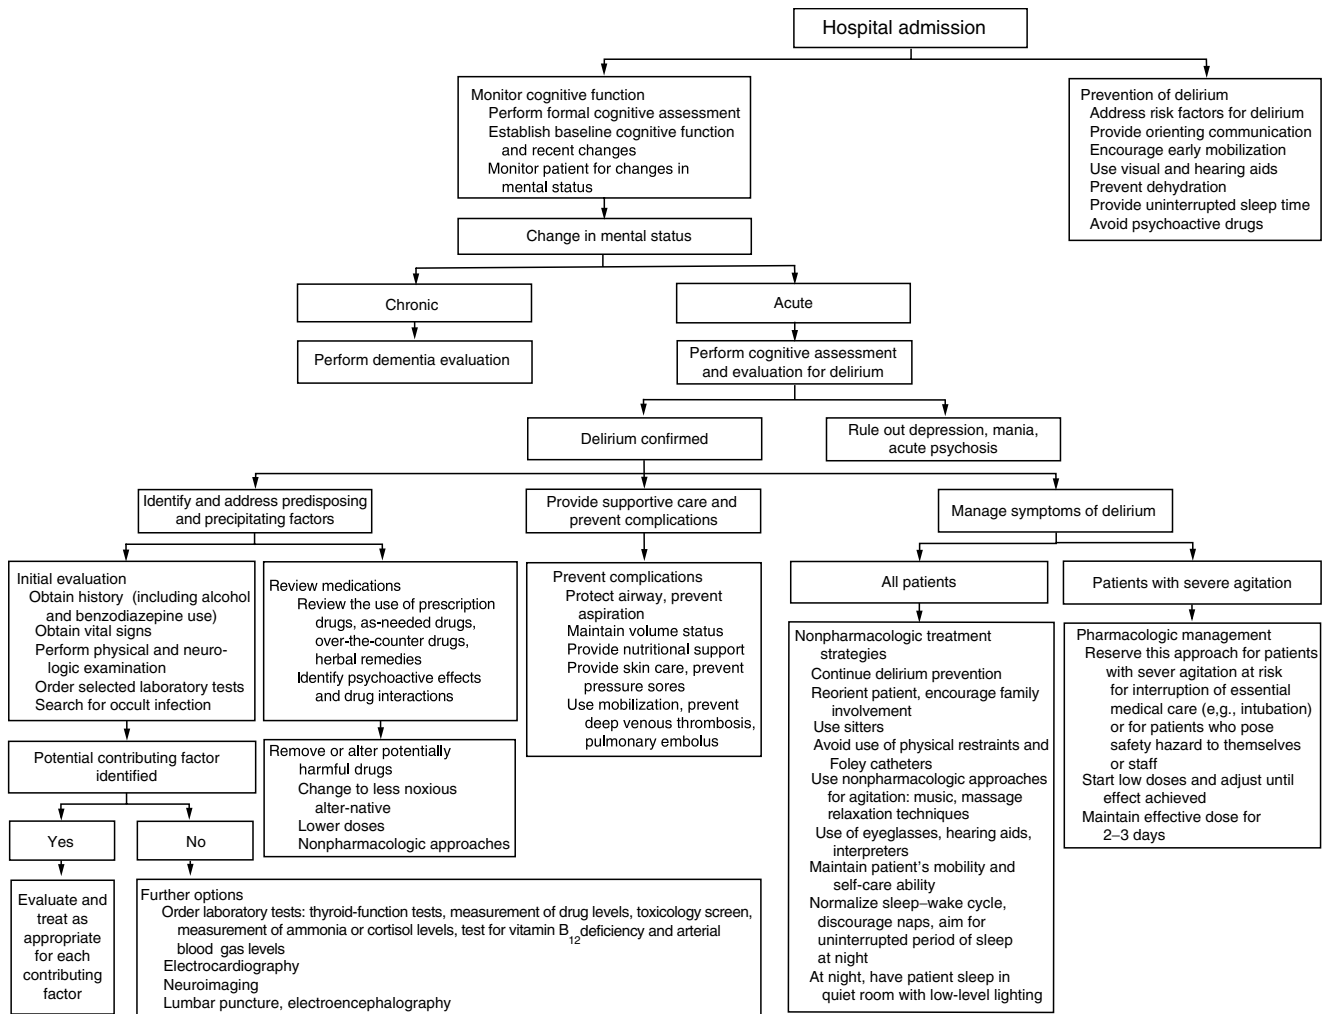

FIGURE 29.1 Prevention and management of delirium (reprinted from Inouye [11]. Copyright © Massachusetts Medical Society. All rights reserved).

for the most severe cases where patients are in danger of injuring themselves. Haloperidol (0.5–1 mg) is the preferred medication for pharmacologic intervention. Benzodiazepines – lorazepam is preferred – should only be used in cases of alcohol or benzodiazepine withdrawal.

Prevention

Strategies to prevent postoperative delirium are outlined in Table 29.5. Effective preventative measures involve multi-component interventions. An early trial demonstrated a reduction in the number and duration of episodes of delirium in medical patients [13]. The interventions to prevent cognitive impairment were orientation and therapeutic activities, prevention of sleep deprivation, early mobilization, communication methods and adaptive devices for hearing and visual impairment, and early intervention to treat dehydration. A subsequent randomized trial in patients with hip fracture found that geriatrics consultation with structured intervention

TABLE 29.5 Delirium prevention strategies

Orientation	Adequate oxygenation
Avoidance of restraints	Adequate pain management
Hearing aids	Medication review and avoidance
Eyeglasses	Adequate hydration
Family presence	
Bowel and bladder regimen	
Early mobilization	
Adaptive equipment	
Normal sleep/awake cycle	

reduced the rate of postoperative delirium when compared with standard care [16].

Studies on pharmacologic prevention of delirium have focused on several different medications. Randomized, placebo-controlled trials in surgical patients have evaluated the antipsychotic drug haloperidol [17], the cholinesterase inhibitor donepezil [18, 19], and the analgesic gabapentin [20]. Haloperidol prophylaxis was associated with reduced severity and duration of delirium in patients at intermediate or high risk

for this complication following hip surgery. Hospital length of stay was also reduced; however, the incidence of delirium was unchanged [17]. The trials evaluating prophylactic treatment with donepezil also did not find a reduction in the incidence of delirium or a reduction in hospital length of stay [18, 19]. A single small study of gabapentin found reduced analgesic requirements and a reduced incidence of delirium in patients undergoing spine surgery when compared with placebo [20].

Falls

Greater than one third of persons 65 years of age and older fall each year [21]. Falls are common in the postoperative period although they are likely to be underreported as is the rate of functional disability. Various risk factors for falls have been identified including previous history of falls, dehydration, frequent toileting, cognitive dysfunction, gait disturbances, impaired balance and mobility, and conditions such as Alzheimer's disease. Sleep apnea is known to cause sleep fragmentation and daytime drowsiness, leading to a higher risk of falls [22, 23].

Behavioral disturbances occasionally require the use of restraints in older patients in the postoperative period. Restraints should be used only when clinically justified and with strict adherence to guidelines and required monitoring. Restraints do not reduce the incidence of falls. In a case control study, patients with restraints were more likely to fall than those without restraints [24].

Fall risk should be judged preoperatively by assessing the patient's ability to ambulate and by inquiring about any history of falls in the recent past, both from the patient and family. Those with a history of falls and difficulty ambulating can be referred for perioperative physical therapy. A history of problem alcohol drinking is also associated with increased fall risk [25].

The "Get Up and Go" test is an excellent method to evaluate mobility and balance. It requires a patient to get up from a chair, walk three meters, turn around, and sit down. The test is scored on a five-point scale with 1 = normal, 2 = very slightly abnormal, 3 = mildly abnormal, 4 = moderately abnormal, and 5 = severely abnormal. The patient is rated as a low fall risk (1) or a high fall risk (5) during the maneuver. If an elderly patient is able to accomplish the task in 20 s or less, they are likely to be independent in activities of daily living. Inability to complete the maneuver suggests a high risk of fall [26]. During a 6-month period following hip fracture surgery, 95% of subjects who fell had a test score of >24 s, while 93% of patients who did not fall had scores <24. The limitation of this study is that a moderate functional capacity is needed at the time of discharge to be able to perform in the test [27].

Another useful test for assessment of balance and mobility in frail older adults is the Hierarchical Assessment of Balance and Mobility [28]. The Hierarchical Assessment of Balance and Mobility is designed to be sensitive to changes in mobility of a patient in the postoperative period. A patient's mobility varies from being unable to move off pressure points to being able to grab the bed rail and roll and eventually being able to sit and ambulate. The assessment, therefore, measures mobility (unlimited, limited, limited with aid, one person hands on, one person stand-by, lying or sitting independently, positioning self in bed, in need of positioning), transfers (independent, one person standing by, one person minimal assist, one person assist, two person assist, or total lift), and ambulation (stable ambulation, stable dynamic standing, stable static standing, stable dynamic sitting, stable static sitting, impaired static sitting). Interventions that can prevent falls in the older hospitalized patient include medication review with removal of the offending medication, adequate hydration and monitoring of orthostatic blood pressure, management of postoperative delirium by identifying and treating the cause of delirium, balance and gait training, and adherence to a regular voiding schedule [29]. Problems with vision can lead to a higher incidence of falls in the postoperative period. Vision aids may have been taken away preoperatively, and it is critical that these are returned and made available to the patient in the postoperative period [13].

Functional Decline

Deconditioning is a complex process of physiological change following a period of inactivity, bed rest, or sedentary lifestyle. It results in functional losses in such areas as mental status, degree of continence, and ability to accomplish activities of daily living (Table 29.6). It is frequently associated with hospitalization and the postoperative period in the elderly. The most predictable effects of deconditioning are seen in the musculoskeletal system and include diminished muscle mass and decrease of muscle strength that can seriously limit mobility [30]. Deconditioning following surgery can be debilitating and impede functional recovery. Incontinence and constipation are consequences of deconditioning and can have a significant impact on functional recovery and restoration of Activities of Daily Living (ADL).

Prolonged bed rest following surgery is a risk factor for functional decline [31]. In a study of 223 patients older than 75 years of age who underwent elective surgery for gastric and colorectal cancers, 24% of patients showed a decrease in activities of daily living (ADL) at 1 month following surgery. However, only 3% of patients showed a decline at 6 months. This suggests that older patients are able to attain functional independence and also report better quality of life

TABLE 29.6 Immobility, deconditioning, and functional decline

Musculoskeletal	Metabolic
Atrophy	Negative nitrogen balance
Contractures	Impaired glucose tolerance
Bone loss (osteoporosis)	Altered drug pharmacokinetics
Cardiovascular	Genitourinary
Deconditioning	Infection
Decreased plasma volume	Retention
Orthostatic hypotension	Bladder stones
DVT and PE	Incontinence
Pulmonary	Psychological
Atrophy	Sensory deprivation
Contracture	Delirium/dementia
Bone loss	Depression
Gastrointestinal	Skin
Anorexia	Pressure ulcers
Constipation	
Impaction/incontinence	

after surgery [32]. Patients who show signs of functional decline in the early postoperative period benefit from early physical therapy consultation and discharge to a skilled nursing facility or to a nursing home until satisfactory recovery. A study conducted in patients in intensive care units and ranging from 40 to 70 years have shown that initiation of early physical therapy was safe in older adults, did not increase cost, and decreased length of stay in the intensive care unit as well as hospital length of stay [33]. Another study in patients between 36 and 69 years of age also showed that whole-body rehabilitation – consisting of interruption of sedation – and physical and occupational therapy in the earliest days following a critical illness resulted in better functional outcomes at hospital discharge [34].

Cognitive impairment has been shown to be associated with poor rehabilitation outcomes and increased surgical mortality [35], and dementia is also a predictor of functional disability [36]. Older patients with preexisting chronic renal disease are more likely to be frail and also have a higher risk of developing functional limitation and disability [37, 38]. This may be secondary to a heightened inflammatory state in chronic renal disease [39].

Other General Complications

Infection

Postoperative infections are an important cause of morbidity and mortality in elderly patients. Although little is known about specific decreases in immunologic competence,

elderly patients may have diminished immune function, predisposing them to infection [40]. The most common sites of postoperative infection are the urinary tract, lungs, and surgical site [40].

Urinary tract infection (UTI) is typically due to prolonged bladder catheterization. Up to 25% of hospitalized patients have urinary catheters inserted; of these, 10–27% develop UTIs [41]. Eighty percent of nosocomial UTIs are associated with the use of urethral catheters [41]. The need for catheterization is increased in elderly patients for several reasons including medication side effects, preexisting incontinence, prostatism, and decreased mobility, all of which hinder urination [40]. Symptoms of UTI in the elderly may be subtle. Postoperative confusion may be the first and only sign of a UTI [40].

As UTIs are associated with significant morbidity and excess hospital cost [42], methods to decrease this complication are warranted. Silver impregnated catheters have been shown to reduce the risk of asymptomatic bacteriuria in short-term catheterization and to provide a cost savings when compared to standard catheters [43]. Urethral catheters impregnated with antibiotics (minocycline, rifampicin, nitrofurazone) have also shown a reduction in asymptomatic bacteriuria for urethral catheterization of less than 1-week duration [43]. However, as the inappropriate use of urinary catheters in the elderly has been documented [44] and the risk of UTI increases with increasing duration of catheterization [45], avoidance of catheterization if possible and early removal of the catheter are important steps in preventing urinary tract infections postoperatively [40].

Nosocomial pneumonia (NP) is the second most frequent hospital-acquired infection and is common in patients undergoing general, noncardiac surgery [46, 47]. Ventilator-associated pneumonia (VAP) is an important subset of NP defined as pneumonia occurring 48–72 h after endotracheal intubation. NP is a leading cause of postoperative mortality in elderly patients [46]. Although NP in older patients does not have distinctive features or a different management approach when this illness arises in younger patients [48], certain risk factors including age and functional status render the elderly vulnerable for developing NP. Underlying comorbid conditions, malnutrition, and impaired immune function may increase the mortality associated with postoperative pneumonia in the elderly [40]. Nasogastric tubes, tracheal intubation, dementia, aspiration (see section “Pulmonary Complications”), recent chest or abdominal surgery, and immobility are additional risk factors [40, 46].

NP is diagnosed using clinical criteria such as fever, purulent sputum, leukocytosis, and the presence of new infiltrates on chest radiography combined with a quantitative lower respiratory tract specimen positive for organisms. The early and appropriate initiation of antibiotic therapy for the treatment of NP has been shown to decrease mortality [47].

Because inappropriate initial antibiotic therapy leads to worsened outcomes, broad-spectrum empiric antibiotics are used at first, and therapy is then tailored based upon final culture results and sensitivities. Strategies to reduce the risk of NP include standard precautions like hand washing and the use of personal protective equipment among health care providers; aspiration prevention methods (see section “Pulmonary Complications”) including the use of endotracheal tubes with a dorsal lumen for drainage of tracheal secretions in the subglottic area; and early ambulation, deep breathing, and the use of incentive spirometry [49].

Surgical site infection (SSI) is a significant postoperative complication. SSI is the most common nosocomial infection in surgical patients, accounting for 38% of nosocomial infections in this patient population [50]. Not only is there substantial morbidity and mortality associated with SSI but the economic costs to the patient and health care delivery system are also high [51]. SSI is an infection that occurs somewhere in the operative field after a surgical intervention. Risks of developing SSI include those related to the operative procedure as well as patient-specific risks. Advanced age is considered a host-derived risk factor for surgical site infection [52]. In an analysis of deep incisional and organ/space surgical infections, elderly patients with these infections had longer hospitalizations, more frequent readmissions, and almost double the hospital charges as compared to elderly patients without postoperative infections. Most significantly, the elderly patients with these postoperative infections had a death rate that was more than three times that of the elderly patients without postoperative infections [53].

SSI is caused by organisms introduced into the surgical wound at the time of the operative procedure [51]. Most of these organisms originate from the patient’s own flora, but exogenous sources of bacteria may also lead to infection. The implementation of proven surgical infection preventive practices such as appropriate antibiotic selection and administration, intraoperative maintenance of normothermia, the avoidance of shaving the surgical site until just prior to incising the skin, and ensuring perioperative euglycemia has been demonstrated to reduce the incidence of surgical site infection by 27% [52, 54]. Vigilant surveillance of surgical wounds postoperatively is necessary to ensure the early diagnosis and treatment of a wound infection, characterized by erythema at the wound edges and the presence of purulent drainage involving the wound or organ space. Treatment of SSI involves opening the incision and allowing adequate drainage. The use of antibiotics is discouraged unless there are systemic signs of infection. If antibiotics are to be used, the choice should be determined by the most likely pathogens for the operative procedure performed [51].

Complications of Specific Organ Systems

Cardiac Complications

Myocardial Ischemia and Infarction

Major cardiovascular complications following noncardiac surgery occur in over one million patients per year; many of these occur in elderly patients [55]. Cardiac events such as myocardial infarction or cardiac death occur in 1–5% of patients undergoing noncardiac surgery [56, 57]. Postoperative cardiovascular complications substantially increase the risk of other complications and death [58]. In one study, patients with cardiac complications were six times more likely to suffer a noncardiac complication than were those without cardiac complications [59]. At least 10% of all perioperative deaths result from myocardial complications [60].

The most common cardiac complications associated with surgery in elderly patients are myocardial ischemia and myocardial infarction [61]. In a study of 4,315 patients of 50 years of age and older who underwent nonemergent major noncardiac procedures, patients aged 70 years and older had a higher risk for cardiac complications including unstable angina and myocardial infarction, compared to patients younger than 60 years [62]. The elderly are also more likely to have heart failure associated with the myocardial infarction [63]. The mortality associated with perioperative myocardial infarction is approximately 30% [60].

Preexisting hypertension, diabetes mellitus, and history of cardiac or renal failure contribute to a higher incidence of perioperative myocardial infarction (5.1%), cardiac death (5.7%), or ischemia (12–17.7%) in elderly patients [61, 64]. Patients with coronary artery disease have a 4.1% incidence of perioperative myocardial infarction. The perioperative reinfarction rate in patients older than 65 years is 5.5% [61], compared to a 3.5–4.2% perioperative reinfarction rate in the general population. Additional risk factors in the elderly include the need for emergency surgery, major surgical procedures, American Society of Anesthesiologists (ASA) physical status III or IV, and poor nutritional status [61].

A large number of perioperative myocardial infarctions occur during the first 3 days after surgery, particularly on the 1st postoperative day [65, 66]. Although chest pain is the most common presenting symptom of myocardial ischemia in young patients, elderly patients may not experience chest pain. Myocardial ischemic events are silent in over 80% of elderly patients [66, 67]. Detecting episodes of ischemia during the postoperative period is often missed because of incisional pain, residual anesthetic effects, postoperative analgesia, and the lack of typical angina pain by elderly patients [66]. Atypical symptoms such as tachycardia,

hypotension, dyspnea, respiratory failure, syncope, confusion, nausea, and excessive hyperglycemia in diabetics are more common presentations of myocardial ischemia in the elderly [60, 64, 66].

Monitoring for specific electrocardiographic changes, such as ST segment elevation and Q waves, accompanied by elevated CK, CK-MB isoenzyme, and troponin T and I levels enables the diagnosis of myocardial infarction [61]. Postoperative ST-segment changes more commonly demonstrate depression than elevation, and most myocardial infarctions are non-Q wave. This differs from what is seen in the nonsurgical setting, suggesting that perioperative myocardial infarctions are more often related to prolonged ischemia rather than acute thrombotic occlusion [66]. As such, EKGs should be obtained in the early postoperative period and between the 3rd and 5th postoperative days in high-risk patients [48].

Noncardiac surgery intensifies myocardial oxygen demand by raising catecholamine concentrations, resulting in an increased heart rate, blood pressure, and free fatty-acid concentrations. β -adrenergic blockers attenuate the effects of increased catecholamine levels and prevent perioperative cardiovascular complications [55]. In a large observational study, the perioperative administration of β -blockers was associated with clinically significant reductions in mortality among surgical patients considered at moderate or high risk for major cardiovascular complications based upon their Revised Cardiac Risk Index score. However, β -blockers were of no significant benefit – and were possibly harmful – in patients at low risk, suggesting that careful patient selection remains necessary [58].

β -blockade may have additional benefits in elderly patients. In one study, patients who received β -blockers were extubated sooner, had lower analgesic requirements, and were more alert sooner after surgery [57]. Prophylactic β -blocker therapy may attenuate the impact of myocardial infarction, resulting in lower in-hospital mortality rates [65].

Potential harmful effects from β -blockers include bradycardia, hypotension, bronchospasm, and congestive heart failure [38, 55, 57]. The use of perioperative β -blockade in patients who had not been receiving β -blockers long-term may also pose an additional risk in that withdrawal of β -blockers may lead to adrenergic hypersensitivity and possibly worsen outcomes [68].

Dysrhythmias

Dysrhythmias have been shown to increase postoperative cardiac morbidity in elderly patients [69]. Postoperative atrial arrhythmias are seen in 6.1% of elderly patients undergoing noncardiac surgery [70]. Electrolyte disturbances and/or increased sympathetic nervous system activity in the perioperative period may lead to cardiac dysrhythmias, although

myocardial ischemia or congestive heart failure must be considered [71].

To date, the only consistent preoperative risk factor for an increased incidence of atrial arrhythmias following surgery has been an age of 60 years or older [72]. In patients undergoing elective thoracic surgery, those aged 60 years or older were independently associated with development of atrial fibrillation [70]. Patients who developed postoperative pneumonia or acute respiratory failure were also at risk [70].

The timing of the onset of atrial arrhythmias is similar to that of postoperative myocardial ischemia and likely is related to autonomic nervous system imbalance [72]. These arrhythmias may also be precipitated by pulmonary disease such as pneumonia or pulmonary embolism, volume overload, hyperthyroidism, or sympathomimetic drugs. Atrial arrhythmia-onset peaks 2–3 days following surgery. Although usually well tolerated in younger patients, perioperative atrial arrhythmias can be associated with hemodynamic instability in elderly patients [72]. The complications of atrial fibrillation include stroke and congestive heart failure [73]. Atrial fibrillation is also associated with higher inpatient mortality when accompanied by myocardial infarction (25% vs. 16%) [73].

Management of atrial fibrillation consists of heart rhythm and rate control and prevention of thromboembolism. Although approximately 85% of atrial arrhythmias revert to sinus rhythm with rate- or rhythm-control strategies during hospitalization, recent data suggest that rhythm control by pharmacologic means or direct current electrical cardioversion offers little advantage to a rate-control strategy [72]. Atrial fibrillation responds well to intravenous rate control drugs such as β – and calcium-channel blockers [72]. β -blockers are preferred in patients who have ischemic heart disease but may be relatively contraindicated in patients with severe bronchospastic disease, congestive heart failure, severe sinus bradycardia, or high-degree atrioventricular block [72]. In patients who have Wolff–Parkinson–White syndrome with atrial fibrillation, amiodarone is recommended as first-line therapy [72]. Digoxin should be used as a first-line drug only in patients who have congestive heart failure because of its ineffectiveness in high-adrenergic states such as the perioperative period [72]. As it relates to thromboembolism, oral vitamin K antagonists and aspirin reduce the stroke risk by 68 and 21%, respectively [74]. In the perioperative period, the decision to use bridging anticoagulation with heparin and the timing of resuming anticoagulation postoperatively are dependent on risk of thromboembolism. Clinical prediction rules such as the Congestive Heart Failure–Hypertension–Age >75–Diabetes–Stroke (CHADS₂) assist in risk stratification [75]. CHADS₂ estimates the risk of stroke by assigning one point for each of the five included conditions except stroke, which is assigned two points. The total score ranges from zero to six points; aspirin therapy is

recommended for thromboembolism prevention for low-risk patients (<5% risk per year; CHADS₂ 0–2), whereas oral vitamin K antagonists are prescribed with higher risk patients (>5% risk per year; CHADS₂ 3–6) [76, 77].

Significant, sustained ventricular arrhythmias (ventricular tachycardia, ventricular fibrillation, torsade de point) occur less frequently than atrial arrhythmias perioperatively [70, 73]. In a study of patients undergoing major thoracic surgery with continuous postoperative electrocardiographic monitoring for 72 h, nonsustained ventricular tachycardia occurred in 15% of patients [76]. None of the patients required treatment for hemodynamic compromise. Postoperative atrial fibrillation was independently associated with ventricular tachycardia. This association between atrial and ventricular arrhythmias suggests that similar mechanisms may have a role in precipitating postoperative ventricular tachycardia [76].

Congestive Heart Failure

Congestive heart failure is present in 10% of individuals over 65 years of age and is a leading cause of postoperative morbidity and mortality following surgical procedures [69]. Preexisting congestive heart failure is associated with a two- to fourfold increase in postoperative cardiovascular complications, including myocardial infarction, supraventricular and ventricular dysrhythmias, hypotension or hypertension, and cardiac arrest [69, 78]. Heart failure can arise from any condition that compromises the contractility of the heart (systolic heart failure) or that interferes with the heart's ability to relax (diastolic heart failure) [79].

Risk factors for postoperative heart failure included preoperative symptomatic cardiac disease, male sex, and age ≥ 90 in one study of elderly patients with hip fracture undergoing operative repair [80]. Manifestations of postoperative heart failure usually occur within the initial 3 postoperative days [81]. Patients found to be in pulmonary edema postoperatively should be assessed for myocardial ischemia. This includes cardiac monitoring, electrocardiography, and serial cardiac enzyme measurements.

The treatment of postoperative heart failure with pulmonary edema, whether from systolic or diastolic dysfunction, differs little from the general management of heart failure. Angiotensin-converting enzyme inhibitors and diuretics are first-line therapy. In patients with acute decompensated heart failure, angiotensin-converting enzyme inhibitor therapy may need to be held, reduced, or discontinued if hypotension is a concern. In the presence of diuretic usage, electrolyte abnormalities (e.g., potassium, magnesium) should be diagnosed and corrected. β -blocker therapy can be used in heart failure secondary to myocardial ischemia unless hypotension precludes its usage. Digoxin is first-line therapy in heart failure associated with atrial fibrillation [78].

Pulmonary Complications

Pulmonary complications account for up to 40% of postoperative complications and 20% of potentially preventable deaths [82]. Postoperatively, pulmonary complications occur in 2.1–10.2% of elderly patients and include atelectasis, hypoxemia, hypoventilation, acute respiratory distress syndrome, and pneumonia. Development of these complications is associated with prolonged intensive care unit stay and increased mortality [61]. Increased age elevates the odds of developing a postoperative pulmonary complication nearly twofold [83]. Compared with patients younger than 60 years of age, patients of 70 years of age and above had a higher risk of respiratory complications including bacterial pneumonia, noncardiogenic pulmonary edema, and respiratory failure requiring intubation in one study [62].

Age-related alterations in pulmonary function combined with postoperative pulmonary pathophysiologic changes place the elderly patient at greater risk for complications [82]. The physiologic changes of aging lead to decreased lung volumes, expiratory flow rates, and oxygenation. Upper airway reflexes are also reduced, leading to loss of ability to clear secretions [82].

Clinical predictors of adverse pulmonary outcome include the site of surgery (chest, abdomen), duration and type of anesthesia, chronic obstructive pulmonary disease (COPD), asthma, preoperative hypersecretion of mucus, chest deformation, and perioperative nasogastric tube placement [61, 84]. In one multivariate analysis, postoperative nasogastric intubation was the single most important variable associated with postoperative pulmonary complications [85].

Aspiration

The process of deglutition involves a complex coordination of neuromuscular structures during its oral, pharyngeal, and esophageal phases [86]. Age-related changes affect each phase of the swallowing process, increasing the risk of aspiration in the elderly [86]. Aspiration, defined as the inhalation of oropharyngeal or gastric contents into the larynx and lower respiratory tract, is a prerequisite for aspiration pneumonia [86]. Other alterations with aging that contribute to aspiration pneumonia include a change of oropharyngeal colonization to pathogenic organisms, decreased immunity, and impaired pulmonary clearance [86].

The presence of other risk factors in the elderly make them particularly susceptible to oropharyngeal aspiration including dysphagia, poor oral hygiene, altered level of consciousness, and gastroesophageal reflux disease [60, 86] (see Table 29.7). As such, efforts to reduce postoperative aspiration in the elderly are indicated [87]. Elderly patients with signs and symptoms of dysphagia and recurrent pneumonia

TABLE 29.7 Risk factors for aspiration

Altered consciousness	Advanced age
Alcohol	Dysphagia
Substance abuse	Gastrointestinal motility disorders
Sedatives	Gastroesophageal reflux disease
Anesthesia	Recurrent emesis
Head trauma	Supine position
Seizures	Nasogastric tube
Other neurological disorders	Endotracheal intubation

require an assessment of swallowing function. Patients found on evaluation to be aspirating may require swallow therapy, modification of dietary consistency, upright positioning while feeding, and medications shown to improve dysphagia such as angiotensin-converting enzyme inhibitors, which prevent the breakdown of substance P, a neurotransmitter believed to play a role in the swallowing pathway [86, 88].

Respiratory Failure

Postoperative respiratory failure (PRF), the inability of the patient to be extubated within 48 h after surgery or the need for reintubation after postoperative extubation [89, 90], ranks first among the most serious postoperative pulmonary complications. The incidence of PRF in patients older than 65 years is estimated to be 3.85 per 1,000 elective surgery discharges compared to 1.41 per 1,000 elective surgery discharges in people aged 18–44 [91]. Risk factors for PRF include those that are patient-specific and operation-specific [89]. Age greater than 60 years, functional status, comorbidities, and severity of illness make up patient-specific risk factors. Operation-specific risk factors consist of the location of the incision in relation to the diaphragm, type of anesthesia administered, and the need for an emergent procedure [89]. Pneumonia, pulmonary edema, systemic sepsis, and cardiac arrest are postoperative pulmonary complications associated with PRF [89].

In patients with PRF, mechanical ventilation is used to improve gas exchange, to decrease work of breathing which can utilize as much as 50% of oxygen consumption, and to support fatigued respiratory muscles [91]. Different methods of ventilatory support are available to accomplish these goals. Positive end-expiratory pressure (PEEP) improves oxygenation by recruiting atelectatic areas of the lung. The use of PEEP leads to an increase in oxygenation by reducing intrapulmonary shunting [91].

Ultimately, an assessment has to be made to determine the timing of discontinuing ventilator support. This weaning process may be difficult in patients recovering from severe respiratory failure and prolonged mechanical ventilation. In a study to determine the major cause of planned extubation

failure in critically ill elderly patients, inability to handle secretions was the most common airway cause of failure compared to upper airway obstruction in a younger group matched for severity of illness [92]. Traditional weaning parameters such as rapid shallow breathing index, negative inspiratory force, and minute ventilation were not predictive of elderly patients who ultimately failed extubation [92]. The in-hospital mortality for the elderly patients that failed extubation was 47% compared to 20% for the patients successfully extubated [92].

The need for early tracheostomy in elderly patients predicted to require prolonged intubation is controversial. Potential benefits of early (after 3–7 days of continuous ventilatory support) tracheostomy include improved patient comfort, decreased incidence of ventilator associated pneumonia (VAP), and decreased ICU and hospital lengths of stay. A recent retrospective cohort study of ventilated patients of 65 years or older was undertaken to compare outcomes in patients with more (late group) or less (early group) than 7 days of continuous ventilation who underwent tracheostomy [93]. The early tracheostomy group had shorter ICU and hospital admission time, decreased incidence of VAP, and a trend toward decreased mortality [93]. This study also demonstrated the ability to transfer elderly patients with tracheostomy to ventilator step-down units. Given the growing elderly population and need for ICU beds, early tracheostomy may permit more efficient usage of a valuable resource [93].

Prevention of Pulmonary Complications

Prevention of postoperative pulmonary complications in the elderly begins during the preoperative period. Assessing patients for sputum production is important as a productive cough correlates with respiratory failure [90]. Smoking cessation 8 weeks prior to the operation has been shown to improve mucociliary function and promote sputum clearance. The use of bronchodilators can aid expectoration. Providing instruction preoperatively on deep breathing exercises and the use of incentive spirometry facilitate the utilization of these maneuvers postoperatively when anesthesia and sedatives may decrease awareness and hinder education [90].

Postoperatively, an aggressive pulmonary toilet regimen is necessary to reduce pulmonary complications. Of utmost importance is adequate pain control. Splinting from inadequate pain control restricts lung expansion, limits cough to clear secretions, and leads to an increased risk for atelectasis, pneumonia, and hypoxia [69]. However, avoidance of excessive sedatives and narcotics is equally important. Appropriate analgesia will facilitate deep breathing and coughing, incentive spirometry, chest physiotherapy, and early ambulation [69, 82, 85].

Venous Thromboembolism

Venous thromboembolism (VTE) disproportionately affects the elderly [94]. Age is a well-accepted risk factor for VTE, with a mean age of approximately 60 years based on several studies. There is a linear increase in the prevalence of deep venous thrombosis and pulmonary embolism with age [95]. Ninety percent of all pulmonary emboli are estimated to occur in patients over age 50 [82]. The elderly are more likely to have prior recent hospitalization, atherosclerosis, heart failure, frailty, and immobility as factors responsible for their increased prevalence of VTE [94, 96].

For surgical patients, age over 60 years is associated with a high risk for postoperative VTE [94]. In these older patients not receiving prophylaxis, the incidence of proximal deep venous thrombosis is 4–8% and of PE is 2–4% [95]. These numbers are twice as high in high-risk categories that include cancer surgery, joint replacement, previous VTE, and trauma [94]. Because the elderly have a higher bleeding risk when treated with anticoagulants, a balance has to be achieved between optimal VTE prevention and the risk of bleeding complications [94, 97]. Care should be exercised with the use of anticoagulants in patients with creatinine clearance < 30 ml/min and serum creatinine > 2 mg/dl in that the pharmacokinetics of these medications may be affected, thereby increasing the bleeding risk [94].

Early ambulation can decrease the incidence of venous thrombosis with pulmonary embolus. Unfortunately, owing to comorbidity or deconditioning, elderly patients are frequently unable to accomplish this simple exercise [85]. Mechanical prophylactic measures to prevent VTE include graded compression stockings, intermittent pneumatic compression, and venous foot pumps. These devices are attractive in that they are efficacious and are void of bleeding risk. Compliance with these devices may not be optimal, however, because of patient discomfort [94]. Alternatively, the administration of pharmacologic prophylaxis can be verified in the medical record, and its use does not discourage ambulation [94]. Perioperative prophylaxis with unfractionated or low-molecular-weight heparin offers a cost-effective means of reducing the risk of VTE, thereby avoiding a number of postoperative deaths [82]. In high-risk bleeding patients, mechanical prophylactic measures may be all that is available.

Anemia

Preoperative anemia, characterized by less than the normal number of red blood cells (RBC), may be secondary to decreased production, increased destruction, or increased loss [98]. The World Health Organization has defined anemia

as a hemoglobin count of less than 13 g/dl in adult men and less than 12 g/dl in nonpregnant women [98]. In elderly patients undergoing surgery, perioperative blood loss leading to or exacerbating anemia leads to increased morbidity and mortality, but the correction of anemia with RBC transfusions is fraught with debate [98–102].

RBC transfusions can be associated with transfusion complications, immunosuppression, and increased bacterial infections in hip fracture patients [98–101]. Conversely, perioperative anemia in the elderly may represent a further physiological insult due to increased cardiac demand and potential tissue hypoxia [100]. As such, the appropriate transfusion threshold in the elderly that would limit risk and optimize benefit would be advantageous.

Restrictive (transfusion for hemoglobin less than 7 g/dl) and liberal (transfusion for hemoglobin less than 10 g/dl) transfusion thresholds have been advocated in an attempt to balance the risks and potential benefits of RBC transfusion. In a randomized clinical trial comparing restrictive and liberal transfusion thresholds, critically ill patients in the restrictive group had similar mortality, and fewer patients developed myocardial infarction and congestive heart failure [98]. Caution should be exercised in extrapolating these results to an elderly population. In the elderly, anemia may impede functional mobility after hip surgery [100]; it may be associated with increased cardiovascular complications [101], mortality [101], and postoperative delirium [100] and may negatively impact quality of life [99]. Additional, well-designed randomized studies are needed to determine the optimal transfusion trigger in the elderly.

Urinary and Renal Dysfunction

Postoperative urinary retention is a frequent complication after surgery especially in elderly males. Although it is not a life-threatening complication, treatment with bladder catheterization puts patients at risk for urinary tract infection and its attendant complications. In one report, 69% of males undergoing hip arthroplasty required postoperative bladder catheterization [103]. Using logistic regression, the predicted probability of catheterization was 85% in males aged 70 years and older. In addition to age and male gender, intraoperative fluid requirement [104], operative duration, operation for rectal tumor, and postoperative pelvic infection [105] are associated with postoperative urinary retention. On the basis of the above noted studies, it would seem reasonable to recognize the risk factors for postoperative urinary retention and working to militate against those factors. Factors associated with postoperative urinary retention in elderly patients are outlined in Table 29.8.

TABLE 29.8 Factors associated with urinary retention in elderly patients

Age > 55 years
Intraoperative fluids > 750 cc
Operation duration > 4 h
Procedure for middle or lower rectal tumor
Presence of pelvic drain
Postoperative pelvic infection

Aging is associated with decreased renal cortical mass and a 30–50% decrease in the number of functioning glomeruli by the seventh decade [106]. This results in decreased creatinine clearance and decreased maximal urine concentrating capacity. Loss of muscle mass in the elderly patient can result in normal serum creatinine even in patients with decreased renal function. Creatinine clearance is a more accurate measure of renal function and estimated glomerular filtration rate based on the Cockcroft/Gault equation correlates well with creatinine clearance.

Chronic renal disease is prevalent in 11–25% of the elderly population and is an important comorbid condition in the perioperative period. In the general population, patients with chronic kidney disease are at higher risk for adverse outcomes such as death, cardiovascular disease, and hospitalizations [107]. Chronic renal disease is also associated with development of functional impairment [39]. Patients with chronic kidney disease have a higher incidence of hyperkalemia, infections, cardiac arrhythmia, and bleeding in the perioperative period [108].

Postoperative acute renal failure (ARF) is a significant etiology of renal failure, accounting for 25–50% of all cases [109–111]. However, ARF occurs infrequently after operation in elderly patients. In one study of cardiac surgery patients, 2.7% patients aged 70 years and older developed postoperative ARF [112]. In comparison, 1.9% patients younger than 70 years of age developed postoperative ARF. In contrast, another study of patients undergoing coronary artery bypass demonstrated a 3.2% rate of ARF in patients aged 80 and older; only 0.4% of patients younger than 80 years developed ARF. A study of elderly patients undergoing repair of femur fracture found that 24% developed postoperative kidney dysfunction, but none required renal replacement therapy [113].

Recovery of renal function is possible after developing ARF. Data on postoperative ARF are limited. A systematic review and meta-analysis found that approximately 30% of elderly patients do not recover renal function after ARF [114] as compared with 26% of younger patients. Despite failure to recover normal renal function, only 3–6% of elderly patients require long-term dialysis after ARF [115].

Acute renal failure in elderly patients in general and postoperative ARF specifically is associated with a high mortality rate. The mortality rate for patients with ARF (all causes) is 45–75% [115]. The mortality rate for postoperative ARF

in elderly patients in one study was 39%. In elderly patients undergoing cardiac surgery, postoperative renal failure was the most significant factor associated with postoperative death with an odds ratio of 4.4 [116]. In one study of patients undergoing cardiac surgery, the death rate in patients developing postoperative ARF was 56.1; however, there was no significant difference in mortality rates in the younger (61.9%) and older (50%) patient groups [112].

Gastrointestinal Complications

Postoperative Nausea and Vomiting

Postoperative nausea and vomiting (PONV) is a major concern in surgical patients, but less so in the elderly. Important risk factors for PONV include female gender, nonsmokers, history of PONV, and the use of postoperative opioids. Each risk factor can be accorded a point of 1. Total scores of 0, 1, 2, 3, or 4 are associated with a risk of PONV of 10, 20, 40, 60, and 80%, respectively [117]. Age is not an independent risk factor for PONV. There is >10% decreased risk of PONV for every decade of age in adults, starting at age 30 [118]. One of the factors that could be responsible for decreased PONV in older adults is the decrease in the doses of anesthetic agents administered. In a study involving 30,842 patients, fentanyl, propofol, midazolam, and isoflurane showed a 10, 8, 6, and 4% reduction in dose per decade of age, respectively [119]. Current consensus guidelines recommend use of regional anesthesia whenever possible as it is associated with a lower incidence of PONV in adults [120]. When general anesthesia is administered, use of propofol for induction and maintenance and avoidance of nitrous oxide can decrease the risk of PONV. Proper preoperative and intraoperative hydration are important in prevention of postoperative nausea and vomiting [121]. Metoclopramide should not be used in the elderly due to significant CNS side effects such as dyskinesia, drowsiness, and agitation. Prophylactic antiemetics should be used based on a risk score and are therefore not recommended in the elderly.

Dysphagia

There is an increased incidence of dysphagia in the elderly. ADL score has been shown to correlate with increased swallowing dysfunction [122]. Knowledge of preoperative nutritional habits is important so that appropriate foods can be offered in the postoperative period. Lack of dentures or offering solid foods in patients who are used to pureed/soft foods can result in inadequate intake and compromise postoperative recovery.

Impairment of swallowing is slow to resolve following extubation [122], especially after prolonged ventilation. This increases the risk of aspiration and subsequent aspiration pneumonia [123]. Aspiration precautions should be rigorously implemented in the postoperative period. These include elevation of the head end of the bed, seated position during meal intake, and specific food consistency.

Although it is not necessary to do a fiberoptic endoscopic evaluation of swallowing in all elderly patients, those with impaired preadmission functional status should be considered at high risk for aspiration and evaluated appropriately [124].

Gastroesophageal reflux disease (GERD) is common in elderly patients and prevalent in greater than 30% of the elderly population [125]. Unlike their younger counterparts, older patients with GERD may not complain of worsening symptoms. It is important to continue antireflux medications in the postoperative period. Proton pump inhibitors are more effective in elderly patients than H₂ blockers. Administration of proton pump inhibitors in the immediate postoperative period helps not only to control GERD but also serves as prophylaxis for bleeding from gastritis or peptic ulcer disease.

Postoperative Ileus

Surgical manipulation of the bowel can cause a prolonged postoperative ileus. Another factor in the development of ileus is the stimulation of opioid receptors. In a prospective study designed to compare surgical outcomes in patients greater or less than 80 years of age, the incidence of postoperative ileus was increased in the older patients [2]. Routine measures such as bowel rest, bowel decompression, and attention to nutrition (TPN) should be addressed.

Enhanced recovery after surgery (ERAS) is used in fast track surgery to reduce surgical stress response and support basic body functions by use of optimized analgesia, early mobilization, and early return to normal diet [126, 127]. This type of multidisciplinary intervention has been used effectively following colon surgery with significant success. It has led to a significant decrease in postoperative ileus and a decrease in hospital stay [128]. Prospective randomized trials are still needed to evaluate the effects of fast track surgery on older patients. While age should not be a contraindication to enroll patients in such a study, it will be critical to determine comorbidities in this group that would limit the benefits of such an intervention [129]. It is possible that while ERAS programs benefit those with significant comorbidities, the benefit may be most evident in vulnerable subgroups such as the elderly [130]. An opioid antagonist such as ADL 8-2698 differs from other opioid-receptor antagonists in that it is potent, orally active, and poorly absorbed after oral administration. Once absorbed, the drug has a limited ability to cross the blood-brain barrier. Large doses of ADL 8-2698, thus, have

the potential to antagonize gastrointestinal opioid receptors nearly completely without inhibiting the beneficial analgesic action of systemic opioids. These antagonists are able to counteract the effect of morphine on the GI tract [131]. Selective inhibition of GI opioid receptors by a peripherally restricted opioid antagonist can facilitate early recovery of bowel function, decreased hospital stay and still provide adequate pain relief [132].

Summary

As the number of elderly patients increase, they are accounting for a greater proportion of patients in most surgical practices. Therefore, surgeons, and all adult medical practitioners, must be aware of the unique complications associated with the surgical care of elderly patients. Because of their reduced physiologic reserve, elderly patients are less able to respond to and recover from postoperative complications. However, attempts to recognize, treat, and prevent these complications are complicated by atypical presentations.

Optimal care of elderly patients requires significant diligence. The presence of comorbidities and physiology of aging put this population at risk for “typical” complications such as cardiac dysrhythmias, myocardial infarction, pneumonia, and surgical site infection. Equally important, but often less appreciated, are the “atypical” complications that are more prevalent in elderly patients. Delirium is such a complication. It is much less common in younger patients. It is often misdiagnosed in elderly patients. The importance of this lies in the fact that postoperative delirium is often the initial sign of another postoperative complication.

The surgical care of elderly patients can be a gratifying part of surgical practice. By taking appropriate measures to prevent complications and by remaining vigilant, the perioperative experience for patient, surgeon, and the health care team has the opportunity to be rewarding.

Chapter 30

Management and Outcomes of Intensive Care in the Geriatric Surgical Patient

Gary T. Marshall and Scott R. Gunn

Introduction

Should we admit geriatric patients to the intensive care unit (ICU) at all? Of course, we believe the answer to this question is a qualified “yes”; otherwise, our chapter would be brief indeed. But, it is important to remember that rationing health care based upon age has been advocated as a strategy for limiting cost [1]. Refusal of ICU admission is common across many developed countries and has been reported to range between 24 and 46% of requested admissions [2–6]. In these studies, advanced age and previously poor functional status are the most common reasons for refusal to admit to the ICU. In 2004, Sinuf and coworkers systematically reviewed rationing of ICU resources and found that age and severity of illness were most strongly associated with a refusal to admit to the ICU [7]. Admission to the ICU carries with it a large commitment of health care resources. If we admit geriatric patients, how do we best allocate costly and limited ICU resources? At a time when the numbers of geriatric ICU patients [8] and the costs associated with ICU care are rapidly increasing, it becomes important to examine what outcomes can be expected if we are to provide ICU care to elderly patients.

Outcomes

Mortality

Mortality has traditionally been the primary outcome used to assess health care delivery. Mortality among elderly patients is substantial following hospital discharge. In a study of medical and surgical patients ≥ 70 years, 1-year survival was 56% in patients aged < 85 years and 27% in those ≥ 85 years –

rates markedly lower than in a matched population (93%) [9]. Others have reported mortality rates in critically ill patients ≥ 85 years of 30% at ICU discharge, 43% at 30 days posthospital discharge, and 64% at 1 year [10]. In addition, age is an independent variable in many prognostic scoring systems such as Acute Physiology and Chronic Health Evaluation (APACHE) II [11], APACHE III [12], and the Simplified Acute Physiology Score (SAPS) II [13].

But, chronologic age alone is not the whole story. In one study, the impact of age on outcome weakened as the severity of the acute illness (or physiologic derangement) increased [14]. Margulies and coworkers found ICU mortality among surgical patients related to severity of illness (evaluated as SAPS) and did not differ significantly between nonagenarians and younger patients when stratified for SAPS [15]. In two reports of patients admitted to medical ICUs, old age no longer predicted mortality when acute severity of illness, diagnosis, and prior health were taken into account [16, 17]. As is clear from other chapters on physiologic changes associated with aging, the elderly are less able to maintain homeostasis in the face of pathologic stressors than are younger patients. It is to be expected, therefore, that they will have more marked derangements for any given “insult” (e.g., injury, infection, or surgical procedure) than the young. In other words, prognostic scoring systems which examine abnormal physiology such as the APACHE III or SAPS II should be expected to reflect increased mortality not only as a result of increased age but also – and perhaps more importantly – as a result of a decreased ability to maintain homeostasis.

Health-Related Quality of Life

While mortality remains an important metric for assessing health care, other outcomes such as quality-adjusted life years (QALYs), postdischarge placement status, and health-related quality of life (HR-QOL) are becoming increasingly relevant. To date, the largest review of HR-QOL literature in elderly patients after admission to the ICU was authored by

Hennessy and colleagues in 2005 [18]. After an extensive MEDLINE review, they identified 16 studies that examined HR-QOL or functional status in geriatric patients after ICU admission. These studies included a total of 3,247 elderly survivors of critical care whose HR-QOL or functional status was assessed after ICU discharge. In their review, these investigators were limited in their ability to synthesize results across multiple studies results by study heterogeneity. For example, the authors found that most studies used varying assessments of severity of illness, chronic illness and prior functional status. They found a lack of consensus regarding definition of “elderly” and evaluation of outcomes using various methods and at various times. In addition, many studies suffer from a potential selection bias arising from criteria or policies for ICU admission [19]. Studies usually evaluate convenience samples of patients admitted to an ICU; information about potentially eligible patients who were not admitted is uncommon. Finally, most studies are ICU-based or institution-based rather than population-based and thus are limited by referral bias.

Despite limitations, these investigators found that the majority of published literature in this field (10 of 16 reviewed studies) supports the concept that aged ICU survivors maintain a good functional status and/or HR-QOL. There were some exceptions. For example, Vasquez Mata and coworkers found that their elderly cohort had the most reduction in HR-QOL as compared to a younger cohort [20]. Of note, Vasquez Mata used an assessment tool primarily focused on physical functioning without a subjective assessment of HR-QOL. While physical functioning plays a role in HR-QOL, other significant domains include social functioning, pain, fatigue, and ability to perform activities of daily living. It is possible that while physical function may decrease for geriatric ICU survivors, other domains may become more important in their overall assessment of HR-QOL. In another significant study, Montuclard and coworkers found that independence in activities of daily living was significantly decreased for elderly ICU survivors [21]. However, their unique inception cohort (subjects with an ICU length of stay >30 days) may limit this study’s generalizability.

In the largest, single-center outcome study of geriatric patients who survive ICU admission (published after the review by Hennessy), Kaarlola and coinvestigators evaluated 883 elderly ICU survivors and 1,827 controls [22]. They found that cumulative 3-year mortality was higher among the aged (57% vs. 40% in the control group). Most (66%) elderly non-survivors died within 1 month of ICU discharge (Fig. 30.1).

In addition, geriatric patients had significantly fewer QALYs than age- and sex-matched controls. However, 97% of the geriatric survivors lived at home. 88% described their present state of health as good or satisfactory. In fact, 66% found it similar or better than 12 months prior, and 48% found it similar or better than before ICU admission.

Other Factors

The relation of age and severity of illness to mortality is further modified by specific diagnosis. In one study, patients admitted following trauma had the highest long-term survival compared to other diagnostic groups in a mixed ICU [23]. Age, severity of illness, and diagnosis were independent predictors of 1-year survival in a recent study of medical and surgical patients ≥ 70 years of age [9]. In a study in which many of the patients were admitted to the ICU following surgery or trauma, the survival of those who were alive 6 months following hospital discharge approached that of an age-, year-, and gender- matched general population [24]. The interaction of prior functional status and age may also influence mortality. In one study, patients ≥ 75 years of age who had functional limitations were six times more likely to die in hospital than those aged 50–64 years without limitations [25]. Among patients without functional limitation, there was no difference in mortality between the youngest and oldest groups. Physical activity status and quality of life prior to admission were significant predictors of survival in a mixed ICU population with large proportions of older and chronically ill patients [26].

Conclusions

As age increases and functional status declines, patients may become more willing to accept aggressive medical therapy. For example, Sage and coauthors found that increasing age was inversely related to patients’ assessments of quality of life following discharge, but not to objective scores of physical and psychosocial disability [27]. These observations are consistent with the concept that individual and societal views of quality of life do not necessarily coincide in older patients, who may be more accepting of health-related limitations in life style than young patients [27, 28]. While more research is needed to accurately characterize the mortality and HR-QOL of elderly survivors of critical illness, currently, we believe that despite a higher mortality, aged patients with a reasonable preadmission functional status and severity of illness can likely be expected to benefit from ICU admission. It is probable that postdischarge functional status will be less than that of younger ICU survivors; however, elderly ICU survivors are likely to be satisfied with their postdischarge HR-QOL and may even rate it higher than preadmission. In the rest of this chapter, we examine common ICU-related problems as they relate to geriatric patients: respiratory failure, delirium, shock and hemodynamic monitoring, acute kidney injury and renal replacement therapy, nutrition, and finally care of the dying patient.

FIGURE 30.1 Health status and satisfaction among geriatric and younger ICU survivors. Rockwood and coworkers interviewed 143 geriatric (≥ 65 years) and 225 younger (< 65 years) ICU survivors. They found no significant differences between the groups in self-evaluation of health

status (*top figure*). However, they did find a statistically significant difference between groups (*asterisk*) in the number of respondents who were satisfied with their present state of health (data from Rockwood et al. [28]).

Respiratory Insufficiency and Failure

Changes in Pulmonary Function Associated with Aging

The aging process affects every aspect of respiratory physiology and oxygen transport, with important consequences for the geriatric patient with critical illness [29]. Pulmonary complications and adverse pulmonary events are common in elderly patient, following even elective surgical procedures [30–33]. The age-related changes that are most clinically relevant include declines in vital capacity, forced expiratory volume in 1 s, alveolar–arterial oxygen gradient, arterial oxygen tension, and maximal oxygen consumption. Ventilatory responses to hypoxia and hypercarbia are blunted [34, 35] Also relevant for the aged surgical patient is decreased sensitivity of the airways to noxious stimuli. Diminished airway sensitivity to stimuli such as refluxed gastric fluid in addition to impaired mucociliary transport and decreased cough strength renders the elderly patient at increased risk of silent pulmonary aspiration [36].

Outcomes

Outcomes of geriatric patients who require mechanical ventilation have been the focus of a number of conflicting reports. A hospital mortality of 52% and 1-year mortality of 63% have been identified in data compiled from multiple studies [19]. Age, severity of illness, comorbidity, and diagnosis are predictors of outcome in ventilated geriatric patients, as they are in elderly critically ill patients in general [19, 37]. In some studies, prolonged ventilation (defined as 15 days in one study and a total score of more than 100 for the number of days of ventilation plus age in years in another) has been accompanied by poor outcomes [37, 38], whereas in others, the duration of mechanical ventilation has not been significantly related to outcome [39, 40]. In a study of patients with acute respiratory distress syndrome (ARDS), age > 60 was associated with a fivefold increase in mortality, presumably because of age-related impairments in cardiopulmonary regulatory mechanisms [29]. However other investigators have not found a statistically significant increase in mortality in elderly patients with ARDS [41]. In one of the largest studies on this question, Esteban and coauthors

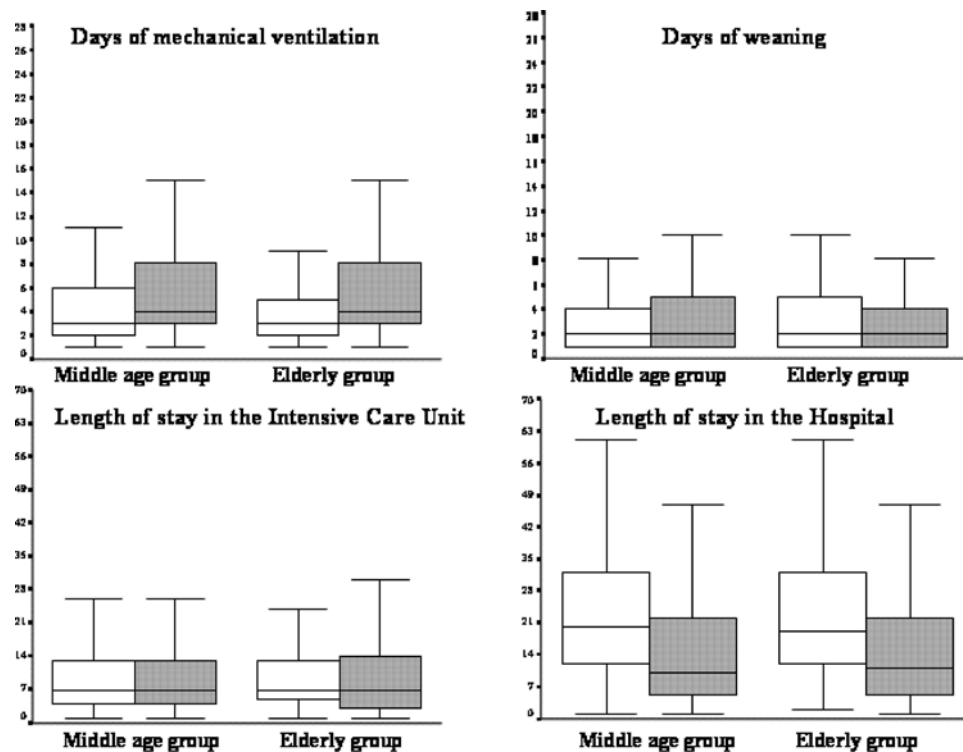

FIGURE 30.2 Comparison of the time of ventilatory support (days of mechanical ventilation and days of weaning) and time of stay in the intensive care unit and in the hospital between patients aged from 43 to 70 years (middle age group) and patients older than 70 years (elderly

group). The *white boxes* correspond to patients who survive and the *gray boxes* to nonsurvivors. *Box plot* indicates the median and the interquartile range. *Bar* indicates the minimum and the maximum number of days (from Esteban et al. [43]. Reprinted with permission).

recently reviewed the database from the International Mechanical Ventilation Study [42] ($n=5,183$) and found that patients >70 of age had similar intensity of care as compared to younger patients [43]. Their work supports conclusions of others that age alone is not a sufficient reason to withhold mechanical ventilation. They found that the most important risk factors for death in the elderly patient requiring mechanical ventilation were coexistent acute renal failure, shock, and limited functional status (Fig. 30.2).

Clinical Management

In our practice, we have found a number of techniques clinically useful on a daily basis. First, we avoid or minimize narcotics when at all possible in the aged. We have found regional techniques such as epidural analgesia or paravertebral blocks to be useful. Parenteral narcotics have been associated with more frequent respiratory disturbances following surgery, and regional techniques for pain management and nonnarcotic analgesics may therefore be particularly valuable in the geriatric patient [30]. It is also important to eliminate other medications, which might contribute to delirium in the aged patient, for example,

anticholinergics. Nonsteroidal pain relief would seem useful in this setting, but in practice, many elderly patients have absolute or relative contraindications to their use [44]. Second, we mobilize elderly patients as soon as possible. Assuming an upright position increases the functional residual capacity and should lessen the closure of small airways that is caused by the supine position. Oxygen consumption following thoracotomy is lower in the sitting than the supine position, suggesting that the work of breathing may be lessened when upright [45].

In the elderly, at-risk patient who is not mechanically ventilated, measures such as incentive spirometry (IS) and other lung recruitment maneuvers complement the basic measures of pain management and mobilization. We use a staged approach for managing pulmonary toileting in aged, compromised patients. First, we start with IS every 6 h. If patients are unable to attain volumes of at least 8–10 ml/kg ideal body weight on IS, then we add a noninvasive, lung expansion therapy: a single-use device attached to an oxygen flowmeter that provides positive airway pressure throughout the respiratory cycle. We continue to monitor IS volumes every 6 h while maintaining lung recruitment. Finally, if volumes are still below the desired 8–10 ml/kg, we initiate noninvasive pressure support ventilation while continuing to follow IS volumes when patients are off noninvasive ventilation.

While the techniques of mechanical ventilation and weaning may not differ in the elderly, they may require a longer period of support, given the impairments imposed by age, comorbidity, and acute illness. Caution should be exercised when liberating elderly patients from mechanical ventilation. Parameters used to predict successful weaning from mechanical ventilation in young patients appear less reliable in the elderly [46]. Even after successfully undergoing a trial of spontaneous breathing prior to extubation, elderly patients may not do as well as younger patients. The ARDSnet investigators examined age as a factor affecting outcome from acute lung injury and ARDS [47]. They found that although patients >70 years of age were able to breathe spontaneously for 2 h without ventilator assistance – a commonly accepted weaning parameter – at a similar time point to younger patients, the older patients had inferior outcomes, such as higher reintubation rates, longer ICU and hospital stays, and lower survival rates at 28 days.

Delirium

Definition, Assessment, and Incidence

Delirium is an acute state of confusion that develops over a short period of time and fluctuates over time. It is often the result of underlying organic derangements, such as infection, medical illness, and drug use or withdrawal. Delirium can be distinguished from dementia by its acute onset and fluctuating course. The assessment of acute changes in cognition is difficult in the ICU setting due to the severity of underlying disease and the frequent loss of verbal communication due to mechanical ventilation. One tool for assessment of delirium in the ICU, which was adapted from the Confusion Assessment Method (CAM), is the CAM-ICU [48]. It has been validated in several studies as being both highly sensitive and specific [48, 49]. Using CAM-ICU, delirium is diagnosed in two steps. First, a standardized sedation scale, such as the Richmond Agitation-Sedation Scale [50] is used to determine the level of consciousness. Any patient not determined to be comatose is then assessed for four features of delirium: (1) Acute onset of mental status changes or a fluctuating course, (2) inattention, (3) disorganized thinking, and (4) an altered level of consciousness. A diagnosis of delirium is made with the presence of both features (1) and (2) in addition to either feature (3) or (4) [48]. In a recent study of elderly patients admitted to the ICU, the rates of delirium were found to be >70% during their hospitalization. In the same study, the effect of dementia was also assessed. Patients with dementia had a 40% higher overall rate of delirium during hospitalization than those without dementia [51]. There is

little doubt that as the elderly population ages, the prevalence and burden of delirium in the ICU will grow.

Predisposing Factors

Predisposing Factors for Delirium in the ICU

The risk factors for delirium are divided into host factors, which are present on admission to the ICU, and precipitating factors, which occur during the course of illness. It is this second group of factors that are potentially modifiable and therefore the target of therapeutic or prophylactic intervention [52, 53] (Table 30.1).

The use of sedative and analgesic medications deserves special attention. Nearly all patients in the ICU receive these medications. However, their use is not without detrimental effects. These effects include prolonged mechanical ventilation and an increased utilization of diagnostic studies for altered mental status when sedatives are used in a continuous, rather than intermittent, fashion. Daily interruption of sedation is one method used to avoid this complication [54]. Benzodiazepines and anticholinergics have been consistently linked to delirium in the elderly [55]. Pisani and coworkers recently published data showing that use of a benzodiazepine or opioid was associated with increased delirium duration, especially the first episode (relative risk of 1.64 with a 95% confidence interval of 1.27–2.10) [56]. Trials of newer agents have shown some promise. In a 2007 trial by Pandharipande et al., the use of dexmedetomidine (an alpha 2 agonist) was compared to lorazepam in mechanically ventilated patients. The use of dexmedetomidine was associated with more delirium-free days than lorazepam [57]. The data regarding the use of opioids is less clear. A study by Ouimet and coworkers demonstrated higher daily use of opioids in ICU patients without delirium [58]. Similarly, in a study of hip-fracture patients, Morrison and coauthors found that patients treated liberally with opioid analgesics were less likely to

TABLE 30.1 Predisposing factors for delirium in the ICU

Host factors	Critical illness related factors	Iatrogenic factors
Age	Acidosis	Immobilization
Alcoholism	Anemia	Catheters
Apolipoprotein E4	Fever/infection/sepsis	Medications
Polymorphism	Hypotension	Sleep disturbance
Cognitive impairment	Metabolic disturbances	
Depression	Fever/hypothermia	
Hypertension	End organ dysfunction	
Smoking	Respiratory disease/hypoxia	
Vision or hearing loss	High severity of illness	

Source: Girard and Ely [53]

develop delirium than those who received less analgesia [59]. Meperidine is the exception, as it is consistently linked to the development of delirium, especially in the aged [60–62]. These findings point to the need for careful use of these agents with attention to providing adequate pain relief while avoiding oversedation.

Evaluation, Prevention, and Treatment

Once delirium is diagnosed, an underlying organic source must first be sought. A diminished level of consciousness may herald underlying infection or metabolic derangements, and these must be ruled out by careful history and physical examination. Within the ICU, risk factors more prevalent in the setting of critical illness must be addressed. These include infection, metabolic and electrolyte abnormalities, and medication exposure. If critical illness related factors are ruled out, other interventions may prove useful in reducing delirium such as repeated reorientation of the patient and activities designed to be cognitively stimulating; a nonpharmacologic sleep protocol; early mobilization and range of motion exercise; prompt removal of restraints and catheters; use of eyeglasses and hearing aids; and the early correction of dehydration [63]. These results were confirmed in patients after hip fracture [64] and in hospitalized geriatric patients [65] but have not yet been studied in the ICU.

After the use of nonpharmacologic strategies to minimize risk factors and addressing the metabolic derangements associated with critical care illness, consideration should be given to the use of pharmacologic agents to manage the symptoms of delirium. Currently, the clinical practice guideline from the Society of Critical Care Medicine recommends haloperidol as the drug of choice for treatment of delirium in the ICU [66]. This is also true for the geriatric patient [67]. Using intermittent intravenous injection, a 2-mg dose is recommended. Repeated doses are administered if symptoms are not controlled, doubling the previously administered dose every 15–20 min until agitation resolves. Once controlled, scheduled doses are given every 4–6 h and then tapered over several days. Side effects of haloperidol include QT interval prolongation, extrapyramidal symptoms, and neuroleptic malignant syndrome. Routine EKG monitoring is suggested to detect any QT prolongation [66]. Atypical antipsychotics, such as risperidone, ziprasidone, quetiapine, and olanzapine, may also have a role in the management of delirium. Although no placebo-controlled studies of these agents exist, early data suggests that these agents may be at least as effective as haloperidol and may have fewer side effects [68].

Outcomes

Among ICU patients, numerous adverse events have been associated with delirium. These include unplanned extubation, removal of catheters and drains, failed extubation, prolonged hospital stay, increased health care costs, and increased mortality. Milbrandt and colleagues studied patient charges in 275 consecutive, mechanically ventilated ICU patients and found the presence of delirium to be associated with 39% increased ICU cost (95% CI, 12–72%) and 31% higher hospital cost (95% CI, 1–70%) [69]. In addition to the acute adverse events associated with delirium in critically ill patients, multiple long-term detrimental effects have been noted. Ely and coworkers reported that delirium was associated with a threefold increase in the risk of death at 6 months [70]. Jackson and coauthors reviewed nine prospective studies a diverse group of hospitalized and critically ill patients and reported that delirium during hospitalization was associated with a cognitive decline over the following 1–3 years [71].

Shock and Hemodynamic Monitoring

Changes in the Cardiovascular System Associated with Aging

During the course of aging, there are structural and functional changes within the heart and vasculature which become important in the critical care of the geriatric patient. For example, there is a significant decrease in the compliance and distensibility of the aorta and vascular tree. This stiffening of the arteries results in an increase in afterload. The results of the increased afterload include left ventricular hypertrophy and decrease in diastolic compliance. Wall thickness increases of up to 30% have been documented. Diastolic compliance is also reduced, and when coupled with delayed diastolic filling observed in the elderly heart, results in nearly a 50% reduction in early diastolic ventricular filling. Ventricular filling becomes much more dependent on atrial contraction. Diastolic dysfunction and decreased left ventricular compliance means that the aging heart must achieve higher-end diastolic pressures to preserve preload and thus stroke volume. The clinical implications of these changes are that cardiac output is much more reliant on adequate preload and atrial systole. Hypovolemia must be avoided, and atrial arrhythmias must be controlled or addressed in the face of surgical stress and sepsis. In addition to normal age-related changes, clinicians must also take into account the effects of ischemic heart disease, which becomes increasingly prevalent

with age. The Framingham Heart Study found that myocardial infarction was silent or unrecognized in over 40% of patients aged 75–84 years compared to under 20% in the group between age 45 and 54 years [72].

Monitoring and Management of Shock

Shock is best defined as a state of inadequate tissue perfusion. In the uncompensated state, it is easily recognized by tachycardia, oliguria, and hypotension. However, most critical care practitioners would prefer to recognize hypoperfusion before overt decompensation. The initial monitoring of the critically ill patient should include close attention to the physical exam, arterial blood pressure monitoring, and the urine output. We have found these parameters – and more importantly, their change over time – most useful in determining the response to resuscitative efforts, but they can fail to detect ongoing tissue hypoperfusion and hypoxia [73]. Even after hypotension has been corrected and urine output restored, a state of “compensated shock” may remain. In this condition, tissue hypoxia is ongoing, leading to multiple organ dysfunction and death. Hypoxia forces tissues to utilize anaerobic pathways, resulting in lactic acid production. Large amounts of H⁺ may then be produced. Base deficit, lactate level, and bicarbonate levels are frequently used to assess both the initial state of shock and to monitor the effects of ongoing resuscitation. Although no single end point is applicable to every scenario, it is important to repeatedly reexamine potentially “shocky” patients and follow them closely to determine the success or inadequacy of resuscitation.

The use of pulmonary artery catheters (PACs) is no longer de rigueur. There is currently no prospective evidence supporting their use. Friese and coworkers analyzed the National Trauma Data Bank and found higher mortality in trauma patients managed with a PAC. They did, however, find that those with severe injury who arrived in shock and older patients had a survival benefit when a PAC was used to guide management [74]. However, most evidence would contradict this. In a large meta-analysis, Shah and coworkers evaluated 13 randomized clinical trials. They concluded that in critically ill patients, the use of PACs neither increased mortality or hospital days nor did it confer benefit. The absence of benefit may have been the result of the lack of any clear or specific guidelines for treatment based on the data collected [75]. The PAC catheter was often used to drive “supranormal resuscitation,” which sought to maximize cardiac index (>4.5 l/min/m²) and oxygen delivery index (>600 ml/min/m²). Achieving these goals was associated with an increase in survival; however, there was no prospective evidence to suggest a benefit to attempting to attain these goals. Rather,

the ability to achieve these goals appears to be a marker of the patient’s physiologic reserve [76].

Mixed central venous oxygen saturation (S_{CV}O₂) may be a useful adjunct in determining the adequacy of oxygen delivery. A value of >70% is considered to be normal. Lower values are consistent with flow-dependent delivery of oxygen, and a variety of strategies have been published using S_{CV}O₂ as an end point for resuscitation. The most promising strategy was published by Rivers and coworkers in a group of patients with septic shock presenting to the emergency department. An early goal-directed resuscitation strategy aimed at achieving an S_{CV}O₂ of ≥70% resulted in a significant decrease in mortality (46.5% in the control group vs. 30.5% in the treatment group) [77]. Of interest, the mean age in the treatment group was 67.1 years (±17.4 SD).

Resuscitation with crystalloid, blood and the administration of vasopressors are all methods to improve tissue oxygen delivery [58]. Guidelines for the optimal use of these techniques are varied, and each approach is not without complications. Early restoration of circulating blood volume with blood products and crystalloid is crucial, especially in the elderly who are more dependent on effective ventricular filling to maximize cardiac output. In the early phase of resuscitation, fluids are probably superior to vasopressors for the maintenance of blood pressure [78]. Care, however, must be taken to avoid excessive amounts of crystalloid as this has been linked to cardiac and pulmonary complications, coagulopathy, and acid–base disturbances [79]. Transfusion of blood to restore adequate oxygen carrying capacity is vital in cases of frank anemia, but exact triggers for transfusion in the elderly are still debated. The Hebert study suggests a transfusion threshold value of <7 g/dl of hemoglobin, and this recommendation has been widely adopted. This study, however, excluded patients with chronic anemia, ischemic heart disease, or any patient in whom the attending physician was unwilling to tolerate a transfusion trigger of <7 g/dl [80]. In elderly patients with acute myocardial infarction, a lower 30-day mortality was associated with blood transfusion for hematocrit values <30% [81]. A hematocrit of <30% during operation is predictive of postoperative delirium [82]. Other studies have documented increased myocardial ischemia when intraoperative or postoperative hematocrit fell below 28% [83, 84]. Given the high incidence of ischemic cardiac disease – often silent in the elderly – care should be taken in setting a “one-size-fits-all” transfusion trigger in the geriatric population.

Once effective volume has been restored, inotropes may be required to augment oxygen delivery. The effects of aging can influence the choice of agents. In elderly patients, the response to β-agonists declines, with subsequent reduction in the inotropic, chronotropic, and vasodilatory effects of these medications. With these changes, nonadrenergic effects

may be more pronounced. The stiffened aorta should also be taken into account, and the addition of afterload reducing agents may be useful [85]. With the geriatric patient, inotropic support may be required in atypical clinical settings such as septic shock. Viellard-Baron and coauthors found a high incidence of global left ventricular hypokinesia, defined as an ejection fraction of <45%, in a mixed group of patients presenting with septic shock (mean age 65 years). Hypokinesia was often present on initial evaluation. However, further cases were frequently unmasked after 24–48 h of therapy with norepinephrine, bringing the total incidence to about 60% [86]. This hypokinesia can be counteracted by the addition of inotropic agents such as dobutamine, the suggested inotrope for use in septic shock [87, 88]. After restoration of adequate circulating volume and the addition of inotropic support as needed to augment oxygen delivery, perfusion pressure should be maintained with vasopressors. In cases of severe sepsis, norepinephrine and dopamine are advocated as the initial vasopressors recommended in the Surviving Sepsis Guidelines, with a target mean arterial pressure of ≥ 65 mmHg [87, 88]. In summary, the clinician caring for the elderly patient with occult or overt shock must walk a fine line, using both fluids and inotropes, while paying close attention to detail. Frequent adjustments will be required as the clinical situation evolves.

Acute Kidney Injury and Renal Replacement Therapy

Changes in the Renal System Associated with Aging

The changes in renal function related to advancing age are significant in the management of critical illness. There are predictable declines in the glomerular filtration rate (GFR) and creatinine clearance. These declines, while significant, have little impact on the measured serum creatinine level, as there is a parallel reduction in the amount of creatinine produced. Fluid and electrolyte management deserves meticulous attention in the aged. With aging, homeostatic mechanisms become less capable of dealing with the fluid losses, acid–base disturbances, and electrolyte abnormalities often associated with surgery, trauma, and sepsis. Insensible losses are increased through surgery, wounds, and mechanical ventilation. The aging kidney is less able to concentrate urine and compensate for these losses. In addition, the normal thirst mechanism is often impaired in the geriatric patient. The net result is an increased propensity for hypovolemia, which can be particularly harmful in the elderly who rely on preload to maintain cardiac function. Compounding this

problem is the diminished capacity of the kidney to excrete acute salt and water loads, which can manifest as pulmonary insufficiency secondary to acute volume overload. Poor bicarbonate elimination also hampers renal compensation in acid–base disturbances. The key factors to successful management include meticulous attention to detail, frequent laboratory and physical assessment, and appropriate fluid administration to avoid any large or rapid changes in volume status, electrolytes, or acid–base loads.

Clinical Management

The incidence of acute kidney injury (AKI) increases with age and is 3.5 times more prevalent in those >70 years of age [89]. The etiology AKI is usually divided into three categories: prerenal, intrinsic, and postrenal. The elderly are especially vulnerable to prerenal AKI due to impaired autoregulation and high risk of hypovolemia. Prerenal causes include fluid losses, decreased intake and diuretic treatment, and reduced effective circulating blood volume secondary to impaired cardiac output, systemic vasodilatation, and renal artery stenosis. Acute tubular necrosis (ATN) accounts for up to 76% of cases of AKI in the ICU [90]. Although causes of AKI (hypovolemia, ATN, contrast induced nephropathy, NSAIDs, etc.) are no different in geriatric patients as compared younger ICU patients, age itself remains a major risk factor for the development of AKI in the ICU [91]. This may be due to the increased incidence of diabetes, hypertension, and underlying chronic kidney diseases in the elderly population.

The diagnostic approach to AKI should include a history and examination. A review of medications should focus on potential sources of kidney injury such as NSAIDs, intravenous contrast, diuretics, and angiotensin-converting enzyme inhibitors or angiotensin receptor blockers. Laboratory examination should include serum creatinine, urinalysis, urine electrolytes, urine creatinine, and osmolarity. These values can be used to determine the glomerular filtration rate and the fractional excretion of sodium. However, the fractional excretion of sodium is often confounded by diuretics in the elderly. Urine osmolarity, when <300 mOsm/kg, is indicative of intrinsic renal failure.

Management of AKI should first involve the treatment of life-threatening complications, such hyperkalemia, pulmonary edema, and metabolic acidosis. Second, all nephrotoxic agents should be discontinued. Finally, fluid and hemodynamic status should be optimized. Although still employed, there is no benefit to the use of “renal-dose” dopamine [92]. Furosemide may improve urine output, but it has no influence on return of renal function or survival, thus its utilization should be limited to maintaining fluid balance [93]. Mannitol has also been shown to have no efficacy in renal protection [93].

Outcomes: Renal Replacement Therapy

Renal replacement therapy (RRT) is required in approximately 85% of patients with oliguric renal failure and about 30% with nonoliguric renal failure [94]. Like tracheotomy, the initiation of RRT in the elderly is a significant decision point in the care of the elderly patient and should be approached with deliberation. Multiple recent studies have examined prognosis and outcomes following RRT during the course of critical illness. In a meta-analysis by Bagshaw, the mortality of ATN treated with RRT was reported at 46–74%. In studies confined to the critically ill, mortality was nearly 60% at 90 days. In the same analysis, quality of life was addressed, and studies consistently demonstrated lower global quality of life scores. However, survivors generally rated their quality of life acceptable [95]. In addition to survival, return of renal function, defined as freedom from RRT, is another important outcome measure. Schmitt and coworkers undertook a meta-analysis addressing recovery of kidney function after AKI in the elderly. They reported that 31.3% of the elderly did not recover function compared to 26% in younger patients (pooled RR, 1.28, 95% CI, 1.06–1.55). An interesting finding in their review was that the relative risk of nonrecovery was only slightly increased in the elderly when continuous RRT was used; however, this did not achieve statistical significance [96].

Nutrition

Body composition changes over the course of aging. Lean muscle mass is reduced up to 40% by the age of 80 with simultaneous increase in body fat. There is a corresponding decrease in muscle strength and decrease in resting energy expenditure by up to 15% [85]. As a result of this loss of muscle mass, the elderly patient may rapidly develop protein–energy malnutrition in the setting of acute illness and surgery. Ideally, nutritional support should be initiated within 24 h of admission to the ICU.

We routinely initiate “trickle feeds” as soon as vasopressor doses have stabilized and lactate levels are decreasing. Our preferred method of nutrition is the enteral route, with the choice of tube and position (gastric or postpyloric) determined by the clinical scenario. The use of early enteral nutrition in surgical patients has demonstrated reduced infection rates. No increase in the incidence of anastomotic failure has been documented, and there is a trend toward reduced mortality [97]. An audit of feeding practices by Taylor found that in patients greater than 64 years of age prolonged starvation (>5 days) resulted in higher mortality than those without nutrition 0–5 days, which was not found in younger patients. This suggested a greater susceptibility to starvation in the elderly [98]. Caloric requirements are reduced in the elderly; overfeeding

results in excess CO₂ production, mandating higher minute ventilation and should be avoided. Overfeeding will not decrease the amount of lean tissue loss, can increase fat synthesis, aggravated hyperglycemia, and can delay weaning from mechanical ventilation [99]. Deficiencies in micronutrients are common, and supplementation should be routine.

Impaired glucose tolerance increases with aging, and nearly 40% of the U.S. population over age 60 has either type 2 diabetes or impaired glucose tolerance. The mechanism of impaired glucose tolerance is a lifelong decline in insulin secretion by B-cells at a rate of 0.7% per year. No specific change in insulin sensitivity, as previously thought, has been identified [100]. Early evidence suggested that strict glycemic control may be beneficial for patients in the ICU with a decrease in mortality, especially when employed for more than 3 days [101, 102]. These initial findings generated controversy and concern over the risk of hypoglycemic events that occur during insulin therapy. The NICE-SUGAR study was undertaken to determine the best target for glycemic control in critical illness. In a study of over 6,000 ICU patients, subjects were randomized to intensive control or conventional control of blood sugar. The incidence of hypoglycemia was significantly greater in the intensive-control group (6.8% vs. 0.5%, $p < 0.001$). Mortality in this study was greater in the intensive-control group as well (27.5% vs. 24.9%, $p = 0.02$). The authors concluded that a blood glucose target of 180 mg/dl or less resulted in lower mortality than did a target of 81–108 mg/dl [103]. A growing problem faced by all clinicians is the epidemic of obesity. An increase in mortality has been documented with increase in BMI, and this trend continues in the elderly. Although not associated with an increase in mortality in the ICU, obesity is associated with increases in the duration of mechanical ventilation and ICU length of stay [104].

Caring for Dying Patients

Caring for dying patients is a natural part of working in the ICU, perhaps even more so with geriatric patients. A more complete discussion of palliative care and end-of-life decision making is presented in Chap. 18. However, this is such an integral part of caring for the geriatric ICU patient that it bears some repetition. Through experience, we have found that establishing consensus, providing open communication, and focusing on goals of therapy are effective tools in our daily practice.

Reaching Consensus

Before serious discussions with families, physicians need to have reached accord that curative therapy is not indicated. Of first importance in these discussions are an accurate

diagnosis and an understanding of long-term outcomes. As we have outlined above, outcomes from critical illness in the elderly are influenced by prior health and functional status, the severity of the acute illness as manifested in the degree of physiologic derangement, and the specific diagnosis. We feel there is no justification for using chronologic age alone to predict the benefit to be obtained from intensive care or to exclude individuals from ICU care. In cases where a clear consensus cannot be obtained among physicians, we usually pursue curative care for a period of time, often 3–5 days. This is useful in the geriatric patient as it allows us to more accurately gauge their underlying physiologic reserve and response to treatment while allowing us to establish trust and rapport with the family.

Open Communication

When consensus among the health care team has been obtained, discussions with families regarding management must address the potential hazards during recovery from critical illness and thoughtful appraisal of the likely short-term and long-term outcomes. Other factors, such as expected life-span, HR-QOL, and potential pain and suffering associated with intensive care must be considered in the elderly. Although some patients may have an advanced directive or a “living will,” we have found these documents are rarely helpful as they usually only apply to conditions that are unquestionably irreversible, such as persistent vegetative state. For example, an advance directive may not be helpful when treating a previously healthy and active septuagenarian who is now facing tracheotomy and possible long-term dialysis after surviving emergent repair of an abdominal aortic aneurysm.

End-of-life discussions are almost never concluded in a single setting and generally mature over time as the disease process and the patient’s physiologic response becomes clear to both physician and family. It is helpful to have a single person in whom the family trusts lead the discussions. Trust from families is earned by being seen frequently at the patient’s bedside. We have learned through sad experience that halls and patients’ doorways are less than ideal locations for end-of-life discussions. Getting the setting right in a small conference room allows you to take control of the situation, provides an atmosphere where families and physicians can talk freely and gives at least the impression that you have the time sit and discuss the issues at length. We have found it important to avoid phrases such as “withdrawal of support” or “withdrawal of care.” Instead, we emphasize with families that we alter our goal from cure to comfort – we provide a different kind of care. A comprehensive review of communicating “bad news” is beyond the scope of this chapter, but an

excellent volume written by and for physicians has formed the foundation for our practice [105].

Goals of Therapy

Discussing goals of therapy and resolving conflicts can be problematic. Schneiderman and colleagues hypothesized that ethics consultations in the ICU reduce the use of life-sustaining treatments delivered to patients who ultimately do not survive to hospital discharge [106]. In a controlled trial, they randomized patients by site to early ethics consultation vs. standard care. The intervention involved ethics consultation in the ICU for conflicts and value disagreements either among the health-care team or between the team and patients or surrogates. Primary end points were ICU and hospital length of stay in patients who do not survive and patient/surrogate and health care provider satisfaction. The authors found that patients in the intervention group who died spent 3 fewer days in the hospital, 1.4 fewer days in the ICU, and 1.7 fewer days receiving mechanical ventilation than nonsurvivors in the control group. The authors concluded that ethics consultations reduced nonbeneficial care without increasing mortality. However, the intervention group had a slightly higher mortality rate (62.7% vs. 57.8%). Although this difference was not statistically significant, it may be meaningful. In a randomized trial, differences in outcomes that are not explained by differences in baseline characteristics or the concomitant interventions are usually attributed to the study intervention. It is not clear whether a higher mortality rate in this study would be good or bad.

In our own practice, we rarely have to resort to an ethics consultation to resolve conflicts regarding goals of therapy. We do not display a smorgasbord of options to patients and families and allow them to pick and choose a plateful of therapies. Instead, we present a therapeutic plan that is aimed at achieving a return to a quality of life that the patient would find acceptable. We are often forced to rely on heavily on information from family members and surrogates for our understanding of the patients’ wishes regarding quality of life. We realize that understanding patients’ wishes regarding quality of life and end-of-life decisions can be difficult. Cook and coworkers writing for the Canadian Critical Care Trials Group prospectively followed 851 patients with a mean age of 61.2 years who were receiving mechanical ventilation. Of these patients, 166 (19.5%) had mechanical ventilation withdrawn. Rather than age or the severity of the illness and organ dysfunction, the three strongest determinants of withdrawal of ventilation in critically ill patients were the physician’s perception that the patient preferred not to use life support (hazard ratio, 4.19), the physician’s prediction that the patient’s likelihood of survival in the ICU was less

than 10% (hazard ratio, 3.49), and a high likelihood of poor cognitive function (hazard ratio, 2.51) [107]. Surprisingly, Cook and coauthors did not find a significant relationship between withdrawal of ventilation and age, previous functional status, severity of illness, or severity of organ dysfunction. It should be concerning to all of us rendering care for elderly patients that the strongest determinate of withdrawal from mechanical ventilation was physicians' perception of patients' wishes. Unfortunately, we know that patients' wishes regarding ICU admission or initiation of ventilation are frequently unknown at ICU admission [108]. In addition, patients' wishes may not correspond with the family members' understanding of these wishes in elderly patients [109]. Finally, patients' assessments of their quality of life do not necessarily correlate with their wishes regarding life-sustaining therapy [83].

Despite these limitations, clinicians are daily called upon to make help families and surrogates navigate these waters with whatever information is available. When we feel that further critical care is unlikely to achieve a quality of life that would be acceptable – as previously defined in our discussions with patients when available or families and surrogates if not – we inform the patient or surrogates that we have done all that we can and that death or an unacceptable permanent debility is inevitable. For example, we would not broach renal replacement as a therapeutic option to the surrogates of nonagenarian with abdominal sepsis and multisystem organ failure. We admit that this approach may seem paternalistic, but we have found that families expect and appreciate this from physicians. The vast majority of families do not want to assume responsibility for a decision that they perceive as leading to the death of their patient, when in reality, it is often that the patient's disease process dictates the outcome. The decision surrogates are faced with is not whether death will occur, but how that death will happen. Occasionally, we are unable to reach a clear consensus with the family or surrogate decision makers. In these situations, we continue supportive therapy – usually with limitations about escalation – and reconvene the discussion in the near future. We have adopted this approach as it has been described by Cassell, a social anthropologist, who has studied extensively end-of-life decision making in the surgical ICU [110]. When employed properly, we have found this strategy effective in our daily practice without resort to ethics committees or outside intervention.

Process

For patients already in the ICU, the change in care from cure to comfort is best handled in the ICU. Patients and families are more at ease with staff they have come to know during

their ICU stay. The challenge of titrating analgesia, removing invasive support, and managing family concerns are best met in the ICU. In this setting, our focus is on eliminating procedures, superfluous lines and tubes, and unnecessary medications while providing open visitation and effective analgesia [111]. Usually removing vasopressor therapy and reducing positive end-expiratory pressure to 0 cmH₂O and the fraction of inspired oxygen to 25% will be all that is required. When weaning from mechanical ventilation, we typically switch to a pressure-targeted mode that delivers an adequate tidal volume and then titrate a short-acting narcotic infusion to a comfortable respiratory rate. We then decrease inspiratory pressures gradually while increasing the narcotics to keep a respiratory rate in the 14–20 breaths per minute range. Once inspiratory pressures are minimal, the patient can be extubated without concerns about distress or the bradypnea associated with bolus narcotic administration. This rapid, terminal weaning process is usually well tolerated by patients [112], avoids the gasping sometimes associated with terminal extubations done without a prior wean, and has been our practice at this institution since first described by Grenvik in 1983 [113]. We do not consider oxygen or feedings comfort measures. When mechanical ventilation has been removed and adequate analgesia obtained, a transfer out of the ICU to a more private atmosphere is usually in order. In conclusion, we have found that most of the difficulties regarding end-of-life care can be handled by assuring consensus among the health-care team prior to family discussions, establishing early, open, and honest communication between families and physicians and focusing on the overall goals of therapy while presenting a plan rather than multiple options.

Conclusion

Critical care of elderly patients both compares and contrasts with that of younger patients. It is different in that age has multifarious effects on all organ systems, and these age-related changes influence the way elderly patients respond to their critical illness and to treatment. It is similar in that the principles, procedures, techniques, and devices used to support organ system insufficiency or failure are the same and that with a comprehensive approach to care and close attention to detail many can survive their critical illness and resume a valued and enjoyable life.

Chapter 31

Care of the Injured Elderly

Jay Menaker and Thomas M. Scalea

Injured Elderly

Trauma is the most common cause of death for those under the age of 44. Thus, some consider trauma to be exclusively a disease of the young [1]. However, as the population in the USA ages over the next several decades, the importance of falls and injuries in older patients will become more apparent. The elderly, defined as persons of age 65 or greater, [2–5] constitute one of the fastest growing segments of the US population. By the year 2030, the number of persons over age 65 will double relative to 2000, representing almost 20% of the nation's total population [6] (Fig. 31.1). This increase is the result of improvement in life expectancy and the aging baby boom generation. The Administration on Aging's Fiscal Year 2009 budget requested 1.381 billion dollars to assist in the long-term needs of these aging baby boomers [7].

In 2006, unintentional death was the fifth leading overall cause of death overall in the USA and the ninth for those over the age of 65 [8] (Table 31.1). Although the geriatric population in 2006 was approximately 12% of the total population [9], accidental deaths in this age group represented almost 31% of such deaths [8]. In 2006, the overall death rate from unintentional injury was 39.3 per 100,000 population [8]. However, in those between the ages of 65–74 years, it was 44 per 100,000, and for those over 74 years, it was 152.6 per 100,000. Decreased physical reserve, preexisting comorbidities, and a lack of provider understanding of the healthcare needs of older patients may all contribute to this finding [10].

Altered Physiology and Comorbidities

Aging causes changes in one's functional status and increases one's susceptibility to injury and mortality (Table 31.2). Progressive deterioration, which begins as subtle changes in the thirties, continues with increasing age. This rate of change varies from organ system to organ system and from individual to individual [11]. Advances in the treatment of debilitating medical conditions have enabled elders to live longer and healthier lives. This improvement in the quality of life allows them to remain physically active and mobile longer [12]. Ironically, an active life style has now been increasingly reported as a risk factor for injury in the elderly, including falls and motor vehicle crashes [13–15].

Preexisting medical conditions limit the ability of older persons to tolerate the increased physiologic demands associated with injury. "Resting organ function often is preserved, but the ability to augment performance in response to stress is greatly compromised" [16]. Comorbid conditions may also be the cause of the injury and, therefore, information must be carefully sought at the time of initial evaluation following the event. Treatment of the comorbid illness will likely be necessary in addition to that of the injury. Identifying the comorbidities may identify interventions to prevent recidivism.

By age 75, over two-thirds of injured patients have one or more chronic medical conditions [17] (Table 31.3). Bergeron et al. demonstrated that two-thirds of those over the age of 64 years had a comorbid disease [18]. In those who reached the age of 95 years, it was 81.5%. In another study, the incidence of having at least one preexisting medical condition was 29.4% for those between the age of 65 and 74 years, 34.7% for those between 75–84 years, and 37.3% for those over the age of 85 years [19]. These comorbidities are associated with decreased survival after trauma and independently predict mortality [15, 17, 18, 20–22]. Milzman et al. showed that mortality rose from 6.1% with one preexisting condition to 24.9% with three or more [17] (Table 31.4). Others have found similar results, demonstrating a two- to threefold

increase in hospital mortality rates for those older than 65 years as compared to younger counterparts [19, 23–25].

Once injured, the elderly may have an increased rate of complications from conditions such as cardiovascular or liver disease, diabetes, chronic obstructive pulmonary disease, and renal insufficiency. Smith and coworkers showed that complications occurred in 26% of their elderly population, the most common being infection (14.5%), followed by pulmonary (10.7%), cardiac (5.5%), and renal (3.7%) [26]. The authors also demonstrated that more than one complication following trauma was associated with a mortality of 30%. Bellemare et al. demonstrated that the elderly who developed pneumonia had significantly increased mortality compared to younger patients with pneumonia [27].

Influences of Senescence and Consequences of Comorbid Diseases

Senescence affects all organ systems but does so at varying degrees and at variable times during the aging process. Functional decline occurs in all organs. Increasing age may make it difficult to distinguish the impact of comorbid diseases on specific end-organ damage.

Central Nervous System

Subtle changes in cognition and memory are common in the elderly. Determining Glasgow Coma Scale (GCS) and distinguishing new neurologic findings from baseline can be problematic [28]. Dementia, hearing and visual difficulty, or fluctuation in an individual’s baseline also make assessment of an elderly patient’s mental status difficult. Family members will often be the best source of information to determine if an elderly patient is at baseline mental status. Once admitted to the hospital, the elderly patient may experience episodes of

delirium, agitation, and confusion, even in the absence of injury. This can make it difficult to assess progression of brain injury.

Age-related brain atrophy between the 5th and 10th decade causes a reduction of approximately 15–20% of the cortical brain volume [28, 29]. A significant amount of blood can accumulate before neurologic symptoms appear [30]. Terry et al. demonstrated that the brain of an elderly person occupies only 82% of the skull, compared to 92% in younger individuals [31]. As the brain volume decreases, the dura remains adhered to the skull, causing an increase in the distance between the inner table of the skull and the outer surface of the brain. This lengthening causes the bridging veins to be pulled taut, thus rendering them more likely to sustain a shear-type injury during rotational stress, such as deceleration force in a motor-vehicle crash. Subdural hematomas are three times more common in the elderly. However, the risk of an epidural hematoma in the elderly is much lower because of the decrease in the epidural space [32].

Similarly, degenerative disease of the bony cervical spine narrows the central spinal canal and leads to an increased frequency of central cord syndrome, especially with extension-type forces [33]. Kato and colleagues demonstrated that degenerative changes and spinal stenosis represent important risk factors for cervical spine injuries [34]. In addition, degenerative changes can limit mobility and strength.

As the population ages, so does the portion of elderly persons who are “physically functional but cognitively impaired.” For instance, patients with Alzheimer’s disease have an additional 14–20% greater reduction in total cortical and fore-brain brain volumes than expected during normal aging [28, 35]. One study documented 58.4 injuries per 100 person-years in patients with Alzheimer’s disease [36]. More than 50% of those injured required treatment, and the likelihood of injury was associated with cognitive impairment and functional limitation.

Cardiovascular

With increasing age, myocardial contractility is depressed, and ventricular compliance falls for any given preload. The aged myocardium also fails to respond to heightened endogenous or exogenous catecholamines [37]. There is a fall in the maximum oxygen utilization, and maximum heart rate is reduced by about 30% between the age of 20 and 85 [38]. The incidence of dysrhythmia and subsequent syncope is increased, probably from conduction system ischemia [39]. Syncope may also be caused by medications, including β -blockers. Ventriculoarterial coupling is hampered by progressive arteriolar stiffening and loss of arterial elastance, leading to an increased frequency of orthostatic hypotension.

Cardiovascular disease is common in the elderly. Wilson described a 13.7% incidence of hypertension and 5.6% occurrence of symptomatic coronary artery disease (CAD) in a series of trauma patients over the age of 65. For those over 75 years of age, the incidence of symptomatic CAD was 12.9% [40]. More recently, Bochicchio et al. have demonstrated a 17% incidence of hypertension and a 9% incidence of CAD in a slightly younger (mean age of 43 years) cohort of critically ill trauma patients.[41].

Medications such as β -blockers, calcium channel blockers, or digoxin may blunt or inhibit tachycardia in response to acute intravascular volume loss and cloud the anticipated pattern of response to injury. In addition, CAD (especially right-sided coronary lesions) causes loss of autoregulation of coronary blood flow. Thus, as myocardial activity increases, the elderly can experience either occult or obvious cardiac ischemia with resultant pump failure [38]. In addition, some authors have reported as many as 78% of those over the age of 70 have amyloid deposits in the myocardium that can stiffen the heart and cause conduction defects and subsequent heart failure [11, 42].

The elderly cannot augment cardiac output and instead increase systemic vascular resistance [36]. This produces a falsely normal blood pressure and may very well correspond to profound shock. Scalea et al. have demonstrated that as many as 50% of those who had “normal” blood pressure in fact had evidence of occult cardiogenic shock and a subsequent poor outcome [16, 43].

Pulmonary

Elderly patients have a decreased respiratory reserve and decompensate quickly [44]. Decreases in respiratory function in the elderly result from changes in both the chest wall and the lungs [45, 46]. After the age of 30, a 4% per decade decrease in alveolar surface area results in a negative effect on gas exchange as well as forced expiratory flow [47]. Alveolar ducts enlarge, and the alveoli become flatter and shallower, reducing the area for gas exchange and leading to ventilation perfusion mismatch.

Decreases in chest wall compliance from anatomical changes such as kyphosis and a decline in respiratory muscle strength from muscle fiber atrophy lead to as much as 50% loss in maximal inspiratory and expiratory force [44]. Accessory muscles help to compensate for the decline in respiratory muscle atrophy. Lung elastance also progressively declines, causing a collapse of small airways and uneven alveolar ventilation. This results in increased closing volume of the lung.

Additionally, responses to hypoxia and hypercapnia are decreased by 50 and 40%, respectively [44]. The aging

mucociliary function worsens, with fewer cilia per square centimeter. Secretion clearance is also impaired. This, in addition to poor dentition, increased oropharyngeal colonization, swallow dysfunction, and a decreased lower esophageal sphincter tone, predisposes the elderly to aspiration pneumonia and pulmonary infection [44]. Gram-negative organisms predominate in the oral flora, increasing the risk of pulmonary infection from aspiration [47].

Osteopenia of the thoracic cage may increase the rate of pulmonary contusions, rib fractures, and pneumo- and hemo-pneumothoraces as the bony thorax cannot absorb transmitted kinetic energy. Accordingly, flail chest in the elderly correlates with prolonged mechanical ventilation [48]. In those with a flail chest, age has been shown to be the strongest predictor of poor outcome and is directly proportional to mortality [49]. Elderly patients who sustain rib fractures have twice the mortality rate of younger patients with similar injuries [50]. The number of rib fractures increases, so does the incidence of pneumonia and death [50, 51]. Pain control is critical to allow deep breathing and prevent pulmonary complications.

Renal Disease

A number of structural changes occur in the kidney as one ages. Decrease in renal tubular length and thickening of basement membranes, as well as interstitial fibrosis and atherosclerosis of capillary beds, lead to ineffective secretion and resorption abilities of the aging kidney [32]. Between the age of 25 and 85, 40% of the nephrons become sclerotic. In addition, between the age of 30 and 85, there is a 20–25% decrease in renal mass, from renal cortical loss [52]. By age 80, the glomerular filtration rate (GFR) has decreased approximately 45%, but serum creatinine remains the same due to concomitant muscle mass loss [44]. Thus, serum creatinine for a given level of renal function is falsely low.

The lower GFR causes a diminished ability to concentrate urine in the aging kidney. A concomitant decrease in response to aldosterone and antidiuretic hormone further prevents the kidney from producing concentrated urine. Furthermore, diuretics prevent the aging kidney from concentrating the urine and make urine output a less reliable marker for renal perfusion in the elderly.

Once injured, the elderly who have renal insufficiency or failure may have additional problems. The platelet dysfunction commonly seen with renal failure may lead to prolonged bleeding even after minor trauma. Electrolyte disorders, most notably hyponatremia, hypo- or hyperkalemia, hypomagnesemia, and hypocalcemia may cause dysfunctional neural transmission, cardiac dysrhythmias, seizures, mental confusion, muscular weakness, or syncope.

Drugs used to evaluate and treat the older trauma victim may further impair renal function. Extensive imaging with iodinated contrast may damage already impaired renal parenchymal and tubular system and lead to contrast-mediated nephropathy. Nonsteroidal anti-inflammatory drugs (NSAIDs) are frequently used to treat pain and avoid the sedative effects of narcotics, but use of these agents is associated with a significant risk of interstitial nephritis. Life-threatening infections with gram-negative organisms may require aminoglycosides, but such therapy may induce renal dysfunction despite seemingly acceptable drug levels. Despite renal replacement therapies, acute renal failure in trauma patients results in a mortality rate of approximately 50%, regardless of cause [53–55].

Musculoskeletal

Degenerative joint disease is common in the elderly and results in limited range of motion around major axial joints and puts the individual at high risk of injury. Lean body mass decreases by 4% every 10 years after the age of 25 and 10% every 10 years after the age of 50 [32]. Osteoporosis, with loss of up to 60% of trabecular bone and 35% of cortical bone [30], has been cited as a major factor contributing to the high incidence of fractures seen in elderly trauma patients [56].

Aging also influences the site of cervical spine fractures. In younger patients, the lower cervical spine region is more mobile and is the location of many cervical spine injuries. However, in the elderly, the lower cervical spine is less mobile due to degenerative changes, and the more mobile region of C1 and C2 is more often the site of injuries in the elderly [57].

Gastrointestinal

There is decreased hepatic function in the elderly due to a 40% hepatic mass loss by the age of 80 [58, 59]. Preexisting liver dysfunction increases mortality after trauma [8, 20, 21]. Hepatic disease has the strongest effect on trauma mortality of all preexisting medical conditions and is associated with an increased mortality in elderly trauma patients with less severe injuries [8, 20]. Morris et al. demonstrated that cirrhosis, in trauma patients of any age, increased the risk of dying, with an odds ratio of 4.5 [21].

The elderly trauma patients are at an increased risk of intestinal infarction. Acute hemorrhage, neurogenic shock, or cardiac dysfunction from acute injury can all result in low flow states. In the elderly with underlying vascular calcification or mural thrombus, any decrease in flow can cause significant

compromise to the bowel and result in intestinal ischemia. Additionally, geriatric patients often do not manifest peritoneal signs and tend not to localize pain, making the diagnosis difficult [32]. This lack of peritoneal irritation can be a result of decreased abdominal musculature. In addition, polypharmacy, dementia, or Alzheimer's can obscure the physical exam in the elderly, making the diagnosis of an intraabdominal injury more difficult.

Metabolic/Endocrine

By age 80, the elderly have lost almost 40% of their lean muscle mass [44]. During muscle breakdown for gluconeogenesis, critically ill patients lose a significant amount of muscle mass. As the elderly start with less muscle mass, the proportion of loss is greater [60]. Thus after injury, the elderly quickly become severely malnourished, and nutritional support should begin early. A 2005 Cochrane review on nutritional supplementation in the elderly suggested that early nutrition reduced unfavorable outcomes, long-term complications, and days spent in rehabilitation [61].

The most notable endocrinopathy of aging is glucose intolerance. This hyperglycemia is a result of both decreased secretion of insulin and increased resistance to insulin [11, 60, 62–64]. Increasing age is associated with an increase in serum glucose, but not an increase in insulin after mild or moderate trauma [63]. There is also a decrease in thyroid function and responsiveness to metabolic stress in the elderly. Aging cause fibrosis of the thyroid gland with a decrease in the amount of T3 released. This results in a lower basal metabolic rate [32]. The elderly also lose their natural responses to cold and are at a higher risk of hypothermia [65, 66]. Warming, therefore, should be implemented as quickly as possible after injury.

Epidemiology of Injury in the Elderly

Falls

Falls are the most common injury in the elderly. Most falls occur in or about the home, with the greatest number during winter [67]. Most tend to be ground-level falls, while falls from great heights are uncommon [30]. Between 30 and 40% of the population over 65 years of age who live in the community sustain a fall each year [68–73]. This is higher for persons living in long-term care facilities [69, 70, 72]. About 30–55% of falls in those over the age of 65 years cause minor injuries such as bruises and abrasions [73–75]. Fractures occur in 4–6%, 25% being hip fractures, while other major

injuries requiring hospitalization occur in an additional 2–10% [72, 76]. Elderly women are no more likely to fall, but sustain serious injury, usually fractures, more commonly than men [13, 77]. Men incur more CNS injuries and have higher mortality following falls [13]. This may be from higher risk-taking and underreporting of less severe fall injuries in men [13].

Inability to get up after a fall is common. In one study, 50% of the elderly could not get up without assistance from weakness or limited motion due to underlying musculoskeletal disabilities [77]. A large prospective study demonstrated that 14% of patients who fell were unable to get up after 5 min or more, and 3% of patients were down for longer than 20 min [73]. Another study showed that 41% of patients treated in an emergency room after a fall reported being unable to get up within 5 min, and 3% of patients lay on the floor for more than 3 h [78]. Prolonged down time can cause decubiti, dehydration, and even rhabdomyolysis.

Numerous studies [13, 76, 79, 80] have outlined the risk factors for falls among the elderly (Table 31.5). Debilitating chronic diseases such as parkinsonism, stroke, arthritis,

^aExercise has an inconsistent effect on the incidence of falls and fall-related injuries (see text)

dementia, and anemia are more prevalent in the population of elderly who sustain falls [81]. Among the other factors are older age, Caucasian race, history of previous falls, polypharmacy (especially psychotropic agents, diltiazem, laxatives, and diuretics), dependence for activities of daily living, low body mass and impaired mobility, muscle strength, gait, balance, vision, hearing, and cognition [73, 75, 76, 82]. These factors have all been correlated with an increased risk of falls and fall-related injury. The role of exercise as a risk factor is not clear. Exercise may lead to increased coordination and strength. While some studies have shown significant decreases in the incidence of falls, exercise also increases the exposure of the elderly to possible fall scenarios [81].

Falls amongst the elderly result from complex interactions of structural and physiologic disabilities. The consequences of a fall depend on such factors as the kinetic energy generated during the fall as well as the ability of the body structures to absorb and the fall surface to accept the energy. In addition, the protective responses, the garments of the faller, and the direction and body location of the impact will affect the outcome of the fall [77]. Functional consequences of the aging process along with an alteration in cognition may lead to increased risk-taking. Lack of realization of their limitations also predisposes the elderly to falls. Duthie suggested that approximately 25% of falls in the elderly were caused by an underlying medical problem [83]. Loss of muscle mass and changes in body composition result in decreased strength. Combined with a limited range of motion due to degenerative joint diseases, the elderly are less able to absorb the kinetic energy during a fall. Thus, many falls that are categorized as accidents are truly interactions between identifiable environmental hazards and increased individual susceptibility to those hazards from accumulated effects of age and disease [72]. Therefore, management of the elderly fall victim must include an investigation into the cause of the fall, which can frequently be determined from a thorough history.

Falls lead to life-altering consequences in the elderly. Approximately 8% of the elderly population seeks emergency care after a fall; 30–40% of older persons treated in the emergency department for a fall are hospitalized, with an average length of stay of 8–15 days [79, 84, 85]. In contrast to the younger patient seen in the ED after a fall, older patients usually do not die as a direct result of the fall. Instead, preexisting medical conditions and secondarily acquired complications are often the cause of death [21, 30]. As a result, complications from falls are the leading cause of death from injury in men and women over the age of 65 years [85].

The economic impact of falls in the elderly is huge. Numerous studies have attempted to estimate this financial impact; however, the wide variation on methodology makes it somewhat difficult to compare the results. Estimates range from \$6.2 billion to \$20 billion per year [86–89].

Motor Vehicle Collision

Motor vehicle collisions (MVC) are the second most common mechanism of injury in those 65 years of age and older. In 2005, over 177,000 elderly people suffered nonfatal injuries as a result of a MVC [90]. Injury pattern, however, is independent of age except for sternal fractures (11% elderly vs. 1.5% younger) [56]. Older drivers who are hospitalized after an MVC have significantly higher mortality rates, longer hospital stays, and are less likely to be discharged directly to their homes [91]. There is a greater frequency of intracranial hemorrhage and chest injury in the elder population that contribute to poor outcome as well. For similar injuries, older adults are five to six times more likely to die than their younger counterparts [30]. For those over 85 years of age, the fatality rate increases to seven to nine times that of younger drivers [92].

Elderly drivers appear to have lower crash rates compared with younger drivers, but they drive less often. When normalized for the number of miles driven, the >65 years group has the second highest crash rate after new drivers. The >85 years group has the highest per-mile-driven crash rate of all age groups. The elderly are more likely to be involved in vehicle–vehicle crashes, usually during daylight hours, close to home and frequently at intersections [93]. Cook et al. found that the elderly were no more likely to have a crash involving a right-hand turn but were more than twice likely to crash during a left-hand turn than younger drivers [94]. The elderly are also more likely to be found at fault by investigation officers [95].

Reduced vision or hearing, impaired judgment, and reduced reaction times are well recognized as factors leading to MVC in the elderly. Koepsell and coworkers showed that diabetes, especially when insulin-dependent, significantly increased the risk of a MVC with injury [96]. Rehm and Ross showed that elderly crash victims had a significantly higher incidence (74 vs. 14%) of underlying disease(s) such as cardiac, hypertension, diabetes, or neurologic diseases than did victims in the young cohort [95]. In addition, alcohol is less often involved in MVCs involving the elderly compared to younger drivers [95, 97].

Pedestrian–Motor Vehicle Collision

McCoy et al. showed the elderly were more likely to be involved in a pedestrian crash as a result of walking into oncoming vehicles, often due to confusion or impairment of visual or auditory acuity [56]. Reduced gait speed of the elderly pedestrian may be inadequate to complete the crosswalk at time-controlled traffic intersections, leaving the elder

in the street exposed to inattentive drivers. In 1961, Haddon et al. demonstrated an increased risk of pedestrian crashes and fatalities with increasing age [98]. Others have corroborated this association [99, 100].

Burns

Deaths from burns are the fifth most common cause of unintentional injury death in the USA [101]. In 2005, there were approximately 3,200 fire/burn-related deaths in the USA. Of these, approximately one-third occurred in those over the age of 65 years [102], most of them sustained at home [103]. Diminished senses, impaired mentation, slower reaction time, reduced mobility, and bedridden states may decrease an elder's ability to identify fire and also to escape harm. This may result in a more severe injury and an increased likelihood of death [104].

Extensive burn in the elderly has a poor prognosis; however, the fatality rates from burns in this age group are variable. Lionelli et al. demonstrated an overall mortality of 47% in patients 75 years of age and older [105], while Covington et al. demonstrated a mortality of 60% in the same age group [106]. Lionelli also demonstrated a nearly 50% reduction in mortality when comparing rats in the 1970s to those in the 1980s and 1990s (77 vs. 41%). A study by McGill and colleagues demonstrated a 72% survival in the elderly burn victim when aggressive burn care was used [107].

The discharge of an elderly burn patient must be well thought out. For those with minor burns, returning to their home with some assistance will most likely be adequate. For those who have suffered more severe injury, rehabilitation will be required. Most importantly, for those who return home, an in-depth evaluation of home safety modification helps prevent recidivism.

Elder Abuse

The US National Academy of Sciences defines elder abuse as: "(a) intentional actions that cause harm or create a serious risk of harm to a vulnerable elder by a caregiver or other person who stands in a trust relationship to the elder or (b) failure by a caregiver to satisfy the elder's basic needs or to protect the elder from harm" [108]. The abuse includes physical, psychological, sexual, and financial, as well as neglect. Such injuries are considerably more subtle in their presentation than those from a physical assault.

Only 1 in 14 incidences of elder abuse come to the attention of the authorities [109]. Thomas estimated that the

TABLE 31.6 Risk factors for elder abuse

Increased frailty of the victim
Cognitive impairment of the victim
Mental illness of the abuser
Substance abuse by the abuser
Family history of violence or antisocial behavior
Victim and abuser live together
Isolation of the victim
Recent life stress

incidence of elder abuse ranges from 2 to 10% [110]. In a random-sample, community-based epidemiologic study, 3.2% of those surveyed reported to having been victims of either physical, or psychological abuse, or neglect since they turned 65 [109]. This number may underestimate the magnitude of the problem owing to the victim's reluctance to admit abuse for fear of loss of care, retribution from the abuser, or from being ashamed to be in an abusive relationship.

Risk factors should alert the healthcare provider to the diagnosis of abuse (Table 31.6) [111, 112]. Once suspicion is raised, the victim should be interviewed one-on-one to increase the likelihood of disclosure of the extent and details of the abuse. Victims may be embarrassed revealing such details to a group of health-care personnel. The details of the abuse should be documented completely in the medical record for the possibility of subsequent legal action. The physician who documents or suspects elder abuse is ethically obligated, and in most states legally bound, to report the case to an adult protective service agency.

The most important intervention is to protect the victim from danger. The victim may be reluctant to leave the care of their abuser because of ambivalence regardless of the perceived danger. Unless the victim lacks the cognitive skills to make informed decisions, individual liberty must not be compromised. The physician should interview the abuser in a nonconfrontational fashion to better understand the situation. The physician should acknowledge and empathize with the difficulty of shouldering the burden of elder care. Armed with this additional information, the physician is better prepared to intervene to break the abuse cycle.

Suicide

In 2004, suicide was the third leading cause of injury-related death for those 65 years of age and older [1]. Those over the age of 75 had the highest rate [113]. Only about 25% of the elderly who attempt suicide are actually successful [114]. Risk factors for suicide in the elderly population include psychiatric disorders, especially depression; medical conditions, especially cancer or chronic lung disease; moderate to heavy

alcohol use; and social isolation. Changes in behavior such as altering a will, new preoccupation with religion, or giving away life possessions may be warning signs of impending suicide.

Management

Triage

Triage for the geriatric patient should provide the appropriate intensity of medical care, taking into account factors including severity of injury, cost, availability, prognosis for functional recovery, and patient desire. This process begins in the prehospital setting when decisions must be made regarding the appropriate facility [115]. In 2006, The American College of Surgery Committee on Trauma suggested that patients over the age of 55 years be triaged to a trauma center [116]. However, in reality, the elderly are the most undertriaged group and suffer increased morbidity and mortality as a result of underresuscitation [117].

Many of the physiologic and anatomic scores used in trauma correlate with outcomes in geriatric patients; however, these scores have little value in that they are not derivable at the time when triage decisions are made. The Trauma Score (TS), comprised of blood pressure, respiratory rate, respiratory effort, GCS, and capillary refill is readily obtainable and can be used to assist in triage. The minimal score is 0, and the maximal score is 16. The Revised Trauma Score (RTS) eliminates respiratory effort and capillary refill, resulting in a score range of 0–8. Osler et al. demonstrated that no patient with a $TS < 7$ survived to reach the hospital and that no patient arriving at the hospital with a $TS < 9$ survived the hospitalization [118]. Knudson and colleagues demonstrated a 100% mortality in those 65 years of age and older having a $TS < 7$ [119]. This suggests that when geriatric patients have a $TS < 7$, one must question the utility of aggressive treatment and resource allocation. A study of 374 patients over the age of 65 demonstrated an overall mortality of only 5% in those with a TS of 15 or 16, 25% in those with a TS of 12–14, and 65% in patients with a $TS < 12$ [120]. These data suggest that appropriate triage and aggressive care, including admission to an ICU, for those with a TS of 7–14 may improve survival.

Initial Management and Resuscitation

The first few minutes of resuscitation of the elderly trauma victims differs very little from that of younger patients. Early intubation in the multi-injured elderly trauma patient should

be considered as it reduces the work of breathing and may avoid progressive respiratory failure and cardiovascular collapse. As the elderly have limited cardiovascular reserve, they are vulnerable to hypotension from induction agents, and reduced doses should be used. In addition, limited pulmonary reserve may make preoxygenation difficult, causing rapid desaturation during intubation.

A normal blood pressure for a younger patient may be a relative hypotension for an elderly patient with history of hypertension. Geriatric patients are more likely to present in shock than younger patients matched for trauma and ISS [121]. In the Major Trauma Outcome Study (MTOS), Champion et al. showed that geriatric patients had four times the incidence of cardiovascular complications as the young cohort, supporting the importance of improving cardiovascular response of the elderly trauma patient to maximize survival potential [3].

Scalea and colleagues demonstrated that significant hemodynamic compromise occurs in elderly patients who were clinically stable after their initial evaluation for blunt trauma [43]. Over a 2-year period, all patients over the age of 65 who were hemodynamically stable after their initial resuscitation had pulmonary artery catheters (PACs) inserted. The authors defined patients to be in cardiogenic shock if they had a cardiac output (CO) of less than 3.5 L/M and/or a mixed venous saturation (MVO_2) of less than 50%. They demonstrated an increase in survival from 7 to 53% by early optimization of all patients with volume, inotropes, and afterload reduction. The authors concluded that emergent invasive monitoring identifies occult shock early and improves outcome. Schultz et al. performed a randomized trial of resuscitation in 70 patients with fractures of the hip [122]. The monitored group had a PAC placed, while the control group only had a central venous line placed. Despite numerous weaknesses in the study, the mortality for the monitored group was 2.9% and was 29% in the control group. In addition, DeMaria et al. concluded that aggressive treatment, including invasive monitoring, decreased mortality in trauma patients over 75 years of age [123]. To avoid potential complications associated with PACs, efforts have been made to develop alternative, less invasive techniques of cardiac output monitoring. Although initial studies have shown comparable accuracy and precision between the PAC and newer less invasive techniques, further studies are ongoing [124, 125].

Davis and Kaups showed that admission base deficit (BD) levels correlate with mortality in the geriatric population [126]. Although the authors used 55 years as their cutoff, a $BD \leq -10$ had an 80% mortality, -6 to -9 a 60% mortality, -3 to -5 a 23% mortality, and ≥ -2 had an 18% mortality (Fig. 31.2). Other studies correlated the rate of serum lactate clearance after trauma with survival [127, 128]. Patients had a mortality rate over 75% if it took more than 48 h to normalize lactate.

Management Considerations for Specific Injuries in the Elderly

Head Injuries

In persons 65 years of age and older, traumatic brain injury (TBI) is responsible for over 80,000 ED visits annually [129]. In 2006, over 2.8 billion dollars were spent on treating TBI in those older than 65 years [130]. Falls are the leading cause (51%), while MVCs are a distant second (9%) [129]. As many as 73% of elderly TBI patients may have at least one comorbid condition as compared to only 29% of younger patients [131]. Treatment of some of these chronic conditions includes the use of aspirin and warfarin, which increases the risk of TBI in the elderly. A study by Lavoie et al. found that 9% of the older patients with TBI were taking warfarin pre-injury and that it was associated with more severe TBI and a higher rate of mortality [132]. Older age has been well recognized as an independent predictor of worse outcome after TBI, even with relatively minor head injuries [133, 134] (Fig. 31.3). Older TBI patients also have been found to have longer length of stays, resulting in greater cost of care [135]. Significant TBI in the elderly can be caused by minimal trauma and may initially present with little or no neurologic deficits. In elderly patients with mild TBI (GCS 13–15), 14% of patients have a lesion on CT scan, four of which required neurosurgical intervention [136]. These authors recommended CT scan for patients over 65 years of age presenting with TBI. Due to the atrophy of the elderly brain, the distance traversed by the bridging veins is increased. This increased distance allows intracranial hemorrhages to have significant amount of room to expand prior to demonstrating any clinical signs. Thus, subdural hematomas are three times more common in the elderly [137].

FIGURE 31.3 Percentage of elderly survivors and nonelderly survivors by GCS score (reprinted with permission from Susman et al. [134]).

Management of the head-injured elder is generally similar to that of the head-injured young patient: specifically rapid diagnosis of the specific neurologic injury using head CT scans and avoidance of secondary brain insult resulting from hypotension and hypoxia. Intracranial pressure (ICP) monitoring is paramount as is ensuring adequate cerebral perfusion pressure (CPP). A study by Czosnyka et al. demonstrated that ICPs decrease in the elderly, with a resultant increase in CPP [133]. The authors also demonstrated that there is a decrease in autoregulation in the elderly. Current guidelines for CPP management may not be appropriate for the elderly. Comorbidities may affect the responsiveness and perfusion needs of the cerebral vasculature in these patients.

Some studies have shown that preinjury warfarin use in the elderly had no effect on mortality in trauma patients [138, 139]. However, others have shown that it is, in fact, associated with increased frequency and severity of TBI, and a higher mortality [132, 140]. A study by Fortuna et al. demonstrated that those with a hemorrhagic brain injury on warfarin had a 34% mortality [141]. This was compared to

those taking aspirin or clopidogrel, who had a mortality of 13 and 6%, respectively. All patients were similar in age and had similar ISS and head abbreviated injury score (AIS).

Any patient who has a traumatic hemorrhagic brain injury and an elevated INR should have the warfarin reversed. The risk of immediate mortality, related to the TBI, far outweighs risk for adverse thromboembolic events from the preexisting condition. Traditionally, fresh frozen plasma (FFP) has been used. Using a reversal protocol of 2 units of uncrossed FFP followed by an additional 2 U of matched FFP, Ivascu et al. demonstrated decreased reversal time from 4.3 to 1.9 h, with a subsequent improvement in mortality from 50 to 10% [142]. However, large volumes of FFP are often required to fully reverse warfarin. This can cause pulmonary edema and volume overload in the elderly patient with compromised cardiac and/or renal function. Alternatives to FFP do exist. Stein et al. demonstrated that a single dose of 1.2 mg of recombinant activated factor VIIa (rFVIIa) rapidly and effectively treats mild to moderate coagulopathy following injury [143]. In addition, they demonstrated that rFVIIa reduced the time to neurosurgical intervention (144 vs. 446 min) and decreased the use of blood products, without increasing the rate of thromboembolic complications [144]. In addition, despite having an increased pharmacy cost for those who have received rFVIIa, overall, the use of rFVIIa may actually decrease overall hospital charges [145]. Other alternatives include prothrombin complex concentrates (PCCs) as well as vitamin K and cryoprecipitate. Cartmill et al. demonstrated a more complete and quicker reversal time in patients on warfarin needing an emergent neurosurgical intervention using PCCs compared to FFP and vitamin K [146].

Elderly trauma patients on warfarin with TBI are particularly susceptible to clinical deterioration. In a recent study by Cohen et al., 56 of 77 patients with a GCS of 13–15 who were either discharged or admitted for observation had a clinical deterioration with a mortality rate greater than 80% [147]. As a result, any elderly patient on warfarin, with head trauma and a therapeutic INR, should be admitted and observed for a minimum of 12–24 h even if the initial head CT scan shows no injury [148]. A repeat CT scan should be done for any change in the patient's neurologic exam.

Spinal Injuries

Cervical fractures have a prevalence of 2.6–4.7% in patients older than 65 years [149, 150]. Low-energy falls are the most common mechanism among the elderly [151]. Injuries at the upper cervical region are associated with the longest hospital treatment. Golob et al. demonstrated a 22% in-hospital mortality in elderly patients with isolated cervical spine fractures [152].

Patients who are awake, alert, nonintoxicated, have no cervical tenderness, neurologic deficit, or distracting injury do not need any radiographic evaluation, regardless of age [153]. Although the three-view plain radiograph has been the traditional initial modality for cervical spine evaluation, many now use CT as the initial evaluation tool for cervical spine injury due to the high rate of missed injuries on plain films [154–159]. If a neurological deficit is present, then magnetic resonance (MR) should be used to evaluate ligamentous and/or spinal cord injury [160, 161].

Cervical stabilization is the primary end point, be it with a cervical collar, halo, or operation. A 1985 report by Pepin et al. stated that patients with odontoid fractures who were over the age of 75 years did not tolerate a halo and that surgical stabilization and an appropriate brace were superior [162]. Halo alone led to an increased rate of pneumonia and decubiti. In contrast, Malik et al. used a halo for ten patients over the age of 75 years, and most tolerated the halo relatively well [151]. Additionally, Weller et al. reported no complication with halo usage in patients over the age of 70 years [163]. The halo allows for mobilization in the early postinjury period, which is paramount in reducing complications.

Central cord syndrome (CCS), usually resulting from hyperextension, is more likely to occur in the elderly due to underlying cervical stenosis [93]. Patients usually present with upper extremity weakness that is greater than lower extremity weakness. A 1990 study by Penrod et al. demonstrated that at follow-up, 97% of younger patients with CCS were ambulatory, whereas only 41% of the elderly with CCS were able to walk. In addition, the younger patients with central cord syndrome achieved independence in self-care of bladder and bowel function more frequently than did the older group [164, 165]. DeVivo et al. demonstrated that the elderly, defined as those aged 61 years and older, had a 59% 2-year survival as compared to 95% in a younger cohort [166].

Thoracic Injuries

The elderly have a higher mortality from chest trauma as a result of the initial injury as well as secondary pulmonary insults [167, 168]. Routine use of cardiac enzymes, electrocardiogram (EKG), and echocardiography to identify cardiac injuries may be beneficial. Early intubation and mechanical ventilation should be considered for any elderly trauma patient that shows signs of respiratory compromise. Although intubation may increase pneumonia and the need for tracheostomy, the procedure may be lifesaving.

A number of studies have focused on rib fractures in the elderly and subsequent outcome. Cameron et al. demonstrated increased morbidity in the elderly with multiple fractures

compared to younger patients [169]. In 2000, Bulger et al. retrospectively evaluated patients over the age of 65 years with rib fractures compared to those younger than 65 [50]. Despite similar ISS and chest abbreviated injury score (AIS), the elderly had fared significantly worse in all outcome measures (Table 31.7). Sharma and colleagues also demonstrated a twofold increase in mortality in the elderly with rib fractures [170]. Mortality increased as the number of rib fractures increased [50, 170] (Figs. 31.4 and 31.5).

Traumatic aortic injuries (TAI) are often initially suspected by a widening of the mediastinum on a plain chest X-ray. Prior to the widespread use of CT scan, TAI was definitively diagnosed with the use of angiography. Over the last 10 years, there has been a significant change in the management of TAI from the traditional, standard operative repair (OR). A 1994 study by Camp et al. that compared OR in the young and the elderly demonstrated a 163-fold increased likelihood of mortality in the elderly [171]. In a 2006 study, Hirose et al. showed promise with nonoperative management in some high-risk elderly patients with small aortic tears [172].

Endovascular stent grafts (SG) were initially used for high-risk, multiply injured patients or those with comorbid disease, i.e., the elderly [173]. However, many centers now use them as their initial treatment of choice for TAI [174]. A 2008 multicenter American Association for the Surgery of Trauma (AAST) study compared 193 patients who had either an OR or endovascular SG for a TAI [174]. The study did not specifically breakdown outcome by age; however, using multivariable analysis, those over the age of 55 who received

TABLE 31.7 Outcome measures

Parameter	Age (years)		p Value
	≥65	18–64	
Mean ventilator days	4.3±9.2	3.1±9.2	=0.16
Mean ICU days	6.1±10.0	4.0±9.4	<0.05
Mean hospital days	15.2±16.5	11.0±13.1	<0.01
Mortality (%)	22	10	<0.001

an endovascular SG had a significantly lower mortality. Unfortunately, the rates of long-term complications including delayed leak, migration, and thrombosis are currently unknown. It seems reasonable to assume an overall benefit for the elderly to have an SG placed as opposed to a thoracotomy performed.

Abdomen/Pelvis Injuries

Significant intraabdominal injury occurs in approximately one-third of elderly patients with multisystem trauma [175]. The clinical abdominal exam is less reliable in the elderly, and as such, liberal use of diagnostic studies is recommended [14, 175]. Ultrasound appears to be a reliable initial radiographic modality for evaluating an intraabdominal injury. Although free fluid on an ultrasound suggests an injury, it cannot differentiate between a solid organ injury and a hollow viscous injury. A study by Rozycki and colleagues demonstrated that ultrasound had an overall sensitivity of 83.3% and specificity of 99.7% [176]. In blunt trauma patients who were hypotensive (systolic blood pressure <90 mmHg), both sensitivity and specificity were 100%. Although the study did not evaluate the elderly per se, the oldest person in the study was 84 years old.

CT scan can be used to evaluate a hemodynamically stable patient to identify the presence of intraabdominal injuries. An IV contrast agent is typically used to better identify vascular injuries. This can often be problematic in the elderly for a number of reasons. Interactions with specific medication, such as metformin, can cause a lactic acidosis. In addition, contrast-induced nephropathy can be as high as 25% in patients with preexisting renal dysfunction, diabetes, advanced age, and concurrent usage of nephrotoxic drugs [177]. A meta-analysis suggested that pretreatment with N-acetylcysteine was most effective in preventing contrast-induced nephropathy [178]. However, most of the studies used pretreatment for 24 h, which is not feasible after injury. Merten et al. demonstrated that a protocol using pre- and posttreatment with bicarbonate was more effective than saline alone in preventing contrast nephropathy [179]. A 2006 review by Pannu et al. supports the use of hydration, bicarbonate, and low volumes of iso- or low-osmolar contrast in at-risk patients [180].

Nonoperative management of blunt splenic injuries has become standard of care. Early studies showed a high failure rate for those over the age of 55 years [181–183]. Recently, however, this has been challenged, and a number of studies have shown that age is not associated with increased failure rate [184–186]. Thus, age over 55 years is no longer considered a contraindication to nonoperative management of splenic injuries. Clinicians must monitor those with high-grade injuries and free pelvic fluid closely, as they have a higher failure rate.

Fractures

Hip fractures remain the most frequent cause of hospital admission after trauma in the elderly. Liberal use of CT scan or MR is wise in patients with high index of suspicion for fracture with negative plain radiographs [187]. Myers et al. showed that the mortality for men with hip fractures was 60% higher than for women [188]. In addition, factors associated with in-hospital death included sepsis, pneumonia, and gastrointestinal disorders. The risk of dying after hip fracture was doubled in patients with cardiac disease, cancer, or cerebrovascular disease. These authors concluded that the most important complication leading to in-hospital deaths after a hip fracture was sepsis.

Almost 30 years ago, Laskin et al. proposed a management scheme for intertrochanteric fractures in the elderly. This included early rigid fixation using compression hip screws to allow early mobilization and immediate weight bearing to assist with vigorous pulmonary toilet [189]. The longer the elderly remain bedridden, the more likely they are to have complications, including atelectasis, pneumonia, need for mechanical ventilation, venous thrombosis, muscle atrophy, and skin breakdown, all leading to longer hospital stay and increase in mortality. Thus, early orthopedic consultation, fracture fixation, and physical therapy are warranted.

Pelvic fractures are common in the elderly. A 2002 study by Henry et al. demonstrated that most elderly patients have lateral compression fractures, which are usually not associated with significant bleeding [190]. However, the authors found that the elderly are more likely to have fracture-associated hemorrhage and require angiography. In addition, the outcome for older patients with pelvic fractures was significantly worse than for younger patients. Recognizing these differences in fracture and bleeding patterns in the elderly identifies those at high risk and helps guide resuscitation.

Few studies have investigated management of other specific fractures in the elderly. Roumen et al. found that external fixation for unstable Colles' fractures was no more effective than nonoperative management in the elderly [191]. Ritchie et al. noted good limb salvage for open tibial fractures in patients over 60 years of age. Thus, age alone should not represent a contraindication to limb salvage in patients with severe open fractures and concomitant vascular injuries [192]. Helfet et al. reported that open reduction internal fixation (ORIF) of displaced acetabular fractures can yield good results in the elderly and obviate the need for a total hip replacement [193]. Bogner and colleagues demonstrated that a percutaneous reduction and internal fixation of the proximal humerus in patients over the age of 70 years provided a comfortable and mobile shoulder [194]. The authors

state that this less invasive method provides a satisfactory alternative to replacement and traditional techniques of internal fixation.

Burns

Advances in burn care over the past 50 years have improved mortality rates across all age groups [195]. Although the elderly have a reduced rate of survival with less severe burns than their younger counterparts, the long-term outlook for those who do survive is somewhat optimistic. Manktelow et al. reported that 53% of those burned elders who survived did not have a more dependent living status on discharge [196]. Another 8% of patients achieved independent status within 5 years of the burn. Discharged patients did not have an accelerated death rate compared to that of the unburned population. In addition to the standard management of burn victims, the elderly present other challenges. The elderly burn victim may suffer hypoperfusion in the face of normal vital signs and adequate urine output. Bowser-Wallace et al. advocated hemodynamic monitoring for routine management of severe burns in the elderly [197]. They noted excellent survival in the elderly who were resuscitated with hypertonic lactated saline. Early wound closure has been viewed as a major advance in the management of young burn patients, resulting in decreased length of hospitalization and decreased mortality. Kara et al. demonstrated that early excision and grafting in the elderly yielded fewer episodes of infection, resulting in a reduction in hospital stay, but it did not improve survival [198]. Others have shown improvement in survival of elderly burn patients with early excision and grafting [199, 200].

Rehabilitation

The aim of rehabilitation is “to restore an individual to his/her former functional environmental status or, alternatively, to maintain or maximize remaining function” [201]. Unlike younger patients in whom rehabilitative outcomes are more apt to be dramatic, the geriatric patient is likely to make subtle progress. The degree of independence the patient is able to attain is dictated by these modest achievements and can mean the difference between living at home and living in a long-term care facility [201]. For many elders, independence is their ongoing reason to live. The physician caring for the injured elder must understand the importance of attaining or maintaining independence for their elderly patients and do whatever is necessary to achieve this. The elderly with chronic debilitating disease more frequently require rehabilitative services following trauma because of the limitations imposed by injury.

Long-Term Outcome

It is generally accepted that both short- and long-term outcomes after injury are considerably worse in the elderly than in younger patients. Despite this, The Eastern Association for the Surgery of Trauma (EAST) practice guidelines recommend that age should not be used as a criterion for limiting care as with aggressive initial management because as many as 85% return to independent living [117]. Others have demonstrated somewhat less promising outcomes of the injured elderly. A study of 38,000 patients over the age of 65 demonstrated that 50% went home and that 25% were discharged to a skilled nursing facility [202]. Taylor et al. demonstrated a nearly twofold increase in mortality risk in geriatric trauma patients even after controlling for comorbid diseases [5]. Inaba et al. reported in a study of injured elderly that, at long-term follow-up, only 68% of patients were living independently as compared to 98% before injury. Furthermore, an additional 20% required skilled home care [203].

Prevention

The first step toward prevention of injury is to recognize the individuals who are most likely to suffer injuries. Many of the factors that predispose the elderly to injury should be discovered on routine history-taking in the elderly patient. There are three injury-prevention approaches: (1) preevent strategies, focusing on increasing public awareness through education or influencing legislation, (2) event strategies, which involve interventions to reduce energy transfer during the injury, and (3) postevent strategies, which deal with efforts to improve resuscitation and reduce complications. In the elderly trauma population, the first two hold the most promise.

As an example, geriatric care groups have developed interventions such as home safety inspections, modifying medications known to affect balance adversely, gait training, and improving any correctable sensory deficits in an effort to reduce the incidence of falls. MVCs may potentially be avoided by identifying and reporting individuals who are unfit drivers. This includes persons with visual or hearing deficits, dementia, or disabling musculoskeletal disorders, and those using medications that decrease driving skills. In an effort to refresh skills and update traffic knowledge, driver education courses for adults over 55 years of age have been established by the American Association of Retired Persons (AARP) and the National Retired Teachers Association. Retting et al. showed that a pedestrian accident-prevention program significantly reduced the fatal and serious injury occurrence by 43 and 86%, respectively [204]. This program implemented prolongation of traffic-light times to accommodate the decreased gait of the elderly, modifications of road

and crosswalk signs, tighter speed-limit enforcement, and safety-education presentations at senior centers.

End of Life/Withdrawal of Care

End-of-life and withdrawal-of-care discussions are often very difficult for families as well as the care providers. Although many elderly have advanced directives or living wills prior to getting injured, many do not. Despite good intention, the documents are often not helpful. It is then left to members of the patient's family to help guide the physician to provide the care the patient would want. It is often difficult to get the families to understand that they are to make decisions based on what their loved one would want, not what they would want.

The discussion regarding end of life and withdrawal of care is often a multistep process. The decision not to perform cardiopulmonary resuscitation or to intubate is often the first

decision that families make. Often, it takes families some time to come to the reality that despite all medical advances, their loved will not survive. It is imperative to get as many family members as possible that want to be involved in the decision process together at one time. Although there is a hierarchy of legal decision makers, having all family members agree on the decision, can be critical. Utilizing pastoral care and or palliative care services often makes the process easier for all involved.

When the decision is made by the family to withdraw care, the physician must ensure a smooth process. Some families want to be present during the removal of life support, some do not. Adequate narcotics and sedatives help prevent any additional suffering. In addition, adequate medication can help minimize any visual discomfort, especially during removal from the ventilator. Turning off monitors and intravenous pumps and ensuring a quiet peaceful atmosphere for the patient and family enhances the family's experience.

CASE STUDY

AB, a 77-year-old female, with past medical history of atrial fibrillation, hypertension, and osteoporosis, was a restrained driver involved in a motor-vehicle collision. The patient was t-boned on the driver side by a car traveling at approximately 45 miles/h. On arrival, she denies any loss of consciousness, complains of some left-sided hip pain, which is worse with movement. In addition, she complains of left-sided chest pain, which is worse with deep inspiration. She denies any abdominal pain or back pain.

Past medical history: atrial fibrillation, hypertension, and osteoporosis

Past surgical history: appendectomy

Medications: warfarin, aspirin, metoprolol, alendronate, and multivitamin.

Allergies: none

Social history: denies alcohol, tobacco, or drug use

Family history: noncontributory

Physical Exam

Vital signs:

Height – 65 in.

Weight – 65 kg

Heart rate – 70 beats/min

Blood pressure – 105/60 mmHg

Respiratory rate – 30 breaths/min, shallow in nature

Oxygen saturation – 95% on 6 L by nasal cannula

EKG – rate-controlled atrial fibrillation

On exam, there is a left-sided scalp hematoma and small laceration that is not currently bleeding. The patient has significant left-sided rib tenderness on palpation; no subcutaneous soft tissue air is appreciated. She also has significant right hip and pelvis pain on palpation. The pelvis does not appear to be unstable. Distal extremities are cool to the touch. Pulse is intact. All other aspects of the physical exam are normal.

Lab work:

Sodium – 139 mmol/L Chloride – 109 mmol/L

Potassium – 4.0 mmol/L Bicarbonate – 19 mol/L Glucose – 100 mg/dl

BUN – 35 mg/dl Creatinine – 1.75 mg/dl

White blood cell count – 12 k/mcl INR – 2.1

Hemoglobin – 10 g/dl PTT – 30 s

Hematocrit – 32.0% PT – 19.5 s

Platelets – 175 k/mcl

Serial cardiac enzymes are normal

Lactic acid – 4.5 mmol/L

Arterial blood gas:

pH – 7.30

pCO₂ – 40 mmHg

pO₂ – 90 mmHg

O₂ Saturation – 95%

Base deficit – 6.5 mmol/L

(continued)

CASE STUDY (continued)**Radiographs:**

Chest X-ray – multiple left-sided rib fractures, no pneumothorax, no hemothorax

CT scan

Head – scalp contusion, no intraparenchymal hemorrhage

Cervical spine – degenerative changes, no acute fractures or subluxations

Chest with IV contrast – left-sided rib fractures 5–10, no pneumothorax, small hemothorax, normal aorta

Abdomen/pelvis with IV contrast – left-sided inferior and superior rami fracture. Left-sided sacral fracture. Active extravasation in the pelvis. No solid or hollow viscous organ injury

Things to Consider

1. Early intubation in an elderly person with multiple rib fractures and labored breathing.
2. Insertion of an epidural catheter for administration of narcotics to assist with pulmonary toilet in setting of multiple rib fractures.
3. Mild hypotension and normal heart rate in setting of acute trauma may be related to medications patient is taking, i.e., beta blockers.
4. Administration of IV contrast for CT scan in the elderly patient with a decreased GFR and creatinine clearance.
5. The need for warfarin reversal in lieu of active bleeding in the pelvis.
6. The method by which warfarin can be reversed.
7. The need for invasive monitoring in the elderly trauma patient.

Hospital Course

AB received 2 U of fresh frozen plasma, which corrected her INR to 1.5. Her elevated INR and the fact that she has been on aspirin precluded her from getting an epidural catheter for pain management. However, she did receive a patient-controlled analgesia (PCA) pump to help with pain control and assist in pulmonary toilet.

Due to AB's signs of hypoperfusion including cold extremities, acidosis, and base deficit, a pulmonary artery

catheter was placed. Initial cardiac index was 1.8 L/min/m², and mixed venous oxygen saturation was 55%. She was started on 2.5 mcg/kg/min of dobutamine, and a transthoracic echocardiogram was ordered.

Based on her abdominal and pelvic CT scan, it was felt that AB would best benefit from an interventional radiology consult, for possible embolization to stop her pelvic bleeding. At this time, AB was ordered a bicarbonate infusion as a strategy to help protect her renal function in the setting of an additional IV dye load. In addition, orthopedics was consulted regarding her pelvic fracture.

AB had successful angioembolization of pelvic bleeding; however, upon arrival at the intensive care unit, her work of breathing had increased. This was most likely multifactorial in nature, including volume from the fresh frozen plasma, volume from the bicarbonate infusion as well as supine posture for the angiographic procedure. AB was subsequently intubated for airway protection and maintenance of adequate oxygenation and ventilation.

The next day, AB had a repeat head CT to rule out delayed intraparenchymal hemorrhage, which was negative. The transthoracic echocardiogram demonstrated mildly depressed left ventricular function with an ejection fraction of 35% and no other abnormalities. Repeat lab values were significant for a decrease in hematocrit to 23% and a rise in the creatinine to 2.1 mg/dl; however, AB had adequate urine output. Because of the decreased hematocrit, she received 2 U of packed red blood cells. Following the transfusion, her cardiac index and mixed venous saturation were 2.9 L/min/m² and 68% respectively. Thus, AB was weaned off her dobutamine without incident.

Six days into her hospital course, AB was weaning from the ventilator, hemodynamically stable, and the pulmonary artery catheter had been removed. At this point, it was felt safe to place an epidural catheter for pain management to help facilitate extubation. AB was successfully extubated; however, approximately 36 h later, she was reintubated due to increased work of breathing and dropping oxygen saturation. After a discussion with her family as well as AB, it was determined that the safest thing for her was, as there was a likelihood of getting her successfully off the ventilator, to perform a tracheostomy. On day 9 of her hospital stay, AB had a tracheostomy performed and within 48 h, she was off the ventilator. She subsequently passed a swallow study and was able to eat on her own. Thirteen days after admission, AB was transferred to a rehabilitation center for further care.

Chapter 32

Maximizing Postoperative Functional Recovery

Leo M. Cooney

CASE STUDY

An 82-year-old man entered the hospital with fever and confusion. He had previously been living by himself in a small apartment, but had been going out of the apartment less and less over the past 6 months. His family noted that his memory had started to become impaired. They brought him to the Emergency Department because of acute confusion and a fever to 102°F. His evaluation revealed that he had acute cholecystitis with bacteremia. He was initially treated with antibiotics and a surgical drain. He then underwent a laparoscopic cholecystectomy.

During his hospitalization, he continued to be acutely confused. He required sedating medications and physical restraints, as he frequently tried to pull out his drains and intravenous lines. He developed a grade two pressure sore on his sacrum. He was initially treated with a Foley indwelling bladder catheter and later with an external catheter.

By the tenth hospital day, he had a normal white count, was afebrile, and his surgical wound had healed nicely. He was, however, unable to get out of bed by himself and unable to control his bladder and bowels and was still acutely confused. He required nursing home placement.

A higher and higher percentage of surgical procedures are now being done on patients 65 and older. The successful outcome of these procedures goes beyond traditional concerns about morbidity and mortality. For most patients, the most important result of these procedures is the ability to continue to live independently. Hospitalizations and surgical procedures often result in a decrease of older persons' ability to care for themselves, resulting in the need for daily care at home or nursing home placement. Surgeons must understand how to return their patients to the highest possible level of function, if they are going to provide them the best possible care.

Katz in 1963 outlined those functions that an individual must be able to do independently to live without the assistance of another individual. These "activities of daily living" include the ability to bathe, groom, dress, feed, and toilet oneself independently, as well as being able to transfer out of bed or chair and walk independently [1] (Table 32.1). "Instrumental activities of daily living" describe higher levels of activities needed to live independently in the community. These include

preparing meals, shopping, using the telephone, cleaning one's home or apartment, driving or using public transportation, and managing one's own finances.

The ability to perform daily living activities is not only essential for the independence and life satisfaction of older adults, but also is the single most important predictor of mortality for older individuals. Virtually every study of prognosis has found that these seven daily living activities are more strongly associated with mortality than standard physiologic parameters. In many studies, the only condition that has a larger impact on mortality than function is metastatic cancer [2]. Difficulty with these daily living activities is also strongly predictive of nursing home placement.

Unfortunately, the process of hospitalization itself often causes a decline in function in older individuals; and 35–50% of patients over 65 experience a decline in function during hospitalization [3]. This decline is often unrelated to the reason for hospital admission and is associated with a prolonged hospital length of stay, increased need for nursing home placement, and increased mortality [4].

Older individuals are at a much higher risk for the complications of hospitalization and medical and surgical interventions than younger people [5]. The limited mental and physiologic reserve of older adults often contributes to these complications.

Elderly patients have a high incidence of complications with therapy, including drug reactions, adverse effects of procedures, hospital-acquired infections, and other iatrogenic events [6].

When older patients are evaluated in acute hospitals, they often have significant functional problems. Warshaw found that 50% of patients over age 65 in a community hospital had mild or moderate confusion, 47% were incontinent of urine or catheterized, 65% could not ambulate independently, and 40% needed help with eating [7].

The most important contributor to loss of functional status during a hospitalization is altered mental status. The development of delirium, or acute confusional state, during a hospitalization has a major impact on a patient's function and long-term outcome. The major predisposing factor for the development of delirium is underlying dementia.

Delirium can now be easily diagnosed. Sharon Inouye's Confusion Assessment Method has become the international standard for the diagnosis of delirium. The four components of this instrument are (1) acute onset and fluctuating course, (2) inattention, (3) disorganized thinking, and (4) altered level of consciousness. The patient is classified as delirious if he/she exhibits 1 and 2 and either 3 or 4. Inattention is the key feature of delirium. Patients with inattention have difficulty focusing attention, are easily distractible, and have difficulty keeping track of what is being said [8].

The hospital environment itself can also precipitate delirium. There is a very high incidence of delirium in patients in intensive care units. The use of physical restraints can themselves produce delirium, and often severely complicate this condition. Lack of sleep caused by in-room intercoms, administration of medications, and the frequent measuring of vital signs often results in acute confusion.

Preoperative Assessment

The first step in promoting postoperative recovery is to assess the patient preoperatively for predictors of functional decline. The most important predictors of functional decline following surgery are patient's preexisting mental status, physical function, and social activities. Dementia is an extremely important predictor of outcome following surgical interventions. As noted above, dementia greatly increases the probability of a patient becoming delirious following surgery.

TABLE 32.2 Predictors of hospital decline

Altered mental status
Physical function prior to admission
Social function prior to admission
Frequency of going out of the home

Dementia increases the mortality for hip fracture patients almost threefold [9]. Patients with dementia are two to three times as likely to die from pneumonia as patients without this condition [10].

Dementia is very common in older adults. The prevalence of this condition is roughly 1.5% between the ages of 65 and 70 and then doubles for each 5-year period after that. Thus, nearly 25% of individuals between 85 and 90 have some degree of dementia and almost 50% of those 90 and above have dementia [11]. Cognitive losses can be subtle. Many patients with mild-to-moderate dementia still have good social graces and do not appear, on casual observation, to have any major problems with their mental status. Although socially appropriate, patients with dementia are at very high risk for the development of delirium following a surgical procedure.

Memory loss is the most common feature of dementia. The best mental status screening test is the Folstein Mini Mental Status Test. This 30 point test takes only 5 min to administer. It has been studied and validated in populations throughout the world. The level of the patient's education must be considered in the interpretation of the results of this test. Patients with a high school education who scored 24 or less on this test should be evaluated for the presence of dementia. For individuals with an eighth grade education or less, a score of 19 is the level which requires a dementia evaluation.

It is important to determine how functional a patient is prior to hospital admission. Was that person able to get in and out of bed and walk independently, climb stairs, and walk good distances? Did that patient frequently fall?

Such measures of independence as how often one goes outside one's home or participates in outside social activities are excellent predictors of return of function following hip fracture surgery. Patients who are socially active have a much better outcome than individuals who stay in their own home or apartment and have limited social contacts.

The best screen for altered physical function is to observe the patient. The "get up and go" test observes the patient getting on and off a chair, walking a short distance, turning, and walking back to the chair. In addition, the surgeon should determine whether the patient can climb stairs, is still driving an automobile, does his/her own shopping, meal preparation, housekeeping, and other such activities. It is also extremely important to know patient's social support. Does that person have someone else living with him or her or other family members who can be available for assistance at home following hospital discharge? (Table 32.2).

Maintaining Function During Hospitalization

“Geriatric Vital Signs”

An older patient’s physical, cognitive, and nutritional function is as vital to their assessment as blood pressure, pulse, and temperature. The geriatric vital signs are (1) Mental status (confused), (2) the ability to transfer in and out of bed and walk (immobility), (3) the patient’s ability to take in adequate nutrition (poor nutrition), (4) continence of bowel and bladder (incontinence), and (5) the presence of any skin breakdown or pressure sores (skin breakdown) (Table 32.3).

Managing patients throughout their hospitalization is an essential step in returning patients to the highest possible level of function. In the first instance, patients who are at high risk for delirium and loss of physical function should be evaluated prior to surgery. Those patients at high risk should be monitored closely throughout their hospital stay. Patients with early or moderate dementia would benefit from close supervision on the part of families. Medications likely to produce delirium should be kept to a minimum.

Although dementia rarely has a medical cause, delirium is often caused by medical problems. The most common precipitants of delirium are an acute illness, being in an unfamiliar environment, and complications of medications [12]. The medications that are most likely to produce delirium are anticholinergic medications as well as sedatives and hypnotics. Long-acting sleep medications are particularly problematic. Medications such as diphenhydramine, often used for its sedating effects, are very apt to produce delirium because of strong anticholinergic qualities. Sedating medications such as benzodiazepines also frequently produce delirium. Long-acting pain medications can be another cause of confusion in elderly patients [13].

Any alteration in a patient’s ability to follow the train of a conversation or follow the instructions of nurses or therapists should initiate an evaluation for delirium. The clinician should determine the presence of inattention, an acute onset and fluctuating course of the confusion, disorganized thinking, or altered level of consciousness. If these symptoms indicate that the patient is delirious, then the surgeon and nurse caring for that patient need to undertake a coordinated effort to control this condition. The surgeon should evaluate the patient for precipitants of delirium such as an acute

illness, electrolyte or other physiologic abnormalities, or medications with anticholinergic, sedating, or hypnotic properties. The clinician should try and remove as many external devices as possible, such as indwelling bladder catheters, intravenous lines, and telemetry, and contact the patient’s family to inform them about the nature and natural history of delirium. The nursing staff should place the patient under close observation, make sure that the patients have eyeglasses and hearing aids, provide continual orientation to the patient, and work with the patient’s family to provide the patient with as much family assistance and supervision as possible. The use of physical restraints should be avoided, if at all possible. It is best to avoid medications in the management of delirium. If medications are necessary, most geriatric physicians suggest the use of low doses of antipsychotic agents such as haloperidol or risperidone if sedation is not needed, or quetiapine or olanzapine if the patient needs sedation in addition to control of agitation. Benzodiazepines, as noted above, should be avoided, as they often worsen delirium.

The very nature of nursing care can contribute to a loss of function for older hospitalized patients. Such activities as providing a bed pan, bathing, dressing, feeding, or administering medications may decrease the patient’s ability to care for him or herself. Nurses prepare patients better for discharge if they assist them with various tasks and ensure that they can carry them out independently, rather than performing the tasks for the patient.

Continence of bowel and bladder is essential to an individual’s independence. Indwelling bladder catheters should be removed as soon as possible after surgery. Transient urinary incontinence is common following surgery. Appropriate management of this problem can decrease the chances of permanent difficulties. If the nursing staff manages the incontinent patient with diapers and external catheters, it may be difficult to regain bladder control. Reassurance, frequent toileting of the patient, and assistance with mobility are likely to result in return of bladder control.

Physicians may also play a major role in the development of patient dependence. Sedatives and sleeping pills should be used with caution in older individuals. These medications often have a prolonged half life in the elderly and can cause lethargy and confusion. They are particularly problematic if the patient has any element of baseline dementia. The use of indwelling or external bladder catheters to monitor urine volume can result in at least temporary result of bladder control. The surgical approach to early postoperative ambulation has been well recognized for a number of years. Physicians and surgeons should realize, however, that the ability to transfer out of a bed or a chair is a more difficult task than walking and is more important to a patient’s ability to live independently (Table 32.4).

Use of physical restraints

Returning a patient to the highest level of function requires a concerted effort on the part of physicians, nursing staff, therapists, social workers, and discharge planners. The nursing staff and the patient's family are usually the best observers of the patient's mental status. A physician's major role is to listen. He/she should determine whether the patient has nighttime confusion, any problems recognizing family members, following commands, or attending to daily tasks. Although temporary confusion is common following anesthesia, any alterations in mental status that persists beyond 24 h after surgery, should be evaluated. Medications should be reviewed and a search undertaken to ensure that there are no acute medical problems causing the patient's delirium.

Patients who have significant care needs at the time of hospital discharge and insufficient help at home to provide these needs may be candidates for a short period of rehabilitation in a subacute or skilled nursing facility. It is essential that the patient's care be well coordinated between the physicians and staff at the acute-care hospital and the physician and staff at the subacute-care facility.

Posthospital Care

The final outcome of any surgical procedure is usually not clear until 4–6 weeks after the procedure. Posthospital rehabilitation and care play a major role in the success or failure of these procedures. It is the surgeon's responsibility to ensure that each patient receives the posthospital care most appropriate to his/her needs.

There are three options to posthospital care (1) acute rehabilitation units or hospitals, (2) subacute care in nursing homes or "skilled nursing facilities", and (3) home care.

Medicare has rather strict criteria for patients going to acute rehabilitation hospitals. Most of these patients have to fit into the small list of diagnostic categories including strokes, hips fractures, and other neurologic or orthopedic problems. To be eligible for this level of care, patients must need and receive at least 3 h per day of physical, occupational or speech therapy, and require a multidisciplinary approach from a team lead by physicians skilled in rehabilitation medicine. Most postoperative surgical patients are not eligible for this level of care, unless they have a complication such as a stroke.

Medicare does reimburse short-term rehabilitation care in skilled nursing facilities as long as the patient needs and receives restorative care or extensive nursing care that could not be provided at home. Although there is a 100-day maximum for this care, this care is covered only if the patient continues to make progress in his/her rehabilitation. In addition, there is a very substantial copayment required after the first 20 days of the nursing home stay. This copayment can make continued stay at these facilities difficult, if the patient does not have appropriate secondary insurance coverage.

Subacute Care

Medicare diagnosis-related group (DRG) reimbursement policies and the push to limit hospital lengths of stay have moved a great deal of the rehabilitation of older individuals into skilled nursing facilities. A number of these facilities have set up special units for "subacute care" [14].

A Swiss group has developed a predictive score to identify patients hospitalized on acute medical service risk of discharge to a postacute-care facility. These investigators found that data measured on the first hospital day was predictive of the need for posthospital care. The factors most predictive of discharge to a postacute-care facility were (1) the patient's partner's inability to provide home care, (2) inability to self-manage drug regimen, (3) number of active medical problems on admission, (4) dependency in bathing, and (5) dependency in transfers from bed to chair [15].

Although it may be logical and reasonable to use lower-acuity facilities for rehabilitation, use of these facilities without careful coordination of care between the acute and chronic care providers can lead to adverse outcomes. Fitzgerald et al. reported two important studies that demonstrated the problems associated with early transfers to skilled nursing facilities. These studies pointed out that the frequency of transfer of patients from acute hospitals to skilled nursing facilities for rehabilitation of a fractured hip more than doubled with introduction of the Medicare DRG-based reimbursement system [16, 17]. The greatest concern, however, was the increase of permanent nursing home placement from 13 to 39% after the introduction of prospective payment. These studies should caution the surgeon to ensure that temporary nursing home placements do not become permanent.

Bonar et al. studied the factors associated with permanent nursing home placement for patients transferred from hospitals to skilled nursing facilities for rehabilitation following hip fractures. She found that patients who were oriented, younger, could bathe independently, could transfer and walk independently, and had increased family involvement were more likely to be discharged from the nursing home to home. In addition, the number of physical therapy hours available in the nursing home predicted discharge home [18] (Table 32.5).

TABLE 32.5 Returning home from subacute facilities

Good mental status
Good daily living function
Integrated medical care
Intensity of rehabilitative services
Intensity of discharge planning
Good social support

Several studies have evaluated the outcome of older patients transferred from hospitals to rehabilitation hospitals, subacute nursing homes, and traditional nursing homes. Kramer et al. found that after adjusting for patients' admission cognitive and physical functions, stroke patients admitted to rehabilitation hospitals were more likely to return to the community and recover function in ADLs. For patients with fractured hips, however, there was no difference in outcome for patients admitted to rehabilitation hospitals, subacute nursing homes, or traditional nursing homes [19]. Kane et al. also found that stroke patients fared better when treated in rehabilitation hospitals and rehabilitative nursing homes. Although healthier hip fracture patients who received rehabilitative nursing home care fared better, the functional change for sicker hip fracture patients was not different between regular and rehabilitative nursing homes [20].

Fitzgerald et al., in their studies, found that one interesting fact about hip fracture patients who were able to return to their own home: patients followed by their own health maintenance physicians in the nursing home had a better chance of returning home than those who had a separate nursing home physician [17].

Although subacute-care facilities and traditional nursing homes may have a role in the rehabilitation of older surgical patients, it is important to ensure that the care given in these facilities is as coordinated as possible with the acute-care facility [21]. Surgeons should recognize that patients with altered mental status, substantial deficits in their ability to carry out ADLs, complex medical conditions, and limited social support at home are at substantial risk for permanent nursing home placement. The most complex aspect of returning an old person to his or her own home is the discharge planning process. The surgeon must ensure that the subacute-care facility has all the requisite resources and skills to carry out this complex process.

The integration of care between the acute-care and chronic-care facility requires, first and foremost, that the physicians caring for the patient in the nursing home setting be closely integrated with the acute-care physician. Communication between the acute-care providers must be complete and ongoing. Systems in which there is integrated physician coverage appear to have better rehabilitative outcomes and a higher frequency of patients returning home. An integrated system of care, in which the staff of the nursing home facility has complete access to the laboratory, diagnostic imaging, and

other reports of the acute hospital, also increases the potential for improved care. The transition from an acute hospital to a skilled nursing facility requires very careful transmission of clinical information from the acute-care to the chronic-care providers. The most important information to transmit to the skilled nursing facility is the name of the responsible physician who has knowledge of the patient's hospital course, and how to readily reach that physician [22].

The discharge summary should give careful instructions for wound care [23], weight-bearing, diet, and medications. Medication lists should include the last doses given in the hospital. If medications are to be tapered or discontinued, a clear outline by date of the tapering course should be included. All recent significant laboratory tests should be listed within the discharge summary. Those tests that are still pending should be listed with appropriate follow-up outlined.

The goals of the subacute stay should be outlined. If the patient is on anticoagulation, the orders for anticoagulant should be listed with goal results for INRs, along with the most recent dose of anticoagulants and INR results.

Nutritional problems should be identified during the acute hospitalization and goals of nutritional therapy in the skilled nursing facility should be outlined. Nutritional supplements should be given at least 1 h before a meal. If parenteral feeding is used, instructions for these feedings should be clearly outlined [24].

The physician ultimately responsible for the patient's rehabilitation is the attending surgeon. He or she must ensure that those caring for the patient after hospitalization have a clear outline of the therapies indicated and should have easy access to that surgeon to answer any questions that they might have. Electronic access between the skilled nursing facility and discharging hospital is best, as this access could provide laboratory, diagnostic imaging, and operative and clinical information to the skilled nursing facility staff. In the final analysis, returning an individual to the highest possible level of function requires a concerted effort on the part of surgeons, physicians, nurses, physical therapists, discharge planners, and social workers to provide the patient with the highest possible level of function.

Patients who are confused or delirious at the time of hospital discharge do not do well in subacute-care facilities. The best management of delirious patients is to return them, as quickly as possible, into their own home environment. Another health care facility can often worsen patient's confusion. It is very difficult to rehabilitate a confused patient. If the patient's family cannot take the patient home in this condition, care must be coordinated very closely between the acute providers and physicians and nursing staff at the skilled nursing facility.

At the time of hospital discharge, the discharging surgeon must ensure (1) that the patient's mental status will allow continued rehabilitation at a subacute or home setting, (2) that the appropriate medical and rehabilitation care is

well outlined to the subacute or home care providers, and (3) that those providing chronic care to the patient have immediate access to the responsible surgeon. Surgeons must recognize that this posthospital care is an important part of the recovery period from surgery and is the responsibility of the discharging surgeon.

Section IV
Endocrine System/Breast

Chapter 33 Invited Commentary

Samuel A. Wells

Age-related alterations in endocrine function are important considerations in the surgical patient. Because the endocrine system is integrally related to virtually all bodily functions, it is unreasonable to think of the singular effects of a specific hormone deficiency. It is impossible to cover all aspects of the endocrinology of aging; however, we address some of the most significant.

Arguably, the most important endocrine change associated with aging arises in the pancreas and relates to the decreased availability of insulin. Forty percent of individuals aged 65–75 years have impaired glucose tolerance, the incidence of which increases with age. The abnormality goes undetected in many elderly patients, and they are at risk for developing vascular, ocular, and neurologic complications. In addition to decreased insulin secretion from the pancreatic beta cell, physical inactivity, poor diet, increased body weight, and decreased lean body mass contribute to glucose intolerance.

The incidence of thyroid abnormalities including autoimmune thyroiditis, the metabolic states of hypothyroidism and hyperthyroidism, thyroid nodules, and thyroid cancer also increases with age. The surgeon must be aware of the possibility of occult thyroid disease in the elderly. The failure to recognize the presence of occult hypothyroidism or hyperthyroidism in acutely ill surgical patients may result in increased operative and perioperative mortality.

There are significant decreases in cortical and trabecular bone as one ages. Loss of bone mineralization is particularly problematic in women, where trabecular bone loss accelerates at menopause and reaches a rate of 4% per year. Estrogen deficiency accounts for a 15–20% decrease in skeletal density, which is increased further in the presence of hyperparathyroidism, a disease that occurs primarily in postmenopausal women. Understandably, there is an increase in fracture rate in elderly patients not only due to decreased bone density but also because of a decrease in muscle strength and impaired coordination.

Menopause, one of the most dramatic age-related changes, is primarily associated with the loss of cyclic estradiol production. Menopause appears to be brought on by changes in both the ovarian follicles and the hypothalamus and pituitary. Long-term estrogen replacement therapy is beneficial for the skeleton, cardiovascular system, reproductive tract, skin, and central nervous system; however, estrogen replacement is associated with a modest but definitely increased incidence of breast cancer.

In aging men, there is a decline in serum testosterone levels and an accompanying reduction in the number of Leydig cells. Studies show that testosterone replacement in elderly men is associated with increased muscular strength, cognition, and red blood cell mass. However, testosterone administration has a stimulatory effect on the prostate, and the risk of enhancing the growth of an occult prostate cancer is a definite risk.

Hormonal changes also occur in the adrenal cortex, characterized by a decrease in circulating levels of dehydroepiandrosterone (DHEA), and in the pituitary gland, characterized by a reduction in growth hormone and insulin-like growth factor. There have been prospective randomized controlled trials in older adults, of DHEA administration compared to placebo. In subjects receiving DHEA, compared to those receiving placebo, circulating levels of DHEA and androgen were restored, and there was a sense of improved well-being. The risk of administering these agents relates to the direct or indirect stimulatory effect on the breast and prostate gland and perhaps other tissues. Similarly, growth hormone, administered in prospective randomized placebo-controlled trials, has been associated with increased muscle strength and bone mineral content. It has already been shown in patients with fractures or burns that administration of growth hormone has clear benefit in wound healing and return to independent living. As with DHEA, the question remains whether adverse effects will become evident with long-term administration of growth hormone. There is the possibility that administration of selected hormones would have a beneficial effect on the elderly surgical patient, as minimal adverse effects have been seen with their short-term administration.

The surgeon must understand that both profound and subtle changes occur in the endocrine system with aging and that these alterations influence the response of the older patient to surgical procedures. Replacement therapy for endocrine deficiencies is clearly indicated in the elderly patient whether in the emergent or the elective setting.

However, much work remains to be done on the evaluation of hormonal administration in healthful elderly persons to clarify whether the benefits outweigh the risks. The question is important, as the results will influence how elderly patients respond to surgical treatment and to their underlying disease process.

Chapter 34

Surgical Disorders of the Thyroid in the Elderly

Leslie S. Wu, Julie Ann Sosa, and Robert Udelsman

CASE STUDY

JK is a 75-year-old woman with a right anterior neck mass identified on physical examination by her cardiologist. She described a globus sensation and dysphagia with solid foods, and had subjective hoarseness over the last year. She did not have a history of head or neck radiation, and there was no family history of glandular abnormalities. Her past medical history was significant for hypertension, hyperlipidemia, atrial fibrillation on chronic warfarin therapy, diabetes mellitus, osteopenia, and arthritis. Her past surgical history was notable for a cholecystectomy, hysterectomy for uterine fibroids, and left breast lumpectomy and radiation therapy for ductal carcinoma in situ. Family history is significant for “bad hearts.” She was a former smoker. Her medications included warfarin, metoprolol, amlodipine, simvastatin, glucophage, glipizide, niacin, fish oil, calcium supplements with vitamin D, multivitamin, and acetaminophen as needed.

Physical examination revealed a well-developed woman in no acute distress. Her vital signs were within

normal limits, and she appeared euthyroid. Focused exam was notable for a nontender 4-cm firm but mobile mass in the right anterior neck. The trachea was distracted slightly into the contralateral neck. The left thyroid lobe contained no palpable nodules. There was no cervical lymphadenopathy. Pemberton sign was absent, and there was no carotid bruit. The remainder of her physical exam was unremarkable.

On blood work, the patient was biochemically euthyroid with a thyroid-stimulating hormone (TSH) 2.5 mIU/L (normal 0.4–4.0 mIU/L). JK’s geriatrician referred her to an endocrinologist, who, in turn, consulted a thyroid surgeon. JK underwent a dedicated neck ultrasound, which revealed a 60-g thyroid and a 4-cm nodule in the right lobe. It was hypoechoic with a small cystic component, microcalcifications, an irregular border, and possible extension into the overlying strap muscle. The left lobe contained two 4-mm nodules that were too small to characterize. Ultrasound-guided fine-needle aspiration (FNA) of the dominant right nodule was performed. Cytopathology was consistent with papillary thyroid cancer.

Introduction

The proportion of elderly people is growing steadily in Western societies as a consequence of increased life expectancy and reduced birth rates. Americans aged 80 years and older constituted 3.3% of the population in 2000; this is projected to increase to 7.7% in 2050 and 8.2% by 2070. In comparison, Americans 65–79 years of age constituted

9.3% of the population in 2000 and are projected to increase to 12.5% by 2050 and 12.9% by 2070 [1]. This phenomenon has generated numerous studies aimed at clarifying the physiologic and pathologic aspects of aging. Thyroid dysfunction can have profound clinical implications for elderly patients. Thyroid nodules are common, and the incidence of thyroid cancer increases with age.

Thyroid disease is common; 6.6% of the US population has thyroid disease, requires thyroid hormone supplementation, or both [2]. Based on results of autopsies performed on the general population, thyroid nodules have been found in up to 50% of asymptomatic patients [3]. The incidence of thyroid cancer has increased from 3.6 per 100,000 in 1973 to

J.A. Sosa (✉)
Department of Surgery, Maine Medical Center,
22 Bramhall St., Portland, ME, USA

8.7 per 100,000 in 2002 – a 2.4-fold increase – with 87% of the increase due to the diagnosis of small differentiated thyroid cancers [4]. The association between increasing age and incidence of thyroid nodules makes diagnosis and treatment an important public health issue.
