The bladder is affected most commonly [164, 165]. Symptoms include pneumaturia and fecaluria. Sepsis can also occur. Diagnosis is made most commonly by the patient's history. CT scan is most accurate for diagnosis, showing air in the uninstrumented bladder and inflammation of the sigmoid colon and dome of the bladder [159]. Contrast enema or endoscopic evaluation is required to rule out colon cancer. Cystoscopy may be performed to rule out a neoplastic process originating in the bladder. In some patients, the fistula cannot be demonstrated. Elective sigmoid resection with primary anastomosis is curative [164]. The fistula is pinched off the bladder. A small bladder defect is best treated by Foley catheter drainage for 7–10 days. Large defects should be closed in two layers with absorbable suture and drained by

Foley catheter for a similar length of time. Bladder resection should be reserved for malignant disease [165].

Colovaginal fistulas occur most commonly in women who have had a hysterectomy. Diagnosis is simply made by the history, including flatus or stool per vagina. It is confirmed by transvaginal and transanal endoscopy. Air may be heard exiting from the vagina during sigmoidoscopy. Contrast enema or endoscopic evaluation of the colon is required to rule out neoplastic and inflammatory bowel disorders. Patients generally are not septic at the time of presentation and may undergo elective sigmoid resection with primary anastomosis. The vagina can be left open for drainage or may be closed with absorbable sutures and omentum interposed between the vagina and the anastomosis. Other organs, including the uterus, may be involved with the fistulous process. Hysterectomy may be required if the uterus is involved with the infectious process or if a neoplastic process is suspected [166]. Spontaneous colocutaneous fistulization is uncommon and can be treated with resection and primary anastomosis if sepsis is controlled.

Obstruction complicating diverticulitis occurs uncommonly [167]. Repeated episodes of edema, spasm, and inflammation cause a chronically strictured bowel lumen to become narrowed. Acute inflammation can then complete the luminal obstruction. Gentle water-soluble enema or endoscopy by a skilled endoscopist with minimal air insufflation can confirm the diagnosis and exclude a neoplasm. With proper diagnosis and treatment, the inflammation usually resolves, and the obstruction abates. This allows it to be treated as uncomplicated diverticulitis with preoperative bowel preparation followed by elective resection and primary anastomosis after complete resolution of inflammation. Emergency operation for obstruction due to diverticulitis generally requires removing the diseased bowel with creation of an end colostomy. The unprepared and dilated proximal bowel often precludes safe primary anastomosis. On-table lavage has been used more frequently in selected cases to allow primary anastomosis [168].

Right-Sided Diverticulitis

Right-sided diverticulitis has a different etiology, pathophysiology and affects a different patient population group compared with left-sided disease. Right-sided diverticula are true diverticula, with all layers of the bowel wall involved with the outpouching. They most commonly affect Far-Eastern populations. Presentation mimics appendicitis with right-sided pain and infectious systems. Preoperative diagnosis is uncommon. X-ray findings often suggest neoplastic diseases. Nonoperative treatment is usually effective if accurate diagnosis is made before surgery. Not infrequently, the diagnosis

is in doubt at time of operation, and right colon resection is performed with a presumed diagnosis of tumor. Resection, diverticulectomy, and inversion of the diverticulum have been reported.

In conclusion, diverticulitis is common in the elderly. Symptoms may be avoided with a high-fiber diet and fiber (psyllium) supplement intake. Older patients frequently present atypically and are difficult to be accurately diagnosed. Diverticulitis appears to be a more virulent disease at initial presentation in the elderly. More than one-half of patients require emergent operation with many having ostomy formation. Ostomies are commonly permanent in these old patients. CAT drainage of abscesses allow for safer, elective resection. Most patients who avoid surgery at initial presentation can be managed without subsequent operation. Laparoscopic approaches allow for decreased morbidity, mortality, shorter hospital stays, and early discharge to home, and these advantages are more pronounced in the elderly.

Appendicitis

Many investigators have tried to assign an immune function to the appendix, as it does secrete immunoglobins, but the appendix is an organ whose function is unknown. Certainly, normal life results after its removal. Inflammation and neoplastic transformation are by far the most common afflictions that affect the human appendix. Infectious diseases (typhoid and tuberculosis), regional enteritis, and congenital defects of the appendix are beyond the scope of this chapter. Similarly, neoplasms of the appendix are not addressed. Appendectomy is one of the most common operations performed, with more than 500,000 appendices removed annually in the USA; 5–10% of acute appendicitis occurs in the elderly. Old patients delay presentation, present atypically, and suffer delay in diagnosis and treatment more often than young patients. Perforation is found more frequently in the elderly. Higher mortality rates and prolonged hospital stays result. The following section attempts to explain these findings.

Etiology

Obstruction of the lumen of the appendix is the predominant cause of appendicitis, and fecaliths are a common cause of obstruction (Figs. 67.4 and 67.5). After the lumen has been obstructed, a closed microenvironment is produced, which allows fluid sequestration, stasis, distension, and bacterial overgrowth. Mucosal secretion and bacterial multiplication increase the distension and intraluminal pressure. As the

FIGURE 67.4 Fecalith within an acutely inflamed appendix.

FIGURE 67.5 Same patient, coronal view.

diameter of the lumen expands to accommodate the increased pressure, venous and then arterial pressures are overcome. Ischemia, necrosis, bacterial translocation, and appendiceal perforation result. Interestingly, humans are one of the few animals able to secrete fluid into the lumen of the appendix at pressures high enough to produce necrosis and perforation [169].

Perforation occurs owing to vascular compromise, causing necrosis, usually on an antimesenteric border. There are thought to be many differences in the elderly appendix that predispose it to obstruction and perforation. The appendiceal lumen is small or obliterated, and the blood supply is decreased, predisposing to necrosis; the mucosa is thinned, and there is fatty infiltration of the wall [170]. These changes may lead to increased rupture rates with decreased pressures, thus altering the natural history of appendicitis in the elderly. NSAIDs have been implicated in appendicitis as well. Campbell and DeBeaux [171] found that 37% of patients over the age of 50, with the diagnosis of acute appendicitis, were on NSAIDs compared with only 11% of a similar age group admitted with other emergencies.

Epidemiology

Appendicitis is the most common acute surgical condition of the abdomen. Six to eight percent of the population will suffer from acute appendicitis in their lifetime [172–174]. Life-table analysis estimates that 12% of males and 23% of females have their appendixes surgically removed [173]. Acute appendicitis occurs at all ages but is most frequent during the teenage years [173, 175]. This age peak is thought to result from the peak in lymph tissue in the appendix during these years. The extra lymph tissue presumably narrows the lumen, predisposing it to obstruction and the resulting appendicitis. Males are more commonly affected at young age, but during later adult life, the male/female ratio equals out [176]. There is a decrease in the incidence of acute appendicitis in the young over recent decades, and the reason is unknown [170, 173, 175–177]. Five to ten percent of all acute appendicitis occurs in the elderly [172, 175, 177, 178], and in fact, the incidence of acute appendicitis in the elderly is increasing [170, 176, 177]. It may be due to longer life spans, as Thorbjarnarson and Loehr [170] found that old patients accounted for only 1% of appendicitis between 1932 and 1937, whereas this percentage increased to 6–8% after 1957. Altogether, 1 of 35 women and 1 of 50 men over age 50 years develop acute appendicitis [174]. Furthermore, appendicitis accounted for 2.5–5.0% of all acute abdominal disease in patients over 60–70 years of age [74, 178].

Acute appendicitis is the third most common cause of abdominal pain in the elderly after gallbladder disease and small bowel obstruction [179, 180]. It is the leading source of intraabdominal abscess, which in turn is the most common cause of fever of unknown origin in the elderly [77]. About 33–50% of the mortality due to acute appendicitis occurs in the elderly [172, 173, 181]. Whereas mortality from appendicitis in general has been decreasing, the percentage of deaths among the elderly is on the rise [170], often

due to delays in diagnosis and treatment. Also, lowered immune responses to foreign antigens and decreased production of lymphocytes with advancing age limits the older patients' ability to wall off peritoneal inflammation and fight overall infectious events [182, 183]. It has been postulated that changes occur in the appendix as we age, including atrophy of the intraluminal lymphoid tissue and thinning of the appendiceal wall, which render the appendix more susceptible to inflammation. Atherosclerosis diminishes the blood supply, narrowing the lumen. Small changes in intraluminal pressure can produce rapid ischemia, gangrene, and perforation at rates much quicker in older persons than the young [184].

Symptoms and Diagnosis

Abdominal pain, fever, and leukocytosis are the hallmarks of acute appendicitis. Distension of the obstructed appendix stimulates visceral afferent nerve fibers, producing vague, dull, midabdominal pain. Pain classically begins in the periumbilical area and migrates to the right lower quadrant within hours [169, 185]. This pain is peritoneal in origin and as such is constant and increases with time. Anorexia is common. Vomiting occurs up to 75% of the time. Protracted vomiting and diarrhea should lead the clinician away from the diagnosis. There are many variations in presentation.

Physical examination reveals the site of peritoneal inflammation. Usually, tenderness is found at McBurney's point. Rovsing's sign (pain referred to the right lower quadrant with palpation of the left side) indicates localized peritoneal irritation. The appendix may be found anywhere in the abdomen and thus can cause pain during psoas muscle stretch, obturator muscle stretch, rectal examination, or palpation of any abdominal site [185]. Continued irritation results in rebound and referred peritoneal irritation. Frank peritonitis can ultimately result with perforation. Elevated core temperature is usually not more than 39°C. The WBC count is generally between 10,000 and 18,000/mm³ with a left shift [169]. Higher or lower counts and extreme left shifts are indications of diffuse peritonitis. Acute-phase reactants are being examined in an attempt to increase the accuracy of the preoperative diagnosis. Urinalysis should be done but may be abnormal if the appendix is adjacent to the bladder or ureter.

The presentation and difficulty with diagnosis of acute appendicitis in the elderly deserves special consideration. Most importantly, older patients more frequently delay seeking medical attention for a variety of reasons: difficulty leaving home, fear of hospitalization, decreased ability to appreciate or express symptoms. An elderly patient with a perforated appendicitis who was incorrectly treated for alcohol withdrawal for 5 days prior to being accurately diagnosed has been reported [186]. Burns et al. [187] found

that 20% of older patients with acute appendicitis had WBC counts $<10,000/\text{mm}^3$ and neutrophil counts $<75\%$. Lau et al. [188] found only 43% of old patients with simple appendicitis to have elevated WBC counts. Thorbjarnarson and Loehr [170] recorded an average duration of symptoms prior to admission in patients over age 60 to be 2.5 days. Horattas et al. [189] found that one-third of patients over 60 years of age waited more than 48 h from onset of symptoms before presenting to the hospital. Fewer than two-thirds had “typical” right lower quadrant pain, and one-half had a temperature $<37.6^\circ\text{C}$. Similarly, Smithy et al. [190] found that only 55% of patients over age 80 had right lower quadrant pain, and 18% did not have abdominal pain. They also noted that only 1 of 13 patients had “typical” periumbilical pain localizing in the right lower quadrant. They hypothesized that because of the smaller lumen diameter of the elderly appendix, which requires less pressure to produce rupture, the old patient does not necessarily experience the prodromal phase of appendicitis with the generalized abdominal pain, anorexia, nausea, and vomiting thought to be caused by visceral distension. Nausea, vomiting, fever, and anorexia were found to be uncommon in old patients by others as well [72, 186]. Burns et al. [187] compared the presentations of young and old patients. They found that twice as many young patients presented “classically,” and old patients were more than two times more likely to delay presentation for more than 72 h after onset of symptoms. Furthermore, in their study, old patients were three times likely to have operation delayed more than 24 h after admission than were the young. Horattas et al. [189] found that 13% of patients had their operations delayed more than 48 h after admission, further illustrating the difficulty of correctly diagnosing this age group. Samiy [191] described a blunted or absent pain response in the elderly and, perhaps more importantly, found that doctors often minimize the importance of the old patient’s pain, attributing it to old age or concomitant diseases [192–194]. Clinicians must be more cognizant of the abdominal complaints in old patients if prompt diagnosis and treatment with resultant decreased morbidity and mortality are to be expected.

The confident diagnosis of acute appendicitis is difficult, and the experienced clinician is wrong 5–25% of the time [175, 195]. Many books and articles have been written describing techniques for diagnosing acute appendicitis [175, 196–198]. The combination of appropriate history, physical examination, and elevated WBC count is thought to be most important for diagnosing appendicitis correctly [199]. Unfortunately, these factors are not often present together [198]. Ultrasonography and focused CT have been used extensively for presurgical evaluation of patients [196, 197, 200]. Despite numerous advances in radiographic techniques, the rate of unnecessary explorations remains at 5–20% [196, 197, 201].

C-reactive protein (CRP) has been studied as a tool to aid in the accurate diagnosis of appendicitis [202]. There is a decline in the production of inflammatory mediators and in the immune system with aging [182, 183, 203]. CRP is preserved with age [202]. CRP has been found to be consistently elevated only in patients with perforation, perhaps since it first appears in the serum about 8 h after the initial insult and takes 24–48 h to reach peak blood levels [202]. Thus, elevated serum levels are often found only with prolonged symptoms, which correspond to high perforation rates. Obviously, if symptoms progress rapidly, there is no time for serum CRP levels to rise. CRP is not specific for appendicitis: It also increases with any inflammation, surgical trauma, and acute myocardial infarcts [202].

CT scanning has made accurate diagnosis easier. More liberal use of CT scanning can lead to the diagnosis of appendicitis in older patients where this diagnosis was not entertained [204]. Despite this, outcomes including perforation rates and duration of hospitalization may not be affected.

Exploratory laparotomy or laparoscopy remains the diagnostic test of choice in appropriately chosen patients. Despite the advances in preoperative modalities, an accurate diagnosis of acute appendicitis is made in only 30–77% of the elderly on admission and in only 70% preoperatively [186, 189, 190, 195, 205]. Between 14 and 33% of older patients have operations more than 24 h after admission [187–190, 205].

Treatment and Outcomes

Nonoperative care of acute appendicitis is appropriate only if emergent surgical expertise is unavailable. Recurrence within 18 months is seen in at least 35% of patients treated only with antibiotics [206]. Early, aggressive treatment is imperative to minimize mortality in the elderly. In fact, Burns et al. [187] suggested “based on the lack of significant complications in those patients with a false-positive diagnosis and the 65% perforation rate in older patients, we feel an even earlier and more aggressive surgical approach is warranted.” Operative treatment for acute appendicitis remains resection of the offending organ. Hydration and correction of electrolyte imbalances prior to urgent operation is prudent. Untoward delay before exploration may allow progression of the disease and ultimately free rupture of the organ with resultant peritonitis. Preoperative broad-spectrum antibiotics are administered intravenously and are continued postoperatively if necrosis or perforation is discovered. All pus should be evacuated, localized abscess cavities irrigated thoroughly, and appropriate closed-suction drains employed if abscess cavities are encountered [187]. The skin should be left open in complicated cases. When a

normal appendix is discovered, the abdomen should be systematically examined to search for the origin of the symptoms; resection of the normal appendix is usually appropriate. Nonoperative management of abdominal abscesses is well known. CT-guided drainage of abscesses allows resolution of the acute septic process followed by elective, interval operative treatment, thereby avoiding emergency surgery with its attendant morbidity (Figs. 67.6 and 67.7) [88, 89, 151, 207]. Acute appendicitis with a contained abscess

FIGURE 67.6 Acute appendiceal abscess with enhancing wall and air within the abscess.

FIGURE 67.7 Percutaneously placed drain within this abscess.

responds well to drainage [208], and most patients with appendicitis respond to antibiotics [207, 209]. Interval appendectomy 6–12 weeks later, after resolution of the infectious process, is suggested because of the high recurrence rates. Some question the need for interval resection [207–209]. Recurrence rates in adult age groups approach 35% [207]. With the well-known delay in presentation, difficulty with accurate and timely diagnosis, and the increased morbidity and mortality seen in the elderly, interval appendectomy is suggested in all but the frailest. Neoplasm must be ruled out in those managed conservatively. Furthermore, elective interval appendectomy lends itself well to the laparoscopic approach, as stressed by Greig and Nixon [209].

Ileocecal resection and primary anastomosis are reserved for the markedly inflamed cecum. Rarely, resection cannot be performed safely because of the inflammatory reaction. In these cases, irrigation and drainage are performed, and interval appendectomy is scheduled for 6–12 weeks later. The reader is referred to general surgical textbooks for the detailed operative technique.

More than 75% of young patients are found to have simple appendicitis at operation [29, 186, 206]. This is in contrast to 48–63% of patients over 50 years of age having a ruptured appendicitis [205, 210] and 49–92% of patients over 70 years of age having perforation, an abscess, or both [29, 176, 179, 190, 192, 193, 209]. Luckmann [175] found an age-related increase in complex appendicular disease in a California population-based study. About 1.8–32.0% of the older patients succumb to their disease, mostly owing to sepsis [170, 173, 175, 178, 188, 190, 195, 205]. In a countrywide population-based study, the mortality was 4.6% for patients over 65 years of age and only 0.2% for those <65 [173].

It is debated whether appendicitis in the elderly progresses more quickly than that in younger patients, which may account for the higher perforation rates found in old patients. Children with symptoms for more than 48 h have perforation rates up to 98% [211]. Franz et al. [205] studied a Veterans Administration hospital population and found that those with simple appendicitis had symptoms lasting a mean of 22 h, perforated appendicitis patients a mean of 50 h, and those with abscesses an average 66 h prior to presentation. They concluded that the delay in seeking care accounts for the increased perforation and abscess rates in old patients. Watters et al. [29] agreed that prehospital delay accounted for the increased rate of perforation found in the elderly compared with the young. Paajanen et al. [212] agreed that duration of symptoms within an age group corresponds well with perforation rates for that group, thus dispelling the concept that in old patients appendicitis progresses more rapidly than in young patients. Others have found an increased rate of perforation in pregnant women, with symptoms lasting longer than 24 h [213], and in children, with symptoms more than 48 h prior to operation [211]. Similarly, Temple et al.

[214] examined 95 consecutive patients and found an average of 31 h from onset of pain to operation for simple appendicitis, whereas patients with perforation had symptoms for 63 h before operation. Interestingly, those with perforation spent less time in the hospital before operation. In contrast, Smithy et al. [190] observed a 92% perforation rate in patients more than 80 years of age, with an average time from admission to operation of 15 h, bespeaking the difficulty of making the diagnosis in the elderly. Thus, the rate of evolution of appendicitis is not different in the elderly. Old patients more frequently delay seeking treatment, increasing the rate of perforation.

Lau et al. [188] found a 38% perforation rate in old patients operated on within 24 h of the onset of symptoms, suggesting aggressive disease. Wolff and Hindman [215] agreed finding a perforation rate of 41% in old patients with onset of symptoms within 24 h of operation. However, Burns et al. [187] found that one-third of young and old patients operated on within 24 h had perforation. Von Tittle et al. [216] also found that roughly one-third of old patients with perforation had symptoms for <24 h. Thus, an equal number of their young and old patients progressed rapidly to advanced disease. They concluded that physicians are responsible for almost two-thirds of older patients' delays in diagnosis and treatment of appendicitis, with the patients themselves being responsible for the rest. Obviously, duration of symptoms correlates with perforation rates in all age groups. Luckmann [175] found that only 53% of patients over 80 years of age in California had their operation on the day of admission, compared to more than 80% of young patients. More impressively, in patients with abscesses, more than 85% of young patients had operations within 1 day of admission, compared to only 57% of those older than 80 years. This further attests to the difficulty accurately diagnosing and treating acute appendicitis in the elderly. One study revealed that 17% of elderly patients were treated without accurate diagnosis prior to being admitted with acute appendicitis [187]. Incorrect diagnosis rates in the elderly are as high as 25% [217].

Most studies show that the progression of appendicular disease in the elderly is similar to that in younger groups. However, old patients frequently present with longer duration of symptoms and are more commonly misdiagnosed, resulting in delayed operation. This prolonged time from onset of symptoms to operation accounts for the increased perforation rates found in the elderly. Their concomitant medical problems most likely account for the high mortality rates reported. Incidental appendectomy should not be performed in patients over 60 years of age and probably not in those over 35 years of age [173].

In-hospital observation has been shown to decrease negative operative rates safely without increasing the perforation rate [217, 218]. This suggests that the out-of-hospital delay is most important for determining the aggressiveness of disease. Lau et al. [188] found a statistically significant increase

in perforation rates in elderly patients when surgeons delayed operation for more than 25 h. Klein et al. [195] also found increased perforation and abscess rates in old patients with increasing delays of operation. Because of the difficulty diagnosing old patients, attempting to decrease perforation rates through hospital observation in the elderly is unwise.

Many authors have examined laparoscopic vs. open appendectomy [198, 219–223]. One prospective randomized study found that patients used fewer analgesics and returned to full activity sooner compared to those exposed to conventional operative techniques [222]. Some have found fewer wound infections with laparoscopic techniques [224–226]. This good record is usually achieved with increased hospital cost. Others have found an increase in abdominal abscesses in laparoscopically treated patients [227]. A recent large comparative study and a prospective randomized study both have found advantages for laparoscopic approach to appendicitis, without increased abdominal abscesses [228, 229]. One obvious advantage of laparoscopic appendectomy is the ability to view the entire abdomen and pelvis in cases where the diagnosis is in question.

Konstantinos [230] examined more than 1,000 consecutive laparoscopic operations for suspected appendicitis. They had a conversion rate of <1 and 1.1% wound infection rate with no intraabdominal abscesses or deaths, despite a 14% ruptured or gangrenous appendix rate and 4% having intraabdominal abscesses. They also found significantly shorter hospital stays and quicker return of bowel function. Paranjape [231] examined three different time periods and how laparoscopy changed outcomes in the elderly. They found an increased use of CT scanning, fewer patients presenting with classic symptoms, increased correct admission diagnoses, fewer perforations, and fewer complications in the most recently treated group. They also found shorter hospital stays with laparoscopy. Their operative time was similar for both open and laparoscopic approaches.

Laparoscopic appendicitis in elderly North Carolina residents has been studied as well [232]. The patients who underwent conventional and laparoscopic operations were comparable with regard to age, gender, and comorbidities. Fifty-five percent presented with perforated appendicitis. There was a steady increase in laparoscopic use over time, rising from 11.9% in 1997 to 26.9% in 2003. Advantages found in the laparoscopic group includes: shorter length of stay (4.6 vs. 7.3 days), higher rate of discharge to home (91.4 vs. 78.9%), fewer complications (16.3 vs. 20.8%), and a lower mortality (0.4 vs. 2.1%). As important is overall hospital cost, which shows a trend for lower total cost for the laparoscopic group, \$17,031 vs. \$19,587.

In conclusion, 10% of all appendicitis occurs in the elderly. Older patients present atypically and often delay seeking medical treatment. Diagnosis is difficult owing to blunted symptoms and response to inflammation. Perforation occurs

more frequently and possibly faster than in younger patients. High index of suspicion and liberal use of CT scanning can facilitate correct diagnosis. Laparoscopic technique decreases complications, shortens hospital stay, increases home discharge, and is not associated with increased hospital cost.

Chapter 68

Benign Colorectal Disease

Elisa H. Birnbaum

The incidence of benign medical and surgical diseases of the colon and rectum increases with age. Although constipation, fecal incontinence, and several other associated benign conditions increase in frequency with aging, a paucity of information exists regarding the normal aging effect on gastrointestinal pathophysiology. Studies documenting anatomic, physiologic, and pathologic changes that occur in the aging colon have not been definitive, and many studies have reported conflicting results. Mucosal atrophy, atrophy of circular muscles, thickening of longitudinal muscles (taeniae coli), increased elastin deposition, and atherosclerosis are several of the changes seen in the aging bowel [1]. These changes may factor into the development of several disease states (i.e., diverticular disease and angiodysplasia). Medications affect gastrointestinal function and many have constipation as a side effect. Preexisting diseases (cardiac, pulmonary, renal, neurologic, psychiatric) may affect colonic motility directly or secondarily. In addition, these comorbidities affect medical and surgical therapy, making geriatric operative risks higher. Early diagnosis and treatment is crucial even for seemingly benign diseases or symptoms. In this chapter, we address benign colorectal diseases frequently encountered in the elderly patient and which may increase as the population ages. Diseases common to both young and old persons, such as hemorrhoids and fissures, are not discussed.

Constipation and Pelvic Floor Abnormality

Constipation is a frequent complaint in the USA and has been estimated to affect more than four million people. Complaints of constipation increase with age and are more common in women, blacks, and persons of lower socioeconomic status [2, 3]. The overall prevalence of reported constipation in

the elderly Western population is approximately 20–25%, but differs according to the source of the sample [3–5]. The incidence of constipation is approximately 12% in the ambulatory geriatric population vs. 41% in acute-care facilities and more than 80% in geriatric nursing homes and extended-care facilities. Elderly women are more likely to report symptoms of constipation than elderly men [5]. Further studies indicate large variation in bowel habits and frequent use of laxatives in as many as 30–50% of the elderly population [6–8]. Subjective complaints of constipation and laxative use increase with age, but true epidemiologic data suggest that clinical constipation does not [9]. Although complaints of constipation increase in those over age 65, about 80–90% of subjects over age 60 report at least one bowel movement per day [6, 7]. Although there may be normal physiologic aging of the colon and rectum, asymptomatic geriatric patients do not seem to differ significantly from their younger cohorts.

It is important to define constipation, as patients and their physicians frequently have different definitions [10]. Several investigators have attempted to define “normal” bowel function in the elderly [6, 8]. The normal number of bowel movements within the elderly population ranges from three per week to two or three per day and does not differ from that found among the young population [11]. It is generally accepted that patients with a reduced frequency in the number of bowel movements (fewer than three per week) are considered constipated [12]. A consensus definition of constipation was developed by a group of experts at an international congress of gastroenterology and is known as the Rome II criteria (Table 68.1) [13].

Decreased motility or prolonged transit diffusely throughout the colon can be caused by several factors. Dietary factors (fluid and fiber) have frequently been implicated. Inadequate fluid intake may decrease the fecal bulk causing decreased intraluminal pressures in the colon, which in turn may decrease the number of propagating motor complexes generated [9]. Fiber plays a questionable role in the development and treatment of constipation. A meta-analysis showed that bran did not affect the stool output or transit time in constipated patients [14]. Many medications taken by the elderly

TABLE 68.1 Rome II criteria for defining chronic functional constipation in adults**Two or more of the following for at least 12 weeks in the preceding 12 months:**

- Straining in more than 25% of defecations
- Lumpy or hard stools in more than 25% of defecations
- Sensation of incomplete evacuation in more than 25% of defecations
- Sensation of anorectal obstruction or blockage in more than 25% of defecations
- Manual maneuvers (e.g., digital evacuation, support of the pelvic floor) to facilitate more than 25% of defecations
- Fewer than three defecations per week

Source: Reprinted from [13], with permission from MacMillan Publishers, Ltd

are known to cause constipation [15]. Anticholinergics, tricyclic antidepressants, β -blockers, and calcium channel blockers are commonly implicated. Over-the-counter medications, such as aluminum and calcium antacids and laxatives, may also contribute to patients' symptoms. Chronic medical diseases such as hypothyroidism, diabetes, scleroderma, multiple sclerosis, and Parkinson's disease can result in decreased colonic motility. Psychiatric conditions (depression and dementia) have been associated with constipation, which may be behaviorally related [2]. Inability to ambulate to the bathroom because of arthritis, for example, or ignoring the call to defecate because of dementia may contribute to symptoms of fecal impaction, constipation, and the development of a megarectum [2, 7]. Constipation is probably not a normal consequence of aging but is associated with and possibly caused by the immobility, chronic illnesses, and increased neuropsychiatric problems of the elderly population.

Generally, patients with constipation can be separated into three groups. The first are those with normal transit or functional constipation. These patients complain of hard, dry stools that are difficult to evacuate and should be treated with life style manipulation: increased fiber, increased fluid, and exercise. The second group is patients with slow transit or colonic inertia. These patients have minimal to no motility of their colon and rarely have spontaneous bowel movements. Many of these patients report going for days and occasionally weeks without bowel function. Patients with colonic inertia commonly report a long history of laxative use and abuse. Chronic laxative use, particularly with the anthracene laxatives, can cause degeneration of the myoneural chains and may impede motility irreversibly over time [16]. The third group are the patients with anorectal dysfunction or pelvic floor abnormalities. The pelvic floor abnormality can be identified with colonic transit marker studies, scintidefecography and dynamic MRI. These patients have normal transit to the sigmoid colon but are unable to evacuate their rectums easily despite having soft stool. Within this group are patients with rectal intussusception, pelvic organ prolapse, rectocele and obstructed defecation (nonrelaxing puborectalis or anismus).

Rectal intussusception results from a loss of fixation of the rectum from the sacrum. The rectum folds in onto itself

and acts as a valve that prevents normal emptying. Symptoms vary from mild constipation with rectal pressure to severe constipation with rectal pain and a "plugging" sensation. Incomplete evacuation and discharge of mucus and blood per rectum are frequent complaints. Other associated disease entities are colitis cystica profunda, solitary rectal ulcer syndrome, and mucosal prolapse. Rectal intussusception may be identified as a component of pelvic organ prolapse. The etiology of outlet obstruction is unclear, although dysfunction and discoordination of the pelvic floor muscles is the most common explanation. In patients with chronic fecal impaction, the rectal capacity increases over time and rectal sensation becomes blunted. These patients cannot feel the urge to defecate until a fecal bolus is too large to pass. These patients often report the need to use digital maneuvers, suppositories, or enemas to evacuate to their satisfaction.

Patients with complaints of severe constipation should be completely evaluated. Initially, a history and physical examination are performed. A detailed medication list, including all over-the-counter medications, is imperative. A diet and defecation diary is helpful to attempt to define the extent of the problem. The American Gastroenterological Association consensus guideline recommends that most patients with severe constipation have a complete blood count, serum glucose, calcium and creatinine, and thyroid-stimulating hormone levels checked [17].

A digital rectal examination should be done to exclude low rectal carcinomas, anal strictures, and other anorectal abnormalities. Contrast studies or colonoscopy should be performed to rule out obstructing colonic lesions, particularly if the symptoms of constipation are recent or associated with bleeding, mucus, or altered stool caliber. On proctosigmoidoscopic examination, the typical patient with significant intussusception is found to have an erythematous anterior rectal wall approximately 5–8 cm from the mucocutaneous junction. Patients with solitary rectal ulcer syndrome frequently have more severe symptoms of straining, passage of bloody mucus per rectum, and incomplete evacuation. On examination, the solitary rectal ulcer appears as a heaped-up lesion in the anterior midline 5–8 cm from the mucocutaneous junction. This lesion can often be palpated and may be mistaken for a rectal carcinoma. Biopsy of the lesion reveals cystic proliferation of fibroblasts and muscle hypertrophy in the lamina propria, epithelial hyperplasia, colitis cystica profunda, or excess mucosal collagen [18].

Several tests are available for assessment of constipation and can aid in creating a strategy for management although it is not uncommon that patient's complaints and concerns do not correlate well with colonic and anorectal physiologic tests. Colonic transit time is a simple radiographic test which helps assess the bowel motility and can identify patients with colonic inertia or outlet obstruction. Patients are placed on a high-fiber diet and taken off all laxatives and enemas for several days prior to testing. A capsule with 24 radiopaque

markers is given to the patient to take orally on day 0. A plain radiograph is obtained on the third and fifth days. The markers are counted and their location should be noted. The presence of more than 10% of the markers on the fifth day is considered to be an abnormal study. It is important to ensure that the patient took the capsule, did not take laxatives, and did not have abnormal bowel function (i.e., diarrhea) during the study period, as these possibilities may give a false normal examination. Patients with colonic inertia have markers scattered diffusely throughout the colon that remain through the fifth day. In patients with rectal intussusception or outlet obstruction, the markers move through the colon and are held up in the rectosigmoid region. Total colonic transit times in healthy asymptomatic elderly subjects show no change with aging but are prolonged in healthy elderly subjects who report symptoms of constipation [19, 20].

Physical examination is limited in the complete evaluation of the pelvic floor and can miss a significant number of rectoceles, enteroceles, sigmoidoceles, and cystoceles [21]. Scintidefecography may identify patients with severe rectal intussusception or rectal prolapse and can identify patients with significant rectoceles and enteroceles if vaginal contrast is used. This test is done by placing a thickened barium paste in the rectosigmoid to simulate a bowel movement. The patient is then placed on a commode and asked to evacuate the paste while radiographs are obtained. In a normal test the rectosigmoid remains stable along the presacral space, and the puborectalis is seen to relax as the patient passes the contrast bolus. With an abnormal test, the rectosigmoid falls away from its attachments to the presacral space, and the

proximal rectum is seen to infold (intussuscept) (Fig. 68.1). Internal intussusception of the rectum can block the rectal outlet, resulting in incomplete evacuation of the rectal contrast. With severe straining, the intussusception may worsen, and occasionally the entire rectum is seen prolapsing through the anorectal ring.

One of the shortcomings of defecography is the utilization of ionizing radiation. MRI is noninvasive, does not use ionizing radiation, has a larger field of view, has improved soft tissue contrast, and has multiplanar capability. Dynamic MR imaging has been used to assess the complex pelvic anatomy and changes in these structures during attempts at evacuation. Older methods had long acquisition times (6–12 s) which did not allow for real-time evaluation. Newer techniques have near real-time continuous imaging and can be performed in less than 2 min [22, 23]. Dynamic radiologic examinations of the endopelvis may reveal multicompartamental dysfunction [24]. Segregation of the pelvic floor into posterior, middle and anterior compartments, however, is artificial because these structures are closely interrelated [25]. Pelvic organ prolapse can be detected and characterized using dynamic MR imaging but cine defecography is more sensitive in detecting parietal alterations [26].

Anal manometry has limited value in the workup of constipation in the elderly. In select cases, anal manometry, rectal anal inhibitory reflex, minimal sensory rectal volume, and balloon expulsion may identify patients with megarectum and patients with nonrelaxing puborectalis muscle. These tests require specialized manometric instruments and can be done utilizing a capillary perfusion system or microballoon system.

FIGURE 68.1 Scintidefecogram showing progressive outlet obstruction secondary to internal intussusception (from [72], with permission from the McGraw-Hill Companies).

The systems measure the pressures within the anal canal and test the function of the anal sphincter mechanism. Anal sensation is tested by inserting a rectal balloon just above the anal sphincter and insufflating increasing amounts of air until the patient notes sensation. Patients with megarectums require large amounts of distension before any sensation is noted. The rectoanal inhibitory reflex is absent in the setting of Hirschsprung’s disease and is also absent in patients with megarectum who require large volumes to induce the inhibitory reflex. A rectal examination performed on an “unprepped” patient with megarectum may reveal a rectum full of stool. The inability to expel the rectal balloon is tested by asking the patient to evacuate a rectal balloon filled with 60 cc of air in the privacy of the bathroom. If patients have an outlet obstruction and the puborectalis muscle does not relax properly they have difficulty doing this simple task. The inability to relax the puborectalis muscle and evacuate the contrast on scintidefecography helps confirm the diagnosis.

Treatment of constipation in the younger population is generally medical, and treatment of the elderly constipated patient is no different. A trial of dietary fiber and increased fluid intake should be initially instituted once a malignancy has been ruled out (Fig. 68.2). The daily recommended fiber intake is 20–35 g daily, even in the elderly [27]. By adding approximately 5 g of fiber per week until the goal is met the excessive gas and bloating that occurs with high-fiber diets can be minimized [28]. A bowel evacuation routine is often helpful for those patients with outlet obstruction. The patient

is instructed to take bulk-forming agents daily and to use a glycerine suppository or tap water enema at the same time daily. To maximize the effect of the gastrocolic reflex patients are encouraged to perform this evacuation routine upon wakening in the morning and approximately 15–20 min after drinking a warm beverage. Biofeedback has had some success in the treatment of pelvic floor outlet obstruction but requires a motivated patient [29, 30]. Surgical intervention is rarely necessary for older patients with constipation. A total colectomy with ileorectal anastomosis has been successful in the treatment of severe colonic inertia if there is no element of outlet obstruction. This operation should be reserved for the younger, medically stable patient. Other patients with colonic inertia are probably best treated by accepting the need for continuous laxative use.

Treatment of patients with intussusception is primarily medical. Surgery should be limited to patients who are incapacitated because of the pressure or who have a persistent solitary rectal ulcer after intensive medical therapy. Surgery involves low anterior resection or retrorectal sacral fixation of the mobile rectum. Many patients have persistent postoperative symptoms of constipation and difficulty emptying. Patients with symptoms of nonrelaxing puborectalis or colonic inertia must have these symptoms addressed and treated preoperatively to have a successful surgical result [31]. Patients with pelvic organ prolapse, enterocele, cystocele combined with intussusception may benefit from a combined procedure. Women with severe symptomatic rec-

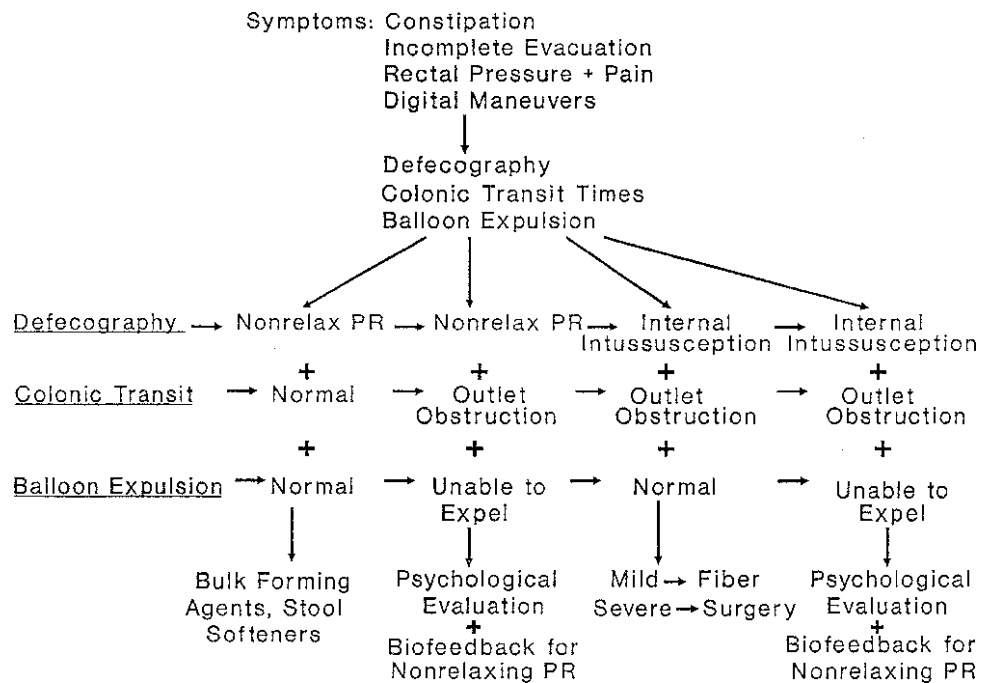

FIGURE 68.2 Management plan for the treatment of severe constipation. PR, puborectalis muscle (from [73], with permission of The McGraw-Hill Companies).

tal intussusception and pelvic organ prolapse may benefit from a multidiscipline approach including urology and gynecology. The decision for surgical intervention for pelvic organ prolapse should not be determined by age alone [32].

Rectal Prolapse

The most severe rectal abnormality of the pelvic floor is rectal prolapse. Rectal prolapse can be partial (mucosal) or full (complete extrusion of the rectum through the anal canal). Circumferential rings are typical of a full rectal prolapse, whereas radial folds are more typical of mucosal prolapse or prolapsing hemorrhoids. Rectal prolapse is associated with chronic constipation and straining and is more frequent in elderly women and institutionalized patients who often have neurologic or psychiatric comorbidities [33]. In addition, since the prevalence of this abnormality increases with age, many patients have other significant medical problems [33, 34].

Rectal pressure, mucous discharge, rectal bleeding, and fecal incontinence are frequent symptoms of rectal prolapse. Once the prolapse begins to occur the patients complain more of fecal incontinence and rectal bleeding than they do of constipation [35]. Often the patient does not mention that the rectum extrudes through the anal canal, and it is not uncommon for the symptoms to be attributed to prolapsing hemorrhoids. Direct questioning may result in the history that the patient's rectum protrudes with bowel movements (especially with straining) and occasionally when assuming an upright position. Manual replacement by the patient or their caretakers is common. A lax anal sphincter and prolapsing rectum are usually found on physical examination. Incarceration or strangulation of the prolapsed rectum is a rare presentation but can occur if there is normal tone to the anal sphincter or the prolapsed rectum has become extremely edematous. An erythematous edematous circumferential region (the "leading edge") may be seen approximately 5–8 cm from the dentate line on proctosigmoidoscopic examination. Asking patients to strain to evacuate their rectum may allow visualization of the prolapse by the examiner. If the prolapse cannot be demonstrated in the office setting, defecography, or dynamic MRI may be done to demonstrate the redundant prolapsing rectosigmoid. A complete evaluation with contrast studies or colonoscopy is necessary to rule out a tumor as a lead point of the rectal prolapse. Occasionally a solitary rectal ulcer is seen at the leading edge of the prolapsing rectum and may be confused with a rectal tumor. Biopsy of the ulcer should give a more definitive diagnosis. The anal sphincter may be assessed using anal manometry and electromyography although the results typically show extremely low rest and squeeze efforts. Unilateral or bilateral neurogenic injury may result

from chronic stretching of the pudendal nerve. Stretch injury may also be a direct result of repeated trauma to the anal sphincter by the prolapsing rectum. Preoperative motility studies with colonic transit times should be done in patients with complaints of severe constipation to identify a group of patients with colonic inertia and prolapse who may require more extensive resection [36].

The surgical approach to rectal prolapse is transabdominal or perineal; more than 100 operations have been cited as forms of treatment for rectal prolapse. Surgical therapy must be tailored to the individual patient. Abdominal suture rectopexy with or without sigmoid resection can be done in patients who are good surgical risks [36, 37]. Low anterior resection may improve the bowel habits of patients who complain of preoperative constipation in whom a markedly redundant distal colon is found [36, 38] (Fig. 68.3a). Complete encirclement of the rectum with a band of mesh (Ripstein procedure) can be modified to leave the anterior bowel wall free [39, 40] (Fig. 68.3b), which minimizes the stenosis by the foreign material and may decrease postoperative fecal impaction at the level of the mesh. Resection should not be done in the presence of foreign material. Modifications using the laparoscope to perform rectopexy have been described [41].

The functional and recurrence rates are similar if the rectopexy is done laparoscopically or open, the benefit is in the shorter hospital stay [42, 43]. Recurrence rates after abdominal procedures are generally less than those after perineal procedures but morbidity can be higher. Abdominal procedures are generally reserved for patients who can tolerate general anesthesia. Recurrence rates do increase over time with both the perineal approach and abdominal approach [44, 45].

Perineal procedures (anal encirclement or proctosigmoidectomy) can be done under regional anesthesia, minimizing the anesthetic risk in the high-risk patient. Thiersch wire or other synthetic material may be used to encircle the anal canal to prevent rectal prolapse (Fig. 68.3c). The synthetic material acts as an obstruction to defecation and prevents the rectum from prolapsing through the anal canal. The anal encirclement procedures do not treat the underlying condition, and the symptoms of rectal intussusception persist in most patients. It is not uncommon for patients to require laxatives and enemas for fecal evacuation after anal encirclement, as the synthetic material acts as an obstruction to defecation. Because septic and mechanical complications are high, anal encirclement as a primary treatment for rectal prolapse is generally reserved for moribund patients with limited life expectancy.

Perineal proctosigmoidectomy, first described in 1889 by Mikulicz [46], has been modified and popularized by others [33, 47] (Fig. 68.4). It can easily be performed under regional anesthesia in either prone jackknife or lithotomy position. The redundant rectum and portion of sigmoid colon can be

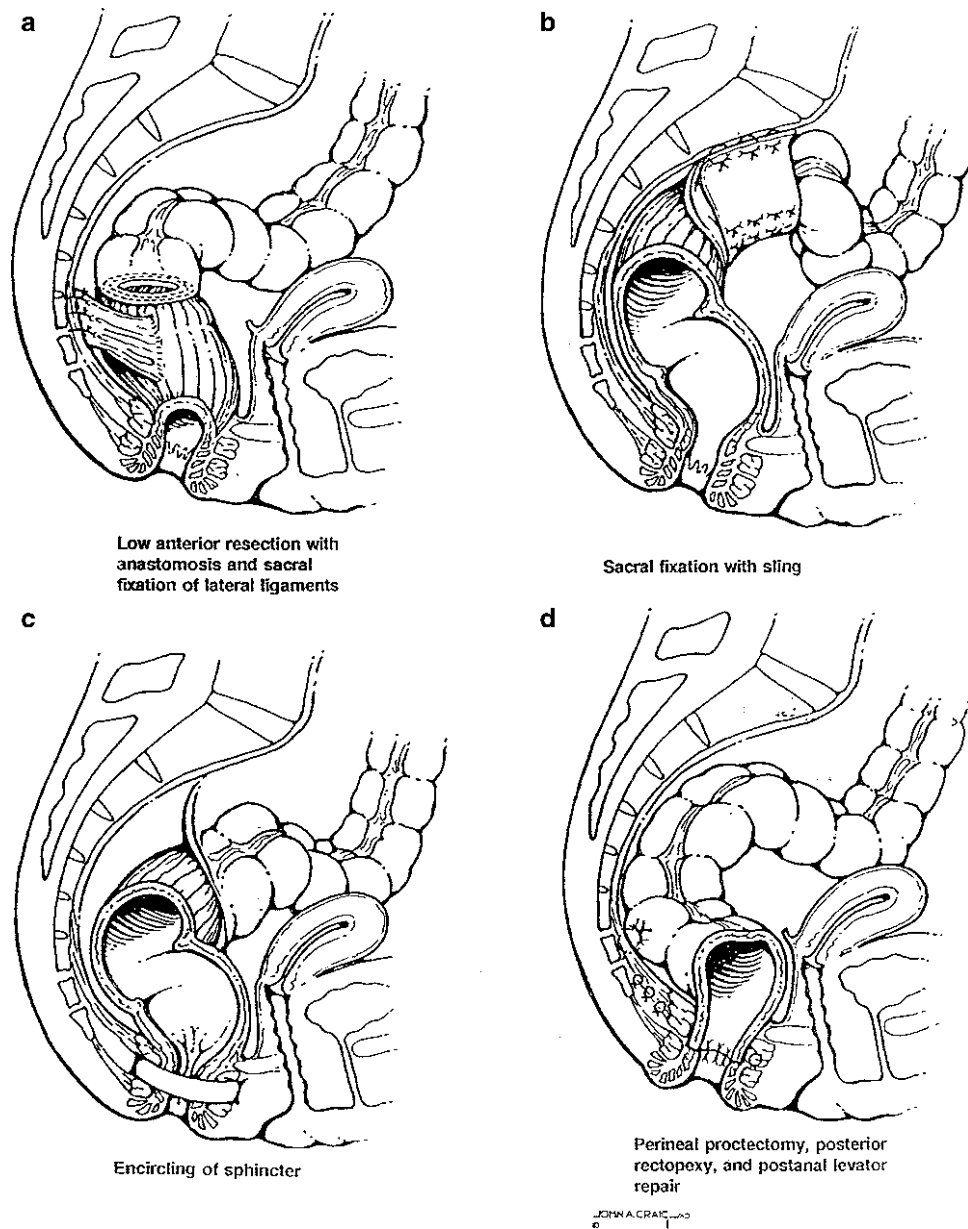

FIGURE 68.3 Surgical options for the treatment of rectal prolapse (from [73], with permission of The McGraw-Hill Companies).

FIGURE 68.4 Perineal proctosigmoidectomy (reprinted with permission from The ASCRS textbook of colon and rectal surgery, publisher Springer 2007, Chap. 47 Rectal prolapse, pp. 665–677).

easily removed via the anal incision. Addition of a posterior levator repair described by Prasad et al. re-creates the anatomic anorectal angle and may help patients gain fecal control postoperatively [47]. Minimal pain and little physiologic alteration are associated with this procedure, and most patients can be discharged from the hospital within 3–4 days. The recurrence rate of a perineal proctosigmoidectomy is related to the length of follow-up and ranges from 0 to 22% [33, 34, 47]. The morbidity is 3–12%, and mortality is less than 5% [33, 34, 47].

Another perineal approach, the Delorme procedure, has been recommended for the treatment of rectal prolapse since the morbidity and mortality is relatively low [48]. This procedure is not a full thickness rectal resection but rather the redundant rectal mucosa is stripped circumferentially. The remaining, redundant outer rectal wall is then plicated with a series of circumferential sutures which then allows the mucosal edges to be reapproximated. It has not been used as widely for the treatment of full rectal prolapse because of concerns for recurrence [49]. A recent study found that the Delorme procedure could be done with minimal morbidity, a short hospital stay and a recurrence rate of 14.5%. The mean time to recurrence was 31 months. They found that the recurrence rate was relatively low in patients under 50 (8%) and felt that this procedure could be offered to younger patients as well [35].

Stercoral Ulceration

Ischemic pressure necrosis by a large fecal mass causing fecal peritonitis is a rare cause of free perforation of the colon. Mortality can be as high as 35% in patients presenting with perforation [50]. Although considered a disease of the elderly, the average age of patients presenting with stercoral ulceration is in the fifties. Associated medical diseases occur in about one-third of patients, and almost all patients complain of chronic constipation requiring laxatives. The sigmoid and rectosigmoid are the most common sites of perforation, which almost always occurs along the antimesenteric border [50]. The symptoms of abdominal pain and peritonitis start acutely and the clinical picture is usually one of sepsis. If there is a free perforation, an upright chest radiograph will show free air under the diaphragm. A CT scan, if done before free perforation, may show focal colonic wall thickening and mild pericolonic fat stranding indicating a localized process. Small air bubbles in the vicinity of a large fecal bolus indicate wall compromise and perforation [51]. The actual diagnosis is rarely made preoperatively. At exploration, the bowel wall adjacent to the perforation is usually thin and rarely inflamed, in contrast to the colonic findings of diverticulitis. Irrigation of the abdominal cavity and distal

rectal stump help to decrease the fecal load. Several surgical procedures are recommended for treatment in the literature. Resection with end colostomy, with a mucous fistula or Hartmann's procedure has the lowest operative mortality rate (23%). A proximal colostomy with closure of the perforation is rarely done and carries a mortality of approximately 44%. Proximal loop colostomies and exteriorization of the perforation have the highest mortality rate (71%) [52]. Since this is an uncommon diagnosis and there are limited reports in the literature, morbidity and mortality rates may only reflect the small numbers of very ill patients with this diagnosis.

Volvulus

Colonic volvulus occurs when an air-filled segment of colon twists about its elongated mesentery. In the USA, colonic volvulus is a rare cause of intestinal obstruction and accounts for approximately 3% of colonic obstructions [53]. In parts of Iran and Russia, colonic volvulus is one of the predominant causes of intestinal obstruction. The high incidence of sigmoid volvulus in other parts of the world has been attributed to the high-fiber diets of those regions. Chagas' disease, which causes megacolon, may play a role in the development of sigmoid volvulus, particularly in countries where the disease is common [54]. In North America, the incidence increases over the age of 50. The disease is associated with chronic constipation, laxative use, psychiatric illness, and institutionalization [53]. A dilated, redundant colon with a narrow mesocolon is a prerequisite for a volvulus to occur, and therefore the intra-abdominal portions of colon are at risk. Colonic volvulus most commonly occurs in the sigmoid colon; cecal volvulus and volvulus of the transverse colon occur less frequently (<10%) and are generally seen in young patients.

Patients with sigmoid volvulus usually present with abdominal distension, obstipation, and pain. Peritoneal irritation on physical examination, fever, or an elevated white blood cell count indicates ischemic or gangrenous bowel. Plain abdominal radiographs may show an inverted, U-shaped, air-filled bowel loop ("bent inner tube"), with a dense line running toward the point of torsion. This radiologic finding is highly suggestive of a sigmoid volvulus. If peritonitis is not present, sigmoidoscopy should be performed to the point of obstruction. The volvulus can often be reduced by inserting a soft rectal tube past the point of obstruction. A release of gas and liquid stool follows successful detorsion. The rectal tube should be left in place for several days to assist with further decompression. The success rate with this technique is good, and reduction of the volvulus can be expected with approximately 75% of attempts. The colonoscope may be used to attempt reduction, but its use should be limited to patients in whom a rigid proctoscope has been unsuccessful in reaching

FIGURE 68.5 Hypaque enema showing sigmoid volvulus. Note the “bird’s beak” deformity (*arrow*) (from [73], with permission of The McGraw-Hill Companies).

the point of torsion. Contrast enemas may be necessary when plain radiographs are not diagnostic for volvulus but suggest a colonic obstruction. The column of contrast tapers at the point of torsion (“bird’s beak” deformity) (Fig. 68.5). Occasionally, reduction occurs with contrast enemas, but detorsion occurs in fewer than 10% of attempts [55]. Evidence of mucosal ischemia, bloody discharge, or unsuccessful detorsion indicates strangulation and possibly gangrene. If the patient has signs of peritoneal irritation or if gangrene is suspected, contrast studies and tube decompression should not be attempted and the patient should undergo emergency exploration.

Nonoperative reduction is successful in approximately 90% of patients but does not constitute adequate treatment in good risk patients [56]. Recurrence rates following nonoperative reduction range from 20 to 60% but can be as high as 90% [56, 57]. Once the volvulus is reduced, medically stable patients should undergo mechanical bowel preparation and elective resection. The choice of operation depends on the adequacy of the bowel preparation and the viability of the colon. A sigmoid resection with primary anastomosis can be done after bowel preparation and if the colon shows no signs of ischemia. The presence of ischemic or gangrenous bowel is an indication for resection and colostomy.

Mortality is related to the presence of gangrenous bowel and to delay in decompressing the ischemic bowel. The operative mortality following elective resection of a primary volvulus is approximately 6 vs. 21% for recurrent volvulus [56]. Some investigators have found high mortality rates associated with elective resection and recommend elective resection only in good risk, young patients [58]. Patients who require emergency operation for sigmoid volvulus have a mortality rate of more than 30% [56].

Cecal and transverse colonic volvulus are less common than sigmoid volvulus. Anomalous fixation of the cecum may be an important reason why cecal volvulus occurs in a young age group [59]. Other predisposing factors, such as prior abdominal surgery, pregnancy, and distal obstruction, have been implicated as causes of cecal volvulus. Ninety percent of patients with cecal volvulus have a full axial volvulus twisting the associated mesentery and blood vessels [53]. In the remaining patients, the cecum folds in an anterior cephalad direction (cecal bascule). Although a bascule is not a true volvulus around the mesentery, gangrene can result from tension on the bowel wall. Patients with cecal volvulus clinically appear to have a small bowel obstruction. Abdominal pain, nausea, vomiting, and obstipation are common symptoms. Many patients give a history of chronic intermittent symptoms of partial bowel obstruction [53]. Plain abdominal radiographs show the cecum as an air-filled, kidney-shaped structure pointing to the left upper quadrant. Multiple air-fluid levels are suggestive of a distal small bowel obstruction. Contrast enemas may show the “bird’s beak” tapered edge of the contrast pointing toward the site of torsion (Fig. 68.6). Contrast studies are useful in difficult cases but should not be performed routinely if the diagnosis of cecal volvulus is clear. Contrast studies and colonoscopy have rarely been successful in reducing a cecal or transverse volvulus.

Once a cecal volvulus is diagnosed operative intervention should be undertaken. Operative detorsion alone has high recurrence and mortality rates and should not be performed as the sole procedure. Cecopexy, cecostomy, and resection have variable rates of recurrence and morbidity. The highest rates of postoperative complications, mortality, and recurrence are seen with cecostomy [60]. Cecostomy or appendicostomy allows decompression of the distended bowel and fixation of the cecum. Although the recurrence rate is similar to that for cecopexy, the intra-abdominal and wound complications are more than 25% [60]. Cecopexy is done by anchoring the right colon to the parietal peritoneum by direct suture or by making a peritoneal flap. This technique eliminates the cecal hypermobility but is technically challenging to perform if the cecum is dilated and thin-walled. The recurrence rate after cecopexy is variable, with some series reporting recurrence as high as 28% [61]. Patients who are medically stable should undergo a right hemicolectomy with primary

FIGURE 68.6 (a) Cecal volvulus, plain radiograph, CE cecum. (b) Barium enema. Arrow indicates the point of obstruction, CE cecum.

anastomosis if there is no evidence of gangrenous bowel. Resection, ileostomy, and mucous fistula are indicated if there is evidence of ischemia or gangrene. Mortality is increased in the presence of gangrenous bowel and is higher with cecal volvulus than with sigmoid volvulus (33 vs. 7%). This increased mortality rate with cecal volvulus is due to the increased presence of gangrenous bowel seen with cecal volvulus (21% vs. 7%) [53].

Fecal Incontinence

Fecal incontinence is a disabling problem in the elderly and in institutionalized patients [62]. A community-based prevalence study estimated that fecal incontinence affects 2.2% of the general population although the incidence and prevalence is probably underestimated [63]. More than 60% of patients who complain of fecal incontinence are women [63]. In community-based women older than 60 it is estimated that the prevalence varies from 12 to 33% depending on the definition used [64].

Incontinence may be neurogenic, mechanical, mixed, or secondary to other medical conditions. Anal sphincter injuries are the leading cause of mechanical incontinence and are most commonly the result of a midline episiotomy. Fecal incontinence may not occur immediately after the injury but rather the presentation may be delayed for years. The majority of women with late onset fecal incontinence have an anatomic sphincter defect [65]. Neurogenic incontinence may be due to central or peripheral denervation of the

puborectalis muscle or external anal sphincter. Rectal prolapse or descending perineum syndrome may denervate the sphincter by a stretch injury to the pudendal nerve. Injury to the sphincter mechanism, traumatic or surgical, may lead to fecal incontinence immediately after the injury or during the ensuing years. Decreased anorectal sensation caused by radiotherapy or diabetes mellitus may lead to incontinence as well. Certain physiologic factors have been shown to occur with aging: decreased rectal tone and weakening of the anal sphincter mechanism [66, 68]. The anal sphincter may decrease in strength secondary to loss of muscle mass or neuropathy. These differences are more pronounced in elderly women. It may be due to weakening of connective tissues, possibly from decreased estrogen secretion. Physical limitations and poor general health are other predisposing factors that contribute to fecal incontinence [62, 63]. A common cause of fecal incontinence in the elderly, however, is fecal impaction with overflow incontinence [63]. Systemic diseases such as scleroderma, polymyositis, multiple sclerosis, and diabetes mellitus can be associated with fecal incontinence. Colorectal carcinoma, colonic ischemia, and inflammatory bowel disease may cause symptoms of fecal urgency, and incontinence may be a result of the patient's inability to respond quickly.

On initial evaluation, constipation with overflow incontinence must be ruled out by history and digital rectal examination. A complete colonic evaluation with colonoscopy or contrast enema should be done especially if the symptoms of fecal incontinence have a short history. The anal physiology laboratory can objectively evaluate the anal sphincter mechanism to determine the cause of fecal incontinence and direct

treatment. Anal manometry, electromyography, and transrectal ultrasonography can help differentiate neurogenic from mechanical injury to the anal sphincter. Anal manometry assesses the rest and squeeze pressures generated by the anal sphincter. The sphincter length can be determined, and some systems can identify the specific quadrant involved in a sphincter defect. The minimal sensory rectal volume is useful for identifying patients with megarectum who do not sense the presence of a large bolus of fecal material in their rectum. Electromyography is used to evaluate the pudendal nerve

terminal motor latency. The pudendal nerve innervates the external anal sphincter and the puborectalis muscle. Both muscles are involved in maintaining fecal continence; and denervation of these muscles, represented by prolonged pudendal nerve terminal motor latency, may cause neurogenic incontinence. Transrectal endoluminal ultrasonography has replaced needle electromyography as the preferred method for evaluating the anal sphincter for defects. Using this modality, the puborectalis muscle and the external and internal anal sphincters can be thoroughly evaluated for defects.

CASE STUDY

Rectal Prolapse

An 86-year-old woman with a several year history of hemorrhoidal complaints presents with increased rectal bleeding, mucous discharge, and fecal incontinence. She has a long history of constipation and currently takes MiraLax and Milk of Magnesia. She complains of prolapsing rectal tissue which occurs daily with defecation. The problem has been ongoing for several years and the rectum is becoming harder to reduce. She uses a pessary for a cystocele and has urinary incontinence. Her past medical history is significant for an irregular heartbeat and coronary artery disease. Her past surgical history is significant for a total abdominal hysterectomy and bilateral salpingo-oophorectomy done years prior. She is gravida 3, para 3. Her current medications include Verapamil, Synthroid, and Digoxin.

On physical exam, she is an alert, elderly woman. Abdominal exam is benign. There is a well-healed Pfannenstiel incision. On digital rectal examination, she has lax anal tone, diminished squeeze efforts, and a normal proctosigmoidoscopic examination. There is hard stool in her rectal vault and full rectal prolapse upon straining on the toilet.

Workup

Anal physiology (including anal manometry, EMG, and transrectal ultrasound) is not needed for evaluation of fecal incontinence in this patient. The full rectal prolapse dilates the anal canal stretching the anal sphincters. The rectal tone is often diminished in patients with longstanding prolapse and is a cause of fecal incontinence.

Defecography is not needed in this patient since the full rectal prolapse is visible on examination. If the rectal prolapse is not reproduced by having the patient strain on the toilet, then defecography or dynamic MRI would be indicated to assess for full rectal prolapse. These tests can also evaluate for enteroceles and vaginal prolapse.

Colonic transit time may be indicated in this patient if she had significant symptoms of constipation. If her complaints were that she had no bowel movements without the use of laxatives or if she had bowel movements every 5–7 days, a colonic transit time would be indicated to assess for colonic inertia.

Medical evaluation is done to determine whether the patient can withstand general anesthesia. If the patient is too frail or general anesthesia is medically contraindicated, then spinal anesthesia and a perineal approach is the preferred approach.

If the patient is extremely frail and medical conditions preclude anesthesia, it is possible to place a Thiersch wire under local anesthesia. However, the performance of a Thiersch wire causes obstruction at the outlet and the patients will need to have continued evacuations. This procedure is not recommended for patients whose life expectancy exceeds 6 months.

If the patient is in poor health and cannot undergo general anesthesia, then a perineal proctectomy would be the operation of choice.

If the patient is in good health with no constipation but elderly and frail, a perineal proctectomy would be a good choice.

If the patient has significant constipation and is in good health, then a resection rectopexy would be the operation of choice.

If the patient is in good health with no complaints of constipation but a urogyn procedure is necessary, then a sutured rectopexy can be done in conjunction with a sacral colpopexy or other urogynecologic treatment.

Initial treatment may be as simple as dietary alteration (avoidance of milk products and food with high fat content) and a bowel evacuation regimen (bulk-forming agents and glycerine suppositories) [68]. Biofeedback has had some success in patients but requires the understanding and cooperation of the patient [69]. Combined pharmacologic and physical therapy may be more beneficial when combined in appropriate patients [70]. Anterior sphincter reconstructions with direct muscle repair has had success in the elderly population [71]. Older women undergoing pelvic floor surgery can expect similar results and outcomes as younger patients [32]. A diverting colostomy is rarely necessary for control of the fecal stream in the elderly population. If the rectum is severely damaged by radiation injury, a diverting colostomy is probably the best treatment option for severely incontinent patients.

Chapter 69

Neoplastic Diseases of the Colon and Rectum

Aundrea L. Oliver, Stanley W. Ashley, and Elizabeth Breen

Colorectal cancer, like many neoplasms, is primarily a disease of aging. The incidence of both colorectal carcinoma and its precursor lesions increases progressively with age. Although there is no evidence that the biologic aggressiveness of colorectal cancer increases with age, delays in diagnosis contribute to the presence of relatively advanced disease at presentation, and therefore a poorer prognosis, in the elderly [1]. These delays in diagnosis may also result in the development of complications of colorectal cancer, requiring emergent surgery, with its higher morbidity and mortality rates. Although recently reported series document

excellent results for some elderly patients undergoing elective operations for colorectal cancer, many elderly patients are more likely to have comorbid conditions and fare poorly with treatment. Elderly patients, thus, represent a heterogeneous group of patients with issues of comorbidity, vulnerability, and life expectancy that can pose unique challenges in the treatment of their colorectal cancer [1–3].

In this chapter, the epidemiology, pathology, diagnosis, and therapy of colorectal neoplasms are reviewed, with an emphasis on elderly patients. A common scenario involving an elderly patient with colorectal cancer would be as follows.

Clinical Vignette

An 82-year-old man with a history of CAD complicated by congestive heart failure with an ejection fraction of 35% and who has smoked 1 pack of cigarettes a day for 60 years presents to his physician with 6 months of increasing rectal bleeding. Colonoscopy reveals only a 3×2 cm posterior tumor 8 cm proximal to his dentate line. Biopsies reveal a moderately differentiated adenocarcinoma. Endoanal magnetic resonance imaging (MRI) scan stages the lesion as T2N0. Abdominal and chest CT

scans do not reveal any evidence of metastatic spread to the liver, lungs, or bones.

How would this patient be best treated? Decisions, as detailed in the following chapter, relate to the goals of treatment—curative intent versus palliative and the potential methods used to try and achieve these goals. The invasiveness of potential treatments and their likelihood of producing a lasting effect together with the patients' comorbidities and resulting ability to tolerate treatment along with their life expectancy all need to be carefully considered before a treatment plan is made.

Epidemiology

Colorectal cancer remains the third most frequently diagnosed cancer and the second leading cause of cancer-related mortality in the USA, where it accounts for about 8–9% of cancer-related deaths. Altogether, 148,810 new cases and 49,960 deaths due to colorectal cancer were estimated to have been diagnosed in the USA in 2008 [4]. Its incidence

progressively increases in populations with advancing age, consistent with the hypothesis that colorectal cancer arises as the result of multiple genetic mutations accumulated in patients over time. The median age at which patients in the USA diagnosed with colorectal cancer is 71 years. The overall incidence of colorectal cancer in the USA is approximately 50 per 100,000. In individuals under the age of 65, the incidence is 18 per 100,000 compared with 273 per 100,000 for those over 65 years. The 5-year survival rate for men and women over 75 is 59.7% compared with 66% for individuals under 65. The cumulative lifetime risk of developing colorectal cancer is approximately 5%, with the lifetime risk of dying from colorectal cancer remaining less than 0.1% [5].

E. Breen (✉)
Department of Surgery, Brigham and Women's Hospital, Harvard
Medical School, Boston, MA, USA

Adenomatous polyps of the colon and rectum, which have the potential to undergo transformation into cancers, are found in approximately 40% of people by the age of 60 years, and their prevalence increases with advancing age. The prevalence of large (>1 cm in diameter) polyps, which have the greatest probability of harboring cancer, also appears to be related to age. In one series, such large polyps were found in 4.6% of patients of age more than 54 years and in 15.6% of patients of age more than 75 years [3]. This may be related to the fact that for adenomas >1 cm in diameter the risk of progression to cancer is 1% per year [6].

Not only are the elderly at greater risk of developing colorectal cancer, but they are also likely to have more advanced disease at the time of diagnosis. In one report, patients over 75 years of age were twice as likely to present with advanced, untreatable colorectal cancer as those under 65 years of age [7]. The relative contributions of physician bias, limited access to health care, poor social support, and impaired cognition to this observation are not clear. Comorbid conditions play a significant role in survival for elderly patients with colorectal cancer. A recent review article outlined the fact that for individuals over 67 years with stage III disease at the time of diagnosis, the life expectancy could range from approximately 8.5–7 to 4.5 years with zero, one to two, and three or more comorbidities, respectively. Interestingly, patients still fared better with adjuvant therapy versus none regardless of the degree of comorbidity [8].

Risk Factors

Epidemiologic studies have suggested that an increase in the consumption of dietary fiber, fruits, and cruciferous vegetables as well as a reduction in the consumption of fat is associated with a decrease in mortality from colorectal cancer. However, the efficacy of modifications in diet in preventing colorectal cancer has not yet been demonstrated in prospective trials. Similarly there have been several studies investigating the chemopreventative effects of NSAIDs, aspirin, calcium, and folate. Unfortunately there is little compelling data to support such claims as independent preventative measures for colorectal cancer. Again, the efficacy of modifying these risk factors in colorectal cancer prevention remains to be shown [9, 10].

In addition to older age, factors clearly associated with an increased incidence of colorectal cancer include a history of colorectal cancer, either in oneself or in one's relatives. Patients with colorectal cancer are more likely to develop a subsequent (metachronous) lesion than is the general population to develop primary cancer. Patients who have a first-degree relative with colorectal cancer, but not one of the specific genetic syndromes discussed below, have approximately twice the probability of developing colorectal cancer as those without

such a family history. This probability is higher if more than one first-degree relative is affected or if the age at diagnosis of the relative's cancer is less than 55 years. A similar increase in risk is found for patients with a first-degree relative found to have an adenomatous polyp prior to the age of 60 [6].

In the USA, approximately 25% of cases of colorectal cancer occur in individuals with a family history of the disease or an underlying condition specifically associated with the development of colorectal cancer. Patients who have first-degree relatives with colorectal cancer, but not any of the defined genetic syndromes, account for most of these cases (15–20%). Hereditary nonpolyposis colon cancer (HNPCC) accounts for 4–7% of cases, and familial adenomatous polyposis (FAP) accounts for 1%. An additional 1% of cases are accounted for by a combination of patients with inflammatory bowel disease, Peutz–Jeghers syndrome, and familial juvenile polyposis. Keeping in mind that the majority of patients who develop colorectal cancer will not have an identifiable risk factor, screening remains an important part of minimizing the incidence of this disease [11]. The main relevance of potential inherited risk and familial syndromes for elderly patients is to mainly to inform younger family members of their diagnosis should changes in screening recommendations be appropriate for those younger family members.

Pathology

Polyps

Polyps are mucosal masses in the colon and rectum. There are several histologically distinct types of polyps of varying clinical significance, including adenomatous polyps (which are premalignant and represent 50–66% of all colorectal polyps), hyperplastic polyps (which have no malignant potential and represent 10–30% of all polyps), mucosal tags (which are of no clinical significance and represent 10–30% of polyps), and a variety of more unusual other histologic types, such as lipomas and hamartomas. Polyps in which the bulk of the lesion projects into the bowel lumen and is tethered to the mucosal surface through a narrow stalk of submucosa surrounded by mucosa are characterized as pedunculated. Polyps that are flat and have a broad base are characterized as sessile.

Adenomatous polyps can be found throughout the colon and rectum, with approximately 30% occurring proximal to the splenic flexure. With advancing age, a larger percentage of adenomatous polyps are found in the proximal colon. Histologically, adenomatous polyps are subclassified as tubular, tubulovillous, and villous. Tubular and tubulovillous adenomas tend to be pedunculated, whereas villous adenomas tend to be sessile. The potential for malignant transformation is least for tubular adenomas and highest for villous adenomas.

The size of an adenomatous polyp is directly related to the probability that it is harboring high-grade dysplasia, which is likely to be the direct precursor of preinvasive carcinoma, and that the patient will develop other adenomatous polyps and colorectal cancer. In one report, 1.1% of adenomatous polyps <5 mm in diameter, 4.6% of those 5–9 mm in diameter, and 20.6% of those ≥1 cm exhibited high-grade dysplasia [12]. Fewer than 1% of adenomatous polyps <1 cm in diameter harbor invasive carcinoma, whereas more than 10% of larger adenomatous polyps do so.

Colorectal Cancer

Approximately 95% of all colorectal cancers are adenocarcinomas. Macroscopically, the lesions can have a polypoid, infiltrative, or ulcerated appearance. Histologically, they are characterized as being well differentiated, moderately differentiated, or poorly differentiated. Lesions that have an infiltrative or ulcerated appearance and are less well differentiated are associated with poorer prognosis. Cancers associated with increased production of mucin are typically characterized by the presence of signet ring cells. The prognostic implication of these signet ring cells is not well-defined.

Extension of colorectal cancers occurs through three routes: (1) via the bloodstream to distant sites, particularly the liver; (2) via the lymphatics to regional lymph nodes and ultimately the systemic circulation; and (3) by direct extension into adjacent organs, such as the posterior vaginal wall, uterus, prostate, bladder, small intestine, stomach, and retroperitoneal structures.

The anatomic distribution of cancers is as follows: ascending colon 18%, transverse colon 9%, descending colon 5%, sigmoid colon 25%, and rectum 43%. Cancers are currently found with greater frequency in the proximal colon than they were earlier during the twentieth century. It is unknown whether the advent of colonoscopy (and its ability to detect more proximally located cancers) or a change in the biologic behavior of colorectal cancer explains this shift.

Pathogenesis

Most colorectal cancers presumably arise via transformation of preexisting adenomatous polyps. Several lines of circumstantial evidence support this assertion: (1) cancers and adenomatous polyps occur with the same anatomic distribution; (2) cancers rarely arise in the absence of adenomatous polyps; (3) the average age of onset of adenomatous polyps precedes that of cancer by several years; (4) patients found to have large polyps are at increased risk for subsequently developing cancer, with most of these cancers arising at sites where these polyps are left in place; (5) patients with FAP are at markedly increased risk of developing cancer; and (6) the

detection and removal of adenomatous polyps reduces the incidence of colorectal cancer.

The strongest evidence for the clinical relevance of the concept that most cancers arise from precursor adenomatous polyps is derived from the National Polyp Study. A group of 1,418 patients was followed for an average of 5.9 years after the removal of all identifiable colonic polyps. Only five subsequent malignant polyps (all being Dukes' stage A lesions) were found, and no deaths from colorectal cancer occurred during 8,401 person-years of follow-up [13]. The incidence of malignant transformation of adenomatous polyps has been estimated to be 2.5 polyps per 1,000 per year. The mean time required for an individual polyp to undergo such transformation has been estimated to be 10 years [14].

The transformation of an adenomatous polyp to invasive cancer (and that of normal mucosa to adenomatous polyp) is associated with an accumulation of acquired genetic mutations. This model of tumorigenesis, proposed by Fearon and Vogelstein, is shown in Fig. 69.1. Genetic changes include mutational activation of dominantly acting cellular oncogenes and mutational inactivation of recessive tumor-suppressor genes. Protooncogenes are present in normal cells; their protein products tend to be positive regulators of cell growth. When these genes undergo mutation, they can become oncogenes, whose protein products are produced in excessive quantities or act in an unregulated manner, thereby promoting tumor formation. The protein products of tumor-suppressor genes, on the other hand, tend to suppress cell growth, and their loss may promote tumor development.

Mutations characteristic of colorectal cancer have begun to be identified. Approximately 50% of colorectal cancers and adenomatous polyps >1 cm in diameter have been found to harbor mutations in the *ras* oncogene [15–17], whereas fewer than 10% of adenomas <1 cm in diameter are associated

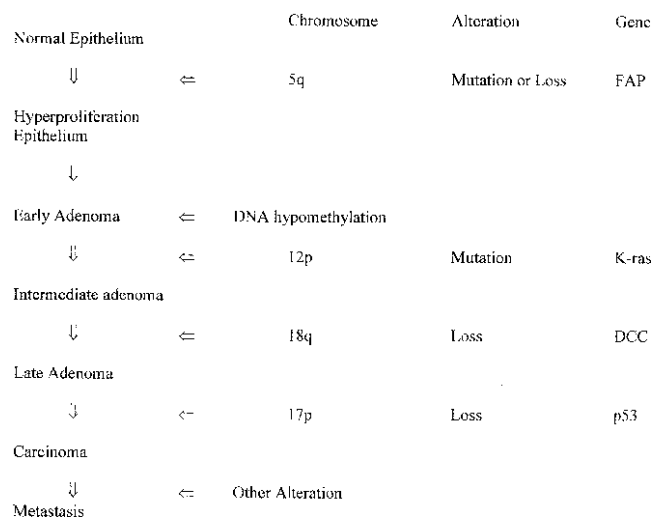

FIGURE 69.1 Genetic model for colorectal tumorigenesis as proposed by Fearon and Vogelstein (from Vogelstein et al. [15], © Massachusetts Medical Society, with permission).

with such mutations. The highly conserved *ras* protooncogenes (*N-ras*, *H-ras*, and *K-ras*) encode for the production of signal transduction G-proteins (guanosine triphosphate-binding proteins). Mutations in the *ras* gene result in the production of an abnormal G-protein that is associated with unregulated cell growth. In vitro and animal studies have suggested that mutations in the *ras* gene may also inhibit programmed cell death (apoptosis).

The development of colorectal cancer is also associated with the deletion of chromosomal fragments. This phenomenon is also known as *allelic loss* or *loss of heterozygosity*. This process primarily affects chromosomes 17 and 18 and to a lesser degree chromosome 5. The DNA lost in such deletions may contain tumor-suppressor genes. One such gene whose loss is associated with FAP has been localized to chromosome 5q and is known as the adenomatous polyposis coli (*APC*) gene. The *APC* gene is thought to be a tumor-suppressor gene, although the function of its protein product is not yet known. Therefore, allelic loss of *APC* may promote neoplastic transformation. Allelic loss of chromosome 5q is present in approximately 20–50% of sporadic colorectal carcinomas and 30% of sporadic adenomatous polyps.

The loss of chromosome 17p, which contains the *p53* tumor-suppressor gene, is seen in 75% of sporadic colorectal cancers but rarely in adenomas of any size. Therefore, loss of chromosome 17p may be particularly associated with the progression of an adenoma to cancer. The allelic loss of chromosome 17p is also seen in a wide range of cancers, including those of the brain, breast, lung, and bladder. Evidence has indicated that reconstitution of wild-type *p53* expression in human and murine cell lines inhibits growth through induction of cell cycle arrest, apoptosis, or both.

Approximately 70% of colorectal cancers and 50% of large adenomatous polyps are associated with allelic deletions of chromosome 18q. *DCC* (deleted in colorectal carcinoma) is a candidate tumor-suppressor gene that has been mapped to chromosome 18q. The protein product of the *DCC* gene has significant homology to the neural cell adhesion molecule (N-CAM). It has been speculated that deletion of the *DCC* gene may modify cell–cell or cell–basement membrane interactions (or both), which are important for regulating cell growth and differentiation.

Several germ-line mutations (*MLH1*, *MSH2*, *PMS1*, *PMS2*) on chromosomes 2, 3, and 7 have been identified in patients with HNPCC. These genes are human homologues of the bacterial mutHLS complex, which is involved in genetic proof-reading (the repair of mismatched basepairs in DNA). Loss of this function is thought to allow basepair mismatches to accumulate, resulting in a replication-error phenotype, which is seen in a high percentage of patients with HNPCC and approximately 15% of those with sporadic colorectal cancer.

It is likely that specific mutations, for sporadic and familial forms of colorectal cancer, will be identified at an increasingly

rapid pace in the years to come. Tailoring therapies to specific mutations is becoming a reality in the treatment of colorectal cancer [18]. Furthermore, as the functions of the protein products of these abnormal genes are characterized, genetic interventions may become a reality.

Staging

A variety of pathologic staging systems have been used. Dukes, a pathologist, in 1932 proposed a staging system for rectal cancer based on the depth of invasion of the bowel wall by the primary tumor. The TNM, however, recommended by the American Joint Committee on Cancer is the most widely used system. With the TNM system, staging is based on the depth of invasion of the primary tumor (T), status of regional lymph nodes (N), and the presence of distant metastasis (M). The advantage of the TNM staging system is its applicability to both presurgical clinical-diagnostic staging and postsurgical resection-pathologic staging [19].

Screening

The terms screening, diagnosis, and surveillance have distinct clinical definitions. *Screening* identifies those patients who are at risk for having colorectal cancer or adenomatous polyps from among the population who are without signs or symptoms of the disease. *Diagnosis* classifies patients who, because of a positive screening test or symptoms, are suspected of having colorectal cancer or adenomatous polyps into those with and without the disease. *Surveillance* monitors patients with previously diagnosed colorectal disease (polyps, colorectal cancer, or inflammatory bowel disease, for example) for the development of adenomatous polyps or colorectal cancer.

Screening for a disease is justified when the following four criteria are met: (1) the disease is common and associated with serious morbidity and/or mortality; (2) screening tests are accurate for detecting early stage disease; (3) treatment after detection by screening improves prognosis relative to the treatment after diagnosis in the absence of screening; and (4) potential benefits outweigh the potential harms and costs of screening. Several screening modalities for colorectal cancer fulfill all of these criteria [14].

Screening for colorectal cancer has clearly been demonstrated to have efficacy in reducing cancer-related mortality. There has been controversy, however, related to which screening and surveillance methods are optimal, how frequently the tests should be done, who should undergo testing, and the cost-effectiveness of the various strategies. In addition, only a small number of the elderly population undergo screening

of any kind for colorectal cancer. The Behavioral Risk Factor Surveillance System (BRFSS), a telephone-based survey designed to monitor utilization of preventative services, has indicated that from 1991 to 2004 consistently less than 60% of individuals over 50 years of age have utilized colorectal screening modalities according to recommended guidelines. The 2004 BRFSS data indicated that only 57% of older individuals had either an FOBT within the prior year or sigmoidoscopy/colonoscopy within the last 10 years. The same study indicated that socioeconomic factors and consistent health care (insurance and services) were key predictors of compliance with screening recommendations [20]. Education (for both patients and physicians) and investigation related to screening would likely have a major impact on the overall management of colorectal cancer. In this section, the terminology related to screening is defined, tests and strategies used for screening are discussed, and recommendations are outlined.

Fecal Occult Blood Testing

The rationale for using FOBT to screen for colorectal cancer is based on the observation that colonic neoplasms have a greater tendency to bleed than does normal mucosa. This propensity increases with polyp size and cancer stage, although the bleeding is usually intermittent and unevenly distributed in the stool.

The most widely used test to detect fecal occult blood is the guaiac-based assay for peroxidase activity. Hemoglobin, which has pseudoperoxidase activity, in blood yields a positive test result. This test has considerable limitations. The test is not specific for cancer, as nonneoplastic processes such as gum disease, gastritis, peptic ulcer disease, and hemorrhoids can also cause gastrointestinal hemorrhage. The test is also not specific for blood, as other substances with peroxidase or pseudoperoxidase activity such as red meat, bacteria, and some fruits and vegetables can cause false-positive reactions. False-negative tests may result if the cancer did not bleed when the sampled stool was being formed or if the quantity of bleeding is below the limits of test detection. The antioxidant activity of vitamin C can interfere with the test reaction, causing a false-negative result. Iron supplements do not interfere with the reaction; but by making the stool dark they interfere with the interpretation of test results. The patient should therefore observe a diet restricted from these confounding substances for 2 days prior to stool sampling.

The sensitivity of FOBT is increased with the number of samples per stool and the number of stools sampled. Therefore, it is recommended that patients provide several specimens from several consecutive stools and that each

stool be sampled at two sites. A single specimen obtained by digital rectal examination has questionable value and should not be considered adequate when screening for colorectal cancer. Typically, several days elapse between stool collection and testing it for blood. The sensitivity of a guaiac-based test is increased if the test slide is rehydrated with a few drops of water before performing the test. The best available evidence that FOBT is effective in preventing death caused by colorectal cancer is from a study with rehydrated tests on two samples from each of three consecutive stools in patients who followed a restricted diet prior to testing [21].

In a program of repeated screening (rather than a single test), the nonhydrated form of FOBT has a reported sensitivity for detecting cancer that ranges from 72 to 78%, a specificity of 98%, and a positive predictive value of 10–17%. Rehydrating the slides increases the sensitivity to 88–92% but decreases the specificity to 90–92%, and the positive predictive value to 2–6% [14, 22].

The FOBT for detecting colon cancer has been reported to be of lower specificity for patients over 60 years of age than for younger patients. This observation may be related to a higher prevalence of other etiologies for gastrointestinal hemorrhage with increasing age. On the other hand, there is no evidence that the value of FOBT is diminished in the very elderly. In fact, the positive predictive value of FOBT has been reported to increase with age from 1.6% for those under 60 years of age to 3.6% for those over 70 years of age [23].

Fecal Immunochemical Testing

Fecal immunochemical testing (FIT) was originally developed in the 1970s. It is a screening technique based on immunochemical detection of human globin in stool. This test sheds some of the false negative and false positives caused by the peroxidase-based stool testing influenced by dietary factors or medications. In addition it has a higher sensitivity for colonic blood due to the fact that upper gastrointestinal bleeding is subject to degradation by digestive enzymes and would not be detected in the stool sample by this technique. A large study comparing a high-sensitivity guaiac-based study with FIT found no clear superiority in performance. The one-time sensitivity FIT was evaluated in another study of over 20,000 patients scheduled for colonoscopy. This particular study found 5.6% of patients to be FIT positive with a sensitivity of 27.1% for advanced neoplasia and 65.8% for cancer. Another study evaluating the sensitivity of FIT in both asymptomatic and symptomatic patients scheduled for colonoscopy, the sensitivity and specificity was raised to 94.1 and 87.5% respectively when the sample number was increased to 3 and a hemoglobin threshold set to 75 ng/ml. Overall the specificity appears to be higher with FIT in

comparison to high-sensitivity FOBT; however, the FOBT has higher sensitivity for adenomas. The advantage to the FIT includes the lack of dietary restriction prior to testing, and with some assays, greater ease of sampling procedures in comparison to the FOBT [22].

sDNA

The most recent development in the stool assay arena is the stool DNA test. It is based on the principle that cancers and adenomas harbor known DNA alterations in the transformation of adenoma to carcinoma in colorectal cancer. This DNA is continuously shed in the stool, and remains stable in the feces for reliable detection. This tool relies on a multiple marker array targeting mutations in *K-ras*, APC, and p53, as well as markers of microsatellite instability and DNA integrity to assess for possible adenomatous or carcinomatous changes. Of note this test requires at least 30 g of stool for assay. Sensitivity has ranged from 52 to 91% and specificity from 93 to 97%. The majority of effect on sensitivity relates to DNA degradation after obtaining the specimen, usually during transport. When compared with low-sensitivity FOBT in the setting of colonoscopy, sDNA was found to have superior sensitivity for detecting cancer and high-grade dysplasia (40% vs. 14% for FOBT). However, since this is a relatively new modality and there are no programmatic studies to evaluate screening technique or frequency, no definitive recommendations can be offered at this time. It may prove a modality that could benefit from combination with high-sensitivity FOBT or FIT [22].

Sigmoidoscopy

Although supporting data from randomized trials are lacking, several case-control studies support the efficacy of screening sigmoidoscopy for reducing mortality due to colorectal cancer. As a screening method, sigmoidoscopy has three advantages over FOBT: (1) the bowel is directly visualized; (2) lesions can be biopsied during the procedure; and (3) it has high sensitivity and specificity for detecting polyps in the bowel examined. Its primary limitation is that only the rectum and distal colon are examined.

Patients usually do not require sedation or full bowel preparation for screening sigmoidoscopy. Although lesions are biopsied, full polypectomies are not routinely done, as cautery used for polypectomies can result in complications in colons subjected to less than full bowel preparation. Prophylactic antibiotics are given to patients at risk for developing endocarditis.

The performance of the flexible 60 cm sigmoidoscope is superior to that of the 25 cm rigid scope. With the flexible scope, a larger area of colon can be examined, the optics are better, and there is more comfort for both patient and examiner. Within the area of reach, nearly all cancers and all polyps >1 cm in diameter and 70–85% of smaller polyps are detected by flexible sigmoidoscopy. False-positive findings are rare, although many polyps identified prove to be nonadenomatous. The 60 cm scope, which reaches up to or beyond the proximal sigmoid colon in 80% of examinations, should be able to detect 40–60% of adenomatous polyps and cancers based on the known anatomic distribution of these lesions. The rigid scope would be able to detect only 20–30% of these lesions.

What constitutes a positive finding on screening sigmoidoscopy requiring full colonoscopy is somewhat controversial. Cancer or an adenomatous polyp >1 cm in diameter should be followed by colonoscopy. Polyps shown to be hyperplastic and normal mucosa do not require follow-up. It is not yet clear whether a small adenoma (<1 cm in diameter), especially if it is tubular and without high-grade dysplasia, needs follow-up. When an adenomatous polyp is found in the rectosigmoid, there is an approximately 33% probability that more proximally located adenomatous polyps are present. However, if the rectosigmoid adenoma is <1 cm in diameter, it is unlikely that adenomas >1 cm or with high-grade dysplasia will be found more proximally.

Barium Enema

Barium enema examination allows the entire colon and all but the most distal rectum to be evaluated, although there are no specific data that its use as a screening test is associated with a reduction in mortality from colorectal cancer. This test can be performed in two ways: as a single-contrast study using barium alone or as a double-contrast study, in which air is instilled into the colon after most of the barium is removed. With the single-contrast study lesions appear as filling defects, whereas with the double-contrast study lesions are outlined by the retained barium against a background of air. The double-contrast study has considerably more sensitivity and specificity than the single-contrast study and has generally replaced it, except in patients who are not able to tolerate the more complicated and uncomfortable study. The sensitivity of double-contrast barium enema has been reported as 50–80% for polyps <1 cm in diameter, 70–90% for polyps >1 cm in diameter, and 55–85% for TNM stage 1 and 2 cancers. False-negative results are related to inadequate visualization of segments of bowel, especially the sigmoid colon, and to errors in interpretation. False positives are the result of stool in the bowel and of nonneoplastic mucosal

irregularities. When a finding on double-contrast barium enema is interpreted as cancer, the false-positive rate is less than 1%; the rate ranges from 5 to 10% when the interpretation is a large polyp and 50% when it is a small polyp. Another limitation of the test is that 5–10% of studies are technically unsatisfactory, requiring another attempt at barium enema or colonoscopy.

Colonoscopy

Colonoscopy is the only screening technique that offers the potential to both detect and remove premalignant lesions throughout the colon and rectum. With respect to technical difficulty and the risk to the patient, it is more formidable than either sigmoidoscopy or barium enema. Colonoscopy is poorly tolerated without intravenous sedation. Because there is potential for the development of cardiorespiratory complications, elderly patients, particularly those with significant comorbidities, should undergo cardiorespiratory monitoring. As is the case for sigmoidoscopy, patients at risk for developing bacterial endocarditis should undergo appropriate antibiotic prophylaxis.

Sensitivity rates for colonoscopy are difficult to discern, as colonoscopy itself is often used as the gold standard for the presence or absence of lesions. However, studies in which colonoscopy is done prior to surgical resection for polyps and cancers suggest that colonoscopy misses 3% of such lesions. In comparison to barium enema, colonoscopy has

more sensitivity for detecting small polyps, but its ability to detect polyps >1 cm is equivalent. It is unclear which procedure causes less discomfort and is therefore associated with greater patient acceptability. Models of diagnostic strategies for patients with a positive screening FOBT have shown that barium enema and colonoscopy are associated with comparable cost-effectiveness [14].

A limitation of colonoscopy is that in only 80–95% of procedures the entire colon is visualized. The probability of reaching the proximal colon depends primarily on the skill of the examiner and the adequacy of the bowel preparation. If the entire colon cannot be visualized, another examination is required: another attempt at colonoscopy or a barium enema.

Computed Tomographic Colonoscopy

Computed tomographic colonoscopy (CTC) or virtual colonoscopy was introduced in the mid-1990s as a minimally invasive technique to visualize the colon for possible neoplasm. This technique generates both high-resolution 2D and 3D reconstructions of the large bowel allowing for both polyp detection and limited investigation of adjacent structures (Fig. 69.2). A recent meta-analysis of both screening and high-risk cohorts of a sensitivity and specificity of large versus small (>10 mm vs. 6–9 mm) polyps was 85–93% and 97% vs. 70–86% and 86–93%, respectively. The sensitivity of invasive CRC was 96% when compared with standard colonoscopy. The advantages of this technique are the lack

FIGURE 69.2 Example of computed tomographic colonoscopy or virtual colonoscopy image.

of sedation required and the speed of the test as well as the ability to immediately refer for colonoscopy for positive tests without requiring an additional bowel preparation. The disadvantages are the requirement of a second intervention for polypectomy/biopsy as well as the lack of reimbursement in some states. Furthermore, the radiation dose delivered with multiple studies for screening has not yet been evaluated in terms of independent risk. The perforation rate is as much as 22 times less than with standard colonoscopy (1 in 22,000 vs. 1 in 1–2000) [22]. Although this may be a promising modality, there is not enough data at this time to recommend it as a screening tool when compared with standard colonoscopy.

Digital Rectal Examination

A common practice is to screen for colorectal cancer by performing digital rectal examination, followed by a test for fecal occult blood if stool is present in the rectum. Based on the anatomic distribution of cancers, only 5–10% of lesions would be within reach of the examining finger. In addition, stool obtained from the digital rectal examination represents inadequate sampling and is associated with high false-negative rates. Digital rectal examination, by itself, is not an effective method of screening for colorectal cancer.

Screening Recommendations

Screening for colorectal cancer and adenomatous polyps should be offered to all men and women without special risk factors beginning at age 50. A positive screening test should be followed by a diagnostic evaluation. Five screening options have been proposed in guidelines defined by a multidisciplinary panel [14, 22, 24]. These guidelines have been endorsed by a wide range of organizations, including the

American Cancer Society, the American Gastroenterological Association, and the American Society of Colon and Rectal Surgeons; and they represent the current standard of care (Table 69.1).

1. *Yearly fecal occult blood screening.* Those with a positive test should undergo diagnostic evaluation with colonoscopy or double-contrast barium enema (with flexible sigmoidoscopy).
2. *Flexible sigmoidoscopy every 5 years.* If polyps >1 cm in diameter are found, colonoscopy should be done. Polyps <1 cm in diameter should be biopsied, and if adenomatous polyps or cancers are found, colonoscopy should be done. It is not clear whether patients with small tubular adenomas (<1 cm in diameter) should undergo colonoscopy.
3. *Combined fecal occult blood testing and flexible sigmoidoscopy.* The combination of these two methods theoretically compensates for some of the deficiencies of each. However, there are no good data proving that combining the two methods offers any advantage over either alone.
4. *Double-contrast barium enema every 5–10 years.* No data exist to support that this method reduces mortality due to colorectal cancer.
5. *Colonoscopy every 10 years.* No data exist to support that this method reduces mortality due to colorectal cancer.

When to Stop Screening

The recommendations for screening in elderly patients, however, may differ from those of younger patients. Given the more limited life expectancy and the potential for more comorbidities making elderly patients more vulnerable to the risks of screening procedures, the benefits may not outweigh the risks. A recent set of guidelines published by the US Preventative Services Task Force states that for individuals over age 75, the benefit of screening is questionable and for those over age 85 it is not recommended [25].

TABLE 69.1 Screening guidelines for colorectal cancer

Symptoms	Family history	Age to begin (years)	Evaluation
None	None	50	DRE; stool guaiac; colonoscopy: if negative repeat in 3–5 years, otherwise repeat in 1 year to ensure no new lesions
None	One or more FDR	40	As above
None	FAP	10	DRE; colonoscopy: repeat annually if polyps found or at 3 years if no polyps
None	HNPCC	Late teens	As for FAP
Present	None	25	DRE; stool guaiac; colonoscopy: if negative repeat in 3–5 years, otherwise repeat in 1 year to ensure no new lesions

DRE digital rectal examination, FDR first-degree relative, FAP familial adenomatous polyposis, HNPCC hereditary nonpolyposis colorectal carcinoma

Clinical Presentation

Symptoms of colorectal cancer are nonspecific and include abdominal pain, change in bowel movement patterns, and rectal bleeding (Table 69.2). In elderly patients, particularly, the presentation may be varied and insidious, with vague symptoms such as apathy and weight loss sometimes being the only clue to the existence of cancer. Unfortunately, the incidence of benign colonic diseases associated with such nonspecific symptoms is increased in the elderly, and there is a tendency to procrastinate when proceeding with an appropriate diagnostic evaluation in this patient population.

There is some correlation between the location of the cancer and its resulting symptoms. Lesions in the right colon are frequently associated with such symptoms as a dull, aching pain in the right lower quadrant and fatigue and dizziness, which are related to the iron-deficiency anemia of chronic blood loss. Colonic obstruction is rare with cancers of the right colon. Transverse colon cancer frequently manifests as signs of obstruction or pain in the mid-epigastrium. Lesions of the left colon are often associated with an alteration in bowel habits and a decrease in stool caliber, with these changes being related to the narrower lumen and the presence of more solid stool in the left colon. Overt bleeding and colonic obstruction occur more frequently with rectosigmoid cancers than they do with more proximal lesions. Low rectal cancer can be associated with the presence of tenesmus, urgency, and pain.

Signs of colorectal cancer include the presence of an abdominal or rectal mass or tenderness, anemia, and weight loss. Approximately 15% of colorectal cancers are first diagnosed in patients presenting with evidence of complete colonic obstruction. A smaller percentage of cancers present as colonic perforation, with most perforations occurring at the site of the tumor.

TABLE 69.2 Signs and symptoms of colorectal cancer

Fungating lesion

Left colon

Obstructing symptoms
Grossly bloody stool
Change in bowel habits
Circumferential lesion

Rectum

Tenesmus, perineal pain
Gross bleeding
Change in bowel habits
Palpable tumor

On occasion, signs and symptoms of metastatic disease are the first indication of the presence of colorectal cancer. Metastasis to the liver may manifest as jaundice and pruritus. Metastatic pulmonary disease may be seen on a chest radiograph in an otherwise asymptomatic patient. Signs of metastatic disease include the presence of ascites, hepatomegaly, and lymphadenopathy (in the supraclavicular and periumbilical areas, for example).

Treatment of Polyps

In general, sigmoidoscopy allows biopsy of polyps but not their complete removal. Full bowel preparation and colonoscopy are required for polypectomy. The current literature on the need for colonoscopy for small distal tubular adenomas found at sigmoidoscopy is controversial. Markowitz and Winawer [26], in a review of the management of colorectal polyps, proposed the following guidelines. If a small polyp (<1 cm in diameter) biopsied on sigmoidoscopy is an adenoma, colonoscopic polypectomy with examination of the entire colon should be performed to look for synchronous neoplastic lesions. Read et al. [27], in a prospective study of asymptomatic average-risk individuals, reported that 31% of patients with benign adenomas on flexible sigmoidoscopy were found to have a synchronous neoplasm, and 8% with adenomas >1 cm in diameter had invasive cancers. If the polyp is >1 cm on sigmoidoscopy, however, rather than biopsy the lesion, colonoscopic polypectomy with examination of the proximal colon for synchronous lesions should be performed. Finding a nonneoplastic polyp at sigmoidoscopy requires no further evaluation. Radiographic detection of a polyp warrants full colonoscopy to resect the polyp and to examine the entire colon for the presence of synchronous lesions.

Polyps seen on colonoscopy should be excised endoscopically, unless their configuration or size renders them too difficult to be removed endoscopically for technical reasons. For sessile polyps with invasive carcinoma, the incidence of lymph node metastasis is 15%, and the incidence of residual tumor after attempted endoscopic removal is 6%. A local recurrence rate of 21% can be anticipated if formal bowel resection is not done. For pedunculated lesions, polypectomy has the potential to be both diagnostic and therapeutic; although if invasive carcinoma is present in the polyp, further therapy is indicated. Invasive carcinoma in a pedunculated polyp implies invasion of the cancer through the muscularis mucosa. The incidence of lymph node metastases in this circumstance ranges from 8 to 16%. Tumor features predictive of nodal metastasis are the presence of positive or close margins of resection, invasion of the neck or stalk of the polyp, poor differentiation status, and the presence of vascular and lymphatic invasion.

Rectal polyps can be challenging. Unless invasion is proven, transanal sphincter-sparing excision is the procedure of choice.

Treatment of Colorectal Cancer

Colorectal Surgery in the Elderly

Most reported series of operations for colorectal cancer document a higher postoperative mortality rate in the elderly. This age-related increase in postoperative mortality rate is likely to be related to two factors: (1) the higher prevalence of coexisting illnesses in elderly patients; and (2) the higher incidence of emergency operations in elderly patients, as they are more likely to present with complications of colorectal cancer, such as intestinal obstruction and perforation. In one study, the subgroup of patients who were 70 years of age or older, who were without concomitant pulmonary, renal, hemopoietic, or cardiac disease had a postoperative mortality rate of 4% following colon surgery; those younger than age 70 had a postoperative mortality rate of 3.2% [28]. In another review of 357 patients over the age of 50 undergoing colon resection, the postoperative mortality rate was directly correlated with the number of preexisting illnesses; age was not an independent risk factor for postoperative mortality. The postoperative mortality rate for all studies was 4.8%. For patients with no or one concomitant disease, the postoperative mortality rate for patients younger than age 70 was 0%, and it was 1.5% for those older than age 70 [29]. In this study, for all age groups mortality for elective colon surgery was 3.4%, but it was 18% for emergency surgery. In another report of 101 colon resections in patients 70 years of age or older, the postoperative mortality rate was 5%, but no deaths occurred following elective procedures [30].

It appears, as demonstrated in contemporary series, that elective colon resection can be performed safely in the elderly and that age is an independent risk factor for postoperative mortality following surgery for colorectal cancer. Existing data also suggest that early detection of colorectal cancer, allowing elective rather than emergent surgery, with careful preoperative assessment and optimization of organ system function, should be the goal in elderly patients.

When cancer stage is taken into account, the long-term survival rates following curative resection for colorectal cancer are comparable in elderly and younger patients. In one reported series, 3-year survival following surgery for colorectal cancer in patients older than 80 years was equivalent to that for patients under age 80, although increased age was associated with longer hospitalization and higher hospital costs [31]. Although there are few data regarding quality of

life issues following surgery for colorectal cancer in the elderly, in one report of patients older than 80 years, 82% of those who were admitted to the hospital from home for colon surgery were able to resume their normal level of activity postoperatively [1–3, 32]. When surgical treatment of colorectal cancer can potentially be most influenced by a patient's age, therefore, is when the patients comorbidities makes them unable to withstand aggressive surgical management and/or their life expectancy is not expected to be long enough that they will develop significant symptoms from their tumor. Trade-offs and compromises in surgical treatment options are discussed further below within each specific treatment.

Preoperative Evaluation

Prior to surgery, elderly patients should undergo careful evaluation to diagnose and treat preexisting medical illnesses and to detect the presence of synchronous lesions and metastatic disease. The operative approach to be taken depends on the results of the preoperative evaluation.

Once a cancer in the colon or rectum has been diagnosed, the incidence of synchronous cancer is 5%, and the incidence of a synchronous adenomatous polyp is 28%. Preoperative colonoscopy or barium enema to detect such lesions is the standard of care. In general, colonoscopy is preferable. Barium enema or virtual colonoscopy can be performed if the cancer is nearly obstructing and prevents proximal passage of a colonoscope.

The hematocrit should be checked because of the possibility of anemia, which might require correction prior to surgery. Liver function tests should be checked, as they may indicate the presence of metastatic disease in the liver. Tumor markers such as carcinoembryonic antigen (CEA), CA 19-9, and CA-50 have been used for patients with colon cancer. Of these, CEA has had the most clinical application. Its preoperative concentration correlates well with tumor stage, as well as postoperative survival and recurrence rates. Elevated CEA concentrations are not specific for colorectal cancer, however. The CEA concentration in normal individuals ranges from 0 to 2.5 ng/ml. Benign elevations in CEA concentration are usually less than 10 ng/ml and are reversible. Known benign conditions associated with elevations in CEA concentration include biliary obstruction, hepatocellular dysfunction, cigarette smoking, bronchitis, gastric ulcer, gastritis, inflammatory bowel disease, diverticulitis, adenomatous polyps, renal disease, and benign prostatic hyperplasia. CEA concentration can also be elevated with noncolorectal cancers.

A preoperative chest radiograph is obtained to detect the presence of lung metastases and cardiopulmonary disease.

For colon cancers, a preoperative computed tomography (CT) scan is not necessary as information that would change the operative plan is rarely found, although in some practice settings it is obtained routinely. It would be indicated in patients with abnormal liver function tests or who have a palpable mass on physical examination, potentially indicating that the patient had a burden of metastatic disease or technically unresectable disease that would signal a nonoperative approach to their diagnosis.

Rectal cancers should undergo a somewhat different preoperative evaluation from cancers of the colon to clarify curative versus palliative intent, to determine whether preoperative neoadjuvant therapies might be indicated, or if a more conservative surgical approach can be used. A careful digital rectal examination should be done to evaluate tumor size, fixation, and ulceration and to evaluate possible extension of the cancer to pararectal lymph nodes or adjacent organs. A woman should have a complete pelvic examination to determine if the tumor has invaded the vagina or has spread to the ovaries. Rigid sigmoidoscopy is done to assess size, ulceration, and distance of the distal edge of the tumor to the anal verge. Flexible instruments are unreliable for assessing distance. CT scanning is indicated in patients with rectal cancer to evaluate pelvic extension and to look for distant metastases. Transrectal ultrasound or endoanal MRI examinations are the best attempts to accurately determine the depth of cancer invasion (T stage) and nodal involvement (N stage) helping to determine which patients are candidates for preoperative chemoradiation to allow for more sphincter-sparing operations and reduce local recurrence of their disease [33].

Preoperative Bowel Preparation

In the past, it had been standard to perform a mechanical bowel preparation prior to surgical intervention under the premise that it would reduce the risk of anastomotic leak and fecal soilage resulting in abscess or surgical site infection rates by reducing bacterial load. This has not been borne out in statistical analyses [34]. Moreover, there have been case reports, including an FDA alert in May 2006, regarding sodium phosphate products in particular. The case reports have described renal failure, in particular, acute phosphate nephropathy after oral sodium phosphate, even in patients with normal creatinine clearance. A recent consensus statement was published by the combined task force of ASCRS, ASGE, and SAGES outlining the evidence for various bowel preparations and their efficacy specifically for colonoscopy where preparation is necessary for adequate screening. In an addendum, they outlined particular groups at risk with sodium phosphate preparations. In particular, the elderly independent of renal function were considered at increased risk of acute renal failure with the oral preparation [35].

Statistically significant changes in serum Na, K, and PO_4 were seen; however, all within the range of normal. In addition, a statistically significant correlation between rise in serum phosphate and age was found in patients with normal creatinine clearance [36]. Due to this increasing volume of evidence, the author's institution has phased out phosphosoda preparations in general and has moved away from aggressive preoperative mechanical bowel preparation for colorectal surgery.

Surgical Technique

Colon Cancer

Surgery with curative intent is possible in approximately 85% of patients diagnosed with colorectal cancer. The goal of curative resection is en bloc excision of the primary tumor along with its regional lymphatic system. Prophylactic extensive central or retroperitoneal lymph node dissections are associated with increased operative morbidity but no survival advantage. Tumor-free margins proximal and distal to the lesion along the length of the intestine are most often easily achievable for colon cancer, as pathology studies have shown that longitudinal spread of the disease rarely exceeds 4 cm. Local extension into organs contiguous with the large intestine is found in approximately 10% of cases. Excision with tumor-free margins is still the goal in such cases, as 67% 5-year survival has been reported for patients undergoing curative resection of such lesions.

Traditional resections for colon cancer are based on the pattern of lymphatic drainage. As the lymphatics course together with the major vascular supply of the colon, resection of lymphatic channels draining a particular colonic segment necessitates devascularization of that segment. This approach sometimes requires resection of segments of colon beyond what longitudinal margins alone would require.

Cancers of the cecum and ascending colon are treated with a right hemicolectomy. The ileocolic artery, right colic artery, and right branch of the middle colic artery are ligated. This requires resection of the distal 5–8 cm of the ileum, cecum, ascending colon, and proximal transverse colon.

For cancers of the transverse colon, transverse colectomy with ligation of the middle colic artery and anastomosis between the ascending colon and the descending colon can be done, although there may be tension at the anastomosis, even after full mobilization of the colon. Cancers of the proximal and mid-transverse colon can be resected with an extended right hemicolectomy, with ligation of the ileocolic artery, right colic artery, and middle colic artery. The terminal ileum, cecum, ascending colon, hepatic flexure, transverse colon, and splenic flexure are resected; and an anastomosis between the ileum and the descending colon is performed.

Cancers of the splenic flexure and descending colon are treated by left hemicolectomy. The left colic artery is ligated, the splenic flexure and the descending colon are resected, and an anastomosis is created between the transverse colon and sigmoid colon.

A sigmoid colectomy is performed for sigmoid cancers. The inferior mesenteric artery is ligated distal to the origin of the left colic artery, and an anastomosis is created between the descending colon and the rectum.

Rectal Cancer

Surgical options for curable rectal cancer are summarized in Table 69.3. The surgical approach to rectal cancer is different from that for colon cancer, largely because of anatomic factors. Wide excision of the cancer and surrounding structures, possible in colon cancer, is difficult for rectal cancer, as the rectum resides within the confines of the pelvis. The proximity of the anal sphincter mechanism, organs of the urogenital tract, and enervation of the urogenital system pose significant challenges.

The desired distal margin in rectal cancer excisions has been the focus of much interest. A 5 cm margin of normal tissue distal to the grossly visible lesion was once the standard of care. This concept was based on observations by Dukes, who failed to detect submucosal or lymphatic spread more than 4.5 cm distal to the tumor. Unfortunately, tumor differentiation status was not considered in his study. More recent pathology studies have shown that for well-differentiated and moderately well-differentiated rectal cancers, a 2 cm distal margin is adequate. In recent years, the importance of margins lateral to the rectum has received greater attention. Clearance of these margins can be difficult to achieve, a factor that may account for the high local recurrence rates observed for rectal cancer.

Cancers of the upper rectum are treated by anterior resection, during which the proximal rectum is resected through an

abdominal incision, and intestinal continuity is reestablished by colorectal anastomosis. Resection of the rectosigmoid colon performed proximal to the pelvic peritoneal reflection is known as a high anterior resection, whereas an operation in which it is necessary to open the pelvic peritoneum is known as a low anterior resection. Typically, the sigmoid colon is resected in continuity with the rectum, as the inferior mesenteric artery has been divided. The more generous collateral circulation to the descending colon provides a safer anastomosis.

Cancers of the lower rectum (<4 cm from the anorectal junction) have traditionally been treated by abdominoperineal resection (APR). Patients should understand that a permanent colostomy, which is integral to APR, does not signify a hopelessly advanced cancer. Other surgical options for low rectal cancers include a low anterior resection with coloanal anastomosis or local excision of the tumor, usually via a transanal approach. The option for these procedures is based on the preoperative stage. Elderly patients, however, in whom a curative goal is being superseded by a limited life expectancy might undergo a local procedure (see below) even if it is of palliative rather than curative intent as local procedures are much better tolerated by patients.

Cancers of the middle third of the rectum require the most surgical judgment to determine whether a sphincter-sparing procedure can be done. Clearly, with the advent of stapling devices and an understanding that a distal margin of 2 cm is adequate, sphincter-sparing operations are more prevalent. Although the distance from the distal edge of the tumor to the anal verge is clinically the most often used criterion for determining whether a patient is a candidate for low anterior resection, other factors also play a role. These factors include body habitus, tumor size, mobility, histologic grade, the presence of metastatic disease, the preoperative continence status, the patient's willingness to accept a stoma and his or her ability to care for a stoma, and the general medical condition of the patient. Elderly patients may have compromised sphincter function and might experience poor bowel control following a low coloanal anastomosis. Careful consideration of this possibility is needed when deciding whether to recommend such an anastomosis over a permanent stoma. Furthermore, in those patients in whom a permanent stoma is determined to provide the best bowel control, the bowel distal to the tumor can be stapled off and left in place as a short rectal stump to avoid the lengthy perineal dissection and morbid perineal wound found in a traditional APR.

Total Mesorectal Excision

Given the probable contribution of inadequate lateral clearance of rectal cancers to high local recurrence rates, modifications of the traditional surgical techniques have been proposed. The technique of total mesorectal excision (TME) has been

TABLE 69.3 Treatment options for curable rectal cancer

advocated initially by Heald [37]. With TME, the envelope of lymphovascular fatty tissue surrounding the rectum and mesorectum are completely excised under direct vision. The avascular plane between the mesorectum and the surrounding tissues is developed using sharp dissection. The excised specimen includes the whole posterior, distal, and lateral mesorectum; the inferior hypogastric plexuses are preserved. Anteriorly, Denonvilliers' fascia is included as part of the excised specimen.

Using TME, local recurrence rates of 4–8% have been reported [37, 38]. These rates are significantly lower than those for historical controls, for whom recurrence rates range from 20 to 45%. However, TME has been associated with a high anastomotic leak rate ($\geq 17\%$), leading some to advocate routine proximal colonic diversion following the procedure. Although many have proposed TME as the standard of care, its overall role in the management of patients with rectal cancer is not yet clear, particularly given the improvements in neoadjuvant therapies [39].

Local Therapies

Although radical surgery is the treatment of choice for most patients, local treatment is a satisfactory alternative under defined conditions. Local resection should be considered with curative intent for early stage rectal cancers that are too distal to allow a restorative resection and as a palliative measure in patients with metastatic disease or comorbid medical conditions who may not be able to tolerate the stress of general anesthesia and a major abdominal operation.

Local techniques include excision, ablation, and irradiation. Local excision can be performed through transanal, transsacral, or transsphincteric approaches, with the transanal approach being used most frequently [40]. Transanal endoscopic microsurgery (TEMS) has allowed local excision to be performed in slightly more proximal lesions. In patients who are particularly poor surgical candidates, transanal electrocoagulation, possibly in multiple stages, offers effective palliation [41].

For curative resections, the success of local excision depends on stringent selection criteria, as described by Ogunbiyi and Fleshman [42] (Table 69.4). Transrectal ultrasonography or endoanal magnetic resonance imaging should be performed to stage the lesions preoperatively. Candidate

lesions should be small (<3 cm in diameter), mobile, confined to the rectal wall (T1 or T2), without evidence of regional or distant metastasis (N0 and M0), exophytic, and well or moderately well differentiated, without lymphovascular or perineural invasion. Graham et al. reported a 5-year cancer-specific survival of 89% in their series of local excisions for rectal cancer using such selection criteria [43]. The local recurrence in this series was 19%.

Special Cases

Synchronous Lesions

Total abdominal colectomy with an ileal to rectal anastomosis may be performed when synchronous lesions or multiple adenomatous polyps are present. This operation is also recommended for patients with HNPCC. Although this operation can be associated with initial postoperative diarrhea, intestinal adaptation allows good long-term function. Total proctocolectomy with mucosal proctectomy and ileoanal anastomosis is done for younger patients with FAP; there is less experience with this operation in the elderly.

Colonic Obstruction

Complete obstruction of the colon or rectum by an obstructing carcinoma is a surgical emergency. Obstructing cancer of the right or transverse colon can be treated by resection and anastomosis without proximal diversion, but treatment of left-sided obstruction is more controversial. The preferred approaches are resection without anastomosis, resection and anastomosis with a proximal diverting ileostomy, or subtotal colectomy with ileorectal anastomosis. In the presence of an extensively dilated proximal colon and unstable patient, a temporary proximal decompressing stoma may be appropriate. The preliminary experience with colonic stenting in patients with advanced tumors presenting with obstruction has been reported to be promising [39]. Such stents, although not long-term solutions, can be used for palliation or for recanalization to allow bowel preparation and safer elective surgery.

Perforated Colon Carcinoma

The surgical approach is resection of the perforated segment of the bowel, together with involved adjacent structures. An anastomosis in a contaminated field should be protected by a proximal diverting stoma. Although the prognosis is poor, a curative operation should be attempted.

TABLE 69.4 Criteria for local management of rectal cancer

Diameter <3 cm
Mobile tumor
Exophytic
Confined to rectal wall (maximum T2) on transrectal ultrasonography
No evidence of extrarenal spread or distant metastases on computed tomography
Well-differentiated or moderately differentiated histology
No lymphovascular or perineural invasion

Laparoscopy for Colorectal Cancer

Laparoscopic surgery has integrated into most realms of surgery; however, its progress into oncologic procedures has been slower and more heavily scrutinized than in other arenas. To answer the question of the efficacy of laparoscopic approach to colorectal cancer surgery, a large multicenter trial was established to prospectively evaluate outcomes. The Clinical Outcomes of Surgical Therapy (COST) study group designed a multicenter, randomized, prospective trial to specifically answer the question of the appropriateness of laparoscopy in colorectal surgery. Their most recent update from 2007 includes follow-up data where they found no statistical difference in 5-year overall or disease-free survival overall, or site-specific recurrence between laparoscopic and open colorectal surgery. Of note this study was restricted to cancer of the right/left or sigmoid colon, and excluded those with locally (T4) or systemically (stage IV) advanced disease. This data provides needed level 1 evidence that laparoscopic colon surgery is equivalent to the standard technique with no higher incidence of tumor seeding than with an open procedure [44]. A recent Canadian study reviewed their center experience with laparoscopic resection for colon cancer between the elderly (>74 years) and their younger counterparts (50–74 years). In their experience, age was not an independence factor predicting poorer outcome after laparoscopy. Furthermore, they found no difference in conversion rate in comparison to the younger cohort. However, they found as others that the elderly were likely to present with more advanced stage of cancer, more comorbidities which would affect their outcome as it would for a younger patient. They concluded that laparoscopy should be considered in the elderly. They were not able to show decreased length of stay with laparoscopy versus open in the elderly but they did find no significant difference based on age alone [45].

Adjuvant Therapies

Adjuvant therapies are designed to eradicate micrometastases present at the time of surgery, with the goal of reducing local recurrence rates and prolonging survival. Several chemotherapy regimens based on 5-fluorouracil (5-FU) have been shown to prolong survival in selected groups of patients following curative resection for colon cancer. For example, the American National Cancer Institute Intergroup Study reported a 41% reduction in tumor recurrence and a 33% reduction in cancer-related mortality during a 3-year observation period in node-positive patients treated with levamisole and 5-FU [46]. Recent advances with more complex regimens adding chemotherapeutic agents in combination potentially along with monoclonal antibodies targeting specific tumor antigens has led to improvements in survival for stage III patients [47].

Ongoing trials are designed to identify chemotherapeutic agents with more antitumor efficacy and to define which patients would benefit from such treatments. Although standard treatment for colon cancer includes adjuvant chemotherapy for patients with stage III disease but not for patients with stage II tumors (who have no lymph node metastases), 20% of patients with stage II tumors die of recurrent disease. The challenge is to identify the subset of patients with stage II disease who would benefit from adjuvant chemotherapy. In a recent report, 192 lymph nodes from 26 consecutive patients with stage II colorectal cancer were examined using a CEA-specific nested reverse-transcriptase polymerase chain reaction (RT-PCR) to detect the presence of micrometastases not otherwise identified by routine histologic methods. Micrometastases were detected by PCR in one or more lymph nodes from 14 of 26 patients (54%). The 5-year survival rate was 36% in this group, but it was 75% in the group without micrometastases. The groups were similar with respect to age, sex, tumor location, tumor differentiation, and tumor size [48].

The proper use of adjuvant chemotherapy in elderly patients raises several issues. Patients are often seen as having more limited life expectancies and thus less potential advantages of adjuvant therapy and more vulnerable to toxicity. Studies have documented that elderly patients are receiving chemotherapy less often than their younger counterparts [49]. Toxicities, aside from myelosuppression and fatigue, however, have not been demonstrated to be more severe in elderly patients (same reference as prior). In addition, many studies do show a benefit from chemotherapy in the small groups of elderly patients that have been studied that age alone has not been recommended to be a criterion on which adjuvant chemotherapy is limited. It is rather the patients' life expectancy and comorbidities that are most helpful to assess when making this determination.

Adjuvant radiation therapy is rarely used following curative resection of colon cancers, as local recurrence rates are low and adjacent structures (e.g., small intestine) are sensitive to radiation-induced toxicity. For rectal cancer, however, the reported local recurrence rates are usually 30–35% for stage II disease and 40–60% for stage III disease. The use of adjuvant radiation therapy has clearly been shown to be associated with a reduction in local recurrence rates [50–52]. Postoperative adjuvant radiation therapy and chemotherapy for transmural and node-positive rectal cancer is the current standard of care. However, the optimal timing of adjuvant therapy for rectal cancer remains controversial.

The advantage of postoperative radiotherapy is that it allows patient selection based on surgical and histopathologic findings. Preoperative radiation therapy protocols may include patients who do not need such adjuvant treatments, given the limitations of currently available imaging studies. However, preoperative radiation therapy has the potential to downstage tumors and allows sphincter-sparing surgery in patients who otherwise might have required abdominoperineal resection.

At least ten modern randomized trials of preoperative radiation therapy for resectable rectal cancer have been reported. In five reports, the authors found a significant reduction in the rate of local recurrence. In some studies, a significant improvement in survival, as determined in subgroup analyses, was reported. In only one trial, a significant survival advantage for the whole group of treated patients was reported [53]. In this trial, done in Sweden, 1,168 patients received either a short course (five fractions over 1 week) of radiation therapy preoperatively combined with surgery or surgery alone. Irradiation was not associated with an increase in postoperative mortality. The local recurrence rate was 11% in the group who underwent irradiation and 27% in the group who were subjected to surgery alone. The difference in local recurrence rate was statistically significant for lesions of all stages. The overall 5-year survival rate was 58% in the group who received radiation and 48% in the surgery-alone group ($p=0.004$).

The Swedish trial has been criticized, as more than 100 surgeons at 70 hospitals participated, with each surgeon, on average, performing fewer than four operations per year [53]. The local recurrence rate for stage I cancers in the trial (4% after irradiation and 12% after surgery alone) was higher than is typically reported, and radiation delivered all in 5 days rather than 4–6 weeks is not the protocol used most often in the USA. This study also did not address the role of preoperative irradiation in combination with preoperative chemotherapy. Additional studies are required to define the optimal adjuvant therapy regimens for rectal cancer.

Postoperative Surveillance

There are two goals of postoperative surveillance: (1) to increase the detection of recurrent carcinoma at a potentially curable stage and (2) to detect metachronous lesions. Recurrent disease following resection for colorectal cancer, even at distant sites, is potentially treatable. Hepatic resection for metastatic lesions is safe and appears to prolong survival in selected patients. In a report of 128 patients over the age of 70 undergoing major hepatic resections for colorectal metastasis, those over 80 years of age had perioperative outcomes and 5-year survival rates equivalent to those of younger patients. Hepatic resection for colorectal metastases with clear margins of resection is associated with a 5-year survival of 25–48% and mean survival of 20–40 months. The lung is the second most common site of metastases from colorectal cancers. In selected patients, complete resection of pulmonary metastases is associated with a 5-year survival of 20–44%.

The best surveillance strategies remain to be determined. Postoperative surveillance following surgery for colorectal cancer is highly variable in clinical practice. In one report,

the number of office visits during the first 5 years ranged from 6 to 18, CEA measurements ranged from 0 to 44, liver ultrasound examinations ranged from 0 to 10, and sigmoidoscopy ranged from 0 to 13 [54].

Traditional surveillance protocols have included periodic history and physical examination, FOBT, complete blood count, liver function tests, tumor marker sampling, colonoscopy, and chest radiography. Surveillance tests are generally performed more frequently during the initial postoperative period, as 80–90% of all recurrences become evident during the first 2–3 years after surgery. One standard textbook of surgery has recommended that the history, physical examination, FOBT, and blood studies be obtained every 3 months during the first 3 years and every 6 months for an additional 2 years. Tumor markers are measured every 8 weeks by some investigators and monthly by others for 3 years and then every 3 months for another 2 years. Traditionally, colonoscopy has been done 6–12 months after resection, at yearly intervals for an additional 2 years, and at less frequent intervals thereafter.

In another recent report, the efficacy of a surveillance strategy using the history, physical examination, liver function tests, CEA assay, and colonoscopy 5 years postoperatively is as good as a more intensive strategy using yearly colonoscopy, CT, and chest radiography [55]. Survival rates were equivalent, regardless of the surveillance strategy used.

In guidelines recently published by a multidisciplinary panel, patients in whom large (>1 cm in diameter) or multiple adenomatous polyps have been removed should have an examination of the entire colon 3 years after the initial examination. If the first follow-up is normal or if only a single, small, tubular adenoma is found, the next examination can be at 5 years.

Patients with a colorectal cancer who has been resected with curative intent (but who did not undergo complete adequate colonoscopic examination preoperatively) should have a complete examination of the colon within 1 year after resection. If this or a complete preoperative examination is normal, subsequent examination should be offered after 3 years and then, if normal, every 5 years [56]. As with original cancers, subsequent cancers are preceded by adenomatous polyps that occur with increased frequency. There is no evidence to suggest that these polyps progress to cancer at a different rate from those in average-risk people.

Chapter 70

Abdominal Wall Hernia in the Elderly

Catherine Straub and Leigh Neumayer

CASE STUDY: PART 1

The following case study, woven throughout the chapter, highlights the nuances and difficulties that inguinal hernias present in the elderly.

A 70-year-old male presented to the General Surgery clinic at the VA Hospital with complaints of a new bulge in his right groin. He first noticed the bulge 2 months ago after moving heavy boxes into a new home. Though initially painful it has not bothered him in weeks. He has not had any symptoms of obstruction. His past medical history is significant for well-controlled hypertension and a 30-pack-year smoking history. He is not enthusiastic about surgery and wants to know if he truly needs it.

Abdominal wall hernia repair is the most common surgical procedure in the USA. More than 1,000,000 herniorrhaphies are performed annually. Of these 750,000 are inguinal, 166,000 are umbilical, 97,000 are incisional, and 25,000 are femoral [1]. The incidence of groin hernias, in men over age 65 is approximately 13 per 1,000 population [2]. The incidence in women is 12–25% that of men. In a British study of more than 30,000 inguinal hernia repairs, 27% were in an elderly population; 85.5% of repairs on patients aged 65 or older were elective, and the remaining 14.5% were classified as emergency procedures [3]. Since the majority of all hernias are inguinal or femoral, the focus of this chapter will be on the preoperative evaluation, repair options and complications of groin hernias. Incisional, umbilical, and other hernias will be discussed separately at the end of the chapter.

Inguinal Hernias

The inguinal and femoral canals are anatomically one of the most confusing areas of the human body (Fig. 70.1). The inguinal canal is bordered anteriorly by the external oblique fascia and posteriorly, also called the floor of the canal, by the transversalis fascia. The superior border is the transverses abdominus and the inferior border is the inguinal ligament, which is itself the inferior edge of the external oblique muscle. The spermatic cord in males or round ligament in females, courses through the inguinal canal from deep to superficial inguinal rings. The spermatic cord itself is composed of cremasteric muscle, pampiniform plexus, testicular artery, genital branch of the genitofemoral nerve, ductus deferens, cremasteric artery, lymphatics, and processus vaginalis.

An important concept in groin anatomy is the myopectineal orifice (Fig. 70.2). Through this anatomic opening, structures traverse from the pelvis to the leg. The spermatic cord and the femoral vessels pass through this orifice anterior and deep to the inguinal ligament, respectively. The myopectineal orifice can further be divided into three triangles – the medial, lateral, and femoral [4]. The medial and lateral triangles are separated from the femoral triangle by the inguinal ligament. The majority of groin hernias in older individuals occur through a weakening in the floor of the medial triangle. The majority of recurrences occur through the lateral triangle when it is not dealt with appropriately during the primary operation [5]. Accordingly, femoral hernias occur through the femoral triangle, more specifically through the empty space of the femoral canal medial to the femoral vessels.

Inguinal hernias are divided into two types: direct and indirect. Indirect hernias pass through the deep inguinal ring, lie anterior and medial to the vas deferens within the spermatic cord, and descend through the inguinal canal to the scrotum. These are more commonly congenital and arise from a patent processus vaginalis. Direct hernias pass directly through the floor of the inguinal canal and point anteriorly. This area in the floor of the canal is referred to as Hesselbach's triangle and is bordered by the lateral border of the rectus abdominis muscle, the inferior epigastric vessels and the

inguinal ligament. These are acquired hernias that are due to a weakness of the inguinal floor. A pantaloon hernia has both a direct and indirect component. Femoral hernias are a variation of direct hernias in which the inguinal ligament prevents

the sac from protruding through the inguinal floor. Instead, the sac passes through the femoral canal [6].

Inguinal hernias in elderly persons present very specific challenges. For example, they are frequently long-standing. Many have been present for 10–20 years, although some may have occurred as long as 50–60 years prior to presentation for repair [7–9]. As a result of the chronic nature of these hernias, the surrounding normal anatomic architecture is disrupted and there is loss of appropriate tissue planes to facilitate repair. Furthermore, with age comes the anticipated loss of muscle mass and tissue strength, making an anatomic repair more difficult. By the age of 80 up to 40% of muscle mass may be lost, with a proportional increase in body fat [10]. Increased comorbidities in this age group can make elective repair challenging, but operative morbidity and mortality is still remarkably low. Prolonged neglect, however, can result in a high incidence of preoperative complications, such as bowel obstruction, incarceration, and strangulation. These conditions frequently necessitate emergency treatment. In a Swedish study, patients undergoing emergent operation for inguinal hernias were on average 12 years older than those undergoing elective repair (70 vs. 58 years old) [11]. However, new data suggest that watchful waiting is a viable option in this population [12]. There are also new and emerging techniques for hernia repair, including laparoscopic and the use of biologics, that may be of particular interest to this demographic. These issues will be discussed in more detail later in the chapter.

Etiology and Distribution

The etiology of abdominal wall hernias differs somewhat in the elderly population. Indirect inguinal hernias, which are often congenital, comprise 90% of the hernias in young men, account for only 50–60% of hernias in older men. The incidence of direct hernias increase to 35% in men over age 65 [8]. Furthermore, the incidence of sliding hernias also increases from 0.5% during the third decade of life to as much as 13% during the sixth to eighth decades [13]. In youth indirect hernias are repaired by a simple herniotomy, the Marcy repair; however, indirect hernias in the adult population treated this way have a significant rate of recurrence indicating additional factors are present. Studies have shown that the presence of a persistent processus vaginalis does not change with age – roughly 20% [14]. Autopsy studies have shown that despite this high number, a very low proportion of patients suffered from a hernia in their life [15]. In addition, increased intra-abdominal pressure from such activities as coughing and straining put tremendous forces on the abdominal wall where there are natural weaknesses such as the internal inguinal ring and the transversalis fascia. Given the high proportion of patent processus

vaginalises and the physiologic necessity of increased intra-abdominal pressure, more patients suffer from inguinal hernias. Abrahamson describes a mechanism that may explain why this is not so. The “shutter mechanism” explains that when intra-abdominal pressure increases the muscles of the abdominal wall contract and the fibers of the aponeuroses within the inguinal region shorten. This essentially tightens around physiologic weaknesses such as the inguinal ring and the myopectineal orifice [16].

Acquired hernias are more common with increasing age and are often associated with other physiologic changes or disease processes. In most cases the pathophysiologic mechanism of an acquired hernia is a structural inadequacy of the inguinal floor, which manifests as a direct inguinal hernia. A recent study compared the structure of the rectus sheath in patients undergoing inguinal hernia repair and those undergoing appendectomy. There was a significant difference in the alignment and quality of collagen and elastic fibers. In those with inguinal hernias there was increased disorganization of collagen fibrils, thinning of elastic fibrils, and generalized replacement with ground matter [17]. A similar study showed that these changes were present in the transversalis fascia of both the herniated side as well as the nonherniated side [18].

The inguinal floor may therefore be weakened by any factors that interfere with normal collagen and elastin production. These include congenital connective tissue disorders such as Marfan and Ehler–Danlos Syndromes, as well as metabolic defects in collagen formation. Cigarette smoking also plays a significant role in hernia formation. The same proteases and elastases found in the lungs of smokers that lead to emphysema are also found in their serum and can bring about the destruction of elastin and collagen in other tissues. Systemic illnesses with an enhanced leukocyte response can also lead to the release of proteases and antioxidants having a similar effect [16, 18, 19].

Other factors associated with groin hernia formation involve conditions that lead to chronically increased intra-abdominal pressure, such as long-standing constipation and straining, bladder outlet obstruction, chronic cough, obesity, and kyphoscoliosis. In the elderly patient it is not uncommon for several of these factors to be present simultaneously. Occasionally, this confluence of factors contributes to the development of a giant hernia or one with a large scrotal component. These hernias can become extremely large and may contain a significant portion of the abdominal viscera. When forced reduction of the viscera into the contracted abdominal cavity is attempted, severe respiratory compromise due to increased intra-abdominal pressure and decreased diaphragmatic excursion may occur.

Approximately 15–30% of all herniorrhaphies in the elderly are performed on an emergent basis as a result of incarceration. Overall, 50–60% are indirect and 17–25% are femoral. When separated by gender, 73% of incarcerated hernias in men are

indirect and 15% are femoral, whereas femoral hernias account for 50% of incarcerations in women [7, 20, 21]. Although rare, once strangulation has occurred, the hernia changes from a simple mechanical problem to a complex life-threatening systemic illness, and the repair changes from correction of a simple mechanical defect to reversal of a major abdominal catastrophe.

Diagnosis

In most cases, the diagnosis of inguinal hernia in the elderly is clear. More than 70% of patients with groin hernias complain of a groin or scrotal mass and pain in the inguinal region. The pain may wax and wane if the hernia is reducible. In many cases the patient has been aware of, or diagnosed with, a hernia for many years. Symptomatic control is often achieved at the expense of physical activity. Trusses have been historically used to palliate the symptoms of a hernia; however, recent studies have shown that they are infrequently worn, uncomfortable, improperly fitted, and under the best circumstances only provide appropriate relief in 31% of patients [22].

The presence of a femoral hernia, however, is more difficult to recognize. Typically, poorly localized pain is present in the groin area without an obvious, visible bulge. Unfortunately, because of the subtle findings, femoral hernias are frequently not diagnosed until they incarcerate. In 1 review of 83 femoral hernias over 40% were repaired emergently for incarceration [23].

Historic factors that contribute to the development of inguinal hernias should always be elicited. Respiratory symptoms with chronic cough, chronic constipation, and symptoms of bladder outlet obstruction are most prevalent in an older population.

Examination for the presence of groin hernias should be part of the standard physical exam. Patients should be examined in the erect position, as a reducible hernia is sometimes more difficult to appreciate in the supine position. The only visible abnormality may be groin asymmetry. Indirect inguinal hernias appear as a small mass in the region of the deep ring, midway between the pubic tubercle and the anterior superior iliac spine. Direct hernias appear more medially, although this distinction is not always clear. Invaginating the skin of the scrotum and introducing the examining finger along the spermatic cord structures into the external inguinal ring is usually necessary for accurate diagnosis. Prolonged standing or increasing intra-abdominal pressure by coughing or with Valsalva maneuver causes the sac and its contents to descend toward the examining finger, where it is felt as a mass or a transmitted impulse. A small hernia defect or a sac that is difficult to reduce presents the greatest risk for future incarceration. In women, inguinal hernias may be difficult to diagnose until they become quite large.

It is important when examining the groin to include an examination of the upper thigh below the inguinal ligament

as well. Most femoral hernias can be felt as a soft mass medial to the femoral vessels. Frequently, hernias in this location are mistaken for inguinal lymph nodes or lipomas. Increased intra-abdominal pressure may transmit an impulse through the sac, but this too can be mistaken for normal transmission of the increased pressure in the femoral vein.

A rectal exam to assess prostate size, the presence of a rectal mass, and fecal occult blood, is an essential part of every physical exam for hernia, particularly in elderly patients. Although there is no association between inguinal hernia and colonic abnormalities, the high risk of colon neoplasm in these patients, in general, justifies a screening procedure, such as flexible sigmoidoscopy, for all patients over age 50 (see Elective Surgical Repair).

The differential diagnosis of a groin mass is extensive and includes hernias as well as lipomas, lymphadenopathy, abscess, varicocele, hydrocele, testicular mass, testicular torsion, epididymitis, and femoral artery aneurysm [24]. For this reason a imaging modality for the diagnosis of groin hernias has been sought for years. Herniography consists of injecting a small amount of contrast material directly into the peritoneal cavity and taking a radiograph during a valsalva maneuver. This is an accurate but invasive and painful technique with a complication rate reported at 5.8% [25]. Ultrasound has been shown to have an accuracy of 92% for all groin hernias and a 75% accuracy for those without a palpable bulge (Fig. 70.3) [26]. Therefore, it may be a useful adjunct in qualified hands. Computed tomography and MRI scans may also be beneficial in the evaluation of the difficult groin, but history and physical examination remain the mainstays of groin hernia diagnosis (Fig. 70.4).

FIGURE 70.3 Ultrasound of inguinal hernia (reprinted from [90], with kind permission of Springer Science + Business Media).

FIGURE 70.4 CT image of inguinal hernia (reprinted with permission from [91]. Copyright © Radiological Society of North America).

The diagnosis of an incarcerated hernia is usually not difficult to establish. Most often patients present with a previously recognized hernia that has recently become increasingly painful and “stuck out.” In the case of a femoral hernia, a painful mass in the groin may be the first indication. Obstructive symptoms such as nausea, vomiting, and obstipation may not be present early in the course but develop if the incarceration goes untreated. Strangulation, or ischemia to the incarcerated portion, is indicated by increasing pain and signs of systemic sepsis. On physical examination, a tender, nonreducible mass is present in the groin. Erythema and edema of the overlying skin are suggestive of strangulation of bowel in a hernia sac, as is severe tenderness to palpation.

CASE STUDY: PART 2

The 70-year-old veteran is not too concerned about his hernia and knows many of his friends who have been ignoring theirs for years. He has never had surgery and does not want to start now. He is hoping you are going to tell him not to worry about it.

Watchful Waiting

Surgical repair has been the gold standard for even asymptomatic hernias for decades. However, awareness of complications from hernia repairs including recurrence and chronic groin pain are now better defined and so also should carry weight when determining the benefits of operative intervention. It is also apparent that the risk of incarceration and strangulation from these minimally symptomatic hernias may have been previously overstated. For these reasons the

concept of watchful waiting has recently been considered as a viable option. Fitzgibbons et al. performed a trial of over 700 patients where patients were randomized to either open mesh repair or watchful waiting. Thirty-three percent of patients in each group were over 65 years of age. After 3 years of follow-up, pain and health outcomes were similar in each group. Eighty-five patients crossed over to the repair arm mostly because their hernias became more symptomatic. The rate of hernia accident was only 1.8 per 1,000. There were no deaths associated with hernia accidents [12]. This study seems to support a trial of watchful waiting in all asymptomatic or minimally symptomatic patients. A cost analysis performed as part of the Fitzgibbons study showed that a 2-year watchful waiting was a cost-effective option for such patients [27].

An additional study by O'Dwyer sought to answer a similar question looking at the geriatric population. One hundred and sixty patients over the age of 55 were randomized to watchful waiting or operation. There were 23 patients who crossed over to the repair arm, which is over 20% of those randomized to watchful waiting. This article argues that given longer follow-up there would be more cross-over to surgery and that elderly patients' health would only deteriorate over that time, making the risks associated with a hernia accident more severe [28]. In this study, like that of Fitzgibbons, the incidence of hernia accident (strangulation) was rare. There were two patients who crossed over from watchful waiting to repair and experienced significant postoperative complications not related directly to the hernia repair (myocardial infarction and stroke) but presumably to the decrease in the patient's overall health. Clearly as a patient ages, his or her general risks for undergoing any type of procedure increases.

CASE STUDY: PART 3

Upon further questioning the veteran has enough discomfort from his hernia that it limits his daily activities around the house. He lives over an hour from the nearest VA hospital and after hearing the potential complications of not repairing his hernia he has elected to proceed with repair.

Elective Surgical Repair

Prior to elective repair, conditions that may cause increased intra-abdominal pressure should be investigated and corrected if possible. Increased intra-abdominal pressure puts stress on the repair, interferes with normal wound healing, and may

predispose to recurrence. Constipation, symptoms of prostatic hypertrophy, chronic cough, and obesity are common conditions associated with increased tension on the abdominal wall. Managing the first three conditions with medications sufficiently to proceed with operation can often be accomplished in several weeks. Obesity cannot, however, and should not be controlled rapidly. Therefore, significant weight loss should not be used as an absolute prerequisite for repair.

Although there was a previously made association between inguinal hernias and colon cancer, those theories have been proven incorrect by multiple studies [29]. Current recommendations are to follow colon cancer screening guidelines. However, the majority of the elderly population does not currently follow these guidelines and their presentation with a hernia may be one of the best ways to enter them into the system. In a recent study, polyps were found in 62% of patients over the age of 60 undergoing screening colonoscopy, 86% of which were asymptomatic. Colon cancer was detected in 2.4% of patients [30]. The high incidence of colonic abnormalities in the elderly justifies screening. For patients with primary-care providers, this screening can be accomplished at any time. For those who enter the health-care system primarily to have the hernia repaired, screening should be part of the preoperative assessment. Elective repair should not be extensively delayed, however, to perform a screening procedure.

Anesthesia

The first step in elective hernia repair is the choice of anesthesia. Avoiding anesthetic techniques that place unnecessary stress on cardiac, pulmonary, and renal reserves may minimize the surgical morbidity and mortality. This is more important in elderly patients who often present with multiple co-morbidities. Both general and spinal anesthetic techniques are associated with perioperative complications. Guillen and Aldrete reported that in men over age 70 undergoing elective inguinal hernia repair the incidences of hypotension with spinal and inhaled anesthetic were 43 and 36%, respectively [31]. In a randomized trial of local vs. general and regional anesthesia, those patients receiving local anesthesia had less postoperative pain, fewer micturition complications, and shorter hospital stays. These results have been backed up by multiple other studies [32–34]. These data support the concept that local field block is the ideal anesthesia method for elective hernia repair in the geriatric age group. There are, however, a few limitations to this method. Patients with dementia or those who for other reasons are unable to understand commands and lie still on the operative table, as well as those who are unusually anxious, are considered poor candidates for local blocks. The excessive

use of sedation necessary to control these patients frequently worsens the confusion and results in respiratory complications, which defeats the whole purpose of using local anesthetic. Further problems are encountered in obese patients for whom adequate local anesthesia may not be achievable because of limitations in dose and absorption.

With a detailed understanding of the neuroanatomy of the inguinal region, painless inguinal herniorrhaphy may be accomplished in the elderly patient. The innervation of the inguinal region is complex (Fig. 70.5). A clear understanding of the intercostal nerve supply is paramount. Following the pattern of dermatome distribution, the tenth thoracic nerve innervates the umbilicus, the first lumbar nerve innervates the inguinal area, and the twelfth thoracic nerve innervates the area in between. The iliohypogastric and ilioinguinal nerves lie deep to the external oblique fascia and lateral to the anterior superior iliac spine. The iliohypogastric originates at the first lumbar nerve and lies under the external oblique aponeurosis after penetrating the internal oblique muscle. This nerve supplies sensory fibers to the suprapubic region. The ilioinguinal nerve follows the same course as the iliohypogastric nerve but lies closer to the crest of the ileum and inguinal ligament. The ilioinguinal nerve penetrates the internal oblique muscle approximately 1.0 cm from the

FIGURE 70.5 Nerve supply to the groin (from Mulvihill; *Surgery: Basic Science and Clinical Evidence*; 2001, reprinted with kind permission of Springer Science + Business Media).

anterior superior iliac spine and supplies sensory innervation to the base of the penis and part of the scrotum (and comparable areas in the female body). The penile skin and a small area of the scrotum are supplied by sensory fibers from the sacral plexus. When repairing a femoral hernia, more attention must be paid to the ilioinguinal nerve and the femoral branch of the genitofemoral nerve, which supply the upper thigh. The genitofemoral nerve originates from the first and second lumbar nerves to supply sensory fibers to the scrotum and upper thigh and motor fibers to the cremasteric muscle via the genital branch. The genital branch reaches the inguinal canal at the internal abdominal ring. When performing herniorrhaphy under local anesthesia, pain is also felt when traction is applied to the sac or the spermatic cord or when a finger is inserted into the peritoneal cavity. Knowledge of this anatomy is also paramount during the operation to avoid injury to these nerves and thusly postoperative inguinodynia (see below).

A simple five-step method has been advocated for the use of local anesthetic during inguinal herniorrhaphy. Appropriate use of this method requires minimal IV sedation with Midazolam and does not necessarily require monitoring or the use of anesthesia staff. A 50:50 mixture of 1% Lidocaine and 0.5% Bupivacaine is used. (1) Approximately, 5 mL of solution is injected subdermally along the entire length of the proposed incision. (2) A skin wheal is then raised using an additional 3 mL along the same path. (3) A total of 10 mL is then injected subcutaneously 2 cm apart. (4) After making the skin incision and beginning to expose the external oblique fascia, 10 mL of solution is injected directly underneath the fascia. This bathes the entire inguinal canal and should anesthetize all three major nerves in this area. (5) Additional injections of a few milliliters of solution may also be injected into the pubic tubercle and the hernia sac and additional solution may be used to bathe the incision prior to closure of the external oblique as well as the skin (Fig. 70.6a, b) [35].

In this era of cost analysis and health-care economics, inguinal herniorrhaphy is becoming predominantly an outpatient procedure. Even though outpatient general anesthesia is possible, local block facilitates earlier ambulation and is associated with fewer immediate postoperative complications.

Tissue Repairs

Inguinal hernia repair has previously been dominated by an anterior, open approach that was first proposed by Bassini, who introduced the concept of repair of the inguinal floor in 1887. This basic tenet of hernia repair has undergone many modifications, with various combinations of suturing the transversalis fascia, conjoined tendon, internal oblique, or transversus abdominis to the inguinal or Cooper's ligament.

FIGURE 70.6 (a) Making the skin wheal. (b) Subfascial infiltration.

The choice of herniorrhaphy technique must take into account the risk of recurrence and patient tolerance of the procedure. The actual rate of recurrence is difficult to establish. There are, however, no randomized, prospective studies comparing the various techniques with comparable lengths of follow-up in the world's literature. The best reported recurrence rates by conventional tissue repairs range between 1 and 20%. Prospective data on hernia repair in the elderly are even more difficult to interpret. There is no good evidence that the choice of technique significantly affects outcome. There is, however, a general move away from tissue repairs toward "tension-free" repairs using synthetic patches.

CASE STUDY: PART 4

Many of the veteran's friends have undergone hernia repairs and he has heard about the use of synthetic materials in the repairs. He is concerned about the use of a foreign material and wants the best and most up-to-date method for repairing his hernia.

Synthetic Repairs

In 1909, McGavin was the first to use a prosthetic material, a filigree of silver wire, to repair an inguinal hernia [36]. Throckmorton introduced tantalum gauze for use when there was insufficient tissue for adequate primary tissue repair.

This material, however, did not prove to be durable. During the 1950s and 1960s, Usher et al. used polypropylene mesh to bolster primary tissue repairs of direct and indirect hernias [37–39].

The premise behind using synthetic materials is to provide a tension-free repair with fewer recurrences and a quicker return to normal activity. It was not until 1986, with the published work of Lichtenstein and Shulman, that synthetic mesh became accepted for primary hernia repair without approximation of the underlying hernia margins (Fig. 70.7) [40]. With this technique, one single layer piece of mesh is secured over the inguinal floor with a slit to go around the internal ring. Data regarding recurrences with a particular hernia repair technique can be difficult to interpret because so much of it comes from specialized hernias center. However in a recent study comparing the Shouldice (a tissue repair) and the Lichtenstein repair in a general surgery practice, recurrence rates for the mesh repair were 0.7% compared to 4.7% for the tissue repair [41]. A meta-analysis comparing over 11,000 patients from various institutions demonstrated an overall recurrence rate of 2.0% for Lichtenstein mesh repair compared with 4.9% for various tissue repairs and persistent groin pain in 5.1 and 10.1% of patients, respectively [42].

Since the institution of the Lichtenstein method was first described, a multitude of other methods have attempted to supplant it. The plug-and-patch system was first described in 1993 and utilizes a polypropylene mesh plug to obliterate the defect in the internal ring or the inguinal floor. An additional patch is often used to provide additional support to the inguinal floor (Fig. 70.8) [43]. Recurrences remain as low as

FIGURE 70.7 Lichtenstein repair (from Fitzgibbons RJ, Jr., *Abdominal Wall Hernias*, Fig. 8. Available at: [http://knol.google.com/k/bob/abdominal-wall-hernias/Ilo7ZexB/MyZquQ#What_is_an_abdominal_wall_hernia\(3F\)](http://knol.google.com/k/bob/abdominal-wall-hernias/Ilo7ZexB/MyZquQ#What_is_an_abdominal_wall_hernia(3F))). FIGURE 70.8 Plug and patch repair (from Mulvihill; *Surgery: Basic Science and Clinical Evidence*; 2001, Chap. 43; reprinted with kind permission of Springer Science + Business Media).

the Lichtenstein method but complications of plug migration and shrinkage were reported [44]. This remains a simple and viable method for hernia repair. The Kugel Patch consists of two layers of mesh placed preperitoneally through an anterior approach, thus placing the mesh where it would be placed during a laparoscopic approach. A small muscle splitting incision is used to gain access to the pre-peritoneal space [43]. Though initial results were very promising showing a recurrence rate of 0.45, these results have never been reproduced and there is a very steep learning curve with recur-

rence rates as high as 18.2% in the initial learning period and rates as high as 27.8% for recurrent hernias [45, 46].

The Prolene Hernia System (PHS) is another method of prosthetic repair. It consists of two pieces of mesh that serve to overlay and underlay the inguinal floor attached by a mesh connector that is placed either through the internal ring or a defect in the transversalis fascia. The benefits of the PHS are that it touts to repair indirect, direct, and femoral hernias all at once by covering the entire myopectineal orifice preperitoneally [43]. Theoretically, this should reduce hernia recurrence through the lateral triangle of the orifice. As of now, studies demonstrating long-term recurrences with the PHS have not been performed but preliminary results show similar operating times and short-term recurrence rates as both the Lichtenstein and plug-and-patch methods. Some studies have demonstrated less pain with the PHS (Fig. 70.9) [47, 48].

Currently there are no studies comparing any of the above techniques specifically in the elderly population. In fact, the majority of studies exclude elderly patients or those with elevated ASA status. It would stand to reason though that any repair amenable to local anesthesia with a relatively short operating time would suit the elderly population well. Currently all of the above techniques qualify.

CASE STUDY: PART 5

On further examination, our veteran has a small asymptomatic hernia on the opposite side. He wants to get them both repaired at once but is worried about the increase in pain and inactivity if he has incisions in both of his groins.

Laparoscopic Repairs

Shortly after the success of laparoscopic cholecystectomy became apparent, surgeons began to apply minimal access techniques to a wide variety of other surgical procedures. This approach has become generally accepted for some procedures, whereas for others there is still considerable disagreement. Hernia repair is one of the latter group. Although some skilled laparoscopists prefer the approach for all inguinal hernias, many others believe the benefits do not outweigh the risks, particularly in the elderly.

The advantages of laparoscopic inguinal herniorrhaphy include less postoperative pain, reduced recovery time and earlier return to full activity, easier repair of recurrent hernia through unoperated tissues, the ability to treat bilateral inguinal hernias simultaneously through a single set of incisions, and improved cosmesis [49–52].

FIGURE 70.9 Placement of the Prolene Hernia System.

The laparoscopic approach to the inguinal hernia may be performed by either a transabdominal preperitoneal (TAPP) approach or a totally extraperitoneal (TEP) approach. In a TAPP repair the abdomen is entered in the typical laparoscopic fashion and once anatomy is appropriately identified a peritoneal flap is made. The hernia sac is then reduced and dissected free. A piece of mesh is then rolled out over the entire myopectineal orifice and in most instances is tacked in place being careful to avoid the bladder and the epigastric vessels. The peritoneal flap is then replaced and tacked in place as well (Fig. 70.10). In the TEP repair the preperitoneal space is entered. This is most often done with a balloon dissector placed through the umbilical port (Fig. 70.11).

Once the preperitoneal space is insufflated the anatomy of the groin is identified and the hernia sac dissected in a similar fashion as the TAPP repair. Mesh is placed and may be tacked in place. Any defects in the peritoneum are repaired. Previous lower abdominal incisions and radiation are a relative contradiction to the TEP repair, due to the difficulty of dissecting the peritoneum free from the abdominal wall [53].

The difficulty when operating from either of these approaches is the ability to obtain adequate exposure of the inguinal anatomy. Most recurrences are due to incomplete dissection of the region or inadequate placement of mesh to cover the defect. The TAPP repair provides the largest operating space and the most unobstructed view of the inguinal region and is probably the procedure of choice when learning to perform laparoscopic herniorrhaphy and master the elements of the preperitoneal space. There is no doubt that the more proficient a surgeon is in either of these techniques the fewer complications they will encounter. A recent study examining the experience of the surgeon demonstrated that surgeon age (>45 years old) and laparoscopic inexperience were risk factors for recurrence; however, the only risk factor for recurrence in open mesh repairs was a PGY level <3 [54].

A meta-analysis performed in 2003 examined 41 facilities with a total of over 7,000 patients comparing open to laparoscopic herniorrhaphy. Operating time was longer for the laparoscopic groups. The rate of injury, both visceral and vascular, was higher in the laparoscopic groups but was consistent (<0.3%) for both groups. Return to work, postoperative pain and postoperative numbness were both significantly decreased in the laparoscopic group [55].

FIGURE 70.10 View of inguinal anatomy (printed with permission from Charles H. Booras, M.D., All about Inguinal Hernias: Symptoms and Causes 5/16/98 <http://jaxmed.com/articles/surgery/inguinalhernia.htm>).

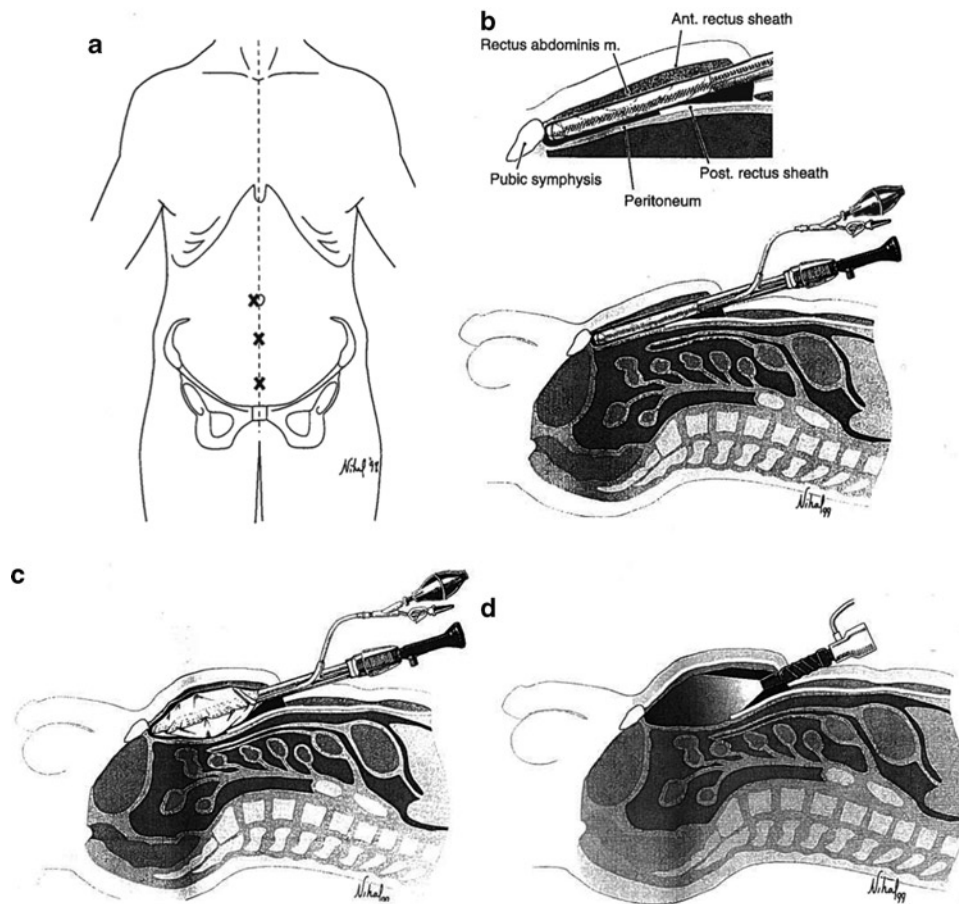

FIGURE 70.11 Use of balloon dissector during TEP repair (from Mulvihill; *Surgery: Basic Science and Clinical Evidence*; 2001, Chap. 43; Fig. 43.18, reprinted with kind permission of Springer Science + Business Media).

There are some significant disadvantages to the laparoscopic approach. Laparoscopic herniorrhaphy requires general anesthesia, is frequently performed by a transperitoneal route, is technically more difficult to understand and learn than mesh repairs, and in most hands, takes considerably longer. In comparisons of anesthetic techniques for open hernia repair, general anesthesia in the elderly is associated with far higher complication rates than local anesthesia. Therefore, the need for general anesthesia alone could obviate most of the benefits of the laparoscopic approach in some elderly patients. In addition, the transperitoneal route exposes the patient to the risk of inadvertent bowel injury, which in any age group could be devastating. Although the increased time to return to full activity may be an important consideration in a young person, the length of recovery may not be as important in old patients so long as mobility is not significantly compromised. Postoperative pain after the tension-free open approach is rarely severe enough to curtail activity.

There are a paucity of studies specifically involving the elderly population and laparoscopic hernia repair. One study evaluated 110 patients over 65 years old with an ASA of either 2 or 3. Operative time was longer than that for open repairs;

however, return to work was similar. Fifteen percent of patients experienced complications, the overwhelming majority of which were urinary retention. There was an alarmingly high recurrence rate of 9.7%. Hospital length of stay correlated with ASA status, but recurrences, complications, and return to activities did not [56]. Though the overall conclusion of this paper was that laparoscopic hernia repair in the elderly was safe, there was no assertion that it was in fact superior to open

CASE STUDY: PART 6

The veteran decided to postpone his surgery but was then lost to follow-up. He returned to the Emergency Room 2 years later stating that his hernia is now “stuck out” he is having significant pain from it. He cannot remember the last time he had a bowel movement. On exam, his hernia is incarcerated, and due to some erythema over his groin there is concern for strangulation. He is taken urgently to the operating room.

repair in this population. A review of laparoscopic surgery in geriatric patients reached the same conclusions [57]. It is clear that until further investigation is performed, laparoscopic hernia repair in the elderly should be reserved for the most experienced surgeons and the most appropriate patients, those with lower ASA status and recurrent or bilateral hernias.

Emergency Repair

The consequences of emergency surgery in the elderly population cannot be understated. There is a threefold increase in morbidity and mortality after emergent operation, regardless of the type of procedure [58]. Accordingly, there is also an increase in the need for intensive care and extended hospital stay in these patients, as well as rehabilitative services.

A representative study reports incidence of incarcerated inguinal hernia as 16.8% in patients over age 65, compared to only 4.4% in younger patients [59]. Unfortunately, acute incarceration and the sequela, strangulation, are also less well tolerated in the elderly. Strangulation occurs when the blood supply to the incarcerated organ becomes occluded at the neck of the hernia sac. Initially there is venous compression with subsequent edema, venous occlusion, and eventually arterial occlusion. Strangulation occurs in 1.3–3.0% of all groin hernias, most often in the elderly and children [60]. Indirect inguinal and femoral hernias are the most likely hernias to strangulate. The probability that an indirect inguinal hernia will strangulate is reported as 2.8% within 3 months of diagnosis and 4.5% after 2 years, compared to 22% at 3 months and 45% at 21 months for femoral hernias [61].

Kuleh et al. examined risk factors for strangulation and bowel resection in elderly patients with acutely incarcerated hernias. In examining 189 patients over 65 years old, it was found that femoral hernias were more frequently strangulated and required bowel resection at presentation. Although males were more likely to present with incarcerated hernias, females were likely to have strangulated hernias, possibly due to the increase in femoral hernias in this population. Late admission was also a significant risk factor for strangulation, bowel resection, and hospital stay. Morbidity increased from 15 to 33% when admission was delayed 48 h after symptoms began, and mortality increased from 2 to 9%. ASA status >3 was only a risk factor for prolonged hospital stay and morbidity but not mortality [11].

The approach to an incarcerated hernia in the elderly depends on the nature of the incarceration. Chronic incarcerations pose less of a threat of strangulation and can be treated on an elective basis. Acute incarcerations, on the other hand, require immediate surgical treatment. Forceful attempts at nonoperative reduction may result in an en masse reduction of a compromised loop of intestine within the

hernia sac. This ischemic bowel may not produce significant abdominal findings in the older patient until full-thickness necrosis and perforation occur. Any patient with skin changes or systemic symptoms – tachycardia, hypotension, fever, leukocytosis, or lactic acidosis – should raise suspicion for progression to strangulation.

The type of repair for incarcerated hernias depends to some extent on the viability of the contents of the hernia sac. A general or regional anesthetic is usually necessary. In the presence of inflammation, local anesthetic agents are usually not effective. In addition, the muscle relaxation provided by regional or general anesthesia may facilitate reduction of the incarcerated organ. If the incarceration is of short duration and there is no erythema or induration of the overlying skin suggesting strangulation, the choice of approach is less critical. Open anterior repair, which allows careful inspection of the sac contents outside the peritoneal cavity, is usually preferred. Frequently, a recently incarcerated hernia is reduced spontaneously or with minimal force when anesthesia is induced. In this setting, identifying the incarcerated loop of bowel through the hernia defect may be difficult but is usually not impossible. Skilled laparoscopists may prefer to inspect the bowel and repair the hernia laparoscopically through a transperitoneal approach. A recent study examining TAPP repair of 28 strangulated inguinal hernias demonstrated a conversion to open rate of 10.7%, for either extensive adhesions or bowel distention. Morbidity was only 4% and there were no deaths or recurrences [62]. The same precautions mentioned previously for laparoscopic herniorrhaphy should be considered here.

If the incarceration is of longer duration or there are signs of local inflammation suggestive of strangulation, an open procedure is safest and most expeditious. Many surgeons prefer a direct anterior approach to the hernia. If ischemic bowel is found in the hernia sac, resection can generally be accomplished through the hernia defect. The not infrequent need to use synthetic materials to repair the hernia defect in the presence of dead bowel creates a difficult clinical dilemma. Every attempt is then made to repair the defect with tissue rather than synthetic material, accepting the higher risk of recurrence in exchange for a lower chance for infection. Others advise that if there is high suspicion for compromised bowel preoperatively, a small lower midline laparotomy or laparoscopy should be performed for more careful inspection of the bowel and a more controlled resection. After the abdomen is closed, an open anterior repair of the hernia with mesh can be accomplished through a reprepared field.

A new innovation in hernia repair is the use of acellular dermal matrix. Most often made of cadaveric or porcine skin, these biologics are composed entirely of basement membrane and collagen bundles. They are highly resistant to infection and have been used for the repair of ventral hernias for years. They are uniquely helpful when there is compromised bowel

and the potential for contamination. A small retrospective study examined 12 patients with strangulated hernias and contaminated operative fields where bio-prosthesis (specifically Alloderm™) was used. Two patients developed superficial wound infections that were treated conservatively and in a short follow-up there were no recurrences [63]. This may represent a viable option in elderly patients with compromised bowel to avoid further infectious complications.

CASE STUDY: PART 7

The veteran underwent a mesh repair of his incarcerated hernia and did not require bowel resection. He followed up in clinic for a few months but once again became lost to follow-up. He called the general surgery clinic 3 years later to say he thought his hernia was back. The resident on call reminds him of the signs and symptoms of incarceration and makes an appointment for him the following week.

Recurrence

When performing hernia repairs, the primary focus of success is determined by the incidence of recurrence. There is a wide variation in the time frame over which recurrences are reported. There is, however, general agreement that follow-up should be at regular intervals and recurrence determined by direct examination rather than by patient report. Hernias recur for one or more reasons: tension on the tissues created by the repair, inherent abnormalities in collagen that predispose to the development of new hernias, an unrecognized second hernia component at the time of the initial repair (usually a small indirect component), and technical error.

Hernia recurrences can be classified as early or late. Most early recurrences are due to undue tension on the repair. For instance, when a hernia is due to a defect of the musculofascial abdominal wall, covering the defect with endogenous tissues results in suturing together tissues that are not normally juxtaposed. This then subjects these structures to undue tension [64]. Suture lines under tension exhibit an inadequate fibroblastic response for healing, which results in a weak scar and a subsequent recurrence of the hernia. Furthermore, these suture lines are subject to the same degenerative process that resulted in the initial herniation. The increasing use of tension-free repairs has significantly reduced this type of recurrence.

Late recurrences are usually due to missed components or new hernias at the site of a previous repair or in a new location. This type of recurrence is more appropriately termed

reherniation. Following a mesh repair, reherniation occurs because the mesh was not sutured in place or it was not of sufficient size to cover beyond the inguinal floor. Progression of tissue degeneration is of great concern and can be compensated for by placing a large sheet of mesh underneath the external oblique aponeurosis well beyond Hesselbach's triangle. This dissection is extensive but can be necessary, particularly in some patients with severe tissue loss. This is of particular importance when performing a preperitoneal or laparoscopic repair. Appropriate and extensive dissection of the entire myopectineal orifice is necessary to facilitate choosing the right size mesh and performing appropriate fixation. The most common causes of failure are mesh size being too small or inappropriate fixation either inferomedially or infero-laterally [65, 66]. Another study found that the vast majority of recurrences after laparoscopic herniorrhaphy were medial. For this reason a large piece of mesh should be chosen, sufficient enough to cross the midline with multiple tacks in the pubic tubercle and Cooper's Ligament (Fig. 70.12). Bilateral hernias should be managed with a single piece of mesh, large enough to cover both groins, the so-called bikini repair [67].

Risk factors for recurrence of hernias are similar to those for the formation of primary hernias. It would stand to reason that the elderly would be more susceptible to recurrence because of an increased risk of those factors already known to cause hernias: Obesity, chronic cough, constipation, bladder outlet obstruction, and general degradation of tissue. Age >50 has been shown to be an independent risk factor as well. Those undergoing repair for a recurrent hernia are at greater

CASE STUDY: PART 8

The veteran was an appropriate candidate for a laparoscopic repair and during his TAPP repair was noted to have a small indirect hernia on the opposite side. Both the recurrence and the incidental hernia were repaired laparoscopically with mesh.

CASE STUDY: PART 9

Two weeks after the above-mentioned laparoscopic repair, the patient is still complaining of significant pain. Rather than incisional, his pain shoots down his medial thigh. On physical exam there is no evidence of occurrence or infection, but there is significant numbness in the skin over his thigh.

FIGURE 70.12 Appropriate placement of mesh in a laparoscopic hernia repair (from Online Laparoscopic Technical Manual, Laparoscopic Inguinal-Femoral Hernia Repair, Step 5, Deploying and Anchoring the Mesh; <http://www.laparoscopy.net/inguinal/ingher11.htm>).

risk for recurrence than those undergoing a primary repair, as are those with two or more relative who also suffered from a recurrence [68].

Inguinodynia

As recurrence rates continue to decrease with advances in inguinal hernia repair techniques, a greater emphasis is being placed on other complications of the surgery. The most common is inguinodynia or inguinal pain. Although not proven, the potential causes include partial transection or entrapment of a nerve, which eventually leads to neuroma formation and chronic pain. In an open repair the most common nerves involved are the ilioinguinal, iliohypogastric and genital branch of the genitofemoral nerve. All three of these nerves supply sensation to the genitals and medial upper thigh. Refer to the previous section on anesthesia for a more in-depth discussion of this anatomy. The nerves most commonly injured during laparoscopic hemiorrhaphy are the lateral femoral cutaneous nerve (supplying the upper lateral thigh), and the femoral branch of the genitofemoral nerve (supplying the skin over the femoral triangle). These nerves lie near each other in a space nicknamed the “triangle of pain” (Fig. 70.13).

FIGURE 70.13 Triangles of doom and pain – representing where injuries to vessels and nerves occur, respectively, during a laparoscopic inguinal hernia repair (from [92] © Moore and Hasenboehler; licensee BioMed Central Ltd. Available from: <http://www.pssjournal.com/content/1/1/3>).

A study from the Swedish Hernia register examined 3,000 patients undergoing unilateral primary hernia repair. All techniques (tissue, mesh, laparoscopic) were examined. Overall 30% of patients were still experiencing pain over a year after surgery and 6% were having significant enough pain to impair their activities of daily life. Risk factors for inguinodynia included age, with those >59 years old having significantly less pain than those younger (21 vs. 33%). Patients having pain prior to their operation were more likely to continue to experience pain afterwards. Operative technique was also important. Anterior approaches, either tissue repair or mesh repair, had the highest incidence (~30%), whereas preperitoneal repair, either open or laparoscopic, had a significantly lower incidence (~20%) [69].

During an open repair careful dissection and identification of all the nerves is the best way to avoid injury. If injury is already suspected, complete transection of the nerve is preferable. During laparoscopic repair careful dissection is also important, as well as judicious tack placement avoiding the “triangle of pain.” Some have advocated not securing the mesh, which effectively alleviates this problem [23]. Recent studies have advocated prophylactic ilioinguinal neurectomy during open hernia repair. A double-blind randomized study showed a significant reduction in groin pain in the neurectomy group (8 vs. 28%) without any difference in postoperative numbness [70].

Patients suffering from injury to these nerves typically have pain in the immediate postoperative period, which intensifies over the next few weeks. In most cases it will regress over 2 months. Initial management consists of injections of local anesthetic and corticosteroids, as well as analgesics and anti-convulsants. In refractory cases the surgical treatment of choice is a triple neurectomy of the ilioinguinal, iliohypogastric, and genitofemoral nerves. This has shown 85% complete resolution and 15% partial resolution of pain in some case series [71].

CASE STUDY: PART 10

Initial conservative management with anti-inflammatory medications fail to alleviate the veterans pain. He is seen again 1 month later and lidocaine injection is prescribed. At 6 month follow-up his pain has been largely relieved and his quality of life has returned to normal.

Other Hernias

Although groin hernias are by far the most common, there are several other types of hernias that are also of concern in the elderly: some because of the frequency and technical challenge they present, and others because they are relatively uncommon and are not discovered until they incarcerate.

Incisional Hernias

Incisional hernias in the elderly are common and can often be challenging to repair. The incidence of hernias in patients with a midline surgical incision is 2–11% [72]. The etiology of these hernias is often multifactorial. Wound infection, suture failure, malnutrition, increased age, obesity, excessive straining, smoking, ascites or peritoneal dialysis, chemotherapy, steroids, and tension on the wound closure are factors that have been implicated. The symptoms of incisional hernia often begin with a noticeable bulge in a previously healed incision. Incarceration is the presenting symptom in 17% of patients leading to a perioperative mortality rate three times higher than that for elective repair [73].

Technically, these hernias may be challenging for several reasons. First, it is possible for most of the abdominal contents to become a fixed part of the hernia, which may result in a decrease in the intra-abdominal compartment volume. This in turn complicates complete reduction of the contents at the time of repair. This is known as a loss of domain. Second, the defects are usually multiple, reflecting failure of wound healing throughout the length of the incision. Identifying all the defects in the “Swiss cheese”-type abdominal wall and freeing all of the underlying adhesions may be tedious and time-consuming. Finally, extreme care must be exercised not to enter the bowel lumen during dissection because most incisional hernias are large and require synthetic materials for repair without tension. Biologic materials mentioned previously are now used to repair these hernia defects, especially in the presence of the contaminated operative field. They may also be used to overlay primary repairs to provide additional stability to weakened tissues, not uncommon to the elderly.

Laparoscopic techniques are being used with increased frequency to repair these large defects. Unlike laparoscopic inguinal hernia repair, there is a clear benefit to utilizing this technique in elderly patients, as long as preexisting comorbidities does not preclude the use of laparoscopic techniques. A recent meta-analysis shows that operative times are similar between open and laparoscopic groups while complications and hospital length of stay were significantly decreased in the laparoscopic group [74].

Umbilical Hernias

The umbilical hernia was first noted in 1 AD by the Hindu physician Charaka, who mistakenly believed it to be an abdominal tumor. The treatment of umbilical hernia has run the gamut from external compression devices to amputation. Umbilical hernias occur in 10–30% of live births but defects <2 cm are likely to close spontaneously. When repairs become necessary they are performed primarily. In adults, umbilical hernias occur through an umbilical canal that is bordered by the umbilical fascia, the linea alba, and the two rectus sheaths [75]. Because of the tight limitations of this canal, this type of hernia is apt to incarcerate and strangulate. For years the “vest over pants” method of repair as first described by Mayo was the standard of care. As with inguinal hernias, mesh repairs have begun to supplant primary repairs. There are a variety of meshes available, from simple sheets, to plugs and a combination of the two. Studies have shown that while complication rates between primary and mesh repairs are similar, recurrence rates are vastly lower in mesh repairs, 1% compared to 11% for primary repairs [76].

Umbilical hernias are common in cirrhotic patients and in those with ascites of other etiologies because of the increased intra-abdominal pressure against a thinned umbilical ring and fascia. An incidence as high as 24% has been reported in this patient population [77]. Umbilical hernia is also an important consideration in patients on peritoneal dialysis. Dialysis must be interrupted and ascites controlled prior to repair to decrease the incidence of recurrence. There are significant difficulties in closing this type of hernia, in order to prevent complications such as ascitic leak, wound infection and recurrence. Therefore every effort should be made to avoid strangulation and protect the thin skin over the defect. When necessary, these hernias may be repaired under local or regional anesthesia. Primary repair is optimal, but occasionally a prosthetic or biologic material is needed for tension-free closure.

Richter's Hernia

A partial enterocele is a form of hernia that bears the name Richter's hernia after August Gottlieb Richter, who first described it in 1785. This hernia is unique because only one side of the bowel wall becomes entrapped in the hernia defect (Fig 70.14). The classic signs and symptoms of small bowel obstruction that usually accompany incarceration are absent. The first indication of the incarceration may not become apparent until strangulation and necrosis occur. There is some concern that the incidence of Richter's hernia may be

FIGURE 70.14 Richter's hernia (from [93], reprinted with permission of the American Journal of Roentgenology).

increasing as laparoscopic surgery becomes more prevalent. Small port-site hernias are the perfect size to involve only a small portion of the bowel [78].

Kadirov and associates reviewed 350 incarcerated hernias at their institution between 1977 and 1994 [79]. Of the 350 patients, 14 had Richter's-type hernias (4%). These 14 cases were compared to 14 non-Richter's incarcerated hernias matched for location of the hernia and the age and sex of the patient. The average patient's age was 69 years. In the Richter's group, there was a significantly longer delay to diagnosis and treatment (15.8 vs. 4.4 h). As a result of this delay, 50% of the Richter's hernias required bowel resection compared to only 7.1% of the non-Richter's incarcerations. Mortality reflected the degree of established sepsis by the time of operation, with 21.4% of Richter's patients dying; none of the non-Richter's patients succumbed. Imaging modalities add little to the diagnosis of a Richter's hernia. Only astute clinical examination and a high level of suspicion identify these hernias before devastating necrosis and perforation have occurred, especially devastating in the elderly population.

Obturator Hernias

Arnaud de Ronsil first described the obturator hernia in 1724 at the Royal Academy of Science in Paris. This hernia is rare, accounting for 0.05% of all hernias and 0.2% of bowel obstructions [80]. It is usually found in frail, elderly debilitated women, but may also be associated with profound weight loss in other groups. Obturator hernias may be

bilateral or associated with hernias through the femoral canal. The obturator foramen, through which the hernia occurs, is the largest foramen in the body. The obturator membrane, however, occludes most of the foramen. The obturator canal consists of a 1–2 cm long and 1 cm wide opening in the superolateral part of the foramen. Usually, this canal is obliterated with fat, which prevents herniation of abdominal contents. In the frail and malnourished, this fat disappears and the potential space is unmasked.

A preoperative diagnosis is difficult because the complaints are not specific and the physical manifestations are minimal. A history of symptoms suggestive of intermittent or partial intestinal obstruction may be elicited. The Howship–Romberg sign – pain radiating down the medial aspect of the leg to the knee due to compression of the obturator nerve – is pathognomonic and is present in up to 50% of cases [23]. However, this sign is often overlooked in the elderly or attributed to other causes. The optimal way to look for an obturator hernia is with the patient supine and the thigh flexed, abducted, and externally rotated. The hernia mass is often concealed underneath the adductor muscles in the thigh. Occasionally, it is possible to feel a small mass on vaginal or rectal examination. The four indicators of obturator hernia – intestinal obstruction, Howship–Romberg sign, prior similar symptoms, a palpable mass on vaginal or rectal examination – are rarely seen together.

Ijiri and colleagues reviewed 17 obturator hernias [81]. There were 16 women and 1 man with an average age of 79.9 years (range 69–89 years) and an average body weight of 35 kg (range 25–43 kg). The average duration from onset of symptoms to surgery was 6 days (range 1–13 days). The diagnostic modalities ranged from computed tomography (CT) scans to exploratory laparotomy. The diagnosis of an obturator hernia was made in eight of eight cases when CT scan of the pelvis was performed (Fig. 70.15). An additional study showed that the use of CT decreased the time from symptoms to surgery by 3 days. In addition, bowel resection was performed half as often, and perioperative mortality decreased from 30 to 5%. This highlights not only the utility of CT scans in the diagnosis of obturator hernias but also the benefit of early diagnosis [82]. Others have supported the use of Ultrasonography, especially in the diagnosis of strangulation [83]. Even so diagnosis is only made prior to laparotomy in 10% of cases, and surgery should not be delayed while attempting to make the diagnosis.

Primary repair of an obturator hernia is impossible because the surrounding tissues are immobile. Some studies have reported using sac ligation alone or flaps of bladder, periosteum, uterine ligament, or rib cartilage to close the defect [84–86]. These repairs are unsuitable for large or bilateral hernias and may lead to postoperative pain and bladder dysfunction. A synthetic material is usually necessary. A plug system has been described as tension free

FIGURE 70.15 CT scan of obturator hernia (reprinted with permission from [91], Copyright © Radiological Society of North America. Available at: <http://radiographics.rsna.org/cgi/content-nw/full/21/2/341/F8>).

and easy to perform; however, there is the potential for chronic obturator neuralgia [87]. If the diagnosis has been established preoperatively, the most suitable approach is an open preperitoneal repair, as described by Stoppa et al. [88]. With this repair, a large piece of mesh is placed extraperitoneally to cover both sides of the pelvic floor. If the viability of the incarcerated bowel is questioned once the hernia is reduced, the peritoneum may be opened. In the usual case where the diagnosis is not known preoperatively, an initial transabdominal approach with a preperitoneal mesh repair is optimal. The use of laparoscopic methods has also been described, but there is no current data supporting benefits of this approach.

Spigelian Hernias

The Spigelian hernia, another unusual abdominal wall hernia, is named for Adriaan van den Spiegel, who was the first to describe the semilunar line. The semilunar line is the demarcation from muscle to aponeurosis in the transversus abdominis muscle. Protrusion of a peritoneal sac, organ, or preperitoneal fat from its normal location through this aponeurosis, is termed a spigelian hernia. These hernias are usually superior to the inferior epigastric vessels. Once they enter Hesselbach's triangle, they are termed low Spigelian hernias. These hernias are often located within different aspects of the abdominal wall and may also be termed interparietal, interstitial, intermuscular, intramuscular, or intramural. Most Spigelian hernias occur in individuals 40–70 years of age.

The etiology of these hernias is most often related to the inherent weakness in the transversus abdominis aponeurosis. Increased intra-abdominal pressure further increases the incidence. Erect posture puts most of the pressure on the lower abdomen, which could be another cause of hernias in this region. In their earliest form, these hernias are small protrusions of fat or omentum with a peritoneal covering. They may progress to include more fat or even bowel. The symptoms are usually localized abdominal pain, although signs of obstruction or a palpable mass on the abdominal wall may occur.

The diagnosis is difficult in patients with defects too small to produce overt manifestations on the abdominal wall. It is best to examine patients by having them alternately tense and relax the abdominal wall.

Imaging studies are usually necessary to elucidate the source of the localized symptoms. Ultrasonography is a good method for determining a hernia orifice and locating hernia contents. CT scan may also be used to examine the abdominal wall, but the sections must be close together to enable localization of the hernia orifice. Helical CT scans may increase the diagnostic yield. The CT scans may also provide information about the hernia sac and the nature of the abdominal contents in the sac (Fig. 70.16).

When the hernia itself is palpable and open approach may be performed. There is often enough laxity in the surrounding tissues to allow for primary closure, although mesh can be used [23]. As with all hernia repairs there have been recent advances in the use of laparoscopic techniques for the repair of these hernias as well. A recent prospective randomized trial comparing open vs. extraperitoneal laparoscopic repair showed significant improvement in complications and hospital stay in the laparoscopic group [89].

FIGURE 70.16 Preoperative CT showing Spigelian hernia (from [94]. Available at: http://www.rcsed.ac.uk/Journal/vol45_3/4530046.htm).

CASE STUDY: PART 11

Despite his complicated course, the veteran has ultimately returned to his normal level of activity. In follow-up he has had no further recurrences and he has had resolution of his inguinodynia.

Conclusions

Abdominal wall hernias in the elderly, whether common or unusual, are ultimately surgically correctable disorders. Recent studies have shown that watchful waiting is safe for asymptomatic or minimally symptomatic inguinal hernias. Other hernias wherein the fascial defect is large can also be managed nonoperatively if not symptomatic. Pain is frequently what leads the patient to operative repair.

Elective repair of inguinal hernias, in particular, is safe even in patients with significant co-morbidity. With local anesthesia and tension-free repairs, nearly all patients can ambulate immediately; and they can obtain excellent pain control with minimal oral pain medication. Complications are uncommon, and mortality is nearly zero in many large series. For elderly patients with significant co-morbidities, a complete preoperative evaluation of their fitness for surgery is in order.

Patients with chronically incarcerated hernias are not at significant risk for strangulation while those with an acute incarceration do have some risk of progressing to strangulation. Therefore, acutely incarcerated hernias present more of an urgent to emergent situation and surgical consultation early in the patient's course is of utmost importance.

Once strangulation has occurred, a hernia is no longer just a defect in the abdominal wall, and repair is not just patching the hole. The systemic consequences of bowel obstruction and ischemic tissue stress the limited reserves that define the physiologic state of the older patient. Once the inflammatory state is initiated, the cascade of events demands a response that the elderly are frequently unable to mount. Fluid and electrolyte imbalance, dehydration, and systemic sepsis become the major problems, and the mechanical issue of fixing the hernia defect fades in comparison. Morbidity and mortality rates soar.

For those hernias that are rare or the presentation more obscure, an increased level of awareness is necessary to avoid the consequences of incarceration. Although we may have to accept the higher complication rates that accompany the unusual hernia, we should never allow the common hernia to progress from a simple mechanical problem to a deadly systemic illness.

Section IX

Hepatobiliary System

Chapter 71 Invited Commentary

Seymour I. Schwartz

Almost a decade has past since the original publication of this reference work. As the population continues to enjoy increasing longevity, the need to consider the unique elements in the surgical care of those advanced in years becomes more evident. As was the case in my previous commentary, the two major issues are the substitution of physiologic status for chronologic age as a criterion for undertaking the more extensive elective resections of the liver and pancreas, and the broader application of minimally invasive procedures.

Laparoscopic cholecystectomy remains the gold standard. This has led to surgical training issues; namely, providing residents with experience in performing open cholecystectomy. In reference to cholecystectomy, a new approach has been introduced. NOTES, Natural Orifice TransEndoscopic Surgery. Successful removal of the Gall bladder transendoscopically through the gastric wall remains a curiosity and has not gained broad enthusiasm. It is doubtful that it will. Endoscopic palliation of jaundice secondary to malignant obstruction of the extrahepatic bile ducts has become increasingly successful.

Symptomatic nonparasitic cysts of the liver are preferentially unroofed by laparoscopy. Similarly, smaller nonanatomic hepatic resections and segmentectomies are readily performed by minimally invasive techniques. With the introduction of improved techniques of hemostasis during transection of the hepatic parenchyma, laparoscopic resection with

hand-assist has been extended to hemihepatectomy. In regard to resection for primary and, in some instances, secondary hepatic malignancies, the argument continues as to whether major resection or orthotopic transplantation is preferable. Another visible change related to hepatic pathology is the disappearance of surgical portal-systemic procedures, which have been replaced by transcutaneous intrahepatic portal systemic shunts (TIPS). But one recent assessment indicates that the operation is preferable.

An increasing number of pancreaticoduodenectomies are being performed disregarding the nodal status and the involvement of the adjacent major veins suggesting that better palliation is achieved. This remains to be affirmed by irrefutable evidence. Distal pancreatic resection is readily performed laparoscopically and several series of laparoscopic pancreaticoduodenectomy have been reported.

Splenectomy, in the face of a normal sized or minimally enlarged spleen should be performed laparoscopically. In the case of splenectomy for hematologic disease and particularly Idiopathic Thrombocytopenic Purpura deliberate inspection of the peritoneal cavity to identify accessory spleens is mandated. The massively enlarged spleens associated with myeloproliferative disorders are more safely removed by open operation and these patients should be protected by the preoperative administration of anti-platelet-aggregating drugs.

Chapter 72

Hepatobiliary and Pancreatic Function: Physiologic Changes

Vadim Sherman and F. Charles Brunicardi

Morphologic and physiologic changes in hepatobiliary and pancreatic function observed in elderly persons

Parameter	Change with age	Functional impact
Liver		
Organ size (absolute and relative)	↓	No significant change?
Hepatocyte number	↓	↓ Metabolic function
Cell volume, ploidy, organelle constituents	↑	↓ Metabolic function
Hepatic blood flow	↓	↓ Metabolic function
Liver function tests	No change	No significant change?
Biliary system		
Bile duct size	↑	None
Gallbladder contractility	↓	↑ Gallstone incidence
Gallbladder absorptive capacity	No change	None
Cholecystokinin plasma levels	↑	No significant change?
Gallbladder cholecystokinin sensitivity	↓	No significant change?
Bile cholesterol saturation	↑	↑ Gallstone incidence
Pancreas		
Organ size	↓	None
Ductal size	↑	None
Acinar glands	↓	None
Exocrine function	?	None
β-Cell function	↓	↑ Incidence of glucose intolerance
Glucagon levels	↑?	↑ Incidence of glucose intolerance
Pancreatic polypeptide levels	↑	Unknown

↑, increased; ↓, decreased; ?, not proven or consistent

The normal variation in physiologic parameters of the hepatobiliary system and pancreas should be taken into account when managing an elderly patient. Appreciation of these alterations allows the surgeon to distinguish between expected physiologic variation and intercurrent pathophysiology in the clinical setting. A review of normal versus expected aging hepatobiliary and pancreatic physiology, as well as a review of select pathophysiology, will be presented in these organ systems.

Liver and Biliary System

Liver Anatomy

The liver is the largest solid organ in the body and is situated in the right upper quadrant of the abdomen. Protected by the thoracic cage, its borders extend from the level of the nipples to slightly below the costal margin. The horizontal axis spans the right hemidiaphragm and a portion of the left hemidiaphragm. The Couinaud nomenclature is currently accepted as the main classification system of liver anatomy, rather than historic classifications based on external topography (Fig. 72.1). The gross anatomical landmarks include the ligamentum teres (round ligament of the liver) which appears to divide the liver into a small left and larger right lobe. However, the anatomic classification divides the left and

FIGURE 72.1 Anatomic division of the liver into right and left lobes by the interlobar line of Cantlie extending from the gallbladder fossa to the inferior vena cava. (From Feldman M et al (eds) (2006) *Sleisenger & Fordtran's Gastrointestinal and liver disease*, 8th edn. Saunders, Philadelphia. Reprinted with permission from Elsevier).

right lobe of the liver based on Cantlie's line, which represents the plane of the middle hepatic vein and the primary bifurcation of the portal vein. Cantlie's line can also be visualized as the plane extending from the gallbladder fossa to the inferior vena cava. The liver benefits from dual vascularization from the portal and systemic vasculature. The portal vein, hepatic artery, and biliary ductal system generally run in parallel, each bifurcating just before entry into the hilum and sending major branches to each hepatic lobe. Couinaud's functional anatomical classification divides the liver into eight segments according to the anatomic relation of portal vein and hepatic vein branches (Fig. 72.2) [1]. The right lobe is divided into an anterior and posterior segment by the right hepatic vein and the left lobe is divided into a medial and lateral segment by the left hepatic vein. The lobes are divided into their eight subsegments based on the transverse plane through the bifurcation of the portal vein.

Hepatic Physiology

The liver is vital to a number of processes aimed at maintaining health and homeostasis. The functions of the liver include detoxification, protein synthesis, bile acid synthesis, storage

FIGURE 72.2 Hepatic segmental anatomy as defined by Couinaud, based on the anatomic relation of the portal vein and hepatic vein branches (reprinted with permission from Blumgart LH (ed) *Surgery of the liver and biliary tract*. Edinburgh: Churchill Livingstone, © Elsevier, 1994).

of substances, and metabolism of proteins, carbohydrates, and lipids. Whether toxins originate internally or result from external sources, the liver is integral in filtering the toxins from the blood. Toxins are cleared through a series of enzymatic reactions that render the toxins water- or fat-soluble,

thereby allowing for their secretion in urine or bile. The liver's production of bile further adds to the process of detoxification by providing a vehicle of export for various offending agents.

In addition to toxins, bile also transports bilirubin, cholesterol, bile salts, and phospholipids to the intestinal tract for excretion. Moreover, bile acids aid in the digestion of fats, thereby facilitating their absorption. Approximately 500–1,000 ml of bile is secreted per day. The amount of hepatocyte bile acid synthesis is the determining factor of the amount of secretion; however, additional secretion is aided by vagal stimulation, gastrin, secretin, and cholecystokinin (CCK) [1]. Once bile acids are excreted into the intestines, they undergo transformation into secondary bile acids. In the jejunum and ileum, these bile acids are then absorbed into the portal venous system and ultimately 90% are extracted by hepatocytes. This extremely efficient extraction of bile acids prevents their loss into the systemic circulation. The hepatocytes reconstitute the extracted product into the formation of new bile, thereby completing the circuit. This is referred to as the enterohepatic circulation of bile acids. The rate of new bile acid formation is therefore dependent on the rate of intestinal reabsorption and hepatocyte extraction. At the level of hepatocytes, bile is formed by the oxidation of cholesterol. The cholesterol secretion rate of the liver is dependent on the activity of two hepatocyte enzymes: 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, which catalyzes the rate-limiting step in the synthesis of cholesterol, and cholesterol 7- α -hydroxylase, which converts hepatic cholesterol to bile salts. Dietary intake and availability of lipoprotein carriers also affect cholesterol metabolism. Although insoluble in water, cholesterol remains soluble in bile if the relative concentrations of bile salts and phospholipids are maintained within certain limits. As first presented by Admirand and Small in 1968, the solubility characteristics of cholesterol are depicted by plotting the percentages of bile constituents on triangular coordinates [2] (Fig. 72.3). The area under the curve represents relative percentages of bile constituents that are required to maintain cholesterol in solution. If the relative percentages fall outside this area, supersaturation and crystallization of cholesterol can occur, which of course, can be a prelude to gallstone formation.

Carbohydrate metabolism is centered in the liver where it manages the surplus or deficit of metabolic fuels by engaging in storage or distribution of glucose. Both the liver and muscle are capable of glucose storage; however, only the liver is involved in the conversion of glycogen to glucose for systemic use. Other catabolic functions of the liver include gluconeogenesis and ketogenesis. Anabolic functions of the liver include glycogenesis and synthesis of plasma proteins, such as albumin, transferrin, haptoglobin, and numerous coagulation factors.

FIGURE 72.3 Triangular coordinates of the primary bile constituents for prediction of cholesterol solubility or crystallization. Any single point within the triangle represents a solution of bile with unique relative proportions of cholesterol, phospholipid (lecithin), and bile salt. Solutions represented by points under the curve are likely to maintain cholesterol in solution, whereas points above the curve are likely to represent solutions with cholesterol supersaturation and propensity to crystallization (reprinted with permission from Admirand and Small [2]).

Hepatic Function in the Elderly

Grossly, the change in liver size in elderly subjects is referred to as “brown atrophy.” This brown discoloration is caused by accumulation of pigmented lipofuscin granules in hepatocytes and Kupffer cells. These granules are thought to be the depository of residues, predominantly exogenous dietary contaminants, that the liver cannot metabolize. Few studies have examined the structural and functional changes associated with normal liver aging. The pertinent morphologic and physiologic changes are summarized in the physiology table at the beginning of this chapter. On average, liver weight is decreased 6.5% in males and 14.3% in females [3]. The absolute number of hepatic lobules remains constant, but they undergo a decrease in the size of each lobule. Consequently, the number of hepatocytes decreases, yet each hepatocyte assumes an increased volume. Postmortem liver tissue analysis in subjects over 60 years old demonstrates decreased microsomal enzyme activity and a decreased hepatic concentration of smooth endoplasmic reticulum [4]. Furthermore, the number of mitochondria per hepatocyte decreases with age [5]. Although these are not significant changes on their own, when coupled with a decreased hepatic blood flow, this may account for a reduced capacity for metabolism of certain drugs and toxins. Hepatic blood flow, measured with dye clearance

tests, shows a corresponding decrease with age at an estimated 0.3–1.5% decline per year. Reduced blood flow is attributed to the diminution of hepatic parenchymal mass with aging. As a result of this decline, individuals aged 65 years have 40–45% less total hepatic blood flow than they had at age 25 [6].

Examination of human and rat hepatocytes has provided insight into mechanisms of impaired drug metabolism by the aging liver. Hepatocytes isolated from young and old rats and humans demonstrated no difference in rates of oxidative phase I drug metabolism and phase II conjugation reactions [7]. In contrast, *in vivo* rates of oxidative phase I drug metabolism was impaired in older rats, yet glucuronidation was preserved [8]. A possible explanation for these observations is that older animals experience a degree of hypoxia. The decreased oxygen delivery may be a result of the creation of a diffusion barrier secondary to pseudocapillarization of hepatic sinusoids. The sinusoids of older rats has been found to have thicker endothelium and increased deposition of type IV collagen. Therefore, the pseudocapillarization and subsequent relative hypoxia in older rats may have implications for elderly humans. That is, this finding may impact drug therapy in the elderly, specifically those drugs whose clearance involves undergoing oxidative metabolism [9].

Despite the morphologic changes the liver undergoes with normal aging, the great functional reserve of this organ allows little or no clinical impairment. Several studies have documented that standard liver function tests (LFTs) do not vary significantly with increasing age alone [3, 10, 11]. Therefore, presence of abnormal liver chemistries in the elderly should not be considered normal and investigation of possible hepatobiliary disease should be undertaken. Regardless, standard LFTs – including serum bilirubin, aminotransferases, and alkaline phosphatase – do not reflect the true dynamic function of the liver. Evaluation of dynamic hepatic function requires measuring clearance of anionic dyes, such as sodium sulfobromophthalein (Bromsulphthalein or BSP) and ¹³¹I-rose bengal, or various drugs that require hepatic microsomal enzyme activity. Prior studies investigating hepatic clearance or retention in the elderly have been controversial and conflicting, requiring control for multiple comorbid diseases, medications, and decreased hepatic blood flow [10, 12, 13]. To date, the most definitive study is that of Kampmann and associates, which demonstrated no significant variation in retention of anionic dyes in 43 carefully-selected patients aged 50–88 years when compared with younger persons [11]. Patients who were obese, alcoholic, receiving potentially hepatotoxic medicines, or showing evidence of renal, hepatic, or bone disorders were excluded from this study. Additionally, liver biopsies were performed in all patients to rule out hepatic pathology that could secondarily elevate dye retention rates, such as fatty degeneration, cirrhosis, or chronic hepatitis.

Although the liver is prone to the aging process, the changes it undergoes are less significant than those seen in other organ systems. Studies in old rats have demonstrated that although hepatic regeneration following hepatectomy is slower, these livers will eventually achieve their original volume [14]. In humans, clinical data has also demonstrated the longevity of aging livers through results garnered from liver transplants. Five patients whose transplanted livers were from donor patients over 80 years old experienced similar clinical outcomes to the group ($n=35$) that received livers from patients under 80 years old [15]. In terms of function, synthesis of most hepatic proteins remains intact with some impaired catabolism. Also, the activities of certain hepatic enzymes necessary for cholesterol metabolism are thought to be affected by the aging process. These age-related changes in hepatic enzyme activity may well be contributing factors in the pathogenesis of gallstone formation in the elderly.

Biliary Anatomy

After being secreted by the hepatocyte, bile drains along canaliculi that form into progressively larger intrahepatic ducts. These continue to coalesce within each lobe to form the right and left lobar ducts, which then exit the hilum and join to form the common hepatic duct (CHD). The CHD, in its course to the intestine, becomes the common bile duct (CBD) once it joins with the cystic duct from the gallbladder. The gallbladder is a pear-shaped, blind-ended, organ lying on the inferior surface of the liver that receives and drains bile through the cystic duct. The CBD then courses toward the second portion of the duodenum, where it empties into the ampulla of Vater within the duodenal wall. Shortly before entering the duodenum, the CBD also joins with the pancreatic duct, although variations to this anatomy are common. The sphincter of Oddi is a complex muscular structure surrounding the distal portions of the CBD, main pancreatic duct, and ampulla of Vater that is separate from the duodenal musculature. This sphincter coordinates appropriate release of biliary and pancreatic secretions during a meal while preventing harmful reflux of duodenal contents into the CBD.

Biliary Physiology

The purpose of the gallbladder is to store and concentrate bile during the fasting state. Following ingestion of a meal, the secretion of gastrointestinal hormones such as secretin, gastrin, and CCK results in the release of bile from the gallbladder into the intestinal tract. Although the gallbladder generally holds only 40–50 ml of bile, its remarkable absorptive capacity

allows it to accommodate the 500–1,000 ml of bile produced by the liver each day [1]. The electrolyte and water content of bile secreted from the liver is modified during passage through the extrahepatic biliary system by the biliary ductal epithelium. In comparison, the mucosa of the gallbladder results in significantly more efficient absorption of sodium and water than cholesterol and calcium. The active transport of sodium leads to passive absorption of water, yet each is more significant than the gallbladder's capacity to reabsorb calcium. As the concentration of calcium increases in bile, it also affects the solubility of cholesterol. In turn, the increased concentrations of cholesterol and calcium may result in precipitation and creation of gallstones.

Between meals, the gallbladder passively fills with bile that is continuously produced and pumped into the extrahepatic biliary system. With the sphincter of Oddi contracted, the pressure within the common bile duct increases above that of the gallbladder lumen, thereby facilitating passive movement of bile into the cystic duct. Periodically, a small amount of bile (10–30%) is released from the gallbladder. This process of partial emptying and filling seems to be coordinated with late phase II and phase III activity of the gastrointestinal migrating myoelectric complex (MMC), which is associated with increases in plasma concentrations of the hormone motilin [16]. The turnover of gallbladder bile during fasting may serve as a mechanism to prevent or expel cholesterol crystals prior to macroscopic stone formation.

Following a meal of fatty acids or amino acids, vagal stimulation and CCK result in contraction of the gallbladder and the release of approximately 50–70% of the stored bile. The presence of intraluminal gastric acid, fatty acids, and certain amino acids triggers the release of CCK from epithelial cells in the proximal intestine, primarily in the duodenum. In addition to the release of bile from the gallbladder, CCK also impacts the contraction and relaxation of the sphincter of Oddi. This coordinated reflex allows the flow of bile and pancreatic juice into the duodenum to aid in the digestive process. At physiologic levels, CCK seems to influence vagal cholinergic innervation of the gallbladder by means of CCK-A receptors on postganglionic neurons [17]. This neurohumoral interaction may provide control of basal gallbladder smooth muscle tone and coordination of postprandial gallbladder contraction.

Biliary Function in the Elderly

The gallbladder undergoes minor changes with aging. There is little effect on size, contractility, or absorptive capacity. The effect of a decreased responsiveness to CCK may not have clinical significance. Khalil et al. demonstrated that gallbladder sensitivity to CCK decreases with age, but

fasting and fat-stimulated plasma levels of CCK are significantly higher in older individuals. These physiologic alterations appear to offset each other functionally, as the rate of gallbladder emptying in the elderly is similar to that of younger individuals [18]. The age-related increase in serum concentration of pancreatic polypeptide may also depress gallbladder emptying; however, the data to date is conflicting and further studies are needed to clarify the role of this hormone in hepatobiliary function in the elderly [19].

The most significant age-related change involving the hepatobiliary system involves the common bile duct. Namely, the duct increases in size, in a similar fashion to the pancreatic duct. One study by Nagase and associates used intravenous cholangiography to measure the CBD size in 84 healthy Japanese persons and documented a mean diameter of 9.2 mm at age 70 compared to 6.8 mm at age 20 [20]. Other studies have confirmed the upper normal size of the CBD as 10 mm in patients over 75 years old and 14 mm postcholecystectomy [21]. The distal portion of the CBD and the sphincter of Oddi become progressively narrower with age, possibly predisposing to stone impaction. Biliary obstruction in older adults is usually due to malignancy rather than to choledocholithiasis. The most common malignancy is adenocarcinoma of the pancreas but may be caused by other malignancies such as ampullary, gallbladder, bile duct, duodenal, and metastatic cancers. Benign strictures can result from cholangitis or common duct injuries. Primary sclerosing cholangitis is rare in those older than 65 years of age.

Gallstone Pathogenesis

Gallstone disease is a significant health-care problem in the United States, with an overall prevalence of 10–12%, translating to 25–30 million people. Risk factors for gallstone development include female sex, obesity, ethnicity, and age [22]. Epidemiological studies have shown that cholesterol gallstones occur infrequently in adolescence and the presence increases linearly with age (Table 72.1) [23–27]. The incidence of gallstones increases approximately 1–3% per year [28]. Recent studies have indicated that the incidence of gallstones in females approaches 50% by age 70 [29]. In fact, the most common abdominal operation performed in the geriatric population is cholecystectomy, with the total number of cases performed annually for nonfederal inpatients 65 years of age and over approximating 161,000 [30]. Furthermore, the risk of complications from gallstone disease is increased in elderly patients, with an increased incidence of CBD obstruction, perforation, and gangrene [31].

As discussed earlier, gallstone formation is dependent on relative concentrations of cholesterol, calcium, and other

TABLE 72.1 Prevalence of gallstones at autopsy in women in various countries

Age (Years)	Prevalence of gallstones (%)			
	UK [14]	USA [15]	Sweden [16]	Chile [17]

The table illustrates the geographic variation of gallstone disease and increasing prevalence with advancing age

biliary solutes. Gallstones are classified according to their cholesterol content as either cholesterol stones or pigment stones. Pigment stones are further classified as black or brown. In the United States, gallstones are most commonly composed of cholesterol (70–80%) with pigment stones accounting for the remaining 20–30% [1].

Cholesterol Gallstone Pathogenesis

Three independent but mutually inclusive processes appear to be necessary for gallstone formation are as follows: (1) cholesterol supersaturation, (2) nucleation (also known as crystallization), and (3) stone growth. As previously mentioned, cholesterol is a highly hydrophobic molecule requiring appropriate relative concentrations of bile salts and phospholipids to remain soluble in bile. These biliary solutes are arranged in cholesterol–phospholipid vesicles and mixed micelles when in solution. Excess biliary cholesterol can result from hypersecretion of cholesterol with a normal bile acid pool or with normal cholesterol secretion in conjunction with a diminished bile acid pool. Therefore, cholesterol supersaturation can be produced by decreased activity of cholesterol 7- α -hydroxylase (decreasing the conversion of hepatic cholesterol to bile acids), overactivity of HMG-CoA reductase (the rate-controlling enzyme in the synthesis of cholesterol), or terminal ileal disease or resection (interrupting the enterohepatic conservation of bile acids).

In addition to cholesterol supersaturation, the second necessary requirement for gallstone formation is the process of crystallization. Cholesterol supersaturation alone is a common finding in normal patients free of biliary pathology [32, 33]. Nucleation, or the precipitation of supersaturated bile cholesterol into solid cholesterol monohydrate crystals, usually occurs due to a combination of depressed biliary kinetics and procrystallizing protein action on the bile. Nucleation

TABLE 72.2 Factors contributing to cholesterol gallstone formation

Cholesterol supersaturation
Cholesterol hypersecretion
Diminished bile acid pool
Ileal disease or resection
Nucleation
Mucin glycoproteins
Pronucleating substances: phospholipase C, fibronectin
Nucleation-inhibiting substances: apolipoprotein A1
Calcium concentration
Gallbladder dysmotility
Altered cholecystokinin (CCK) plasma levels or receptors
Neurohumoral influences: CCK somatostatin, estrogen
Vagolysis, mechanical or functional

time, the rate at which cholesterol crystals form, is decreased from approximately 15 days in control patients free of biliary disease to 3 days in patients with gallstones [34]. Mucin glycoproteins secreted under prostaglandin control and immunoglobulins secreted by the gallbladder mucosa are thought to serve as pronucleating agents, perhaps using the mucous gel coating on the mucosa as a nucleation matrix. Other substances that have demonstrated pronucleating effects in vitro include phospholipase C, fibronectin, and a low-density lipoprotein, whereas apolipoprotein A-I has been shown to inhibit nucleation [23]. Concentration of bile within the gallbladder causes the formation of large, cholesterol-rich multilamellar vesicles that can precipitate cholesterol crystals. Also, concentration of calcium salts within the gallbladder leading to saturation may serve as a nidus for nucleation.

Lastly, the gallstone attains clinical significance when its size grows to the point at which it causes an obstruction of the biliary system. Macroscopic stone formation from cholesterol crystals results from progressive enlargement of individual crystals with deposition of insoluble material onto its outer surface or by fusion of crystals into a larger conglomerate. However, patients may present with typical biliary disease symptoms, yet routine radiological assessment may not visualize a definite stone formation. This biliary “sludge,” also known as biliary microlithiasis, is a precipitation of cholesterol crystals and calcium bilirubinate granules in bile with a high mucin content, not infrequently observed in states of prolonged bowel rest or with use of total parenteral nutrition (TPN). Nevertheless, the pathogenesis of cholesterol gallstones is clearly multifactorial (Table 72.2).

The effects of aging on hepatic and biliary cholesterol metabolism are difficult to elucidate; however, it has become increasingly clear that gallbladder mucosal function and contractility play key roles in this process. Gallbladder hypomotility with infrequent or incomplete emptying of the gallbladder contents may predispose to bile stasis and crystal formation. As previously discussed, gallbladder kinetics are decreased in the elderly population, thereby increasing the risk of development of cholelithiasis. It is also important to consider other mechanisms that predispose to cholelithiasis,

that may be present within a comorbid illness in the elderly patient. For instance, the elderly patient may require TPN, which further delays gallbladder emptying. Another notable condition that may predispose a patient to gallstone formation is rapid weight loss, which may be due to poor dietary intake or chronic illness [35, 36].

Although gallstones are associated with abnormal gallbladder contractility, it is not known whether altered motility is the primary problem or a secondary consequence. The presence of cholesterol-supersaturated bile alone has been shown to impair gallbladder emptying before cholesterol crystals or gallstones are evident [34]. Mechanisms proposed to explain the apparent effect of cholesterol-rich bile or gallstones on gallbladder motility, include a possible myotoxic or neurotoxic effect of cholesterol or bile salts, the development of hypertrophic myopathy with chronic inflammation or inflammatory mediator release, and disordered regulation of hormonal influences, such as CCK, motilin, or somatostatin [34, 37].

As part of a series of studies evaluating the characteristics and regulation of gallbladder motility in patients with and without gallstones, Thompson et al. reported that most gallbladders containing gallstones contract like normal controls when evaluated by ultrasonography after a lipid meal [38]. These “contractors” exhibited a diminished release of endogenous CCK measured with plasma bioassay, but an increased sensitivity to the hormone was apparent relative to controls. A few patients with gallstones displayed depressed gallbladder contractility but with CCK output equivalent to that of the controls. Gallbladder muscle strips obtained from these “non-contractors” were subsequently shown to have significantly reduced in vitro responsiveness to CCK [39] and a decrease in the number of CCK receptors [40]. The cause-and-effect relation between gallstones, gallbladder dysmotility, and neurohumoral influences is an area of active investigation.

Pigment Gallstone Pathogenesis

Although pigment stones comprise approximately 20% of the total in the Western population, the rate is much higher in the Asian population. Pigment stones are formed by the precipitation of bilirubin in bile. Like cholesterol, bilirubin is insoluble in water. The liver conjugates bilirubin, making it soluble, and secretes it into bile. A small percentage (3%) remains unconjugated. However, in healthy patients, this amount of insoluble bilirubin does not lead to formation of pigment stones. Hyperparathyroidism may predispose a patient to pigment stones by increasing the level of ionized calcium. Pigment stones may also occur secondary to an increase in unbound bilirubinate. This is due to chronic hemolysis (cirrhosis or sickle cell disease) or increased synthesis of unconjugated bilirubin as a result of increased activity of β -glucuronidase (which converts conjugated bilirubin to

unconjugated) [41]. When an increase in insoluble bilirubin comes into contact with insoluble calcium, a black pigment stone of solid consistency forms. Brown pigment stones are more common in Asian populations and are associated with chronic biliary tract infections or bile stasis. They are almost always associated with colonization of bile by *Escherichia coli*, *Bacteroides*, or *Clostridium* [42]. The stones are much more fragile than cholesterol or black pigment stones, crumbling readily when manipulated. Brown pigment stones are usually found in the bile ducts where β -glucuronidase produced by bacteria hydrolyzes conjugated bilirubin to the free form, a hydrophobic solute that readily combines with calcium to produce a nidus for gallstone formation.

Lithogenic Factors in the Elderly

A multitude of factors is responsible for the increased incidence of gallstones in the elderly. Einarsson and associates demonstrated age-associated changes of biliary cholesterol saturation and bile acid kinetics in a group of nonobese, normolipidemic subjects known to be gallstone-free [43]. Specifically, this investigation was able to show a direct correlation between advancing age and increasing cholesterol saturation of bile, presumably due to an increased rate of hepatic cholesterol secretion (Fig. 72.4). Additionally, bile acid synthesis and pool sizes were noted to decrease with advancing age (Fig. 72.5). Each of these changes contributes to the enhanced lithogenicity of bile in the elderly.

sion from Einarsson et al [43]. © Massachusetts Medical Society. All rights reserved).

The relation of these physiologic changes with possible age-related changes in hepatocyte enzyme activity for HMG-CoA reductase and 7- α -reductase has been investigated, with studies available that both support [44] and refute [45] this position.

To explore whether aging increases cholesterol supersaturation of bile and gallstone prevalence, Wang studied age-related changes in hepatic and biliary lipid metabolism in gallstone-susceptible and resistant mice of varying ages [29]. The rats were fed a lithogenic diet for 8 weeks and then evaluated for gallstone prevalence, gallbladder size, biliary lipid secretion, and HMG-CoA reductase activity. These outcomes were all increased in the gallstone-susceptible mice. Furthermore, increasing age-augmented biliary secretion and intestinal absorption of cholesterol, reduced hepatic synthesis and biliary secretion of bile salts, and decreased biliary contractility, all of which increased susceptibility to cholesterol gallstones in susceptible mice. The research concluded that aging was an independent risk factor for cholesterol gallstone formation.

As previously mentioned, gallbladder stasis may play an active role in formation of gallstones. Factors that may lead to gallbladder dysmotility in older patients include increasing saturation of bile with cholesterol and altered sensitivity of the gallbladder smooth muscle to CCK. Reviews of CCK receptor stimulants, motilin agonists, and procholinergic agents provide encouragement for emerging pharmacotherapy as treatment options for gallbladder hypomotility [34, 46].

Pancreas

Pancreatic Development and Anatomy

The pancreas is a retroperitoneal organ in the upper abdomen. It lies posterior to the stomach, with its head nestled at the C loop of the duodenum and tail extending toward the hilum of the spleen. Pancreatic tissue is of endodermal origin and develops in tandem with the hepatobiliary system. During the 4th week of gestation, two buds develop from the duodenum, a hepatic diverticulum and a dorsal bud. The anterior bud develops into the liver and biliary system while the dorsal bud eventually forms the body and tail of the pancreas. During the 32nd week of gestation, the hepatic diverticulum gives rise to the ventral bud, which ultimately forms the uncinate process. It then rotates 180° clockwise around the duodenum and fuses with the dorsal pancreatic bud to form the mature pancreas (Fig. 72.6). The main pancreatic duct of Wirsung, formed by fusion of the ventral duct and the distal portion of the dorsal pancreatic duct, drains most of the pancreas into the duodenum at the ampulla of Vater. The diameter of the main pancreatic duct is 2.0–3.5 mm in healthy young adults [47]. The common bile duct joins with the main pancreatic duct at the ampulla of Vater and empties through the greater duodenal papilla. The proximal ductal system of the dorsal bud persists as the accessory pancreatic duct of Santorini, draining the superior portion of the

FIGURE 72.6 Anatomy of the mature pancreas, relative to surrounding structures (reprinted with permission from Trede M, Carter DC, (eds). *Surgery of the pancreas*. Edinburgh: Churchill Livingstone, © Elsevier, 1993).

pancreatic head via the lesser papilla into the duodenum proximal to the greater papilla.

Pancreatic Physiology

The pancreas has dual functions, both exocrine and endocrine. The exocrine activity is geared toward facilitating digestion, neutralizing gastric acid, and regulating intraintestinal pH. Pancreatic endocrine activity is vital for glucose homeostasis. Because of the great functional reserve of this organ, 90% of pancreatic function can be lost before signs of insufficiency become clinically evident [48].

Exocrine Function

The exocrine pancreas accounts for approximately 85% of the total mass and produces 500 ml of secretions per day. The acinar cells of the pancreas secrete enzymes responsible for digestion, and centroacinar cells and the ductal system direct the exocrine secretions to the duodenum, modifying the electrolyte concentration and water content of the pancreatic fluid as it passes. The acinar cells are innervated by the sympathetic and parasympathetic nervous systems. The parasympathetic system increases secretions, whereas the sympathetic system inhibits them [49]. The enzymes produced by the acinar cells include amylase (isoamylase type P), lipase, trypsinogen, chymotrypsinogen, procarboxypeptidases A and B, deoxyribonuclease, ribonuclease, proelastase, and trypsin inhibitor.

Pancreatic juices are secreted based on a three-phase response to a meal, including a cephalic phase, a gastric phase, and an intestinal phase. The cephalic phase accounts for 10–15% of meal-stimulated pancreatic secretion and occurs in response to the sight, smell, or taste of food. This is thought to be mediated by direct stimulation and increased gastric acid secretion in the stomach, which indirectly stimulates pancreatic secretion due to duodenal acidification and secretin release. The gastric phase also accounts for 10–15% of meal-stimulated pancreatic secretion and is due to gastric distention brought on by the ingested meal. This can lead to release of gastrin and vagal stimulation, both thought to have a weak direct effect on the pancreas. More importantly, the gastrin and vagal stimulation increases gastric acid content, leading to duodenal acidification, which triggers the release of secretin. This, in turn, leads to pancreatic secretions aimed at raising the pH. Pancreatic secretions are alkaline and have a pH that varies from 7.6 to 9.0, depending on the rate of bicarbonate secretion from the ductal epithelium. This alkaline pH is necessary to maintain the inactive proteolytic enzymes and transport them to the appropriate acidic milieu of the duodenum where they undergo activation. Secretin is the major stimulant for pancreatic electrolyte and water secretion, with CCK, gastrin, and peripherally released acetylcholine acting as weaker stimulants. Lastly, the intestinal phase is secondary to food and gastric contents entering the proximal intestine, which again increases secretin release. Dietary fats and proteins in the duodenum also stimulate the release of CCK, which then stimulates acinar secretion. The intestinal phase is the most important determinant of pancreatic secretion.

In addition to the water and electrolyte secretions, the exocrine pancreas secretes digestive enzymes. The major proteolytic enzyme is trypsin, initially secreted within the pancreas in an inactive form but activated within the duodenum by increasing acidity and enterokinase, a hormone produced by duodenal mucosa. Only amylase is secreted directly from the acinus in an active form. The other enzymes are initially secreted as inactive proenzymes, requiring trypsin and the acidic environment of the duodenum for activation. Inappropriate early activation of enzymatic action can result in autodigestion of the pancreatic substance, as may be seen in acute pancreatitis. The protein, fat, and carbohydrate constituents of diet alter the absolute amount and ratio of enzymes secreted. Regulation of enzyme secretion is primarily through the hormones CCK and acetylcholine. Secretin, vasoactive intestinal peptide (VIP), and pancreatic islet hormones weakly stimulate acinar secretion [47].

Endocrine Function

The main physiologic function of the endocrine pancreas is the regulation of energy through the hormonal regulation of

carbohydrate metabolism. This is achieved via the islets of Langerhans, clusters of specialized endocrine cells which are scattered throughout the exocrine tissue. Most islets contain approximately 3,000 to 4,000 cells, consisting of four major cell types: alpha cells which secrete glucagon, beta cells which secrete insulin, delta cells which secrete somatostatin, and PP or F cells which secrete pancreatic polypeptide.

The predominant and most studied pancreatic hormone is insulin. Insulin, a 51-amino-acid polypeptide, is synthesized as a prohormone in the beta cells of Langerhans islets. The proinsulin is synthesized in the endoplasmic reticulum, then travels to the Golgi complex where the C peptide is cleaved from it to create the insulin molecule. Upon stimulation, insulin is transported into secretory granules and released into the bloodstream by extrusion of the 6-kd polypeptide through the cell membrane. Insulin secretion occurs in response to elevated blood glucose levels and is suppressed by hypoglycemia. Insulin secretion is greater in response to orally administered glucose than intravenous glucose, even when serum glucose levels are equal. Insulin secretion occurs in two phases, the first being the release of stored insulin. The first phase is short (approximately 5 min) and is in response to a glucose challenge, whereas the second phase is longer and related to the sustained release of newly produced insulin. Maximal secretion of insulin occurs at serum glucose concentrations of 400–500 mg/dl. Type I diabetes results from a combination of genetic, environmental, and autoimmune factors which lead to selective destruction of β -cells. The endocrine tissue of the pancreas has excellent reserve, thereby requiring destruction of at least 80% of the tissue before clinical manifestations are evident [50].

Insulin binds to specific membrane-associated glycoprotein receptors that effect an increase in membrane-bound glucose transporters (GLUT-1 to GLUT-5), thereby facilitating glucose transport from the blood into cells. Skeletal muscle accounts for the majority of insulin-mediated glucose uptake and impaired insulin action at the level of the muscle is the cause of insulin resistance in type II diabetes [51]. In the liver, insulin facilitates glycogen deposition while inhibiting gluconeogenesis and glycogenolysis, resulting in a net increase in glucose uptake. Insulin also promotes lipogenesis and protein synthesis. As part of the insulin resistance syndrome, malfunction of insulin at the level of the liver can lead to abnormal lipid accumulation in hepatocytes, leading to non-alcoholic steatohepatitis (NASH) [52].

Glucagon is also synthesized as a 29-amino-acid propeptide and its purpose is to counteract the effects of insulin and increase the concentration of blood glucose. Similar to insulin, glucose is the primary regulator of glucagon secretion, although with glucagon, it causes an inhibitory effect. Furthermore, insulin and somatostatin also serve as negative regulators of glucagon secretion. Secretion is stimulated by hypoglycemia, acetylcholine, and generalized stressed states such as that occur with infection, trauma, or inflammation.

Glucagon promotes an elevation of blood glucose levels, with mobilization of intracellular fuels by hepatic glycogenolysis, gluconeogenesis, ketogenesis, and lipolysis. It is the provision of metabolic fuels during times of stress that resulted in glucagon being grouped with epinephrine, cortisol, and growth hormone as stress hormones.

Somatostatin is a 14-amino-acid polypeptide that has a wide anatomic distribution in neurons, pancreas, intestines, and other organs. It was originally isolated in 1973 as a hypothalamic extract that inhibited the release of growth hormone. Endocrine release of somatostatin occurs during a meal, in response to intraluminal fat; however, its exact role in the pancreas remains unclear, but it has been shown to inhibit the release of almost all peptide hormones and to inhibit gastric, pancreatic, and biliary secretion. Some researchers have suggested that somatostatin may regulate adjacent islet cell functions, but this has not been proven *in vivo*. The potent inhibitory effects of somatostatin and octreotide, a long-acting synthetic analogue, have been used to treat a variety of endocrine and exocrine disorders.

Pancreatic polypeptide (PP) is a 36-amino-acid polypeptide secreted in response to protein and less so to glucose from F cells. Although they are distributed throughout the pancreas, the predominance of these cells is concentrated in the pancreatic head and uncinate process. One of its most important roles may be as a mediator of the hepatic response to insulin. It has been demonstrated that abnormal glucose homeostasis associated with PP deficiency in patients with chronic pancreatitis is due to impaired suppression of hepatic glucose production by insulin [53]. This relative hepatic resistance to insulin is a consequence of diminished insulin receptor concentration, rather than altered receptor affinity, and can be ameliorated by administration of PP [54]. This mechanism of glucose metabolism has been further clarified by studies suggesting that hepatic insulin resistance in chronic pancreatitis is due to impaired transcription of the insulin receptor gene. Additionally, PP increases hepatic insulin-binding sites perhaps by upregulating insulin receptor gene expression [55]. PP is known to inhibit pancreatic exocrine secretion, choleresis, and motilin release [56]. PP release is augmented by cholinergic stimulation, with the normal postprandial rise in PP levels being ablated by vagotomy, antrectomy, or both [47].

PP is part of the polypeptide-fold family of peptide hormones, along with the central nervous system peptide, neuropeptide Y, and peptide tyrosine-tyrosine (PYY). Each of these is believed to play an important role in the regulation of appetite. PP was the first of these hormones to be isolated, from an impure insulin extraction. PP functions as a component of the “ileal brake” since it acts in various ways to slow the transit of food through the gut. It delays gastric emptying, attenuates pancreatic exocrine secretion and inhibits gallbladder contraction [57]. The role of PP in obesity is undergoing increasing investigation. Preliminary data suggest that PP reduced postprandial secretion is associated with

obesity, whereas elevated postprandial levels of PP are found in patients with anorexia nervosa [58].

Pancreatic Anatomy in the Elderly

The pancreas undergoes an aging process resulting in minimal amounts of atrophy, fatty infiltration and fibrosis. One of the main age-related changes occurs with ductal anatomy, specifically an increase in the caliber of the main pancreatic duct and ectasia of branched ducts. One review by Kreel and Sandin [59] of in situ retrograde pancreatography at necropsy in 120 subjects older than 30 years revealed the main pancreatic duct width to increase with age at a rate of 8% per decade. A study using ultrasonography demonstrated an increasing pancreatic duct diameter with age. Regardless, the pancreatic duct was not found to be more than 3 mm, which if detected, should be considered a pathologic finding and not solely age-related [60]. The pancreatic duct widens proportionally along its entire length such that a uniform taper in caliber is maintained. This ductal anatomy can be distinguished from ductal dilatation associated with obstruction as seen with chronic pancreatitis and periampullary cancer. In some elderly patients, ductal ectasia becomes cystic as a variant of the aging pancreas. Acinar atrophy, an increased amount of intralobular fibrosis and fatty infiltration, and calcified pancreatic ductal calculi [61] seem to be common findings in the pancreas over the age of 70. Because of the increasing frequency of intercurrent disease states and degrees of malnutrition in the elderly, the proportion of these morphologic changes that are due to age alone vs. pathology has yet to be determined. In summary, the morphologic changes of the aging pancreas can be considerable, requiring clinicians to take caution when interpreting ERCP and computed tomography (CT) findings in the elderly (see physiology table at the beginning of this chapter).

Aging of the Exocrine Pancreas

Regarding the body of literature addressing physiologic changes in pancreatic function, conflicting data has emerged owing largely to a lack of consensus on defining pancreatic exocrine insufficiency. For instance, Laugier determined that patients over 65 years of age demonstrated a decrease in the volume and bicarbonate output of pancreatic secretion and the concentrations of pancreatic protein and lipase in response to stimulation from secretin and CCK stimulation [62]. In contrast, Gullo and associates failed to show any decrease in bicarbonate, trypsin, or lipase in response to continuous stimulation in elderly patients when compared to younger controls [63]. Regardless of the contrasting results, the

clinical significance of age-related changes in exocrine function is limited to a decrease of 10–30%. Therefore, the presence of steatorrhea in the elderly patient must be considered outside of expected aging and in the greater scope of other pathologies such as intraductal papillary mucinous neoplasms or pancreatic carcinoma [64].

Aging of the Endocrine Pancreas

Insulin Resistance in the Elderly

It has long been recognized that persons over 60 years of age more commonly exhibit dysfunction of glucose regulatory mechanisms in response to a glucose challenge [65]. Minimal morphologic alteration occurs in the aging endocrine pancreas, but a number of functional tests suggest progressive impairment of glucose tolerance in the elderly [66–68]. Clinical studies show an age-related increase in fasting blood glucose levels of about 1–2mg/dl per decade, which may be less marked in lean, physically active individuals [66, 69]. The prevalence of diabetes over the past decade has increased enormously, largely due to a concomitant rise in the prevalence of obesity. As the aging population continues to grow and their life expectancy increases, so too does the rate of diabetes. Currently, about 20% of patients over 65 years suffer from diabetes [70].

Type II diabetes results from a multifactorial, progressive disease state and decompensation. Patients begin with impaired glucose tolerance as a result of the β -cell's attempts to maintain glucose homeostasis under chronic hyperglycemia and elevated free fatty acids. Once the β -cell can no longer compensate for peripheral hormone resistance, frank diabetes ensues. The interaction of many factors associated with aging contributes to the development of diabetes. Proposed mechanisms include altered insulin metabolism (depressed secretion, increased clearance, or diminished prohormone activation), increased resistance of peripheral tissues to insulin (receptor aberration, altered postreceptor pathways, or altered glucose transporter), loss of hepatic sensitivity to insulin, causing reduced glycogenesis, increased glucagon levels, and an age-associated increase in adipose tissue [72]. Studies which have specifically examined age-related effects on β -cell function have demonstrated variable results. This may be due to the small magnitude of the age effect, different techniques of measurement, and the presence of confounding factors such as obesity.

Current theories involving aging and insulin secretion highlight the interplay between a decreased β -cell secretory function and failure of peripheral glucose uptake mechanisms. The number and affinity of insulin receptors are similar across the spectrum of age groups [72]. Therefore, in absence of other risk factors, insulin resistance in the elderly

is also due to impairments at the postreceptor level and β -cell dysfunction. A number of age-related effects on β -cells are known, such as decreased sensitivity to incretins and impaired compensation to insulin resistance, thereby predisposing older people to develop impaired glucose tolerance and diabetes [73]. Future studies aimed at delineating β -cell function may shed additional light on the subject.

Glucagon

Little is known about glucagon metabolism and actions in the elderly. Berger and associates reported that fasting plasma glucagon levels are significantly higher after age 30 when compared to those of a younger cohort [69]. However, after age 30, plasma glucagon levels did not significantly increase with advancing age. These findings are compared with those from the more recent work of Simonson and DeFronzo [74], who showed no correlation between advancing age and glucagon levels in 111 subjects aged 21–75 years. Additionally, this study demonstrated no difference in glucagon concentrations or clearance in young and old subjects receiving glucagon infusion, but hepatic sensitivity to the hormone appeared to be enhanced in the older age groups. Although the mechanism for this effect is not known, heightened hepatic sensitivity to glucagon in the elderly may be one of several factors contributing to progressive glucose intolerance of aging. Although some follow-up studies have confirmed no age-related changes in glucagon concentrations, other studies have shown reduced and elevated glucagon levels in the elderly [75].

Pancreatic Polypeptide

It has been previously noted that plasma levels of immunoreactive PP increase linearly with patient age [69]. The functional consequence of the age-related rise in PP levels is unknown. Studies using an isolated perfused human pancreas model reaffirmed this phenomenon and suggested that elevated PP levels in the elderly are due to enhancement of basal PP secretion, not reduced PP clearance [56].

Chapter 73

Benign Disease of the Gallbladder and Pancreas

Jennifer A. Wargo and Kim U. Kahng

Benign diseases of the gallbladder and pancreas represent significant causes of morbidity and mortality worldwide, particularly in elderly patients. Additionally, asymptomatic benign lesions of the gallbladder and pancreas are diagnosed more frequently with the increased use of imaging, and require thoughtful consideration for appropriate and timely treatment or follow-up. A critical understanding of these diseases is mandatory for proper patient care in the geriatric population.

Benign Disease of the Gallbladder

Disease of the biliary tract is common among adults in the USA: 10–15% of the adult population has gallstones, accounting for approximately 20 million people, and one million new cases are discovered annually. Gallstone disease is the most common and most costly digestive disease causing hospitalization, with an estimated annual cost exceeding \$5 billion [1]. Among the elderly, biliary disease is the most common indication for abdominal surgery [2]. This is undoubtedly related to the progressive increase in the prevalence of cholelithiasis with advancing age (Fig. 73.1), which in some reports exceeds 50% in those older than age 70 [3]. In addition to being common, gallbladder disease in the elderly is more severe than in the young, as indicated by the higher proportion of elderly patients requiring cholecystectomy for acute rather than chronic cholecystitis [4]. Biliary tract disease in the elderly is further complicated by the greater incidence of choledocholithiasis. Common duct stones are found at the time of

cholecystectomy in up to 30% of those in their 60s and in up to 50% of those in their 70s [5].

Manifestations of biliary disease in the elderly differ significantly from those in the young, which may contribute to the higher morbidity and mortality in older patients [6]. The atypical presentation in elderly patients and the frequency of coincidental gastrointestinal complaints often lead to delays in diagnosis [7]. These delays contribute to the higher incidence of the known complications of cholelithiasis and the increased mortality of gallstone disease in the aged population [8]. Recognizing the frequency and understanding the clinical presentation of biliary disease in the elderly is thus imperative for the proper care and treatment of these patients.

Cholelithiasis

Incidence and Epidemiology

The prevalence of cholelithiasis varies widely among populations of the world. The considerable variation in the incidence of cholelithiasis among ethnic groups is perhaps best illustrated by the markedly increased rate of gallstone disease in Pima Indians. The prevalence of cholelithiasis in female Pima Indians exceeds 60% for those over 35 years of age [9]. To a lesser degree, an increased propensity for gallstone formation is also seen in the Scandinavian countries, Chile, and among Native Americans [10]. The prevalence of gallstones in blacks, however, is roughly one-half that of whites [5] and is as low as 3% in some African tribes [11].

Regardless of geographic site or ethnicity, the two primary factors associated with the development of gallstones are gender and age. Female gender unquestionably contributes to an increased incidence of cholelithiasis, as women are twice as likely as men to develop gallstones [10]. Differences in the hormonal milieu have been

FIGURE 73.1 Incidence of gallbladder disease by age.

implicated by studies showing that estrogen and progesterone increase the lithogenicity of bile and alter gallbladder motility [11]. Exogenous estrogen induces hypersecretion of cholesterol into bile in both men [12] and women [13] and affects the motility of the sphincter of Oddi in animal models [14].

Advancing age is clearly associated with an increased prevalence of cholelithiasis. This is true regardless of gender [4] or ethnicity. The effect of age may be magnified in the institutionalized elderly as indicated by a report that cholelithiasis was present in 60% of institutionalized women aged 80–89 years and 80% of those older than 90 years [15].

Classification

Most gallstones in Western countries, including the USA, are composed of a mixture of both cholesterol and pigment. Pure cholesterol stones account for only 10% and pure pigment stones for about 15% of gallstones in the USA [16]. Most mixed stones contain cholesterol as their principal constituent, with alternating layers of mucin glycoproteins [10].

Pigment stones are composed mainly of bilirubin, usually in the form of calcium bilirubinate. These stones may be further categorized as either black or brown, with black stones seen more commonly in the presence of hemolytic disease or hepatic cirrhosis. Brown pigment stones are typically seen in Asian patients and are associated with biliary infection [16]. At the time of cholecystectomy, the percentage of stones that are pigmented increases with advancing age [17]. Whether the type of stone is related to the subsequent development of symptoms is debatable, but the differentiation between cholesterol and pigment stones is important when nonoperative management is considered, as black pigment stones are resistant to dissolution therapy [18].

Pathogenesis

Cholesterol Stones

The pathogenesis of cholesterol stones involves a series of defects that ultimately lead to the formation of stones. These pathogenic factors include cholesterol hypersecretion with subsequent supersaturation of bile, gallbladder hypomotility leading to bile stasis, cholesterol crystallization in bile serving as a nidus for stone formation, hypersecretion of gallbladder mucus [19], and increased concentration of biliary calcium [20].

Hypersecretion of cholesterol is considered the primary requisite factor for the development of cholesterol gallstones in the Western world [21]. Advancing age is associated with increased biliary secretion of cholesterol and decreased hepatic bile salt synthesis [22]. These changes in cholesterol secretion and bile salt synthesis may contribute to the increased prevalence of cholelithiasis in the elderly population.

In addition to factors related to bile composition, decreased gallbladder motility plays a significant role in gallstone formation. The risk of gallstone formation is significantly increased by conditions that impair normal gallbladder emptying, such as pregnancy [23], treatment with total parenteral nutrition (TPN) [24], octreotide therapy for acromegaly [25], diabetes mellitus [26], sickle cell anemia [27], and in patients who have suffered spinal cord injury [28] or who have undergone truncal vagotomy [29].

Normally, there is a continuous flow of bile in and out of the gallbladder. The greatest flow of gallbladder bile is stimulated by food consumption [30], which causes gallbladder contraction in a triphasic pattern of emptying, refilling, then emptying again [4]. Gallbladder emptying and refilling also occurs during fasting. Nearly 10% of gallbladder volume is ejected during fasting in association with migrating motor complexes (MMCs) in the duodenum [31]. This facilitates exchange of bile between the common duct and the gallbladder and may prevent stratification of bile within the gallbladder itself [14]. Gallbladder motility is influenced by several neurohumoral mechanisms. The entry of food into the duodenum stimulates the release of cholecystokinin (CCK) by intestinal endocrine cells. CCK has several effects, including increasing the flow of hepatic bile into the biliary tree and contracting the gallbladder with concomitant relaxation of the sphincter of Oddi [14]. Nearly three-fourths of the gallbladder volume is ejected in response to CCK [32], with approximately 15% released prior to the onset of gastric emptying. The effect of CCK is modulated by several other peptide hormones as well. Secretin has no intrinsic effect on gallbladder motility, but it significantly potentiates the effects of CCK [33]. Somatostatin inhibits CCK-mediated

gallbladder contraction and is thought to act as a physiologic “brake” [32]. Other inhibitors of CCK-mediated gallbladder contraction include vasoactive intestinal polypeptide (VIP) [34], pancreatic polypeptide [35], and peptide YY [36].

In addition to neurohumoral control mechanisms, gallbladder motility may be influenced by the degree of cholesterol saturation of bile. Animal and human studies suggest that cholesterol hypersaturation of bile attenuates gallbladder motility. In animal models, 1 week of cholesterol feeding reduces the gallbladder ejection fraction from 76 to 26% [37]. Gallbladder contraction is considerably diminished in patients with cholesterosis, or “strawberry gallbladder” [38]. The ability to contract both spontaneously and in response to stimulation with CCK, acetylcholine, and potassium chloride is markedly reduced in gallbladders from patients with cholesterol cholelithiasis [38].

Bile stasis may also lead to the formation of biliary sludge, a viscous aggregate composed of mucin glycoproteins, calcium bilirubinate, and cholesterol crystals [14]. The presence of sludge in the gallbladder can be detected by ultrasonography, and its formation is typically related to the presence of lithogenic bile and gallbladder hypomotility [39]. Biliary sludge has been found in 50% of patients receiving TPN for a period of 6 weeks and in nearly 100% of those receiving TPN for more than 6 weeks [40]. This is thought to be related to the lack of oral intake during therapy with TPN, as enteral feeding may reverse the process of biliary sludge deposition [40]. The formation of both cholesterol and pigment stones is virtually always anteceded by the presence of biliary sludge [6].

Investigation into the effects of aging on gallbladder motility have been confined primarily to changes in neurohumoral control mechanisms, particularly age-related changes in CCK sensitivity. In animal studies, aging is associated with a decrease in the gallbladder contractile response to CCK, which appears to be related to a decrease in the number of CCK receptors [41]. The increased incidence of gallstone formation seen in old animals can be prevented by the administration of exogenous CCK [42]. Human studies have also demonstrated markedly reduced gallbladder sensitivity to CCK with aging, but there appears to be a compensatory elevation in the level of serum CCK [43]. In addition to changes in CCK activity, aging is associated with increased levels of pancreatic polypeptide [44], which may contribute to bile stasis because of decreased gallbladder contractility and increased sphincter of Oddi pressures.

Pigmented Stones

Despite their relatively low incidence in the USA, pigment stones are the most common type of gallstone worldwide [45]. The etiology and pathogenesis differ between black

and brown pigment stones. Black pigment stones form in the presence of increased secretion of bilirubin conjugates, which typically occurs with chronic hemolysis and to some degree with hepatic cirrhosis. Normally, unconjugated bilirubin produced by the action of β -glucuronidase constitutes less than 1% of the total bile pigments [46]. In patients with hemolytic disease, the percent of unconjugated bilirubin may increase more than tenfold [47], thus exceeding its solubility in bile. The unconjugated bilirubin precipitates with calcium ions, leading to the formation of insoluble calcium salts [48]. Most pigment stones are composed primarily of calcium bilirubinate and generally form in sterile bile [49].

Brown pigment stones form in the presence of chronic anaerobic infection of bile [50]. This particular type of pigment stone is endemic to Asia, probably owing to the high incidence of biliary infection in this area of the world [51]. The finding of significantly increased bacterial β -glucuronidase activity in the bile of patients with brown pigment stones is supporting evidence that biliary infection is an important etiologic factor [52]. The pathogenesis of brown pigment stones also involves biliary stasis, which predisposes to biliary infection. The incidence of brown pigment stones in the common bile duct in the presence of preexisting cholelithiasis increases with age, probably owing to decreased biliary motility with subsequent stasis and infection of bile [53].

Natural History

Asymptomatic Cholelithiasis

Few studies have addressed the natural history of gallstone disease, particularly in the aged population. Understanding the natural history of cholelithiasis has become increasingly important with the widespread use of abdominal ultrasonography and computed tomography, as the incidental finding of gallstones occurs with significant frequency [54]. This is particularly pertinent in elderly patients in whom the prevalence of cholelithiasis is known to be much higher than in the general population.

Several studies have attempted to describe the natural history of asymptomatic gallstone disease, mainly focusing on the rate of symptom development and complications. Gallstone disease is considered symptomatic with the development of biliary pain or any of its associated complications such as acute cholecystitis, biliary obstruction, or biliary pancreatitis [55].

An early report from the 1940s cited the development of symptoms in nearly 50% of patients with known gallstones when followed for 10–20 years. The complication rate in this study was roughly 19% over 15 years, accounting for

an annual complication rate of approximately 1.4% [56]. In contrast, Gracie and Ransohoff reported much lower rates for the development of symptoms and associated complications [57]. The probability of symptom development in the presence of cholelithiasis in this study was estimated to be only 15% at 10 years and 18% at 15 and 20 years; the complication rate was approximately 20% in those who became symptomatic. Based on these findings, Gracie and Ransohoff introduced the concept of the “innocent gallstone.” The population in their study, however, consisted of exclusively white, predominantly male subjects with a mean age of 54 years who had documented gallstone disease on oral cholecystography [57]. Attili et al. [58] questioned the results of Gracie and Ransohoff and reviewed the natural history of both asymptomatic and symptomatic gallstones in a much more representative population. The probability of symptom development in asymptomatic individuals in their study was nearly 12% at 2 years, 16.5% at 4 years, and close to 26% at 10 years. The complication rate in this study was approximately 3% after 10 years. The authors concluded that the natural history of gallstone disease is less benign than suggested by the studies of Gracie and Ransohoff. A conservative annual rate of symptom development of approximately 2% with about 1.5% requiring cholecystectomy was reported by McSherry et al. in their study of 691 patients with gallstone disease enrolled in a large health maintenance organization [59]. Based on all of these studies it can be estimated that serious symptoms and complications of gallstone disease are likely to occur at an annual rate of about 2% in those with cholelithiasis, with roughly two-thirds of patients remaining asymptomatic over a period of 20 years [60]. In light of this information, prophylactic cholecystectomy for asymptomatic cholelithiasis in the general population is not recommended [61].

The natural history of asymptomatic gallstones in the elderly is much less well defined. Studies that have included a significant number of older individuals have shown that elderly patients are more likely to present with complications of gallstone disease. In a study of 750 patients with gallstone disease, Wenckert and Robertson demonstrated that nearly half of these patients developed severe complications within 11 years after the diagnosis of cholelithiasis [62]. Additionally, the complications of biliary disease are much less likely to be preceded by the typical symptoms ordinarily exhibited by younger individuals with biliary tract disease. In one study, nearly 80% of those who died from complications of gallbladder disease were previously classified as “asymptomatic” [63].

Gallstones may be discovered when patients undergo laparotomy for other reasons. Incidental cholecystectomy is generally not recommended in elderly patients undergoing abdominal surgery. Though early small studies in the 1970s

suggested that it could be done safely [64], other studies demonstrated a slightly higher rate of wound infection and increased length of hospital stay [65].

Symptomatic Cholelithiasis

The natural history of symptomatic gallstones is understandably different from that of asymptomatic gallstones. Studies on the natural history of symptomatic cholelithiasis are somewhat sparse, as treatment is customarily recommended for patients within this population. Some studies are available, however. Annual rates of severe symptom development and cholecystectomy in patients with mildly symptomatic cholelithiasis were 44.0 and 3.2%, respectively, in the National Cooperative Gallstone Study [66]. Annual rates for cholecystectomy in patients with severe symptoms are typically 6–8% [67]. The rate of complications is not significantly different between patients with symptomatic and asymptomatic gallstone disease, suggesting that the presence or absence of symptoms is not a reliable prognostic indicator for the development of complications in cholelithiasis.

The typical initial presentation of symptomatic gallstone disease is that of biliary colic or chronic cholecystitis. Elderly patients are less likely to present with the “typical” symptoms of gallstone disease experienced by younger individuals [2]. Furthermore, elderly patients may present with complications of gallstone disease without any precursor symptoms of chronic cholecystitis. Morrow et al. [68] reported minimal or absent prior symptoms in nearly 40% of elderly patients presenting with grave complications, such as gangrenous cholecystitis, gallbladder empyema, or gallbladder perforation. Because of atypical symptomatology and the predilection for presenting with complicated gallstone disease, clinicians must have a high index of suspicion for biliary tract disease when caring for elderly patients.

Chronic Cholecystitis

The pain associated with chronic cholecystitis, often referred to as biliary colic, is produced by a stone obstructing the cystic duct. The term “colic” is deceiving, as the pain is abrupt in onset and constant in nature, unlike true “colicky” pain that is characterized by a waxing and waning course. The pain is typically located in the right upper quadrant or epigastrium. Although radiation of pain is classically to the right shoulder or the inferior angle of the scapula, the pain may also radiate to other areas of the thorax or abdomen. The pain usually occurs at night, often around midnight, and lasts several hours. The frequency of recurrent pain varies among individuals, with intervals between attacks of pain ranging from days to weeks to occasionally months [69].

Patients may also present with nonspecific symptoms, such as bloating, gassiness, indigestion, nausea, and fatty food intolerance [70, 71]. Elderly patients are more likely to present with dyspepsia and vague epigastric discomfort [73]. The nonspecific nature of biliary symptoms commonly seen in aged patients, along with the multiplicity of coexisting gastrointestinal problems, clearly contribute to delays in diagnosis and treatment.

Physical examination of the symptomatic patient may yield right upper quadrant tenderness but is likely to be normal when the patient is not experiencing symptoms. Laboratory values are usually normal with chronic cholecystitis.

Based primarily on the history, a diagnosis of chronic cholecystitis is confirmed by establishing the presence of gallstones. The use of ultrasonography to detect cholelithiasis is clearly established. Gallstones are best visualized when the gallbladder is examined in both axial and sagittal planes after 8 h of fasting [73]. Gallstones typically appear as echogenic foci that demonstrate acoustic shadowing and gravitational dependence. Ultrasonography may detect stones as small as 1–2 mm in size, which when multiple, are often characterized as “gravel.” Gallbladder sludge, in contrast to gravel, appears as an echogenic layer that does not cast an acoustic shadow and is less gravitationally dependent. The sensitivity and specificity of ultrasonography for cholelithiasis when chronic cholecystitis is suspected are 0.95 and 0.97, respectively [74].

In addition to detecting the presence of gallstones, ultrasonography provides structural information about the gallbladder itself and the biliary ductal system. The ability to detect significant biliary ductal dilatation is particularly useful in the elderly because of the high incidence of common bile duct stones. Furthermore, information is provided about the liver, kidneys, and pancreas. For all these reasons, ultrasonography is the diagnostic study of choice for gallstone disease.

Several other radiologic studies can yield information about the biliary tree but have little role in the diagnosis of chronic cholecystitis. Plain roentgenography alone has limited usefulness in the diagnosis of cholelithiasis, as most of the stones are radiolucent. Fewer than 20% of gallstones can be visualized on plain radiographs of the abdomen [75]. Abdominal CT is far less sensitive than ultrasonography for detecting gallstones [76], as most stones are of the same attenuation as bile and therefore not well visualized. Cholescintigraphy has limited usefulness in the routine diagnosis of chronic cholecystitis, as it cannot provide anatomic information or identify gallstones. In atypical cases of classic biliary symptomatology with no ultrasonographic abnormalities, the functional information provided by cholescintigraphy becomes important. In such cases, analyzing gallbladder motility in response to a prokinetic agent

may be the only means of establishing gallbladder pathology. It must be emphasized, however, that these atypical cases are rare.

When considering treatment for patients with symptomatic cholelithiasis, the natural history of the disease, the general life expectancy and medical condition of the individual, and the risks and benefits of the various treatment modalities are all factors that must be noted [77]. Expectant management of symptomatic gallstone disease is generally not advisable, as severe symptom development in patients with mildly symptomatic cholelithiasis is reported to be as high as 44% per year [66]. Particularly in the elderly, the risk of developing complicated biliary disease requiring emergent treatment with attendant high mortality, weighs strongly in favor of definitive treatment of symptomatic gallstones in an elective setting.

The definitive treatment for gallstone disease is cholecystectomy, which is performed in patients with chronic cholecystitis to relieve symptoms and prevent potentially life-threatening complications. Prior to the introduction of laparoscopic cholecystectomy, open cholecystectomy had been the gold standard for treating cholelithiasis for more than a century [16]. A comprehensive review by Roslyn et al. [78] of 42,474 open cholecystectomies performed at all nonveterans administration (VA) acute care hospitals in California and Maryland for a 12-month period, indicated that open cholecystectomy was a safe, effective treatment for gallstone disease. The study, which included patients undergoing emergent and elective cholecystectomy, reported an overall mortality rate of 0.17%. This is significantly lower than the mortality rate of 1.77% reported by Glenn more than 15 years prior [79]. In this more contemporary study, however, advanced age (more than 65 years) was associated with significantly higher mortality (0.5 vs. 0.03%) and complication (25.7% vs. 10.1%) rates than for the less than 65-year-old group. Significant increases in length of stay and in-hospital charges were also noted in aged patients [78].

Several factors contribute to the increased mortality and complication rates following open cholecystectomy in aged patients. A primary factor is the larger proportion of elderly patients compared to younger patients requiring emergency rather than elective cholecystectomy. Pigott and Williams [80] studied a group of 347 patients over 65 years of age who underwent open cholecystectomy for symptomatic gallstone disease. More than half of the patients in this study presented with an acute complication of gallstone disease, and they often required emergent surgical procedures. There may be multiple reasons for the greater tendency of the elderly to present with complicated gallstone disease. The early diagnosis of symptomatic gallstone disease at an uncomplicated stage (i.e., simple chronic cholecystitis) may not be made as readily, as elderly patients are more likely to present with atypical symptoms such as dyspepsia and vague epigastric

discomfort. Elderly patients often present without antecedent symptoms of chronic cholecystitis. Finally, the increased incidence of choledocholithiasis adds to the complexity of biliary disease in the elderly.

Laparoscopic cholecystectomy has changed the surgical management of symptomatic cholelithiasis dramatically since its advent during the late 1980s [81]. First performed in France by Dr. Phillippe Mouret in 1987 [82], and in the USA by McKernan and Saye in 1988 and Olsen and Reddick in 1989 [83], laparoscopic cholecystectomy is now established as the procedure of choice for symptomatic gallstone disease. The laparoscopic approach offers many advantages when compared to open cholecystectomy, including reduced postoperative pain, shorter hospital stay and recovery, improved cosmetic results, and lower cost. The reduction of postoperative pain is a major benefit, resulting in decreased analgesic requirement and improved pulmonary function following surgery [84].

Mortality rates for laparoscopic cholecystectomy are reportedly lower than those of open cholecystectomy in reviews of both European [85] and US experiences [86], averaging about 0.1%. One of the largest reported series is that of the Southern Surgeons Club, which included more than 1,500 patients who underwent laparoscopic cholecystectomy for symptomatic cholelithiasis [87]. This study reported a 4.7% conversion rate to open cholecystectomy and a complication rate of 5.1%. The most significant complication of laparoscopic cholecystectomy is major bile duct injury, which is reported to occur in 5–10 per 1,000 cases [88]. Bile duct injury tends to occur early in a surgeon's experience with laparoscopy [89]. An updated study by the Southern Surgeons Club reported that 90% of bile duct injuries occurred during the first 30 cases performed by individual surgeons, clearly supporting the existence of a learning curve for laparoscopic cholecystectomy [90]. The overall complication rate for laparoscopic cholecystectomy is noted to be significantly lower than that of open cholecystectomy [91].

Conversion to open cholecystectomy is generally required in approximately 5% of patients undergoing laparoscopic cholecystectomy [92], most commonly because adhesions and chronic inflammation preclude the laparoscopic approach. Advanced age, male gender, obesity, acute cholecystitis, and the presence of a thickened gallbladder wall on ultrasonography are factors associated with a significantly increased rate of conversion from laparoscopic to open cholecystectomy [93]. A study based on the Connecticut Laparoscopic Cholecystectomy Registry, reported a correlation between conversion rates and age among elderly patients. Conversion was necessary in roughly 8% of those aged 70–74 years, 12% of those aged 75–80 years, and more than 12% of those over 80 years of age [94]. Although conversion to an open procedure is not a complication of laparoscopic

surgery and should never have a negative connotation, an appreciation for the likelihood of conversion is important when considering the risk of laparoscopic surgery in an elderly patient.

Laparoscopic cholecystectomy has significant implications in the treatment of elderly patients with gallstone disease. Several studies have reported favorable results in elderly individuals undergoing the laparoscopic procedure compared to those with the open approach [95–98]. A study of 233 patients by Massie et al. [95], demonstrated a seven-fold reduction in postoperative morbidity following laparoscopic cholecystectomy compared to open cholecystectomy in elderly patients and younger patients with clinically significant associated illnesses. A more extensive study of 1,677 patients at McGill University reported similar results [96]. As expected, elderly patients in this study were much more likely to present with evidence of complicated gallstone disease and were nearly twice as likely to require conversion to open cholecystectomy. The mortality rate of 0.6% for elderly patients was roughly five times higher than that for patients under 65 years of age [96] but was markedly lower than rates reported for open cholecystectomy in the same age group [5]. Complication rates were also significantly lower after laparoscopic cholecystectomy in the elderly compared to the historical complication rate following open cholecystectomy [96]. In particular, laparoscopic cholecystectomy in the older patients results in less postoperative impairment of pulmonary function compared to open cholecystectomy [99].

There are few absolute contraindications to laparoscopic cholecystectomy. These include an uncorrected coagulopathy and the inability to tolerate general anesthesia [16]. Conditions that may increase a patient's risks for postoperative complications of laparoscopic cholecystectomy include cardiopulmonary disease, immunosuppression, and cirrhosis with portal hypertension [100]. These factors are particularly pertinent during the preoperative risk assessment of elderly patients, as their presence is associated with an increased frequency of complications [98].

For those patients who are unwilling or unable to tolerate cholecystectomy, the nonoperative methods for treating chronic cholecystitis are primarily oral and contact dissolution as well as extracorporeal shock wave lithotripsy. These methods are limited by their variable efficacy, requiring careful patient selection. Furthermore, even when they successfully achieve clearance of gallstones, the rate of recurrent cholelithiasis approaches 50% over 5 years [16]. It must be noted that although these methods may find application in the treatment of uncomplicated symptomatic cholelithiasis, they should not be used to treat complicated gallstone disease [101].

Oral dissolution therapy involves the use of litholytic bile acids. These substances act primarily by inhibiting the enzyme HMG-CoA reductase, thus decreasing the

biosynthesis of cholesterol and the saturation of cholesterol in bile [101]. Chenodeoxycholic acid (CDCA) was the first of these agents to be used in the dissolution of gallstones [102]. CDCA had an unfavorable side effect profile and poor efficacy and in 1988 was replaced by ursodeoxycholic acid (UDCA) [103]. Patients eligible for UDCA therapy include those with a history of biliary colic, radiolucent stones less than 1.5–2.0 cm in diameter, and a functional gallbladder. By these selection criteria, only 10–20% of those undergoing cholecystectomy would be eligible for UDCA therapy [5]. The dose is 8–10 mg/kg/day [102], and the expense of therapy is approximately \$2,000 per year [5]. Although better than the results with CDCA, treatment with UDCA has limited efficacy, with complete dissolution occurring in 40% and partial dissolution in 20% after 2 years of therapy [104].

Contact dissolution therapy was first described in the late 1800s and is of historical interest only since it is not used today [105]. In this technique, a catheter is placed transhepatically into the gallbladder, and organic solvents are infused to dissolve gallstones. Its use was reevaluated in 1972 when Admirand and Way reported use of contact dissolution therapy to eradicate retained common duct stones [106]. The most commonly used solvent is methyl *tert*-butyl ether (MTBE). The efficacy of contact dissolution with MTBE is reported to be quite high, with complete dissolution of stones in more than 90% of patients [107]. Disadvantages of this technique, however, include a relatively high recurrence rate [108] and cost.

Extracorporeal shock wave lithotripsy (ESWL) for the treatment of gallstones was introduced in 1985 [109]. It is used to fragment gallstones into particles small enough to be expelled by a functional gallbladder and often requires the use of general or epidural anesthesia. Patients eligible for ESWL include those with a history of biliary colic who have one to three radiolucent stones with a combined diameter not exceeding 3 cm and a functional gallbladder [5]. Again, this topic is mostly of historical interest, as it is rarely used in the era of laparoscopic cholecystectomy.

In summary, laparoscopic cholecystectomy has found wide application for treatment of chronic cholecystitis, regardless of age, and has supplanted open cholecystectomy as the new gold standard. The overall improvement in mortality rates and the clear demonstration of the benefits of laparoscopic compared to open cholecystectomy specifically in the elderly, makes it the preferred procedure for definitive treatment of chronic cholecystitis even in the elderly. The crux is diagnosing symptomatic gallstone disease at an early stage to allow elective rather than emergency cholecystectomy. Although it must be acknowledged that age increases the risk for cholecystectomy, it is crucial to understand how this risk is magnified when emergency surgery is required.

Acute Cholecystitis

Acute cholecystitis is by far the most common complication of gallstone disease. It typically results from cystic duct obstruction due to impaction of a stone in the cystic duct itself or in Hartmann's pouch, with resultant bile stasis and distension of the gallbladder. The consequent mucosal release of lysolecithin, prostaglandins, and phospholipase A result in local inflammation. Bile becomes secondarily infected, resulting in positive bile cultures in nearly three-fourths of patients with acute cholecystitis [16]. The organisms most commonly isolated include *Escherichia coli*, *Klebsiella*, and *Enterococcus* species [3].

The classic presentation of acute cholecystitis includes fever and localized right upper quadrant abdominal pain [4]. Initially the pain may resemble that of biliary colic, but it differs in its longer duration and greater propensity to localize to the right upper quadrant. Patients often have associated nausea and vomiting. Physical examination typically yields right upper quadrant tenderness and a positive Murphy's sign. Laboratory values usually reveal a mild to moderate polymorphonuclear leukocytosis and may demonstrate a mild rise in transaminases, bilirubin, and alkaline phosphatase [3], but liver function studies are not universally elevated in those patients experiencing acute cholecystitis.

Acute cholecystitis in the elderly can be a diagnostic challenge, as the presentation is commonly atypical [110] and may vary widely. Abdominal pain remains a common presenting symptom but is often not accompanied by nausea, vomiting, fever, or leukocytosis [6]. Symptoms, however, may be minimal and the presentation may be nonspecific mental and physical disability alone. At the opposite end of the spectrum, nearly 12% of elderly patients with acute cholecystitis present in septic shock [111]. The physical examination may also be misleading. Morrow et al. reported that nearly 40% of elderly patients presenting with acute cholecystitis were afebrile, and more than half did not have peritoneal signs on examination. The absence of these findings did not correlate with milder disease, as 40% of the patients studied had severe complications including gallbladder empyema, gangrenous cholecystitis, and gallbladder perforation [68]. Given the variability and atypical features of presentation, the initial diagnostic accuracy of acute abdominal pain in patients over age 80 is only 29%, which is significantly lower than in younger patients [112].

When acute cholecystitis is suspected, the diagnosis may be established by the ultrasonographic findings of gallbladder distension and wall thickening with intramural sonolucency, pericholecystic fluid, cholelithiasis or gallbladder sludge (or both), and a sonographic Murphy's sign. Ultrasonography may also provide valuable information about the status of the pancreas and biliary tree [4]. It is important to recognize, however, that the presence of gallbladder wall thickening or

fluid around the gallbladder may not be specific for acute cholecystitis. A review by Shea et al. [74] reported the sensitivity and specificity of ultrasonography for acute cholecystitis as 94 and 78%, respectively.

Cholescintigraphy is also useful in the diagnosis of acute cholecystitis. Visualization of the gallbladder typically occurs within half an hour of the administration of tracer. If the gallbladder fails to visualize after 45 min, an intravenous dose of morphine may facilitate visualization by promoting sphincter of Oddi contraction, thereby diverting flow of tracer into the gallbladder [113], assuming that the cystic duct is patent. Nonvisualization of the gallbladder indicates obstruction of the cystic duct, a finding that is highly suggestive of acute cholecystitis. The sensitivity and specificity of cholescintigraphy for acute cholecystitis are 93 and 91%, respectively [74].

As mentioned previously, laparoscopic cholecystectomy is now considered the new gold standard treatment for elective management of cholecystitis, both chronic and acute. The results of laparoscopic cholecystectomy in elderly patients with acute cholecystitis have been encouraging. Lo et al. [114] reported morbidity and mortality rates of 26.7 and 0%, respectively, in their study of elderly patients undergoing laparoscopic cholecystectomy for acute cholecystitis. The conversion rate to open cholecystectomy was comparable to that for the general population. Common bile duct stones were present in four of ten elderly patients evaluated by endoscopic retrograde cholangiopancreatography (ERCP). Elderly patients, however, had a longer hospital stay than those under age 65, owing to greater delays in resumption of regular diet and return to ambulatory status [114].

Although cholecystectomy is the treatment of choice for acute cholecystitis, patients for whom the risk of immediate definitive surgery is considered too high may benefit from several forms of limited intervention. These methods are frequently used as temporizing procedures in critically ill patients who later can tolerate cholecystectomy [115]. Traditionally, decompression of the gallbladder by placing a tube that drained externally (cholecystostomy) was the operative alternative to cholecystectomy. The surgical approach to cholecystostomy has even been reported to be effective as a curative procedure in patients unable to tolerate a more extensive operation [116]. Percutaneous cholecystostomy may be performed under ultrasound guidance at a patient's bedside [117]. Van Steenberg et al. assessed the outcomes of elderly patients treated with cholecystostomy for complicated acute cholecystitis and demonstrated rapid improvement in all patients after percutaneous decompression of the gallbladder. Half of the patients studied underwent elective cholecystectomy 1–12 weeks after cholecystostomy [118]. Mortality rates for cholecystostomy are typically about 10% and relate largely to the severity of illness in

patients requiring this procedure [119]. Morbidity is also acceptably low for this procedure. Once acute cholecystitis has resolved, the role of elective laparoscopic cholecystectomy remains a topic of debate. While it seems self-evident that cholecystectomy would be definitive treatment, it is difficult to recommend routine cholecystectomy in this high-risk group, even under elective circumstances, particularly when no impact on overall survival can be demonstrated [120]. The decision regarding interval cholecystectomy must be made on an individual basis, weighing the likelihood of recurrent acute cholecystitis (feasibility of percutaneous extraction of stones, size of residual stones), the presence of coincident common bile duct stones, and the degree of risk related to comorbidities. For those who are not surgical candidates, cholecystostomy tubes may be removed 4 weeks after resolution in elderly or debilitated patients [119].

Gallbladder Perforation and Gallstone Ileus

Elderly patients are more likely than the young to suffer complications of acute cholecystitis, such as gangrenous cholecystitis, gallbladder perforation, and emphysematous cholecystitis [4]. Rates of gallbladder perforation in acute cholecystitis are reportedly as high as 8% in some series [121], with associated mortality rates approaching 40% for acute rupture [122]. Perforation of the gallbladder may be categorized using the Niemeier classification as acute (type I) with associated bile peritonitis, subacute (type II) with abscess formation in the area of the gallbladder, or chronic (type III) with perforation and fistula formation between the gallbladder and either the skin, bile duct, or digestive tract [123]. Perforation typically occurs at the site of the gallbladder fundus, the area of least blood supply [124]. A study by Roslyn and Busuttill demonstrated that this condition occurs more commonly in elderly patients, probably relating to gallbladder wall ischemia associated with atherosclerotic splanchnic vessels and limitations in cardiac output [125]. The mechanisms implicated in the development of gallbladder perforation involve obstruction of the cystic duct leading to gallbladder distension with subsequent vascular impairment resulting in ischemia, necrosis, and perforation of the wall [126]. It has also been noted that acute perforation is more common in young patients, whereas elderly patients are more likely to develop chronic perforation with fistula formation [127]. Complications of chronic perforation arise when gallstones traverse the fistulous tract and cause obstruction in areas of the gastrointestinal tract. Gallstone ileus accounts for nearly one-fourth of all cases of intestinal obstruction in aged patients [128].

The clinical presentation of acute gallbladder perforation is similar to that of acute cholecystitis. Patients frequently present with abdominal pain, nausea, and fever. Laboratory

findings typically include polymorphonuclear leukocytosis and elevations in transaminases as well as in alkaline phosphatase, γ -glutamyl transpeptidase, and bilirubin. The diagnosis of gallbladder perforation can be aided by several diagnostic modalities, including plain abdominal films, ultrasonography, computed tomography (CT), cholangiography, and radionuclide scanning. Radiographic findings may include calculi within the right upper quadrant (representing spilled gallstones) or soft tissue masses within the area (suggesting the presence of a pericholecystic abscess) [129]. Typical findings in gallstone ileus include evidence of a small bowel obstruction, air in the biliary tree, and a radiopaque density in the right lower quadrant [4]. Ultrasonographic findings of pericholecystic fluid collections with free peritoneal fluid, disappearance of the gallbladder wall, and findings consistent with emphysematous cholecystitis are highly suggestive of gallbladder perforation [130]. CT scanning has been shown to be superior to ultrasonography for diagnosing gallbladder perforation, using criteria of pericholecystic fluid collection, streaky omentum, and a gallbladder wall defect on CT [131].

The treatment of gallbladder perforation relates mainly to the acuteness of the problem and the presence of associated disease. Acute perforation is often not diagnosed preoperatively in patients undergoing cholecystectomy for acute cholecystitis. One should have a high index of suspicion for acute perforation in any patient with a history of immune suppression or vascular disease who presents with abdominal tenderness localized to the right upper quadrant [125]. Initial management in patients with suspected acute perforation consists of intravenous hydration, and antibiotic coverage followed by cholecystectomy. Chronic perforation tends to occur in older individuals with a history of long-standing cholelithiasis and is often only recognized when patients present with small bowel obstruction related to the gallstone. Patients with this condition are treated by removal of the offending stone at laparotomy to relieve the obstruction. Cholecystectomy with fistula repair at the time of laparotomy is generally not recommended for elderly patients with significant comorbidities in the absence of acute biliary tract disease.

Emphysematous Cholecystitis

Another complication of acute cholecystitis that occurs with greater frequency in the elderly population is emphysematous cholecystitis [132], which is a peculiar variant of acute cholecystitis caused by gas-forming bacteria [133]. It is characterized by the appearance of gas in the gallbladder lumen or wall on abdominal radiographs [134] and has an overall mortality rate approaching 15% [12]. It occurs more frequently in diabetic patients and is less likely to be associated

with stones than is the usual form of acute cholecystitis [133]. It is believed to be caused by bacterial invasion of the gallbladder wall, most frequently by bacteria of the *Clostridium* species with *E. coli* often found as a copathogen. This form of acute cholecystitis often progresses to gallbladder gangrene and perforation.

Patients with emphysematous cholecystitis present with signs and symptoms consistent with acute cholecystitis and few added features [134]. In fact, patients are less likely to be febrile and often do not exhibit severe localized abdominal tenderness. Laboratory findings may reveal leukocytosis of less than 16,000/mm [3]. The most distinguishing characteristic in these patients is the presence of air within the gallbladder lumen or wall [132]. Three stages of emphysematous cholecystitis have been described radiographically and relate to the progression of disease, including findings of gas in the gallbladder lumen, the gallbladder wall, and finally the pericholecystic space. The latter two stages are pathognomonic for emphysematous cholecystitis. Ultrasonography has limited application in the diagnosis of emphysematous cholecystitis, as air within the tissues may lead to nonvisualization of the gallbladder [135]. CT scan findings include visualization of gas within the gallbladder or gallbladder wall (Fig. 73.2) [132].

Treatment of emphysematous cholecystitis is surgery after the patient has been adequately stabilized. Delays in surgical treatment of this condition can be devastating. Appropriate antibiotic coverage both pre- and postoperatively is imperative and should include coverage for anaerobes and gram-negative pathogens as well as for *Clostridium* organisms. Although there is some controversy regarding timing of laparotomy, all agree that rapid clinical deterioration with a palpable mass in the right upper quadrant sanctions immediate cholecystectomy. Reports suggest that a laparoscopic approach is feasible in these patients [136].

FIGURE 73.2 Computed tomography scan showing air within the gallbladder wall consistent with emphysematous cholecystitis.

Cholelithiasis

Common duct stones are classified as primary or secondary depending on their site of origin. Primary duct stones, or stones that form within the common bile duct, are rare and account for a small fraction of cases of choledocholithiasis. This subtype of common duct stone is typically associated with infection [5]. Most cases of choledocholithiasis are due to the presence of secondary stones that arise in the gallbladder and later migrate into the common bile duct. The composition of these stones is similar to that of stones found primarily in the gallbladder, consisting of cholesterol and varying degrees of calcium bilirubinate [16].

The incidence of choledocholithiasis increases considerably with age. Common duct stones are reported to occur in 10% of the general population undergoing cholecystectomy and in up to 50% of patients in their 70s requiring surgery for symptomatic cholelithiasis [5]. Additionally, elderly patients with common bile duct stones are more likely to have positive bile cultures [137]. The reasons for this discrepancy are yet to be elucidated. Untreated common duct stones may lead to complications of cholangitis, pancreatitis, and obstructive jaundice [134].

The clinical presentation of patients with choledocholithiasis varies depending on the degree of ductal obstruction and the severity of associated complications. The range of symptoms is broad, as patients may be completely asymptomatic or may present with symptoms typical of life-threatening conditions such as ascending cholangitis. Choledocholithiasis should certainly be suspected in any patient who presents with cholelithiasis and associated jaundice. This presentation is common in patients with common duct stones; however, 10–20% of patients present with symptoms of cholangitis or pancreatitis [138]. Patients who present with cholangitis may exhibit the classic triad of fever, right upper quadrant abdominal pain, and jaundice; but it is important to recognize that more than half of the patients who present with cholangitis do not exhibit all three of these findings [16]. Laboratory values commonly reveal significant elevations in alkaline phosphatase, bilirubin, and γ -glutamyl transpeptidase [139], with elevations in the leukocyte count, amylase, and lipase in patients presenting with complications of choledocholithiasis [5]. Abnormal liver function tests, however, are absent in some individuals with documented common duct stones.

Several studies have attempted to identify predictors of choledocholithiasis. Factors that may lead one to suspect the presence of common duct stones include common bile duct dilation on ultrasonography, age exceeding 60 years, serum bilirubin higher than 2.5 mg/dl [140], and the presence of acute or chronic cholecystitis [141]. The sensitivity of ultrasonography in the evaluation of choledocholithiasis is fairly low, however, with highest estimates around 60% [142]. CT may reveal biliary ductal dilatation but is typically used to evaluate malignant rather than benign common duct

obstruction. ERCP and percutaneous transhepatic cholangiography (PTC) provide the most accurate means of diagnosing choledocholithiasis [5]. Intraoperative cholangiography is useful for this diagnosis in patients undergoing cholecystectomy [143]. MR cholangiography may be helpful in evaluating for choledocholithiasis (Fig. 73.3).

When considering treatment for patients with choledocholithiasis, one must consider the specific conditions under which they occur as well as the advantages and disadvantages of the various forms of treatment. Various endoscopic, radiologic, and surgical methods are available for the treatment of common duct stones. The presence of choledocholithiasis has a major impact on patient outcome in those undergoing cholecystectomy for symptomatic gallstone disease and therefore must be carefully assessed preoperatively [144].

Most agree that patients who are suspected of harboring common duct stones prior to elective or emergent cholecystectomy should have ERCP. Patients who are found to have stones at this time may then undergo endoscopic sphincterotomy (ES) with possible stone extraction [145]. ES has been shown to be the treatment of choice for patients with acute cholangitis [146] or acute pancreatitis [147] before cholecystectomy is performed. Successful stone clearance is possible in more than 90% of patients undergoing ES [148]. Mortality and complication rates for ES are reported to be 0.3 and 4.0%, respectively, for patients under 65 years of age. These rates increase to 0.4 and 6.5% in patients age 65 years or older [149]. Complication rates are noted to be higher when ES is performed in the absence of common duct dilation [150].

FIGURE 73.3 Magnetic resonance image demonstrating acute cholecystitis and common bile duct stones.

Choledochotomy at the time of open cholecystectomy was the treatment of choice for choledocholithiasis before the advent of laparoscopic cholecystectomy, endoscopic sphincterotomy, and other nonsurgical methods [151]. When open cholecystectomy is performed, common bile duct exploration (CBDE) is effective in clearing the duct of stones in 98% of cases. Unfortunately, this procedure is associated with a significant increase in operative morbidity and mortality, particularly in elderly patients. Because of this additional risk, intraoperative cholangiography is used to avoid unnecessary CBDE. In the critically ill patient, management of choledocholithiasis during open cholecystectomy may be restricted to placement of a T-tube. Subsequent clearance of common bile duct stones can be achieved by ES or radiologic manipulation via the T-tube tract, which is successful in more than 70% of patients [152].

The presence of associated choledocholithiasis complicates laparoscopic treatment of symptomatic gallstone disease. Ideally, patients with common duct stones are identified preoperatively and undergo ES with stone removal. Roughly 2–3% of patients with choledocholithiasis, however, do not have any associated laboratory or ultrasonographic evidence of common duct pathology [153]. The routine use of intraoperative cholangiography (IOC) may identify these patients and prevent the occurrence of retained common duct stones [154]. In the past, patients in whom common duct stones have been identified have traditionally undergone either conversion to open cholecystectomy with CBDE or completion of the cholecystectomy laparoscopically followed by ES in 1–2 weeks. More recently, laparoscopic CBDE has become part of the armamentarium against choledocholithiasis. Although still not widely used, this method has been shown to be effective in clearing more than 90% of common bile duct stones [155]. Choledocholithiasis discovered after cholecystectomy is best treated by ES.

There are several nonsurgical treatment modalities for treating choledocholithiasis in elderly and debilitated patients who also have cholelithiasis, but who are poor surgical candidates. ES has become the treatment of choice for common bile duct stones in this situation [156]. Adjunctive therapies to ES in the case of unretrievable common duct stones include the use of both intra- and extracorporeal lithotripsy [157] and temporary biliary stenting [158]. Permanent biliary stenting is associated with a high incidence of late complications and should be reserved for elderly patients with a short life expectancy [158]. The decision to forego cholecystectomy following ES for choledocholithiasis should be made not on the basis of chronologic age alone, but rather on an assessment of surgical risk [159].

Endoscopic sphincterotomy can be challenging in elderly patients. In their study of 182 patients, Deenitchin et al. [160] reported that elderly patients had a higher frequency of peripapillary diverticula and were much more likely to require

lithotripsy, nasobiliary drainage, and biliary stenting than younger patients. Elderly patients typically had larger and more abundant stones.

Acalculous Cholecystitis

Symptoms of gallstone disease may arise in the absence of documented cholelithiasis. Patients with chronic acalculous cholecystitis typically describe pain identical to that noted by patients with calculous biliary disease and often tell of extrabiliary symptoms of nausea, vomiting, and fatty food intolerance [161]. Although ultrasonography reveals no abnormalities, cholecystokinin-stimulated cholescintigraphy (CSC) characteristically reveals pain after CCK injection associated with a low gallbladder ejection fraction (<35%), nonvisualization of the gallbladder, or an absence of gallbladder emptying [162]. The treatment of chronic acalculous cholecystitis is identical to that for chronic cholecystitis secondary to cholelithiasis, which is either laparoscopic or open cholecystectomy [163]. Histologic examination of gallbladders following cholecystectomy for chronic acalculous cholecystitis often reveals evidence of chronic inflammation, cholesterosis, and microscopic cholesterol crystallization. Predictors of symptom relief following cholecystectomy include a convincing history of true biliary colic in conjunction with cholescintigraphic evidence of gallbladder dysfunction.

Acute acalculous cholecystitis is a grave complication of critical illness and trauma [164] that has also been associated with extensive surgical procedures [165], total parenteral nutrition [166], and the acquired immunodeficiency syndrome (AIDS) [167]. This form of cholecystitis is also associated with high rates of gangrene and perforation [168]. Mortality rates for acute acalculous cholecystitis are high, reaching 50% in some reports.

Factors thought to be implicated in the pathogenesis of acute acalculous cholecystitis involve bile stasis, hyper-alimentation, gallbladder ischemia, and systemic infection [168]. Bile stasis in critically ill individuals may be related to prolonged narcotic use or mechanical ventilation, resulting in increased biliary concentration of lysophosphatidyl choline, which may in turn lead to inflammatory changes in the gallbladder wall [169]. Total parenteral nutrition has also been implicated in the pathogenesis of acalculous cholecystitis, with gallbladder sludge occurring in 100% of patients after 6 weeks of hyper-alimentation.

The clinical presentation of acute acalculous cholecystitis is similar to that of acute cholecystitis due to calculous gallbladder disease. It has been suggested that this diagnosis be entertained in any critically ill septic patient with no apparent source of their sepsis [167]. Ultrasonography, cholescintigraphy, and CT are useful for supporting a diagnosis of acute acalculous cholecystitis (AAC). Ultrasonographic

findings supportive of a diagnosis of AAC include gallbladder wall thickness exceeding 3.5 mm, the presence of sludge within the gallbladder, pericholecystic fluid, or the presence of gas within the gallbladder wall. These criteria also apply to the diagnosis of AAC by CT scan.

Acute acalculous cholecystitis is often treated with percutaneous cholecystostomy, as most patients with this condition are too ill to tolerate general anesthesia. In fact, there are some who suggest that percutaneous cholecystostomy may obviate the need for cholecystectomy in patients with acalculous cholecystitis [170].

Benign Disease of the Pancreas

With increased use of imaging, including computed tomography, pancreatic neoplasms are diagnosed more frequently and are often identified in elderly individuals. The natural history of pancreatic neoplasms is widely variable, with a relatively favorable prognosis for some and a dismal outlook for others. The appropriate management of these neoplasms requires a comprehensive knowledge of benign, premalignant, and malignant lesions. The most frequently identified of these lesions are cystic neoplasms, thus will be the focus of the discussion in this chapter. The management of acute pancreatitis and malignant disease of the pancreas in geriatric patients is beyond the scope of this review.

Previously accounting for less than 5% of recognized pancreatic neoplasms, cystic neoplasms of the pancreas are now diagnosed more frequently, certainly because of the increased use of abdominal imaging [171]. The cystic neoplasms include serous cystadenomas (SCA), mucinous cystic neoplasms (MCN), and intraductal papillary mucinous neoplasms (IPMN), with these three families (benign and malignant varieties) comprising more than 95% of pancreatic cystic neoplasms (Table 73.1). Many are diagnosed incidentally on abdominal imaging, although some patients present with abdominal pain and/or pancreatitis [172]. It is critical to differentiate inflammatory pseudocyst from cystic neoplasms of the pancreas, as pseudocysts still account for the majority of cystic lesions of the pancreas [173] and the treatments are completely different.

Serous Cystadenoma

Serous cystadenomas account for 32–39% of all cystic pancreatic neoplasms [174]. They occur more frequently in women, with a peak incidence between 50 and 80 years of age [175], and may also be associated with the von Hippel–Lindau syndrome [176]. A significant proportion of these neoplasms are diagnosed incidentally by ultrasound or CT scan done for other reasons. Symptoms occur in 50–80% of patients, most often abdominal pain [177, 178]. When large and located in the head of the gland, they may produce obstructive jaundice. The location of SCA is fairly evenly distributed throughout the pancreas, with a slightly higher predominance in the body and tail. Serous cystadenomas, once termed microcystic adenomas, may appear either spongiform (honeycomb), multicystic, or unilocular on CT or MRI. The presence of a central scar (sunburst calcification) is highly suggestive for this neoplasm, though it is found in only 20% of cases (Fig. 73.4) [179, 180]. Histologically, serous cystadenomas are characterized by simple, glycogen-rich cuboidal epithelium and have a very low potential for malignancy, with only a few cases reported in the literature [181]. ERCP or MRCP may be useful for distinguishing serous cystadenomas from other cystic lesions in that the serous tumors almost never communicate with the duct system whereas communication is common in pancreatic pseudocysts, IPMNs, and perhaps MCNs. When imaging is equivocal, cyst aspiration may be performed with cytologic analysis of the fluid for a variety of biochemical and tumor markers [182]. Growth rates are variable, though tumors that are <4 cm at presentation have been shown to grow at a rate of 0.12 cm/year whereas tumors 4 cm or larger at presentation grow at a much faster rate (2 cm/year) [183]. Recommendations based on this natural history data include resection for patients with serous cystadenomas 4 cm or larger who have a reasonable life expectancy [183]. Observation of serous cystadenomas with serial imaging is feasible if there are no symptoms or complicating circumstances [180], but some authors recommend resection in all patients with acceptable operative risk [184].

TABLE 73.1 Epidemiologic and biologic characteristics of pancreatic cystic neoplasms [173]

Type	Sex predilection	Peak decade of life	% of cystic neoplasms	Malignant potential/natural history
Serous cystadenoma	Female	7th	32–39	Resection curative, cystadenocarcinoma very rare
Mucinous cystic neoplasm	Female	5th	10–45	Resection curative if adenoma or borderline, diminished prognosis if invasive cancer present
Intraductal papillary mucinous neoplasm	Equal distribution	6–7th	21–33	Excellent prognosis if adenoma or borderline, diminished prognosis if invasive cancer present

Source: Data from Brugge et al. [173]

FIGURE 73.4 CT scan of serous cystadenoma (adapted with permission from Wargo and Warshaw [207]).

In the elderly population, these lesions can be followed with serial imaging if the diagnosis is certain and if they are under 4 cm. If lesions are over 4 cm, a careful assessment of risk of resection must be weighed against patient comorbidities. Lesions in the tail are commonly treated with distal pancreatectomy with or without splenectomy, while lesions in the head of the gland are treated with conventional pancreaticoduodenectomy. Lesions in the neck or body may be treated with middle-segment pancreatectomy [185]. Enucleation has been described for small cystic lesions but has been associated with excessive numbers of pancreatic fistulas [186]. Enucleation with the use of intraoperative ultrasound and closure of the pancreatic defect may be safer in some situations [187].

Mucinous Cystic Neoplasm

Mucinous cystic neoplasms account for 10–45% of all cystic pancreatic neoplasms [183]. Three stages are described by the World Health Organization: benign (adenomatous), low-grade malignant (borderline), and malignant (carcinoma in situ and invasive cancer) [188]. They are much more common in women than men, 90–100% in all series, and are generally found in the pancreatic body and tail in individuals between the ages of 50 and 70 years of age [185, 188]. Patients with MCN often present with symptoms of abdominal pain [188]. The lesions may be unilocular or multilocular [189]. Peripheral calcification on CT scan is specific for this lesion (Fig. 73.5), and when present, is suggestive for the presence of malignancy [190]. Because MCN infrequently communicate with the duct system, ERCP or MRCP may be helpful in distinguishing these from IPMNs. Cyst aspiration, most often guided by EUS, is used to demonstrate the presence of mucin, malignant cells, or elevated tumor markers such as CA 72-4

FIGURE 73.5 CT scan of a mucinous cystic neoplasm.

[191], CA 19-9 [192], or CEA. The most reliable and accessible indicators of MCN are a positive stain for mucin and a CEA level >192 ng/ml [191]. Histologically, they are characterized by a dense ovarian-like stroma, which differentiates them from IPMNs. As a group, MCN have a relatively high malignant potential. A recent study identified several risk factors for malignancy in mucinous cystic neoplasms, including advanced age, presence of symptoms, and the presence of large cysts and mural nodules on CT scan [193]. Five-year survival rates for patients undergoing resection for mucinous cystic neoplasms are excellent (100%) if histology reveals adenoma to minimally invasive carcinoma but are much lower (37%) if invasive cancer is present [193]. These lesions are less commonly found in the elderly population; however, do warrant resection if the operative risk is acceptable.

Intraductal Papillary Mucinous Neoplasm

Intraductal papillary mucinous neoplasms are mucus-producing tumors of the epithelial lining of the pancreatic duct and at present account for 21–33% of pancreatic cystic neoplasms [173]. It may be difficult to distinguish between branch-duct IPMNs and mucinous cystic neoplasms. IPMNs occur at least as often in males and are usually diagnosed in patients between 60 and 70 years of age [194]. Most patients are symptomatic; at least 25% of patients report epigastric discomfort or backache [195] and almost as many have experienced at least one episode of pancreatitis [196]. The pathogenesis of acute pancreatitis is thought to be due to blockage of the pancreatic duct with viscid mucus.

IPMNs occur most frequently in the head of the pancreas and are classified into three types based on location in the duct system: main duct, side-branch, and mixed types [196]. CT or MRI may demonstrate evidence of a cystic pancreatic

mass with or without dilation of the main pancreatic duct, and MRCP can assess the degree of ductal dilation, the presence of mural nodules, and any communication between the cystic lesion and the pancreatic duct (Fig. 73.6) [197]. Mucin extruding from a dilated pancreatic duct orifice, seen at endoscopy, is pathognomonic for IPMN, probably of the main-duct type. Injection of contrast into the pancreatic duct may show ductal dilation, filling defects (mucin or papillary growths), and cystic dilation of side branches off the main pancreatic duct [171]. Side-branch IPMN may not be visualized by pancreatography, making the distinction from MCN uncertain. In some cases, endoscopic pancreatoscopy has been used to visualize the duct directly and to assess for mural nodules [198]. Interestingly, IPMNs are often associated with other malignancies at extra-pancreatic sites [199].

The malignant potential of these lesions is significant. Over 40% of patients in recent series who underwent resection for main-duct IPMN had evidence of invasive carcinoma [200], and as many more had borderline tumors or carcinoma in situ. A number of studies suggest that main-duct IPMNs are more likely than branch-duct IPMNs to harbor malignancy [201].

FIGURE 73.6 MRI/MRCP of intraductal papillary mucinous neoplasm (IPMN) (adapted with permission from Wargo and Warshaw [207]).

Several factors have been identified which may be helpful in predicting malignancy in IPMNs. Involvement of the main pancreatic duct (in main-duct or mixed-type) is an independent predictor of malignancy [202]. A large combined study from the University of Verona and the Massachusetts General Hospital identified cancer in 60% of patients with main-duct IPMNs [200]. Factors associated with a higher risk of malignancy in patients with main-duct IPMNs in this study included older age, the presence of jaundice or new onset/worsening of diabetes [200]. Risk factors associated with malignancy in main-duct, branch-duct, and mixed-type variants were identified in other studies and include the presence of mural nodules, jaundice, the presence of symptoms at presentation, and main pancreatic duct diameter >7 mm [202]. In branch-duct variants, the presence of mural nodules and tumor diameter >30 mm were predictive of invasive carcinoma [202]. The presence of mucus at the time of endoscopy was associated with benign disease in one study, though this remains controversial [203].

The surgical management of IPMN is evolving as we gain more experience. An essential question is whether or not the neoplasms represent a localized process within an otherwise normal pancreas or if they arise within a field defect with the potential to give rise later to more neoplastic tissue in seemingly unaffected portions of the duct [204]. If IPMNs are part of a larger field defect involving the entire pancreas, it would be rational to consider total pancreatectomy to eradicate all disease. However, the significant morbidity associated with total pancreatectomy, including the management challenges of complete endocrine and exocrine insufficiency, must give pause. To date, most surgeons, including ourselves, subscribe to a policy of image-guided resection of the affected anatomic segment with intraoperative frozen sections to ensure noninvolvement of the resection margins [200, 202, 205]. It is generally accepted that most main-duct lesions should be resected in patients who are appropriate surgical candidates [200].

IPMNs have a natural history that is very different than that of pancreatic adenocarcinoma. In the combined series with the Massachusetts General Hospital and the University of Verona, the overall survival for those undergoing resection for IPMNs with adenoma, borderline tumors, or carcinoma in situ was excellent: 100% at 5 years. Sixty percent of those with IPMNs and invasive cancer were alive at 5 years, and 50% at 10 years. Not surprisingly, those patients with invasive cancer and positive nodes (41%) had decreased survival compared to those with negative nodes, though in contrast to pancreatic adenocarcinoma, their survival was reasonable (45% at 5 years). Recurrences in the remnant pancreas occurred in only 7% [200]. These data were corroborated by the Hopkins group, though the percentage of patients presenting with invasive cancer and positive lymph nodes was slightly higher [205].

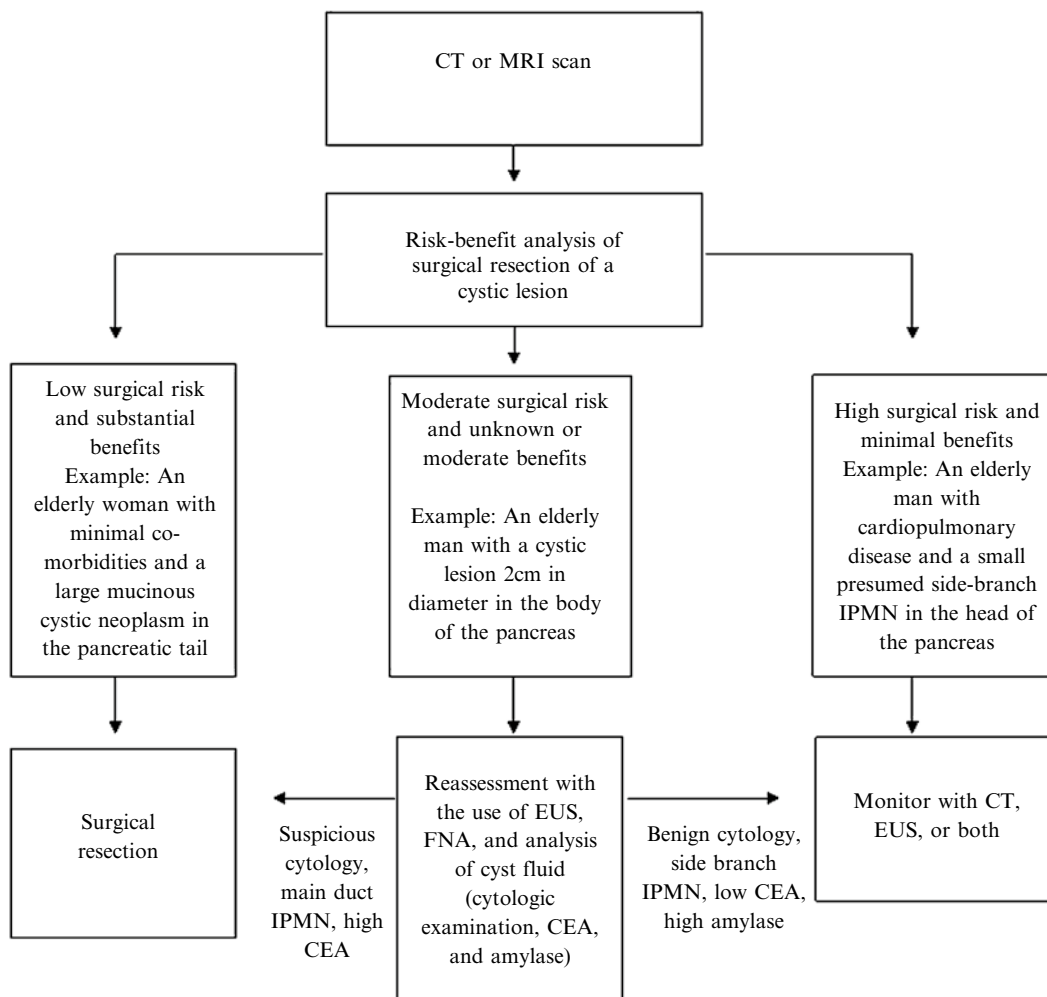

FIGURE 73.7 Algorithm for management of pancreatic cystic neoplasms (adapted with permission from Wargo and Warshaw [207]).

Management recommendations for branch-duct IPMNs are not quite as clearcut. In virtually all series, branch-duct IPMNs were less likely to harbor malignancy. In the recent series published from Johns Hopkins, 70% of branch-duct IPMNs were noninvasive compared to 50% of main-duct IPMNs [205]. Based on this, some have proposed a somewhat more selective approach for patients with branch-duct IPMNs. In general, branch-type IPMNs should be excised when they extend to the main duct, cause symptoms (such as acute pancreatitis), are large (>3 cm), when mural nodules are present, and when the main pancreatic duct diameter exceeds 7 mm [206]. If patients are asymptomatic and do not have any of the above findings, they may be observed with close surveillance with CT scan every 6 months to 1 year. Others recommend a more aggressive posture, performing anatomic oncologic resections for any branch-duct IPMN in a suitable operative candidate [204]. Management strategies

are likely to become clearer with more prospective data from specialized centers. An algorithm for management of cystic pancreatic lesions is shown in Fig. 73.7.

Conclusions

Benign disease of the gallbladder and pancreas remain major causes of morbidity and mortality worldwide, particularly in the elderly population. Their varied presentation in these patients clearly contributes to the complexity in treating these disorders. Advances in the diagnosis and therapy of biliary and pancreatic disease are likely to contribute to improvements in the care of elderly patients, but it is only with an astute understanding of the pathophysiology and treatment of these disorders that one can best manage these conditions in the elderly patient.

CASE STUDY

Eighty-four-year old female is admitted to the hospital with a 24 h history of confusion. PMH is significant for coronary artery disease, chronic renal insufficiency, and obstructive sleep apnea. Initially she is afebrile and has no abdominal findings. Labs are unremarkable. Forty-eight hours into her hospital course, she develops a fever, RUQ pain, and WBC 18,000. PE now reveals a tender RUQ mass. U/S reveals a distended gallbladder, cholelithiasis,

FIGURE 73.8 Computed tomography scan without intravenous contrast showing a distended gallbladder and surrounding inflammation.

and wall thickening. CT (done without contrast) shows a distended gallbladder with inflammatory changes in the mesocolon of the hepatic flexure (Fig. 73.8). There is no evidence of biliary ductal dilatation.

A diagnosis of acute cholecystitis is made. Because of concern about her cardiac function and renal insufficiency, CT-guided percutaneous cholecystostomy is performed. In addition, intravenous antibiotics are administered. She shows initial improvement in her fever, elevated WBC, and RUQ pain; however, within 24 h, her fever and WBC begin to rise. She is taken to the OR for an open cholecystectomy. The cholecystostomy tube is in good position; however, the gallbladder is gangrenous with frank areas of necrosis. A cholecystectomy is performed, and the subhepatic space is drained.

After an initial 48 h in the SICU, the patient is transferred to the floor. She is discharged 5 days later.

Key Points

- The clinical presentation of acute cholecystitis in the elderly may be atypical and/or subtle. In this case, the patient presented with mental status changes rather than the usual RUQ pain and fever.
- Imaging studies may be limited particularly in situations where contrast cannot be administered.
- After placement of a cholecystostomy tube, the patient's clinical course must be closely monitored. Lack of clinical resolution must lead to considering the possibility of gangrenous and/or perforated cholecystitis.

Chapter 74

Malignant Diseases of the Gallbladder and Bile Ducts

Steven A. Ahrendt and Thomas H. Magnuson

Gallbladder and bile duct cancers are relatively uncommon malignancies and tend to occur primarily in elderly patients. Although the overall prognosis of these malignancies remains poor, recent advances in hepatobiliary surgery, perioperative care, and adjuvant therapy have helped to improve overall survival and quality of life. A multidisciplinary approach in the management of these patients, including surgery, medical oncology, radiation oncology, and invasive radiology, is critical to achieving favorable results.

Gallbladder Cancer

Cancer of the gallbladder is an aggressive malignancy that occurs predominantly in elderly patients. It is strongly associated with gallstones but is also linked with other geographic and genetic factors. With the exception of early-stage cases detected incidentally at the time of cholecystectomy for gallstone disease, the prognosis is poor. Most patients present with unresectable tumors, and most can be managed nonoperatively. Recently, an aggressive surgical approach for patients with gallbladder cancer has produced encouraging results at several centers with acceptable morbidity and mortality in the predominantly elderly patient population.

Incidence

Gallbladder cancer is the fifth most common gastrointestinal malignancy following cancer of the colon, pancreas, stomach, and esophagus [1, 2]. Cancer of the gallbladder is two to

three times more common in women than in men, in part due to the higher incidence of gallstones in women [1–3]. With the increase in age of the American population, the incidence of gallbladder cancer has gradually increased, with approximately 5,000 new cases diagnosed annually [4]. The overall incidence of gallbladder cancer in the USA is 2.5 cases per 100,000 residents [1], with the incidence varying considerably with both ethnic background and geographic location [5, 6]. In the USA, gallbladder cancer is more common in American Indians than in the non-Indian populations [6]. The annual incidence of gallbladder cancer in American Indian women with gallstones approaches 75 cases per 100,000 [6]. Similarly, in Chile, where more than 50% of women over age 50 have gallstones, adenocarcinoma of the gallbladder is the leading cause of cancer deaths among women [7, 8].

Cancer of the gallbladder is a disease of the elderly. More than 75% of patients with this malignancy are over age 65 [3]. The peak incidence of gallbladder cancer occurs within the 75- to 79-year age group. The median age for patients with gallbladder cancer (73 years) is more than the median age for patients with pancreatic (67 years) or extrahepatic bile duct (69 years) cancer.

Etiology

Several factors have been associated with an increased risk of developing gallbladder cancer. Mayo was the first who recognized an association between gallstones and gallbladder cancer [9]. More recently, an anomalous pancreatobiliary duct junction (APBDJ) and other biliary disorders, such as choledochal cysts and primary sclerosing cholangitis, have been associated with gallbladder cancer.

A strong association has long been noted between gallbladder cancer and cholelithiasis, which is present in 75–90% of cases [3]. The incidence of gallstones increases with age, and by age 75 about 35% of women and 20% of men in the USA have developed gallstones [4]. The incidence of

gallbladder cancer is approximately seven times more common in the presence of cholelithiasis and chronic cholecystitis than in people without gallstones [6]. Approximately 1% of all patients with elective cholecystectomies performed for chronic cholecystitis and cholelithiasis harbor an occult gallbladder cancer [1, 10]. In the elderly patient population, this percentage is certainly higher [11].

The risk of developing gallbladder cancer is higher in patients with symptomatic gallstones than in those with asymptomatic gallstones [4]. In a review, Ransohoff and Gracie estimated the risk of developing gallbladder cancer in patients with symptomatic or asymptomatic gallstones [4]. The risk of developing gallbladder cancer (0.08% per year) was fourfold higher in patients with symptomatic gallstones over age 50 years than in those who were asymptomatic. Similar results have been observed in a multicenter study evaluating 196 patients with gallbladder cancer [12]. Twenty-eight percent of patients developing gallbladder cancer had undergone a medical evaluation for gallbladder disease in the past. A history of symptoms suggestive of gallbladder disease occurred significantly less frequently in control subjects without cancer.

Pathology and Staging

Ninety percent of cancers of the gallbladder are classified as adenocarcinoma [3]. Six percent of gallbladder cancers demonstrate papillary features on histologic examination. These tumors are commonly diagnosed while localized to the gallbladder and are also associated with an improved overall survival [3]. At diagnosis, 25% of cancers are localized to the gallbladder wall, 35% have associated metastases to regional lymph nodes or extension into adjacent organs, and 40% have already metastasized to distant sites [3].

Lymphatic drainage from the gallbladder occurs in a reproducible, predictable fashion and correlates with the pattern of lymph node metastases seen with gallbladder cancer [13, 14]. Lymph flow from the gallbladder initially drains to the cystic duct node and then descends along the common bile duct to the pericholedochal lymph nodes. The flow then proceeds to nodes posterior to the head of the pancreas and then to the interaortocaval lymph nodes. Secondary routes of lymphatic drainage include the retroportal and right celiac lymph nodes [14].

Hepatic involvement with gallbladder cancer can occur by direct invasion through the gallbladder bed, angiolymphatic portal tract invasion, or distant hematogenous spread [15]. Spread via the angiolymphatic portal tracts is the predominant mode of hepatic metastases; it may extend more

TABLE 74.1 TNM staging for gallbladder cancer [16]

TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ		
T1	Tumor invades lamina propria (T1a) or muscular (T1b) layer		
T2	Tumor invades perimuscular connective tissue, no extension beyond serosa or into liver		
T3	Tumor perforates the serosa (visceral peritoneum) and/or directly invades the liver and/or one other adjacent organ or structure, such as the stomach, duodenum, colon, pancreas, omentum, or extrahepatic bile ducts		
T4	Tumor invades main portal vein or hepatic artery or invades two or more extrahepatic organs or structures		
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastases to nodes along the cystic duct, common bile duct, hepatic artery, and/or portal vein		
N2	Metastases to periaortic, pericaval, superior mesenteric artery, and/or celiac artery lymph nodes		
M0	No distant metastases

than 1 cm from the main tumor mass and correlates well with the depth of direct invasion of the liver. Distant spread beyond the region of the gallbladder is associated with hematogenous metastases elsewhere.

The current TNM classification of the American Joint Committee on Cancer is shown in Table 74.1 [16]. Stage I tumors are confined to the lamina propria, the gallbladder mucosa, submucosa, or muscularis. Stage II tumors extend into the perimuscular connective tissue without penetrating the gallbladder serosa or liver. Stage III tumors penetrate the serosa and can invade the liver or another adjacent organs or structures, such as the stomach, duodenum, colon, pancreas, omentum, or extrahepatic bile ducts. Stage IV tumors have extensive liver invasion, metastatic spread to second-order lymph nodes, or distant metastases.

Diagnosis

Clinical Presentation

Gallbladder cancer most often presents with right upper quadrant abdominal pain often mimicking other, more common biliary and nonbiliary disorders [1]. Weight loss, jaundice, and an abdominal mass are less common presenting symptoms. Piehler and Crichlow described five presenting clinical syndromes occurring in a review of more than 1,000 patients with gallbladder cancer [2]. Altogether, 16% of patients presented with symptoms of acute cholecystitis with a short duration of pain associated with vomiting, fever, and tenderness; 43% presented with symptoms of chronic cholecystitis often with a recent change in the quality or frequency of the painful episodes; 34% had signs and symptoms of malignant biliary obstruction with jaundice, weight loss, and right upper quadrant pain. An additional 29% of patients had symptoms of nonbiliary malignancies with anorexia and weight loss in the absence of jaundice, and a small percentage of patients had signs of gastrointestinal bleeding or obstruction.

The preoperative diagnosis of gallbladder cancer is difficult, particularly in the elderly population. In one series, only 8% of 53 patients with carcinoma of the gallbladder were diagnosed correctly preoperatively [17]. The most common misdiagnoses included chronic cholecystitis (28%), pancreatic cancer (13%), acute cholecystitis (9%), choledocholithiasis (8%), and gallbladder hydrops (8%).

Radiologic Evaluation

Ultrasonography is often the first diagnostic modality used for evaluating patients with right upper quadrant abdominal pain. Ultrasonographic features of advanced gallbladder cancer include a heterogeneous mass replacing the gallbladder lumen (40–65% of cases) or thickening of the gallbladder wall (20–30% of cases) [18]. Most patients have coexistent gallstones, gallbladder wall thickening, or both, suggesting benign biliary disease. Ultrasonography can determine the level of obstruction in patients with biliary ductal involvement. Overall, the sensitivity of ultrasonography for detecting gallbladder cancer ranges from 70 to 100% [18, 19].

Computed tomography (CT) has also improved the detection rate for gallbladder cancer with a sensitivity in the range of 55–100% (Fig. 74.1) [18]. CT scanning can demonstrate extension into the liver parenchyma but can overestimate hepatic involvement because of large perfusion defects. CT is less accurate for determining peritoneal seeding or lymph node involvement.

FIGURE 74.1 Computed tomography (CT) scan demonstrates large gallbladder cancer with extension into the duodenum. Gallstones (calcifications) are present within the mass.

Magnetic resonance imaging (MRI) is also sensitive for detecting gallbladder cancer, but its exact role in preoperative staging remains unclear (Fig. 74.2) [9, 18]. Hepatic artery and portal vein encasement may also be identified by MRI. Dilatation of the biliary tract that may occur with direct extension of gallbladder cancer into the biliary tree can be detected by standard MRI. In the elderly jaundiced patient with gallbladder cancer, the extent of biliary tract involvement should be further defined with cholangiography [9]. Percutaneous transhepatic cholangiography, endoscopic retrograde pancreatography, or magnetic resonance cholangiography are all helpful for the preoperative staging. A typical finding in the jaundiced patient with gallbladder cancer is a long stricture of the common hepatic duct [9].

Resection

The primary treatment of patients with localized gallbladder cancer is resection of the primary tumor along with areas of regional lymphatic involvement. After preoperative staging, patients with clinical stage I–IVa tumors warrant exploration if they are otherwise suitable operative candidates. Most of these patients are elderly, but the patient's general medical condition is more important than age when determining operative risk. Preexisting cirrhosis may dramatically increase the risk of surgery particularly if liver resection is contemplated [9].

Simple Cholecystectomy

The appropriate operative procedure for the patient with localized gallbladder cancer is determined by the pathologic

FIGURE 74.2 (a) Magnetic resonance imaging (MRI) scan demonstrating a mass arising within the gallbladder with extension into the hepatic parenchyma. (b) MR angiogram from the same patient demonstrating the relation between the hepatic artery and the mass. (c) MR angiogram from the same patient showing the relation between the main and right portal vein and the mass.

stage. Patients with tumors confined to the gallbladder mucosa or submucosa (stage Ia) have a negligible incidence of lymph node metastases and an overall 5-year survival approaching 100% [20–22]. These early-stage tumors are usually identified postoperatively by the pathologist and following open cholecystectomy, have had an excellent prognosis. More recently, with widespread use of the laparoscopic approach, recurrent cancer at port sites and peritoneal carcinomatosis have been reported following cholecystectomy even for patients with in situ disease [10]. The correct management of patients undergoing laparoscopic cholecystectomy with or without bile spillage for an incidental gallbladder cancer remains unclear.

Extended Cholecystectomy

Cancer of the gallbladder with invasion into or beyond the gallbladder muscularis is associated with an increasing incidence of regional lymph node metastases and should be managed with an extended lymphadenectomy as part of the operative procedure [22–26]. In addition, local extension into the hepatic parenchyma, colon, or duodenum requires en bloc resection of these structures to achieve an adequate resection margin.

The extent of the lymphadenectomy is based on the operative findings and knowledge of the patterns of lymphatic spread in patients with gallbladder cancer [13, 14]. This dissection should include the cystic duct, pericholedochal, portal, right celiac, and posterior pancreaticoduodenal lymph nodes. In patients without grossly involved lymph nodes, the common bile duct, hepatic artery, and portal vein are skeletonized from the porta hepatis to the pancreas and celiac axis, respectively [24]. Following an extensive Kocher maneuver, the posterior pancreaticoduodenal lymph nodes are included with the specimen. In the presence of any grossly enlarged pericholedochal lymph nodes, consideration should be given to resecting the common bile duct to avoid leaving a positive margin [24]. Biliary enteric continuity is restored with a Roux-en-Y hepaticojejunostomy. Several authors have advocated a pancreaticoduodenectomy in the setting of pancreaticoduodenal lymph node metastases, but this approach increases the operative mortality substantially in the elderly and should be considered in only the good risk patient with no evidence of metastasis to the liver, celiac, or interaorto-caval lymph nodes [24, 25, 27].

Extension of more advanced staged lesions into the hepatic parenchyma is common, and extended cholecystectomy should incorporate at least a 2-cm margin beyond the palpable or sonographic extent of the tumor to include any angiolymphatic extension from the main tumor mass [15]. For smaller tumors, this can be incorporated into a wedge resection of the liver.

FIGURE 74.3 Extent of bisegmentectomy (segments IVb and V) in patients with T4 gallbladder cancer (from Gall et al. [28] with permission).

Extended Resections

For stage IV tumors invading more than 2 cm into the liver, an anatomic liver resection may be required to achieve a histologically negative margin. Cancers originating in the gallbladder fundus can usually be adequately treated with resection of segments IVb and V (Fig. 74.3) [28]. Tumor extension into the right hepatic artery or portal vein may be resectable only with a right hepatic lobectomy or trisegmentectomy [24, 29, 30].

Locally advanced lesions can also extend into adjacent structures. In the absence of distant lymph node, peritoneal, or hepatic metastases, these lesions may still be resectable for cure. Extension into the right colon should be managed with segmental colectomy, whereas duodenal invasion may require a pancreatoduodenectomy.

Palliative Therapy

Adequate palliation of the symptoms of advanced gallbladder cancer is eventually required in most elderly patients with this disease [9, 31]. Pain, jaundice, and gastric outlet obstruction are the common symptoms requiring palliation and can be managed nonoperatively or operatively. Survival in patients with unresectable gallbladder cancer is just 2–6 months, and therefore operative exploration should be avoided in patients with unresectable disease [1, 17, 22]. Narcotics should be given when necessary. Percutaneous celiac ganglion block may be helpful in reducing the need for narcotics. Chemical splanchnicectomy can be performed

in patients whose lesions are found to be unresectable at the time of operative exploration [9].

The presence of jaundice is a poor prognostic sign in patients with gallbladder cancer and usually signifies involvement of at least the common hepatic duct or hepatic duct bifurcation (or both). More than 70% of gallbladder cancers that present with jaundice and are explored with an intent to resect are unresectable for cure [29, 32]. Nonoperative biliary decompression to relieve jaundice and pruritus can be achieved percutaneously or endoscopically by placing metallic or nonmetallic stents [9]. In patients with hilar or intrahepatic ductal involvement, the percutaneous route is preferred. Relief of gastric outlet obstruction is difficult to achieve nonoperatively and usually requires gastrojejunostomy.

Survival

Extended cholecystectomy is reasonably well tolerated in the elderly patient population with gallbladder cancer. Operative mortality in several series was 0–1% [24, 29]. Common postoperative complications include wound or intraabdominal infection, hemorrhage, or delayed gastric emptying. Mortality increases with the magnitude of the operative procedure. Extended cholecystectomy, combined with a major hepatectomy or pancreatoduodenectomy, has a mortality rate of 10–15% and adds the risks of biliary or pancreatic anastomotic leaks to the procedure [25].

Survival in elderly patients with gallbladder cancer is strongly influenced by the pathologic stage at presentation. Patients with gallbladder cancer limited to the gallbladder mucosa and submucosa (stage Ia) have a uniformly excellent prognosis [20–22]; 35 patients with incidentally discovered stage Ia gallbladder cancer reported by Shirai et al. had an overall 5-year survival of 100% [20]. Invasion into the muscular wall of the gallbladder increases the risk of recurrent cancer after curative resection. The reported 5-year survival for patients with stage Ib gallbladder cancer varies widely, ranging from 20 to 100% (Table 74.2) [20–22]. In a survey of 172 major hospitals in Japan, the 5-year survival for patients with stage Ib tumors was 72%, with many patients undergoing simple cholecystectomy, suggesting that this procedure is an inadequate therapy once muscular invasion is present.

Invasion into the muscularis or the subserosa increases the risk of regional lymph node metastases to 15 and 50%, respectively. Tsukada et al. reported a 5-year overall survival of 80% for patients with stage II disease with extended cholecystectomy [24]. Similar results have been reported with an aggressive surgical approach at Memorial Sloan–Kettering [29]. In patients with tumors confined to the gallbladder wall

FIGURE 74.4 Actuarial survival for patients with gallbladder cancer by pathologic stage (see Table 74.1). Survival of patients with stage I and stage II tumors was significantly better than that of patients with stage III tumors. In addition, stage III patients survived significantly longer than patients with stage IV disease (from Tsukada et al. [24] with permission).

or with local extension into the liver or other adjacent organs (stages III and IV), long-term survival with extended cholecystectomy is possible [24, 29]. Several groups have reported 5-year overall survival for patients with stage III and stage IV gallbladder cancer of 40–63% and 19–25%, respectively (Fig. 74.4) [24, 29].

Tsukada et al. identified curative, margin-negative resection as the most significant factor in predicting prognosis [24]. Their 5-year survival of 52% in patients undergoing resection with microscopically negative margins was significantly higher than the 5-year survival (5%) in patients with a microscopically positive margin (Fig. 74.5). In the Memorial Sloan-Kettering series, the presence of lymph node metastases was a significant predictor of treatment failure [29]. Eighty-one percent of patients without lymph node metastases were alive 5 years after radical resection, whereas all of the patients with lymph node metastases died within 18 months. In the Japanese series, 11 of the 35 five-year survivors had lymph node metastases [24]. Age was not predictive of survival following surgery for gallbladder cancer [29].

Adjuvant Therapy

The results of chemotherapy in patients with gallbladder cancer have been poor owing to the limited responsiveness to these agents. Partial response rates to oral 5-fluorouracil (5-FU) alone or in combination with methyl-CCNU or streptozotocin range from 5 to 13% with a median survival of 10–21 weeks in patients receiving treatment [33]. The combination of intravenous 5-FU, high-dose levo-folinic acid, and oral hydroxyurea has achieved a partial response rate of 30% with a median survival of 8 months in patients with unresectable gallbladder cancer [34]. Toxicity was limited, and the regimen was well tolerated in this group of patients (median age 60).

Both external beam and intraoperative radiation therapy have been used for management of patients with gallbladder cancer. In the postoperative adjuvant setting, no randomized data have demonstrated improved survival with external beam radiation alone [9]. In a retrospective review of 38 patients with gallbladder cancer managed with postoperative

FIGURE 74.5 Actuarial survival for patients with stage III and stage IV gallbladder cancer by resection margin status. Results are shown for patients managed with curative (negative margins) resection (R0), noncurative (microscopically positive margin) resections (R1), and palliative (grossly positive margin) resections (R2). Patients managed with

R0 resection survived significantly longer than patients undergoing R1 resection. In addition, patients with extensive tumor resected with palliative intent survived a significantly shorter time than patients with microscopic positive margins (from Tsukada et al. [24] with permission).

adjuvant therapy, overall survival was improved in patients receiving more than 4,000 cGy compared with patients receiving less than 4,000 cGy [35]. However, the response to the radiation therapy in this series was difficult to differentiate from the effect of resection alone. Overall survival was not influenced by patients' age in this series. The use of intraoperative radiation therapy (IORT) in one Japanese series has been reported to provide a slight survival benefit in patients with locally advanced gallbladder cancer [36]. In a collective review of unresectable gallbladder cancers, patients undergoing IORT had a longer survival (11.0 vs. 6.3 months) than patients with standard external beam radiotherapy [37].

Cholangiocarcinoma

Cholangiocarcinomas may occur anywhere along the intrahepatic or extrahepatic biliary tree. The hepatic duct bifurcation is the most frequently involved site, and approximately 60–80% of cholangiocarcinomas encountered at tertiary referral centers are found in the perihilar region [9, 38–41]. Cholangiocarcinoma is an uncommon tumor and occurs in conditions in which bile is stagnant, infected, or both. These clinical situations include primary sclerosing cholangitis, choledochal cysts, and hepatolithiasis. Cholangiocarcinoma usually presents with painless jaundice, so this diagnosis should be considered in every case of obstructive jaundice. Perihilar cholangiocarcinomas involve the region of the

hepatic duct bifurcation and frequently also involve major portal vascular structures, making resection difficult. When possible, surgical resection offers a chance for long-term disease-free survival. Many patients, however, are candidates only for palliative bypass or operative or nonoperative intubation aimed at providing biliary drainage and preventing cholangitis and hepatic failure.

Incidence

Approximately 15,000 new cases of liver and biliary tract cancer are diagnosed annually in the USA, and they account for more than 12,000 deaths per year. About 15–25% of these cancers are bile duct tumors or cholangiocarcinomas. The incidence of cholangiocarcinoma increases with age, and these tumors occur with similar frequency in men and women. Approximately two-thirds of patients diagnosed with cholangiocarcinoma are of age 50–70 years [42, 43]. Overall, the incidence of cholangiocarcinoma in the USA is approximately 1 per 100,000 people per year [9, 44].

Etiology and Associated Diseases

A number of diseases and environmental agents have been linked to cholangiocarcinoma including primary sclerosing

cholangitis, choledochal cysts, and hepatolithiasis. Factors common to a number of these etiologic factors include stones, biliary stasis, and infection [9]. Bile duct cancers in patients with primary sclerosing cholangitis are most often extrahepatic, commonly occur near the hepatic duct bifurcation, and are difficult to differentiate from the multiple, benign strictures associated with this disease [45]. The mean age at presentation in patients with cholangiocarcinoma and primary sclerosing cholangitis is the fifth decade of life, and these tumors occur only rarely in the elderly population. Similarly, choledochal cysts are usually diagnosed during childhood or early adult life. However, choledochal cysts are occasionally diagnosed in the elderly, and the risk of cholangiocarcinoma increases steadily with patients' age [46]. Hepatolithiasis occurs in the elderly population and is a known risk factor for cholangiocarcinoma. Cholangiocarcinoma develops in 5–10% of patients with hepatolithiasis [9, 47–49]. Cholangiocarcinoma has been reported to develop a mean 8 years following treatment for hepatolithiasis and may occur despite complete stone clearance from the intrahepatic biliary tree [49].

Staging and Classification

Cholangiocarcinoma is best classified into three broad groups (1) intrahepatic, (2) perihilar, and (3) distal. This classification correlates with the anatomic distribution and implies the preferred treatment for each site. Intrahepatic tumors are treated like liver lesions, with hepatectomy when possible. Distal tumors are managed in a fashion similar to that for other periampullary malignancies, with pancreatoduodenectomy. The perihilar tumors make up the largest group and are managed with local resection of the bile duct with or without hepatic resection.

Cancers of the hepatic duct bifurcation were further classified by Bismuth et al. according to their anatomic location [50]. With this system, type I tumors are confined to the common hepatic duct; type II tumors involve the right and left hepatic ducts; type IIIa and IIIb tumors extend into the right or left secondary intrahepatic ducts, respectively; and type IV tumors involve the secondary intrahepatic ducts on both sides.

Cholangiocarcinoma is also staged according to the tumor, node, metastasis (TNM) classification of the American Joint Commission on Cancer (Tables 74.3 and 74.4) [16]. Using this system, stage I tumors are limited to the bile duct mucosa or muscular layer; stage II tumors invade periductal tissues; stage III tumors have regional lymph node metastases; and stage IV tumors invade adjacent structures (IVa) or have distant metastases (IVb).

TABLE 74.3 TNM staging for tumors of the perihilar bile ducts

TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ		
T1	Tumor confined to the bile duct, with extension up to the muscle layer or fibrous tissue		
T2	(a) Tumor invades beyond the wall of the bile duct to surrounding adipose tissue; (b) tumor invades adjacent hepatic parenchymal		
T3	Tumor invades unilateral branches of the portal vein or hepatic artery		
T4	Tumor invades main portal vein or its branches bilaterally; or the common hepatic artery; or the second-order biliary laterals bilaterally; or unilateral second-order biliary radicals with contralateral portal vein or hepatic artery involvement		
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Regional lymph node metastasis (including nodes along the cystic duct, hepatic artery, and portal vein)

Diagnosis

Clinical Presentation

More than 90% of patients with perihilar or distal tumors present with jaundice. Patients with intrahepatic cholangiocarcinoma rarely present with jaundice until late in the course of the disease. Less common presenting clinical features include pruritus, fever, mild abdominal pain, fatigue, anorexia, and weight loss [9]. Cholangitis is not a frequent presentation but most commonly develops after biliary manipulation by endoscopic or percutaneous techniques.

TABLE 74.4 TNM staging for tumors of the distal bile ducts

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor confined to the bile duct histologically
T2	Tumor invades beyond the wall of the bile duct
T3	Tumor invades the gallbladder, pancreas, duodenum, or other adjacent organs without involvement of the celiac axis, or the superior mesenteric artery
T4	Tumor involved the celiac axis, or the superior mesenteric artery
NX	Regional lymph nodes cannot be assessed

Laboratory Data

At the time of presentation, most patients with perihilar or distal cholangiocarcinoma have a total serum bilirubin level higher than 10 mg/dl [9]. Marked elevations are also observed in serum alkaline phosphatase and γ -glutamyl transferase levels. Patients with long-standing biliary obstruction may also have a low serum albumin or prolonged prothrombin time. The serum tumor markers carcinoembryonic antigen (CEA) and α -fetoprotein (AFP) are typically normal. Serum CA 19-9 and CA 50 may be elevated in patients with cholangiocarcinoma and may be useful for screening patients in high-risk groups for developing cholangiocarcinoma [51].

Radiologic Evaluation

The goals of radiologic evaluation in patients with cholangiocarcinoma include delineation of the overall extent of the tumor, including involvement of the bile ducts, liver, portal

vessels, and distant metastases. An ordered sequence of tests can usually achieve these goals. The initial radiographic studies consist of either abdominal ultrasonography or CT scanning. Intrahepatic cholangiocarcinomas are easily visualized on CT scans. A hilar cholangiocarcinoma gives a picture of a dilated intrahepatic biliary tree, a normal or collapsed gallbladder and extrahepatic biliary tree, and a normal pancreas. Distal tumors lead to dilation of the gallbladder and intra- and extrahepatic biliary tree.

Perihilar tumors are often difficult to visualize on ultrasonography and standard CT scans [52]. Duplex ultrasonography has been reported to visualize the primary tumor in more than 85% of patients, whereas bolus contrast-enhanced CT scans were able to define the primary tumor in only 59% of patients [53, 54]. Duplex sonography has also been able to determine accurately the extent of bile duct involvement in 87% of patients and the presence or absence of portal vein involvement in 86% [55]. A study comparing enhanced CT scans and MRI in 15 patients with perihilar cholangiocarcinoma managed at Johns Hopkins suggested that MRI is more sensitive than CT scans for detecting these small tumors [56]. However, newer spiral CT techniques are better at detecting the parenchymal extent of the tumor.

After documentation of bile duct dilation, biliary anatomy traditionally has been defined cholangiographically through the percutaneous transhepatic or endoscopic retrograde routes. The most proximal extent of the tumor is the most important feature when determining resectability in patients with perihilar tumors. Percutaneous transhepatic cholangiography is favored in these patients because it defines the proximal extent of tumor involvement most reliably [9]. This approach also allows preoperative placement of percutaneous transhepatic catheters. Recently, magnetic resonance cholangiopancreatography (MRCP) has been documented to have a diagnostic accuracy comparable to those of percutaneous and endoscopic cholangiography. In a series of 14 patients with cholangiocarcinoma, diagnostic quality MRCP images were better at visualizing intrahepatic biliary anatomy than endoscopic retrograde cholangiopancreatography (ERCP) [57]. MRCP also has the advantage of obtaining two-dimensional images to define an obstructing lesion. The sensitivity, specificity, and overall accuracy of MRCP at determining the level of biliary obstruction and the presence of a benign or malignant lesion are similar to those for ERCP.

The advantages of transhepatic catheter placement include (1) assistance in the technical aspects of hilar dissection by allowing palpation of the catheter within the biliary tree at the time of exploration and (2) facilitation of intraoperative Silastic transhepatic stent placement. Currently available randomized studies do not support the practice of placing preoperative transhepatic catheters in an effort to

reduce operative mortality [58–60]. However, if a liver resection is contemplated, preoperative drainage may be justified.

Biopsy/Cytology

Efforts to establish a tissue diagnosis including percutaneous fine-needle aspiration (FNA) biopsy, brush and scrape biopsy, and cytologic examination of bile have been used [61–64]. Prolonged efforts to obtain a preoperative tissue diagnosis are not indicated unless the patient is not an operative candidate. Bile obtained from a percutaneous catheter demonstrates malignant cells in approximately 30% of cases [62]. This yield may be improved to approximately 40% by brush cytologic techniques through transhepatic stents or at the time of endoscopic procedures and to 67% by percutaneous FNA. Even with these efforts, up to one-third of patients with cholangiocarcinoma have negative biopsy and cytologic results.

Assessment of Resectability

A careful evaluation of the overall general medical condition of the elderly patient and an accurate staging evaluation are necessary prior to selecting the appropriate management for the patient with cholangiocarcinoma. The preoperative assessment should include the usual evaluation of cardiac risk factors, respiratory status, and renal function, as well as overall performance status. Patients with obstructive jaundice often have decreased hepatic protein synthesis and altered hemostatic mechanisms, and they are at increased risk for infectious complications.

Several studies have defined preoperative risk factors associated with an increase in morbidity and mortality in patients undergoing treatment for malignant biliary obstruction [39, 60, 65, 66]. In 1981, Pitt and colleagues identified eight risk factors predictive of mortality, including serum albumin less than 3.0 g/dl [65]. Little also defined a mortality index predictive of procedure-related mortality in a prospective analysis of patients with obstructive jaundice [60]. The mortality index was derived from the preoperative serum creatinine and albumin levels and the severity of the cholangitis. Several large series of patients undergoing resection for perihilar cholangiocarcinoma have also identified low preoperative serum albumin concentration and perioperative sepsis as factors contributing to operative mortality [65, 66]. Control of sepsis and intensive nutritional support should be undertaken preoperatively in the malnourished elderly patient with cholangiocarcinoma.

The preoperative evaluation also includes careful staging to determine the extent of the cholangiocarcinoma [38, 53–55,

67–69]. In the past, the combination of an abdominal CT scan, cholangiography, and visceral angiography was useful for determining the extent of disease. CT or MRI scan findings signifying unresectable disease include peripheral hepatic metastases or extrahepatic disease. Findings on traditional or MRI cholangiography suggestive of unresectable disease in patients with perihilar cholangiocarcinoma include proximal extension of tumor into second-order bile ducts in both hepatic lobes. The angiographic or MRI findings of tumor encasement or occlusion of the proper hepatic artery, main portal vein, or both right and left portal venous branches or hepatic arterial branches are also considered contraindications to resection by most.

The combination of angiography and cholangiography provides better data than cholangiography alone for staging the elderly patient with perihilar cholangiocarcinoma [70]. More recently, MRI has provided all the data previously obtained by these two studies and CT scanning [71, 72]. For patients with distal cholangiocarcinoma, a good-quality spiral CT scan can provide sufficient information to predict resectability.

Palliative Therapy

Palliative therapy in elderly patients with perihilar and distal cholangiocarcinoma is directed at relieving obstructive jaundice and pruritus, preventing recurrent cholangitis, and avoiding hepatic failure secondary to unrelieved biliary obstruction. In addition, palliative therapy in patients with distal cholangiocarcinoma is aimed at preventing or relieving gastric outlet obstruction. Palliation can be achieved nonoperatively with percutaneous or endoscopic techniques or by using an operative approach.

Nonoperative Palliation

Patients with unequivocal evidence of unresectable cholangiocarcinoma at initial evaluation are palliated nonoperatively. Tumor extension into the secondary biliary radicals of both right and left hepatic lobes, the main portal vein, or the main hepatic artery or the presence of distant metastases excludes patients from curative resection. In addition, elderly patients in poor general medical condition may also not be operative candidates. Nonoperative palliation can be achieved endoscopically and percutaneously. A significant proportion of the functioning hepatic parenchyma should be decompressed, and this philosophy may require two or three percutaneously or endoscopically placed catheters in patients with hilar cholangiocarcinoma [70, 74, 74].

Percutaneous biliary drainage has several advantages over endoscopic management in patients with perihilar

cholangiocarcinoma. Stent placement is more reliably achieved percutaneously than via endoscopic means [75]. In addition, occluded percutaneous stents are easily changed over a guidewire on an outpatient basis, whereas replacement of an endoprosthesis requires an additional invasive procedure. In contrast, endoscopic palliation is the preferred approach in patients with distal cholangiocarcinoma. Placement of an endoprosthesis in experienced centers has been technically successful in approximately 95% of patients with advanced periampullary cancer, with relief of jaundice and pruritus in 80%. More recently, percutaneous or endoscopically placed metallic stents have been used to palliate patients with malignant biliary obstruction [76–78]. Metallic stents remain patent longer than plastic stents and require fewer subsequent manipulations in patients with distal malignant biliary obstruction [79]. Self-expanding metallic stents have also been effective in patients with unresectable perihilar tumors, with median stent patency rates of up to 1 year [77].

Operative Palliation

In good-risk patients without preoperative evidence of unresectable cholangiocarcinoma, operative exploration is undertaken in an attempt to resect the primary tumor. At Johns Hopkins, approximately 45% of patients with perihilar cholangiocarcinoma were found at exploration to have intra-peritoneal or liver metastases (15%) or extensive tumor involvement of the porta hepatis (30%), precluding resection [38, 42, 70, 80–82]. Ten percent of patients with distal cholangiocarcinoma have unresectable lesions at operative exploration. Patients with peritoneal carcinomatosis undergo minimal operative intervention. Cholecystectomy is performed to prevent the subsequent development of acute cholecystitis from cystic duct obstruction related to the percutaneous catheter [83]. Postoperatively, the preoperatively placed transhepatic catheters are replaced with larger, softer transhepatic stents [84].

In patients with locally advanced unresectable perihilar tumors, several operative approaches are available for palliation, including Roux-en-Y choledochojejunostomy with intraoperative placement of Silastic biliary catheters or a segment III cholangiojejunostomy. The operative procedure for placing transhepatic Silastic catheters begins with obtaining a tissue diagnosis of cholangiocarcinoma. A tissue diagnosis is required prior to initiating postoperative irradiation or chemotherapy.

The gallbladder is then mobilized, and the distal common bile duct is divided and oversewn. Next, the Ring catheters are exchanged for larger Silastic biliary catheters. A hepaticojejunostomy is then performed to a Roux-en-Y limb of jejunum (Fig. 74.6). The advantages of this approach

over nonoperative palliation include (1) removal of the gallbladder [83], (2) placement of larger, softer Silastic stents with a lower risk of hemobilia and improved patient comfort, and (3) positioning the stent into a defunctionalized Roux-en-Y jejunal limb to reduce the incidence of subsequent cholangitis.

In patients with locally unresectable or metastatic distal cholangiocarcinoma, operative palliation is directed at relieving both biliary and gastric outlet obstruction. Symptomatic gastroduodenal obstruction occurs prior to death in approximately 30% of patients with periampullary malignancies. Gastrojejunostomy at the time of initial presentation prevents this complication without increasing the operative morbidity or mortality. Biliary-enteric continuity is restored most often with a hepaticojejunostomy or a choledochojejunostomy.

Surgical Resection

Curative treatment of patients with cholangiocarcinoma is possible only with complete resection. For patients with anatomically resectable intrahepatic cholangiocarcinoma and without advanced cirrhosis, partial hepatectomy is the procedure of choice. After careful exploration of the peritoneal surfaces and regional lymph nodes for metastatic disease, the liver is mobilized and examined with intraoperative ultrasonography. Approximately 40% of resectable intrahepatic cholangiocarcinomas are multiple or involve both hepatic lobes. Hepatic resection is planned to remove completely all tumor with an adequate margin. Most commonly it involves a formal lobectomy or trisegmentectomy.

Elderly patients with tumors involving the hepatic hilum or proximal common hepatic duct (Bismuth types I or II) that have no vascular invasion are candidates for local tumor excision [38]. Preoperatively, bilateral transhepatic Ring catheters are placed to aid in the intraoperative identification of the right and left hepatic ducts [38, 81, 82, 84]. After excluding the presence of metastatic disease, the common bile duct (CBD) is dissected free and encircled just proximal to the suprapancreatic portion. The CBD is then divided, and the distal end is oversewn. It is then reflected cephalad, skeletonizing the portal vein and proper hepatic artery. Once the entire common hepatic duct has been elevated off the portal vasculature, the left and right hepatic ducts can be identified by palpating the diverging Ring catheters. The left and right hepatic ducts are then divided above the extent of palpable tumor. Frozen section examination is used to determine the adequacy of the surgical margin. The percutaneous transhepatic catheters are then exchanged for 16F Silastic catheters. A 60-cm retrocolic Roux-en-Y limb is then constructed, and bilateral hepaticojejunostomies are performed over the Silastic stents.

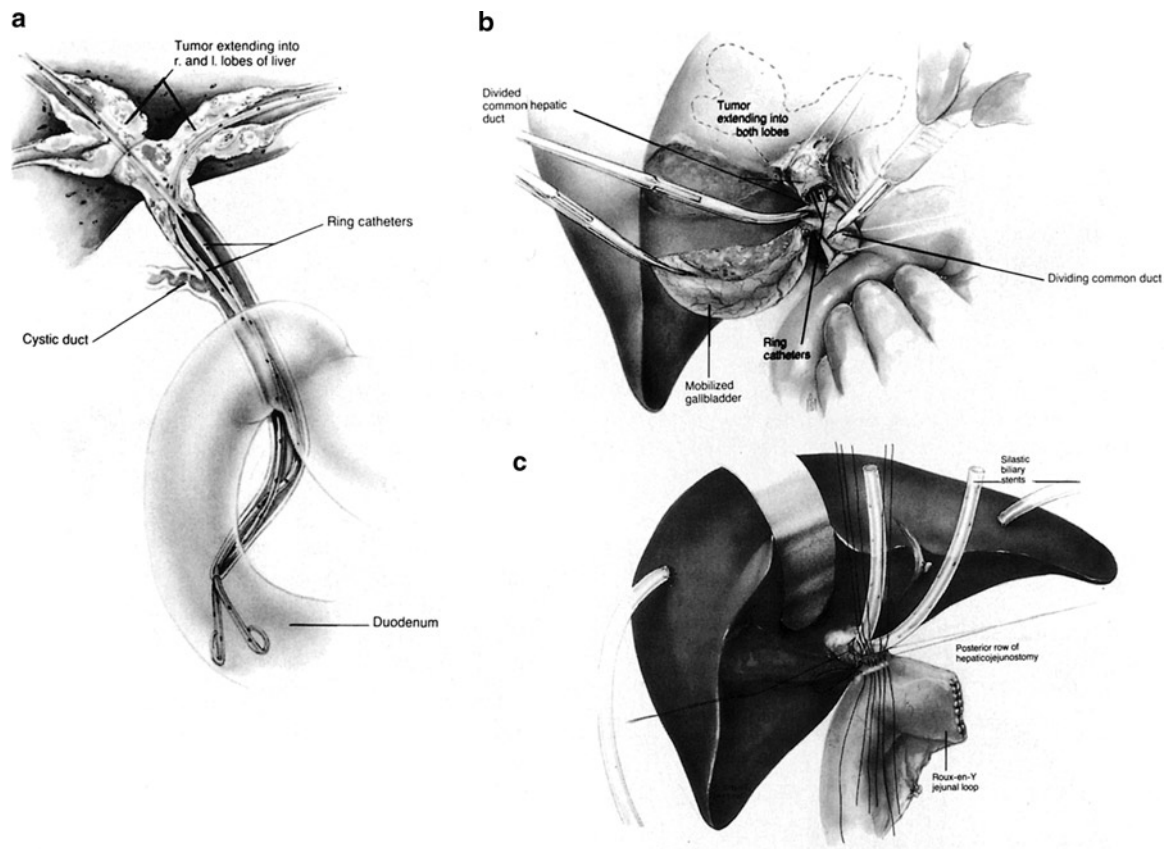

FIGURE 74.6 (a) Palliative intubation of Bismuth type IV unresectable perihilar cholangiocarcinoma with preoperatively placed transhepatic stents changed over guidewires. (b) Common bile duct is divided distal

to the tumor and a cholecystectomy is performed. (c) Roux-en-Y choledochojejunostomy is constructed over Silastic transhepatic stents distal to the tumor (from Cameron [100] with permission).

Proximal extension of a hilar cholangiocarcinoma into either the intrahepatic segments of the right or left hepatic duct renders these tumors incurable by local tumor resection. Complete resection in these patients is achievable only with combined resection of the extrahepatic biliary tree and major liver resection. Improvements in operative morbidity and mortality and in long-term survival when negative surgical margins are achieved support the use of this approach when complete tumor resection is possible [38, 41, 50, 52, 85–99].

The need for hepatic resection can usually be predicted on the basis of preoperative angiography, cholangiography, or MRI. When unilateral neoplastic involvement of the right or left portal vein or hepatic ducts is visualized radiographically, the initial hilar dissection is performed as described previously with division of the uninvolved hepatic duct. A frozen section should be examined to confirm a negative hepatic duct margin on the uninvolved side. Next, the extrahepatic segments of the hepatic vein, portal vein, and hepatic artery to the involved lobe are divided or occluded with vascular clamps. The hepatic parenchyma is then divided using the ultrasonic dissector or cautery. Extension of the tumor into the caudate lobe frequently necessitates caudate lobec-

tomy to achieve negative tumor margins. Biliary enteric continuity is restored to a Roux-en-Y limb of jejunum (see Fig. 74.7).

Elderly patients with resectable distal cholangiocarcinoma are managed similarly to patients with other periampullary malignancies with pancreatoduodenectomy. More than 85% of these patients are suitable for the pylorus-preserving modification, and gastrointestinal continuity is restored with an end-to-end pancreatojejunostomy, an end-to-side hepaticojejunostomy, and an end-to-side duodenojejunostomy. The hepaticojejunostomy is usually stented with a T-tube to decompress the system in the event of a biliary or pancreatic leak.

Survival

Procedure-related morbidity and mortality, quality of survival, and long-term survival are highly dependent on the stage of disease at presentation and on whether the patient is treated by a palliative procedure or complete tumor resection.

FIGURE 74.7 (a). Left hepatic and hilar resection of Bismuth type IIIb cholangiocarcinoma with preoperatively placed transhepatic stents. (b). Resected left hepatic lobe and hilum with perihilar cholangiocarcinoma (*top*) and right hepatic lobe with divided right hepatic duct prior

to reconstruction (*bottom*). (c) Silastic transhepatic stent is placed through a right Roux-en-Y cholangiojejunostomy after left hepatic lobectomy (from Cameron [100] with permission).

Palliative Therapy

Between 1973 and 1989, a group of 65 patients with unresectable hilar cholangiocarcinoma underwent nonoperative percutaneous stenting or operative palliation at The Johns Hopkins Hospital [38, 70]. Altogether, 21 patients were managed with

percutaneous biliary stents; 44 patients underwent laparotomy, with placement of large-bore Silastic transhepatic stents in 33. The procedure-related morbidity was similar for patients undergoing nonoperative palliation and those undergoing laparotomy. Hospital mortality was 14% in the nonoperatively palliated group and 7% in those managed operatively.

Mean survival was 8 months for the patients managed with operative palliation and 5 months for those managed with percutaneous stenting ($p < 0.05$).

Quality of survival measured by the number of readmissions per month of survival, hospital days per month of survival, and episodes of cholangitis was better in the patients undergoing operative palliation. In addition, patients managed nonoperatively required more frequent stent changes than patients managed operatively. On the other hand, eight patients (15%) managed operatively required late operations. These procedures were most frequently required for small bowel or duodenal obstruction. None of the patients managed nonoperatively required laparotomy during the follow-up period.

Several additional studies have examined the results of palliative therapy for hilar cholangiocarcinoma [74, 97, 99, 101]. In a French report, the operative mortality and long-term survival were similar for patients managed with operatively placed biliary stents and those managed with palliative biliary-enteric anastomosis [97]. Guthrie et al. demonstrated more effective palliation with a segment III cholangiojejunostomy than with endoscopic or percutaneous stenting [101]. The operatively managed patients had a lower incidence of cholangitis and jaundice than the patients managed with nonoperative stenting. Lai et al. demonstrated lower procedure-related mortality among patients managed operatively than among those palliated with endoscopic stenting [74]. Overall survival and quality of survival assessed by frequency of cholangitis attacks, episodes of jaundice, and days in the hospital were similar for the two groups. Patients managed with endoscopic stents had a higher incidence of catheter-related problems than patients managed with cholangioenteric bypass. In contrast, Washburn et al. demonstrated better survival in patients palliated nonoperatively than in surgically palliated patients [99]. All of these retrospective analyses are limited, however, by biases in selecting patients for each treatment group.

Several randomized, prospective trials have compared operative vs. nonoperative palliation in patients with perihilar cancer [102]. In general, these trials demonstrated lower procedure-related morbidity and mortality rates for the nonoperatively managed patients. However, the procedure-related mortality in the operatively managed patients ranged from 15 to 24%. In addition, a higher rate of recurrent jaundice or gastric outlet obstruction occurred in the nonoperatively managed patients. Survival was similar among the two treatment groups in each study (mean survival 12–22 weeks).

Between 1987 and 1991, a series of 118 patients with unresectable perihilar tumors were explored at The Johns Hopkins Hospital [102]. Seventy percent of the patients were over age 60. The most common operative procedure was choledochojejunostomy and hepaticojejunostomy,

which were performed in 67% of patients. Perioperative mortality was 2.5%, and gastric outlet obstruction or recurrent jaundice developed prior to death in only 4.0 and 2.5% of patients, respectively.

Surgical Resection

A series of 34 patients with intrahepatic cholangiocarcinoma managed with surgical resection was recently reported by Casavilla et al. [103]; 53% of these patients were over age 60. Multiple tumors were present in 44% of the patients, and 41% had involvement of both hepatic lobes. Histologically negative surgical margins were obtained in 71% of patients. Operative mortality was 6%. Overall patient survival was 60% at 1 year, 37% at 3 years, and 31% at 5 years after resection. Significant predictors of postoperative treatment failure were positive surgical margins, multiple tumors, and metastatic disease in regional lymph nodes. Age was not predictive of operative or long-term mortality.

A group of 109 patients with perihilar cholangiocarcinoma was managed with resection at The Johns Hopkins Hospital between 1973 and 1995 [39]. Following resection, 36 patients had obvious gross tumor remaining, and 81 patients had a positive microscopic surgical margin. Of the 109 patients, 94 underwent local hilar excision, and 15 were managed with hepatic lobectomy with resection of the extrahepatic biliary tree. Four operative deaths (3.6%) occurred among these 109 patients, including one death (6.6%) among the 15 managed with hepatic lobectomy. Actuarial survival among the 109 patients undergoing resection was 68% at 1 year, 30% at 3 years, and 11% after 5 years of follow-up. Survival was significantly prolonged in patients without residual microscopic tumor at the surgical margin. In the 28 patients with a negative margin, the actuarial survival was 68% at 1 year, 56% at 3 years, and 19% after 5 years. Patients' age did not influence operative morbidity or mortality or the long-term survival. Fifty-three percent of these patients also received a combination of external beam radiotherapy, a boost of internal irradiation utilizing iridium 192, or both.

In recent years, the trend around the world has been to perform more hepatic resections for perihilar cholangiocarcinoma. More than 580 patients with perihilar cholangiocarcinoma have been reported in the literature since 1989 (Table 74.5) [39, 50, 66, 88, 90, 92, 94–99, 104]. For 233 patients undergoing local hilar resection, the operative mortality rate was 6%; and for 352 patients managed with combined hilar and hepatic resection, the operative mortality was 8%. The mean age of these 585 patients undergoing aggressive surgical resection for perihilar cholangiocarcinoma was 60 years, with half of them in their seventh, eighth, or ninth

^aDoes not include patients also undergoing portal vein or hepatic artery resection and reconstruction

decade of life. The mean survival rate in the locally resected patients ranged from 19 to 36 months. Similarly, the mean survival of patients undergoing combined hilar and hepatic resection ranged from 16 to 32 months.

Several factors may be important when determining long-term prognosis following curative resection for hilar cholangiocarcinoma. Achieving negative histologic margins is important for determining overall long-term survival [41, 87, 92, 99]. Bengmark et al. initially reported several 10-year survivors following hepatic resection with negative histologic margins for hilar cholangiocarcinoma [87]. In two large series of patients managed with attempted curative resection for perihilar cholangiocarcinoma, both Klempnauer et al. and Sugiura et al. reported a 33% overall 5-year survival for patients with negative histologic margins, whereas no patient with microscopic cancer at the surgical margins survived 5 years (Fig. 74.8) [98, 99, 102–104]. Among patients with negative histologic margins, the addition of a caudate lobectomy significantly prolonged the 5-year survival (46 vs. 12%). In addition, the presence of regional lymph node metastases adversely affected survival. In several large series, multivariate analysis found that patients' age did not influence overall survival.

Seventy-three patients with distal cholangiocarcinoma undergoing pancreatoduodenectomy have been reported from The Johns Hopkins Hospital [39]. The 1-, 3-, and 5-year survival rates were 70, 31, and 28%, respectively. Factors associated with prolonged survival of these patients include tumor differentiation and lymph node status. Negative nodes increased the median survival from 17 to 27 months, whereas poorly differentiated tumors had a lower median survival (10 vs. 22 months).

FIGURE 74.8 Actuarial Kaplan–Meier survival of patients with perihilar cholangiocarcinoma undergoing curative or noncurative resection (microscopic tumor at surgical margin). Survival was improved ($p < 0.05$) in the curatively resected patients (from Sugiura et al. [98] with permission).

Adjuvant Therapy

Radiation therapy has been evaluated in patients with perihilar cholangiocarcinoma using a variety of methods including external beam radiotherapy, intraoperative radiotherapy, internal radiotherapy, radioimmunotherapy, and charged particle radiation. External beam radiotherapy has been the most

commonly used modality and is typically administered to a total dose of 45–60 Gy [38, 105–107]. Internal radiotherapy is normally delivered through percutaneous or endoscopically placed biliary stents using iridium 192 as the radiation source [38, 108, 109]. Multiple retrospective analyses have suggested that radiation therapy may provide some benefit in patients with perihilar cholangiocarcinoma administered via one of these techniques.

In a prospective analysis from The Johns Hopkins Hospital, 23 patients underwent irradiation and 27 did not [110]. The radiation dose ranged from 45 to 63 Gy and consisted of external beam plus iridium 192 seeds. None of the patients underwent adjuvant chemotherapy. Patients undergoing curative resection survived significantly longer than patients undergoing operative palliation. Among those with resection, irradiation had no effect on the mean (24 vs. 24 months), median, or actuarial survival. Similarly, among palliated patients irradiation had no effect on the mean (10 vs. 13 months), median, or actuarial survival. Multivariate analysis identified resection as the only positive predictive factor for prolonged survival.

The use of chemotherapy (along with 5-FU, mitomycin C, or cisplatin) has not been shown to improve survival in patients with resected or unresected cholangiocarcinoma. Response rates using multidrug chemotherapeutic regimens also remain low. Given the potential radiosensitization effect of 5-FU, the combination of irradiation and chemotherapy may be more effective than either agent alone. Preliminary data in relatively small numbers of patients have been reported, but no randomized data are available [35, 111–114].

Conclusions

Despite overall advances in the ability to diagnose and treat elderly patients with malignant tumors of the gallbladder and biliary tract, the prognosis for patients with these malignancies remains poor. Improvements in diagnostic CT scanning, duplex ultrasonography, and MRI will improve our ability to diagnose noninvasively and stage gallbladder cancer or cholangiocarcinoma in the elderly patient. Complete surgical resection remains the only curative treatment for malignancy of the biliary tract. Aggressive surgical approaches are likely to continue, and the challenge remains in being able to perform these procedures safely in jaundiced and sometimes septic elderly patients. Unfortunately, for most patients with malignant tumors of the biliary tract, curative resection is not possible, and optimal palliation remains the goal of therapy. Finally, advances in adjuvant chemotherapy and radiotherapy are required to improve the overall prognosis of patients with gallbladder cancer or cholangiocarcinoma.

Chapter 75

Benign and Malignant Neoplasms of the Exocrine Pancreas

Kathryn M. Dalbec and Keith D. Lillimoe

Introduction

Pancreatic neoplasms represent a major health-care problem for the aging population. The elderly are at risk for the entire spectrum of benign and malignant pancreatic tumors. Pancreatic adenocarcinoma is the most frequent and clinically significant of these tumors. It is the fourth leading cause of cancer death in the United States, and its incidence is associated with advancing age. The diagnosis and treatment of pancreatic cancer often represents a significant clinical challenge in the elderly, as there is a significant bias against aggressive surgical treatment in this population. In recent years, however, advances in diagnostic techniques, improved outcomes with regionalization of care, and a deeper understanding of prognostic factors have improved our ability to treat this challenging disease. In addition to pancreatic adenocarcinoma, the recognition and diagnosis of benign and premalignant pancreatic tumors has become more common in the elderly. These tumors require a thorough understanding of their clinical behavior as one weighs these risks with the risk of surgery in the elderly population. Fortunately, many of these tumors are amenable to less invasive therapeutic procedures with lessened perioperative morbidity and mortality.

Epidemiology

According to the National Cancer Institute, the incidence of pancreatic cancer is approximately 37,000 new cases per year, with 34,000 deaths per year from the disease [1]. Pancreatic adenocarcinoma is also one of the most lethal cancers, with a 5-year survival rate for 1996–2004 of only 5%, due to the fact that more than half of patients have

distant metastases at diagnosis, and only 7% of cases are diagnosed at a stage where the cancer is confined to the pancreas. The incidence of pancreatic cancer among persons aged 55–59 is 18 per 100,000, while the incidence among 75–79 year-olds is 72 per 100,000. Above age 85, the incidence rises to 91 per 100,000 (Fig. 75.1).

Cystic neoplasms represent less than 10% of pancreatic tumors and include a spectrum of benign and malignant lesions. The last two decades have seen a striking increase in the diagnosis of cystic neoplasms, with many detected due to the widespread use of abdominal imaging studies. Intraductal papillary mucinous neoplasms (IPMNs) comprise a significant portion of all cystic neoplasms. The peak incidence of IPMN is in the sixth and seventh decade of life, and IPMNs are more likely to be malignant in patients older than 60 years [2].

Risk Factors

Environmental and genetic factors have been implicated as risk factors for pancreatic cancer. As noted above, advanced age is a significant risk factor for both pancreatic cancer and IPMNs. Male gender and African American race are also associated with higher rates of pancreatic cancer. Among many potential environmental risk factors, cigarette smoking has been confirmed as a major contributor, with a twofold greater risk of developing pancreatic cancer among smokers compared with nonsmokers. Recently, a pooled analysis of cohort studies has found a modestly increased risk of pancreatic cancer associated with the consumption of 30 or more grams of alcohol per day [3]. Chemical and radiation exposure is also associated with increased pancreatic cancer risk. Several preexisting medical conditions are associated with increased risk of pancreatic cancer: chronic pancreatitis, primary sclerosing cholangitis, obesity, and prior gastric surgery. Diabetes mellitus has been shown in some studies to confer an increased risk of pancreatic cancer, but it is also possible that diabetes is an early symptom of the cancer, rather than a risk factor. Thus, new-onset diabetes in an

Cancer sites include invasive cases only unless otherwise noted.
Incidence source: SEER 17 areas (San Francisco, Connecticut, Detroit, Hawaii, Iowa, New Mexico, Seattle, Utah, Atlanta, San Jose-Monterey, Los Angeles, Alaska Native Registry, Rural Georgia, California excluding SF/SJM/LA, Kentucky, Louisiana and New Jersey).
Rates are per 100,000.
Datapoints were not shown for rates that were based on less than 16 cases.

FIGURE 75.1 Increased pancreatic cancer incidence by age. (SEER Cancer Stat Fact Sheets [1]).

otherwise asymptomatic elderly patient could be an early clue to the presence of pancreatic malignancy.

Genetic factors often play a role in the development of pancreatic cancer. There are multiple inherited familial cancer syndromes that increase the risk of pancreatic cancer, including Peutz–Jeghers, hereditary pancreatitis, hereditary nonpolyposis colon cancer (HNPCC), ataxia-telangiectasia, familial atypical mole and multiple melanoma (FAMMM) syndrome, familial breast cancer 2, and familial adenomatous polyposis. There is also a significantly increased risk of developing pancreatic cancer in patients with a family history of the disease without association with a specific syndrome. Patients who have two first-degree relatives with pancreatic cancer have a 6-fold increase in risk, while patients with three affected first-degree relatives have a 32-fold higher risk of developing pancreatic cancer [4]. It is also important to note that age becomes a significant factor in these kindreds, as the age of cancer diagnosis in subsequent generations actually becomes progressively younger.

While the genetic significance in these cancer syndromes is apparent, recent advances in molecular genetics have led to the identification of frequent genetic mutations even

among sporadic pancreatic cancers. These include inactivated tumor-suppressor genes such as p53, p16, and DPC4, each of which are found in >50% of sporadic pancreatic cancers. Mutations in K-ras, an oncogene involved in signal transduction, are found in over 90% of pancreatic cancer, which may prove diagnostically important in the future.

Perhaps the most increasingly identified risk factor for pancreatic cancer is the presence of a precancerous lesion, such as IPMNs or other mucinous cystic neoplasms. The increasingly frequent identification of these tumors, primarily in asymptomatic patients, has led to the development of management algorithms for the management of precancerous lesions and surveillance for disease progression. The optimal techniques and interval for follow-up may vary based on patient-specific characteristics including age. Nevertheless, for IPMNs, both the incidence of malignancy and invasiveness increases with age.

Pathology

Solid Tumors

Solid tumors of the exocrine pancreas are classified according to their cell of origin; which may include the pancreatic ductal epithelium or the acinar cell. Solid tumors can be either malignant or premalignant or benign. Ductal adenocarcinoma is the most common neoplasm of the exocrine pancreas, accounting for more than 75% of all malignant pancreatic tumors. Ductal adenocarcinoma arises most commonly in the pancreatic head (65%) but may also be present in the body or tail (15%) or diffusely involve the whole pancreas (20%). Tumors of the head tend to be smaller at diagnosis, as they are more likely to cause obstructive jaundice earlier in their development. Adenocarcinomas arise from pancreatic ductal tissue, often obstructing ductal branches and causing a desmoplastic reaction with associated fibrosis and chronic pancreatitis. They often infiltrate into vascular, lymphatic, and perineural spaces, leading to early local and metastatic spread. Common sites of local invasion are duodenum, stomach, transverse mesocolon, colon, spleen, and adrenal glands. Pancreatic cancer typically metastasizes to regional lymph nodes and then liver, peritoneum, lungs, and adrenal glands. Pathologic examination of resected specimens often reveals the presence of precursor lesions (see below) in close proximity to the cancer. The recognition of these lesions has broadened our understanding of the development of adenocarcinoma.

Pancreatic adenocarcinoma is staged based on the tumor characteristics, node involvement, and metastatic disease (TNM) classification system, as outlined by the American Joint Commission on Cancer (AJCC) [5]. This system has considerable prognostic significance, with

Stages I and II representing resectable, and therefore potentially curable, disease.

In addition to ductal adenocarcinoma, a very small percentage of solid exocrine tumors is comprised of adenosquamous carcinoma, acinar cell carcinoma, giant cell carcinoma, and pancreatoblastoma. Pancreatoblastoma should rarely be considered in the differential in an elderly patient, however, as it is found almost exclusively in children less than 15 years of age.

Cystic Tumors

Cystic tumors make up less than 10% of all exocrine pancreas neoplasms, although they are being diagnosed with increasing frequency in recent decades. Cystic tumors of the pancreas include serous cystic neoplasms, mucin-producing cystic neoplasms (MCN and IPMN), solid pseudopapillary or Hamoudi tumors, and lymphoepithelial cysts [6].

Serous cystic neoplasms, or serous cystadenomas, are the most common cystic neoplasm of the pancreas, comprising 30–60% of cystic tumors (Fig. 75.2). They are more

common in women and elderly and are often located in the body and tail of the pancreas. Serous cystadenomas have both microcystic and oligocystic variants, both of which are benign. Serous cystadenocarcinoma is a rare malignant variant that is difficult to distinguish histologically from its benign relative.

Unlike serous neoplasms, which are almost always benign, mucin-producing cystic tumors of the pancreas are considered either premalignant or frankly malignant. There are two distinct types of mucin-producing pancreatic tumors, mucinous cystic neoplasms (MCNs, or mucinous cystadenomas) and intraductal papillary mucinous neoplasms (IPMNs). Both types are characterized by abnormal growth of mucin-producing epithelial cells, but IPMNs involve the main pancreatic duct or ductal branches, while MCNs do not. MCNs occur almost exclusively in women and are most common between age 40 and 50. They are typically found in the body or tail and contain a distinctive subepithelial ovarian-type stroma (Fig. 75.3). The degree of dysplasia of MCNs can vary from benign to malignant,

FIGURE 75.2 Serous cystadenoma seen in (a) cross-sectional imaging and (b) histologic section.

FIGURE 75.4 Multidetector CT (MDCT) scan with IV contrast showing main-duct type IPMN.

TABLE 75.1 Comparison between MCN and IPMN [6, 7]

	MCN	IPMN
Age (years)	40–50	60–80
Gender	F>M	M>F
Location	Body/tail	Head
Pancreatic duct involvement	No	Yes
Mucin found at ampulla	No	Yes
Ovarian-like stroma	Yes	No

with up to one-third containing an invasive component. In contrast to MCNs, IPMNs are found more commonly in males, do not contain ovarian stroma, and are more common in the pancreatic head, neck, and uncinate process (Fig. 75.4 and Table 75.1). IPMNs represent about 25% of cystic neoplasms and are classified into 3 types: main duct, branch duct, and mixed type. Histologically, IPMNs can range from benign to intermediate to malignant, with about 35% of resected IPMNs showing a component of invasive carcinoma. Features associated with increased likelihood of malignancy are increased patient age, main duct involvement, jaundice, and diabetes [7] (Table 75.2). Much less common than MCN or IPMN, the solid pseudopapillary tumor, also known as Hamoudi tumor, or solid cystic neoplasm, is found predominantly in young women. This tumor is always considered to be malignant but with very low metastatic potential.

Precancerous Lesions

The recent increase in identification and understanding of premalignant lesions of the pancreas has elucidated the processes associated with the progression from benign to

TABLE 75.2 Likelihood of malignancy in main duct IPMN [2]

	Benign	Malignant	Total	<i>P</i> (benign vs. malignant)
<i>n</i>	57	83	140	–
Gender (M/F)	31/26	40/43	71/69	NS
Median age	60.9	67.3	64.8	0.042
Smoking history (%)	35 (61%)	43 (52%)	78 (56%)	NS
Abdominal pain (%)	43 (76%)	47 (57%)	90 (65%)	0.038

malignant disease. Multiple precursors to adenocarcinoma exist, including pancreatic intraepithelial neoplasia (PanIN), and the cystic precursors IPMN and MCN. PanIN is divided into three grades of increasing dysplasia. PanIN-1 is characterized as a proliferative lesion without nuclear atypia; PanIN-2 is associated with a moderate degree of architectural and cytonuclear abnormalities; PanIN-3 has severe nuclear abnormalities with abnormal mitoses, but without invasion through the basement membrane. PanIN-3 is also referred to as carcinoma in situ and is almost always found in close proximity to an invasive cancer [8]. The prevalence of PanIN lesions increases with age, with one-third of patients greater than 60 years of age, without any known pancreatic disease, having a PanIN-1 lesion. It is proposed that advanced age, in addition to other factors, must be present for a PanIN-1 lesion to progress to PanIN-3 and then to invasive cancer [8]. These factors include genetic events such as telomere shortening, K-ras and p16 mutations, and clonal expansion [9].

IPMNs are macroscopic precursor lesions, which can also progress from benign to malignant histologically. About half the resulting invasive neoplasms are actually colloid (mucinous) carcinomas, with the remainder being the typical tubular adenocarcinoma. The progression to malignant IPMN is directly related to age, with multiple clinical studies demonstrating an increased percentage of malignant lesions in patients of increasing age [2, 10].

Clinical Presentation

History and Physical

Tumors of the exocrine pancreas in their early stage are often asymptomatic or present with the insidious onset of nonspecific symptoms. Tumors in the head of the pancreas typically lead to obstructive jaundice (80%), which is often

the only specific symptom pointing to the diagnosis. In an elderly patient, the development of jaundice, with dark urine, light stools, and pruritis, should lead to prompt diagnostic workup with a high index of suspicion for malignancy. Abdominal/back pain (72–87%) and weight loss (90–100%) are also common presenting symptoms, although these often signify locally advanced disease. New-onset diabetes or the presentation with “acute pancreatitis”-like symptoms may also be the presenting clinical features of pancreatic cancer. Nonspecific gastrointestinal symptoms may also exist, such as nausea, decreased appetite, constipation, or diarrhea.

One interesting trend in the presentation of pancreatic neoplasms has been that of the pancreatic ‘incidentaloma.’ Increased use of computed tomography scanning in the United States has led to increased identification of asymptomatic pancreatic lesions [11]. This has been especially true in the early detection of cystic lesions. The ability of CT scans to distinguish benign vs. malignant cystic disease or risk-stratify patients with very small solid lesions remains unknown, but there is likely some benefit in the early identification of these often asymptomatic lesions [12].

Physical examination of the jaundiced patient may show only a palpable gallbladder. Signs suggestive of advanced cancer, such as cachexia, ascites, abdominal mass, migrating thrombophlebitis, palpable supraclavicular lymphadenopathy (Virchow’s node), periumbilical lymphadenopathy (Sister Mary Joseph’s Node), and pelvic drop metastases (Blumer’s shelf) are obvious evidence of advanced disease with a poor prognosis. Among elderly patients, the presenting signs and symptoms of pancreatic cancer are not significantly more different than in younger patients [13, 14].

Laboratory Studies

Unfortunately, there is no screening test or definitive laboratory diagnostic test for pancreatic cancer. In patients with cancer in the body or tail of the pancreas, laboratory values are typically normal. In patients presenting with jaundice, laboratory studies will reveal an increase in total bilirubin and alkaline phosphatase, with occasional mildly elevated transaminases. Biliary obstruction can also lead to malabsorption of fat-soluble nutrients, which can lead to malnutrition and subsequent decreases in albumin, iron, hemoglobin, and vitamin-K-dependent clotting factors.

The most widely used tumor marker to aid in the diagnosis of pancreatic cancer is CA 19-9, a Lewis blood-group-related mucin glycoprotein. CA 19-9 is present at low levels (<38 U/ml) in most healthy patients, but if elevated, its level often correlates with the presence and even

aggressiveness of pancreatic cancer. CA 19-9, however, may be falsely elevated in patients with obstructive jaundice, cirrhosis, pancreatitis, and other malignancies. CA 19-9 has an overall sensitivity of 83% and specificity of 82%, but by raising the cutoff value to 200 U/ml and combining it with other testing modalities, the accuracy increases to 95–100% [15].

Management of Malignant Neoplasms

Diagnosis and Staging

When clinical symptoms or laboratory abnormalities are suspicious for a malignant pancreatic neoplasm, the first step toward diagnosis is noninvasive imaging. Computed tomography (CT) scan or magnetic resonance imaging (MRI) with or without cholangiopancreatography (MRCP) are noninvasive imaging studies that may aid in the diagnosis of pancreatic cancer. Transabdominal ultrasound can confirm obstructive jaundice by demonstrating a dilated biliary tree but lacks the sensitivity of CT and MRI in actually defining a pancreatic mass. Most clinicians regard CT scan with multiphase intravenous (IV) contrast enhancement as the initial imaging modality of choice. In recent years, the development of multidetector CT (MDCT) scanners has reduced acquisition time and drastically enhanced image resolution, resulting in submillimeter slices [16] (Fig. 75.5). In addition, when dual phases of IV contrast are used, both arterial and venous structures can be well visualized to determine

FIGURE 75.5 Multidetector CT (MDCT) scan with IV contrast revealing a 1cm tumor in the head of the pancreas (arrow).

FIGURE 75.6 Dual-phase contrast MDCT allows clear delineation of peripancreatic vessels, showing a detailed angiographic reconstruction. Note the tumor encroachment of the superior mesenteric vein.

local involvement by the tumor that defines resectability (Fig. 75.6). The inclusion of a “pancreatic phase” of IV contrast often leads to improved pancreas-to-lesion distinction. As well as visualizing the lesion and any associated blood vessels, MDCT is able to detect extrapancreatic disease, including liver, lung, and peritoneal metastases, to again provide preoperative staging with respect to resectability [17]. In spite of these advantages, many clinicians are hesitant to expose elderly patients to the potential toxicity of IV contrast. Recently, Itoh et al. have examined the effect of patient age on contrast enhancement during CT scans of the pancreatobiliary region. Results indicate that the ideal dose of IV contrast in the elderly may be about 10% less, or 0.07 mL/kg instead of 0.08 mL/kg. This dose, which takes into account changes in cardiac output and blood volume in the elderly, optimizes tumor enhancement and lessens the risk of nephrotoxicity [18].

Most studies have found no advantage of MRI over MDCT, with the exception of possible improved visualization of small liver metastases and peritoneal implants [17]. MRCP has the added benefit of 3D visualization of both the bile and pancreatic ducts, often revealing the “double duct” pattern of obstruction and can eliminate the need for invasive cholangiography. Another potential modality for the diagnosis and staging of pancreatic cancer is the positron emission tomography (PET) scan. Although PET scanning shows increased uptake of the glucose tracer by both the primary tumor and metastases in other cancers, it has not been shown to reliably provide useful diagnostic information in patients with pancreatic cancer [19].

FIGURE 75.7 ERCP of patient with adenocarcinoma of the pancreatic head. Note the involvement of both the common bile duct (cbd) and pancreatic duct (pd).

When noninvasive studies reveal a malignant pancreatic lesion, or when noninvasive studies are inconclusive, invasive studies may be indicated to confirm the diagnosis of pancreatic adenocarcinoma. Endoscopic retrograde cholangiopancreatography (ERCP) provides an endoscopic view of the ampulla and visualizes the biliary and pancreatic ductal systems (Fig. 75.7). ERCP can also be used to obtain cytologic brushings of suspicious areas in the pancreatic ductal system. While cytology results approach 99% specificity, the sensitivity is <50% due to a high false-negative rate [20, 21]. ERCP has been shown to be safe and well tolerated in elderly patients [22]. Rodriguez-Gonzalez et al. studied 159 ERCPs performed on patients 90 years of age or older. Complication rate (2.5%) and procedure-related mortality (0.7%) were low, and therapeutic interventions were able to be performed in 96% of indicated cases [23]. Although ERCP can be a safe and valuable tool in many patients, its use as a diagnostic tool has diminished with the use of MRCP. Therefore, ERCP is now currently used predominantly for endoscopic stent placement, for both palliative and preoperative biliary decompression.

Endoscopic ultrasound (EUS) has recently become a valuable tool in both the diagnosis and staging of pancreatic cancer. EUS sensitivity and specificity in detecting pancreatic cancer are 85–100 and 80–100%, respectively (Fig. 75.8). Multiple studies have demonstrated greater diagnostic accuracy of EUS compared to MDCT, particularly in the detection of small tumors less than 2 cm in size [24–27]. EUS can also be used to obtain a cytologic diagnosis via fine needle aspiration (FNA). This technique is typically more accurate

FIGURE 75.8 Endoscopic Ultrasound. (a) The tumor (*black arrow*) is clearly visualized, as well as its relationship to the superior mesenteric artery (sma) and vein (smv). (b) Fine-needle aspiration of the tumor for cytologic examination.

than ERCP brushings, with a sensitivity ranging from 75 to 90%, with a specificity approaching 100% [16, 17]. Complications of EUS are uncommon, even in the elderly.

A preoperative histologic or cytologic diagnosis of pancreatic cancer is not necessary in patients with a clearly defined presentation – obstructive jaundice and a pancreatic mass on CT — in a patient who is considered to be a candidate for surgical resection, regardless of age. When a tissue diagnosis is indicated, EUS-guided FNA has become the preferred method of choice. Yet, even in the elderly patient, a high level of clinical suspicion should override a negative cytologic diagnosis. EUS offers the advantage of the close proximity to the tumor, and for cancers of the pancreatic head, the needle traverses the duodenum, which will be resected. Conversely, percutaneous fine needle aspiration has fallen out of favor both due to the fact that the distance of the pancreatic tumor from the skin surface leads to a higher incidence of false-negative aspirations, as well as the risk of seeding of the tumor along the needle tract, leading to intra-peritoneal spread of the tumor.

Surgical resectability of a pancreatic cancer requires that the tumor both shows no evidence of metastatic disease (liver, peritoneal cavity) or local invasion of key adjacent structures. For most surgeons, direct extension of tumor into adjacent organs, encasement of the celiac or superior mesenteric arteries, significant encasement or occlusion of the portal – superior mesenteric vein (SMV) complex, involvement of distant lymph nodes, or obvious metastatic disease will preclude resection of a cancer of the head of the pancreas [28–30]. For cancers of the pancreatic body and tail, extension into the celiac axis or SMA, the SMV/portal vein, or into adjacent organs or metastatic disease renders the tumor unresectable, whereas isolated splenic vein or splenic artery involvement does not preclude resection. MDCT is the most useful imaging modality in detecting obvious vessel invasion and/or metastatic disease, leading to excellent accuracy in predicting unresectability (90–100%), but its specificity in predicting resectability is relatively low, about 30–50% [16]. Some studies indicate that EUS may be more

accurate in determining local invasion precluding resection of pancreatic cancer, owing to its increased ability to detect tumor invasion into adjacent vessels [17, 24, 27].

Unfortunately, neither MDCT nor EUS is able to detect small peritoneal or liver metastases, which are common with pancreatic cancer. This problem has led to the use of diagnostic laparoscopy at some centers for staging purposes. The role of routine laparoscopy has been controversial as the sensitivity of CT scanning has increased. Several reports have shown that routine laparoscopy for pancreatic head cancer would spare very few patients from a laparotomy (5–15%) [31, 32]. The value of laparoscopy is increased in evaluating cancers of the body and tail, however, as these patients are found to have occult metastatic disease at operation 50% of the time [33]. Diagnostic laparoscopy in the management of pancreatic cancer must be used on an individualized basis, taking into account the age and comorbidities of the patient, as well as the likelihood of finding occult metastatic disease. It would seem appropriate, however, if suspicion exists in an elderly patient that laparoscopy, to spare the patient an unnecessary laparotomy, might be in order. It has been suggested that markedly elevated CA 19-9 levels may correlate with advanced cancer stage [15, 34]. Finally, the need for surgical palliation of biliary and duodenal obstruction must also be taken into account, as patients who require palliative bypass will not benefit from laparoscopy. On the other hand, as the endoscopic and laparoscopic technical ability has advanced, many palliative procedures can be performed using these techniques, avoiding the need for open surgical procedures.

Preparation for Operation

If the decision is to proceed with an operation for pancreatic cancer in an elderly patient, proper preoperative preparation is required. Thorough assessment of cardiopulmonary status, renal and hepatic function, the state of hydration, nutrition,

anemia, and coagulation abnormalities is necessary. All efforts should be made to optimize the patient's overall health prior to proceeding with operation for resection or palliation. Nutritional status can have a major impact on surgical outcome after major abdominal surgery. The method of perioperative nutritional supplementation is controversial, as many methods are currently available. Meta-analyses regarding the use of preoperative total parenteral nutrition (TPN) for at least 7 days show varying results. Some studies have shown a reduction in serious postoperative complications, whereas several other studies show no benefit of preoperative TPN [35]. A recent Evidence Based Medicine Review notes that perioperative TPN is associated with a higher mortality and complication rate after pancreaticoduodenectomy, and recommends cyclic enteral nutrition for the optimal outcome in patients undergoing pancreatic resection [36].

Another major controversy in the preoperative management patients with pancreatic cancer presenting with obstructive jaundice is the role of preoperative biliary decompression. Biliary decompression can be performed by percutaneous transhepatic drainage or by placement of an endoscopic stent at the time of ERCP. In recent years, endoscopic stent placement has become the preferred method, as it is usually accomplished with less pain and complications and is better tolerated by patients. The benefit of routine preoperative biliary drainage is questionable, however, with multiple series suggesting that the use of preoperative stenting increases the incidence of perioperative complications, especially wound

infection [32, 37]. Therefore, preoperative biliary drainage is indicated only in selected patients, including the elderly, with advanced malnutrition, sepsis, or correctable medical conditions. Preoperative biliary drainage may be useful in allowing time for improvement of the patient's overall health status, particularly in an elderly patient. Furthermore, if surgery is to be delayed to facilitate referral of the patient to a high-volume center, endoscopic biliary stenting is advantageous. Finally, if preoperative neoadjuvant therapy is considered, biliary drainage is necessary before such therapy can be initiated.

Resection of Lesions of the Pancreatic Head

Pancreaticoduodenectomy (Whipple procedure) is the appropriate procedure for resectable cancers of the head of the pancreas, regardless of the age of the patient (Fig. 75.9) [38]. While many clinicians have regarded advanced age as a relative contraindication for major surgery, recent evidence suggests that age alone should not preclude surgery for pancreatic cancer. Prior to 1980, when the morbidity and mortality for pancreatic resection were substantially higher in all age groups, several studies found that elderly populations fared worse than their younger counterparts. Herter et al. observed that operative deaths rose from 7.7% in patients in the 41- to 50-year age group to 25% in patients 61–70 years of age [39].

FIGURE 75.9 Pylorus preserving pancreaticoduodenectomy (a) Depicts the extent of resection for a pylorus-preserving pancreaticoduodenectomy for cancer of the head of the pancreas. (b) depicts reconstruction with an end-to-end pancreaticojejunostomy, end-to-side hepaticojejunostomy, and a retrocolic duodenojejunostomy. (Reprinted with permission from Cameron [38]).

Lerut and colleagues also noted a significant increase in mortality, 41% versus 5% ($p < 0.001$), and morbidity, 58.8% versus 16.3% ($p < 0.01$), in patients undergoing pancreaticoduodenectomy over the age of 65 when compared to that in younger patients [40]. Finally, Obertop et al. reported 33% mortality following pancreaticoduodenectomy in patients over age 70 compared to 4% in younger patients [41].

Over the past two decades, however, numerous studies have challenged the view that pancreaticoduodenectomy may be contraindicated in elderly patients. One of the first series to show equivalent outcomes in elderly patients was a report from The Johns Hopkins Hospital, which reported 145 consecutive pancreaticoduodenectomies performed without mortality. Subgroup analysis, which separated patients by age (≥ 70 , $n = 37$; < 70 , $n = 108$), revealed no significant difference in the incidence of postoperative complications. No specific complication was significantly more frequent in the older group, and for many serious complications, patient over the age of 70 had a lower incidence. Operating time, blood loss, and length of stay were also statistically equivalent between the two groups, and no deaths occurred in either group [42].

Since 1990, numerous single-center series have been published, reporting the perioperative outcome of pancreatic resection in elderly (Table 75.3) [14, 43–58]. Most of these studies found equivalent or acceptable morbidity and mortality rates in elderly patients compared with younger cohorts, suggesting that age alone should not be seen as a contraindication to surgery.

In one such study, Delcore et al. reported a series of 42 patients between age 70 and 80 who underwent pancreaticoduodenectomy. The incidence of major complications was 14%, with 2 operative deaths (5%) [59]. Hannoun and colleagues reported perioperative morbidity and mortality in 223 patients undergoing pancreaticoduodenectomy, with 44 patients who were of age 70 and over. Perioperative morbidity was similar in the two groups (35%), while mortality was actually decreased in the older patients (4.5% vs. 10%) [46]. In a large series from Memorial Sloan-Kettering Cancer Center, Fong et al. analyzed the results of 138 elderly patients (≥ 70 who underwent major pancreatic resection compared to 350 patients under age 70 [47]. Length of stay (20 days vs. 20 days), frequency of complications (39% vs. 45%), and perioperative mortality (4% vs. 6%)

TABLE 75.3 Summary of publications comparing perioperative outcome between elderly and young patients undergoing pancreatic resection

Author (Year)	Comparison groups	Complication rate (%), older vs. young (p)	Perioperative mortality rate (%), older vs. young (p)

UCSF Patients from University of California San Francisco, CA Patients from a California statewide database

^a Age > 74 vs. 65–74. Complications and mortality of age group < 65 years old (55% and 3%, respectively) were not significantly different from the other two age groups

^b Age 80–89 vs. < 80 . After controlling for comorbidities, complication rate and mortality rate were not statistically significant between age groups

^c ≥ 80 vs. 70–79 vs. 60–69 vs. < 60 . The mean values of all four groups were compared using analysis of variance (ANOVA)

were no different in the younger vs. older groups. In fact, there were no deaths among the 24 patients aged over 80 years who underwent pancreatic resection. Analysis of the complications in this study identified that a history of cardiopulmonary disease, abnormal preoperative ECG or chest radiograph, and operative blood loss of >2,000 ml were most powerful predictors of a complication [47].

Ultimately, experienced groups of pancreatic surgeons have extended the operative indications for resection to patients over 80 years of age. A series of 46 patients aged 80 and over, undergoing pancreaticoduodenectomy over a 10-year period at Johns Hopkins, were compared to 681 patients under 80 who underwent the procedure during the same time period [49]. The two groups were similar with respect to gender, race, intraoperative blood loss, transfusions, and type of resection performed. The older patients had a shorter mean operative time (6.3 ± 1.3 vs. 7.1 ± 4.0 hours, $p < 0.05$) but a longer postoperative length of stay (median 15.0 vs. 13.0 days, $p < 0.05$) than their younger counterparts. A higher incidence of overall complications was seen in the older patients (57% vs. 41%, $p = 0.05$), with a statistically significant increase in delayed gastric emptying among the elderly (33% vs. 18% $p = 0.03$). Perioperative mortality was slightly higher among the elderly patients (4.3% vs. 1.6%), but this was not statistically significant. Another study several years later by the same group examined the outcomes of pancreaticoduodenectomy in the very elderly, which included patients aged 90 and older [55]. Three groups that underwent pancreaticoduodenectomy between 1970 and 2005 were compared: under age 80 ($n = 2,491$), age 80–89 ($n = 197$), and age ≥ 90 ($n = 10$). While the patients aged 80–89 did have a higher mortality rate (4.1% vs. 1.7%, $p < 0.05$) and complication rate (52.8% vs. 41.6%, $p < 0.05$) than their younger counterparts, these differences were not significant after adjusting for preoperative comorbidities. Multivariate analysis found that coronary artery disease and COPD were independent risk factors for mortality after pancreaticoduodenectomy, but age alone was not.

In addition to these numerous studies that looked specifically at patient age, several large series examined all patients after major pancreatic resection to elucidate overall prognostic indicators for outcome. One such study came from the Massachusetts General Hospital, in which 733 consecutive pancreatic resections performed from 1990 to 2000 were reviewed. The authors found that mean age of patients increased significantly over that time period, from 57 to 65 years of age. Multivariate analysis of this series of patients did not identify age as a significant prognostic indicator of poor outcome [60]. A series published from our institution reviewed 516 pancreaticoduodenectomies performed over a period of 20 years. Multivariate analy-

sis of multiple demographic and preoperative variables revealed several prognostic factors of poor outcome, none of which were age-related. These include preoperative serum total bilirubin level, blood loss, operation type, diagnosis, and lymph node status [61]. Another large series from Memorial Sloan–Kettering studied 555 pancreatic resections for pancreatic adenocarcinoma performed over a period of 17 years. Cox multivariate analysis did not find age to be an independent risk factor ($p = 0.695$) [62]. House and colleagues examined preoperative factors among 356 patients who underwent pancreaticoduodenectomy for pancreatic adenocarcinoma between 2000 and 2005. Multivariate analysis again revealed that age was not an independent predictor of complications, but body mass index (BMI) and visceral fat thickness were predictors of pancreatic fistulas, infectious complications, and increased overall complication rate [63].

A number of factors have accounted for the overall improvement in surgical outcomes following pancreatic resection including improvements in surgical technique, anesthesia, and management of complications. However, the “regionalization” of pancreatic surgery to “high-volume” centers is believed to be a major factor by many. The first data supporting this theory came from a study of patients who underwent pancreatic surgery in all nonfederal hospitals in Maryland that revealed that decreased procedural volume was associated with a significantly increased in-hospital mortality rate [64]. Similar results have been reported by numerous other investigators [65–69]. Perhaps the most convincing data, however, has come from Birkmeyer and colleagues, who drew national medical attention by publicizing major disparities between high- and low-volume centers with regard to outcome after major surgeries including pancreatectomy [70].

The effect of “regionalization” to high-volume centers has also been analyzed with respect to older patients. Several groups have published population-based studies to study the effects of both age and hospital volume on postpancreatectomy outcome. Using a statewide database, Lightner and colleagues studied four groups of patients who underwent pancreatic resection for neoplasia: patients from any California hospital younger than 75 years of age ($n = 2,491$), patients from any California hospital aged 75 and older ($n = 515$), patients from UCSF <75 ($n = 188$), and patients from UCSF ≥ 75 years of age ($n = 30$). Results revealed a striking difference in outcome between older patients who were treated at UCSF, a high-volume referral center, compared with those from a statewide database. While mortality was no different between younger and older patients at UCSF (3%), elderly patients had higher mortality rates statewide compared to their younger counterparts (10% vs. 7%, $p = 0.006$). Length of stay was statistically

equivalent for young and old patients at UCSF (16 vs. 15 days), whereas elderly patients statewide had a longer length of stay (21.4 vs. 19.8 days, $p < 0.05$). Even at UCSF, complications were more frequent in the elderly (70% vs. 56%), and they were more likely to be discharged to a skilled nursing facility (17% vs. 1%, $p < 0.05$) [43].

More recently, Riall et al., using a population-based cohort in Texas, have stratified patients undergoing pancreatic resection in Texas from 1999 to 2005 ($n = 3,736$) by age into 4 groups: < 60 , 60–69, 70–79, and ≥ 80 years of age. Hospitals with low volume (≤ 10 pancreatic resections/year) and high volume (> 10 pancreatic resections/year) were also compared. Mortality increased with increasing age in both types of hospitals, but low-volume hospitals had a more significant increase (Table 75.4). Unfortunately, this study also found that elderly patients were less likely to be resected at high-volume hospitals (62.3% of < 60 year-olds vs. 53.7% of ≥ 80 year-olds, $p = 0.01$). Bivariate and multivariate analysis were performed, which revealed older age as an independent predictor for increased mortality, longer length of stay, and increased discharge to nursing facility [58]. These population-based studies suggest that elderly patients who undergo pancreatic resection would be best served in a high-volume referral hospital and that surgeons must carefully weigh all patient factors before making the decision to operate.

Resection of Lesions of the Body and Tail

The opportunity to resect cancers of the body and tail of the pancreas is typically more limited than that of the pancreatic head, due to high frequency of advanced disease at diagnosis. If an elderly patient appears to have resectable disease based on available imaging, many surgeons favor diagnostic laparoscopy to look for occult metastatic disease before proceeding with resection. In the absence of metastatic disease, distal pancreatectomy with splenectomy is the operation of choice. Although less well studied than outcomes after

pancreatic head resection in the elderly, available data indicate that elderly patients tolerate distal pancreatectomy well. In a study of the risk factors predicting outcome after distal pancreatectomy, multivariate analysis found that age was not an independent predictor of outcome [71].

Palliation

Unfortunately, many cancers of the pancreas are unresectable at the time of diagnosis. Thus, optimal palliation of symptoms to maximize the quality of life is of primary importance. The three primary symptoms warranting palliation are obstructive jaundice, gastric outlet obstruction, and pain. Palliation in patients with unresectable pancreatic carcinoma has evolved over the last few decades with the increased use of endoscopic biliary stenting. Early prospective randomized trials showed that nonoperative biliary stent placement for palliation of obstructive jaundice had both lower complication and mortality rates. Many surgeons pointed out, however, that the mortality rate in the surgical arms (15–24%) was much higher than typical mortality rates for surgical biliary bypass. None the less, nonoperative palliation of periampullary carcinoma, especially in older patients, has become routine. Advocates for surgical bypass, however, remark that most surgical series report mortality rates of less than 5% and a much lower incidence of late jaundice when compared to endoscopic palliation [72]. Furthermore, when Nuzzo and colleagues compared the outcomes of elderly people (over age 70) undergoing surgical vs. endoscopic palliation, surgical palliation resulted in better long-term outcomes with similar morbidity [73]. Mean survival after surgery was significantly higher than that after stent placement (13.2 months vs. 7.29, $p < 0.001$), and total readmissions were fewer after surgery than stenting (1 vs. 25, $p = 0.001$) (Table 75.5).

Although the role of nonoperative palliation in patients found to be unresectable during preoperative evaluation has been well defined, most surgical groups favor performing surgical biliary bypass, should the tumor be determined to be unresectable at the time of laparotomy. This is best

TABLE 75.4 Mortality by age after pancreatic resection at high-volume and low-volume hospitals in Texas

accomplished by an anastomosis of the bile duct to the small intestine as a hepaticojejunostomy. If patients have duodenal obstruction, a retrocolic gastrojejunostomy should be performed (Fig. 75.10) [38].

The role of prophylactic gastrojejunostomy for palliation in patients found to have unresectable pancreatic carcinoma at laparotomy has been considered controversial. The question, however, appears to have been answered by two prospective randomized trials. One such study was performed at Johns Hopkins which evaluated 87 patients with unresectable periampullary cancer who were randomized at the time of laparotomy to either prophylactic retrocolic gastrojejunostomy or no gastrojejunostomy. None of the patients who underwent gastrojejunostomy developed late gastric outlet obstruction, whereas the patients without gastrojejunostomy had a 19% rate of late gastric outlet obstruction requiring intervention ($p < 0.01$). Length of stay, morbidity, mortality, and long-term survival were comparable between the two groups [75]. In a second prospective, randomized multicenter trial, patients with unresectable cancer at the time of laparotomy underwent either a biliary bypass alone (single bypass) with hepaticojejunostomy or a double bypass with both a hepaticojejunostomy and a retrocolic gastrojejunostomy [75]. The group who underwent double bypass had significantly decreased incidence of late gastric outlet obstruction without any increase in complication rate, providing evidence that prophylactic double bypass should be routinely performed in these patients.

Traditionally, patients who present with unresectable cancer and duodenal obstruction required an open gastrojejunostomy to provide palliation. Recent developments including both laparoscopic gastrojejunostomy and endoscopic

FIGURE 75.11 Enteric palliation using an endoscopically placed duodenal stent (*white arrow*) and relief of biliary obstruction with biliary stent (*black arrow*).

metallic stent placement offer less invasive alternatives. A number of series have shown excellent results with laparoscopic gastrojejunostomies [76, 77]. In addition, the role of endoscopic stenting for duodenal obstruction has quickly expanded over the last decade (Fig. 75.11). Several retrospective studies have compared outcome after duodenal stent placement vs. gastrojejunostomy (GJJ). In one study, 42 patients who underwent GJJ were compared to 53 patients who underwent stent placement [78]. There were no differences between the groups as far as minor complications, early major complications, and long-term survival, although the surgical group had fewer late complications (22% vs. 60%), and the stented group had a shorter length of hospital stay (6 days vs. 18 days, $p < 0.001$). This study suggests that gastrojejunostomy is associated with better long-term outcomes, while endoscopic stent placement is associated with better short-term outcomes, with no difference in long-term survival. For many patients, primarily with advanced unresectable disease or elderly patients with poor performance status, duodenal stent placement has become the procedure of choice.

The management of pain in patients with advanced pancreatic adenocarcinoma is one of the most important aspects of their care, and multiple complementary treatment strategies are available. Most patients can be successfully managed with a combination of short- and long-acting oral opiates, often combined with topical sustained-release opiates. However, appropriate dosing of opioids in the elderly must be considered. In a recent review of the pharmacological management of cancer pain in the elderly, the authors note

frequent undertreatment of elderly patients with cancer-related pain [79]. Unrelieved cancer pain in the elderly can lead to disturbances in mood, sleep, appetite, and cognition. Many health-care providers have misconceptions about pain perception in the elderly, tolerance and addiction, and increased potency of medications. In general, opioid use in the elderly should start at low doses and be titrated according to the patient's response and adverse effects. Choice of medication should take into account duration of action, ease of administration, and overall health of the patient. Long-acting morphine preparations are commonly used for cancer pain, but its use in the elderly with renal impairment must be weighed carefully, as renal failure may lead to the buildup of a toxic, antagonistic metabolite. Meperidine is ill-advised in the elderly due to its short duration of action, poor oral availability, and neurotoxic metabolites. Oxycodone is appealing for use in the elderly, as its pharmacokinetics is usually independent of age, renal function, and albumin concentration. Transdermal fentanyl is an analgesic that has also been shown to be well tolerated in the elderly population.

When pancreatic cancer pain is intractable in spite of appropriate opioid analgesics, several invasive techniques are available for pain control. These techniques target either the celiac plexus or the splanchnic nerves. Two methods are available for absolute alcohol neurolysis of the celiac plexus: standard needle placement through the midback (with CT or fluoroscopic guidance) or endoscopic ultrasound (EUS)-guided needle placement. Both methods have been shown to significantly reduce pain for sustained periods of time, with the EUS-guided approach having fewer complications [80–82]. When a pancreatic cancer is determined to be unresectable at laparotomy, intraoperative chemical splanchnicectomy with direct injection into the area of the celiac axis (Fig. 75.12)

FIGURE 75.12 Chemical Splanchnicectomy. After identification of the celiac axis in the lesser sac, 50% ethanol is injected into the celiac plexus for pain control. (Reprinted with permission from Cameron [38]).

[38] should be performed. Lillemoe and colleagues performed a prospective, randomized, double-blind, placebo-controlled trial comparing chemical splanchnicectomy with 50% alcohol to a sham saline injection [83]. The patients who received alcohol injections had significantly improved pain scores compared to those who received saline at 2-, 4-, and 6-month follow-up assessments, as well as at the final assessment ($p < 0.05$). This procedure can also be performed during laparoscopic staging for pancreatic cancer. Neurolytic celiac plexus block also improved multiple quality-of-life measures in those patients. In the elderly population, EUS-guided neurolytic celiac plexus block likely delivers the least invasive, most effective option for intractable pancreatic cancer pain.

Post-Op Care and Complications

Adequate fluid and electrolyte maintenance, glucose regulation, pulmonary toilet, nutritional evaluation and support, and provision of appropriate perioperative antibiotic prophylaxis are routine. Unfortunately, complications are common in all age groups after pancreaticoduodenectomy, with typical rates of 30–40%. The difference in complication rates between elderly and younger patients has been addressed by multiple retrospective comparisons [13, 14, 43–58]. Although numerous studies have found no difference in complication rates between these two groups, others have reported higher rates of delayed gastric emptying [49, 56], bleeding complications [50], cardiac morbidity [43, 55], or pancreaticojejunostomy leaks [14] in older patients. Several studies report that elderly patients with comorbidities have increased complication rates compared to younger patients with the same comorbidities [54, 55]. Similarly, unpublished data from Indiana University demonstrates that elderly patients with few comorbidities and in better overall health (albumin > 3 g/dl, hemoglobin > 10 g/ml) had equivalent outcomes as younger patients, while elderly patients with more comorbidities and poor overall health had significantly worse outcomes than younger patients [84]. This suggests that careful preoperative patient selection and increased postoperative diligence are warranted in elderly patients who undergo major pancreatic resection.

Chemotherapy/Radiation Therapy

Many surgeons believe that the future improvement in outcome of pancreatic cancer will come through advances in adjuvant and neoadjuvant chemoradiation therapy. Traditionally, in the United States, standard adjuvant therapy following pancreatic resection has consisted of external

beam radiotherapy with concomitant 5-fluorouracil (5-FU) chemotherapy. In recent years, gemcitabine has been substituted for 5-FU. These recommendations have been based on a somewhat outdated prospective randomized trial conducted in the 1980s (GITSG trial) [85]. More recently, a large prospective, randomized multi-institutional trial in Europe (ESPAC) has confirmed the benefit of postoperative adjuvant chemotherapy with 5-FU following pancreatic resection [86]. However, this study showed that the addition of radiation showed no benefit and perhaps led to a worsening of outcomes when combined with chemotherapy alone. While neither study specifically addressed age as a factor in determining outcome in patients who were included in these trials, traditionally, a major factor determining the ultimate success of any chemotherapy regimen is the functional status of the patient and their ability to complete the treatment regimen. Elderly patients following pancreatic resection might tend to have a slower overall recovery of functional status limiting either their inclusion in or full completion of adjuvant therapy regimens. Similarly, recent results have suggested that neoadjuvant therapy with preoperative chemotherapy and radiation therapy can be applied safely to patients prior to pancreaticoduodenectomy for cancer of the pancreas [87, 88]. These studies have shown no increase in perioperative complications and comparable long-term survival. Again, the selection criteria for these studies have not defined age as being a prohibitive factor in inclusion in the trials.

In patients with unresectable pancreatic cancer, systemic chemotherapy, usually with gemcitabine is typically applied alone in patients with metastatic disease or in combination with radiation for locally advanced tumors. Traditionally, concerns have been raised that chemotherapeutic side effects may be prohibitive, particularly with concurrent radiation therapy, in elderly patients. Morizane and colleagues reviewed outcome data from pancreatic cancer patients <70 ($n=39$) and ≥ 70 ($n=19$) who underwent 5-FU therapy with concurrent radiotherapy [89]. In spite of lower pretreatment albumin levels and more weight loss in the elderly group, there were no significant differences in toxicity or discontinuation of treatment between groups. In fact, the median survival time was longer in the elderly patients (11.3 months vs. 9.5 months, $p=0.04$). Another study evaluated the tolerance of gemcitabine regimens in patients aged over 70 years with advanced pancreatic cancer [90]. The elderly patients ($n=42$) had a higher incidence of neutropenia and peripheral neuropathy than their younger counterparts, resulting in more frequent dose reductions (62% vs. 40%, $p=0.03$) in the elderly. Overall tolerance was equivalent between the groups, however, and efficacy was similar. In a study investigating the economics of the often-expensive chemoradiation therapy in elderly patients with pancreatic cancer, combination treatment with radiation and chemotherapy was determined to be a cost-effective alternative to no treatment [91]. These

results indicate that standard chemoradiation modalities should be strongly considered in elderly patients who have a suitable performance status.

Long-Term Outcomes

Despite improvements in surgical management and perioperative mortality, long-term survival remains poor following resection for pancreatic adenocarcinoma in patients of all ages. Even the best 5-year actuarial survival rates after pancreaticoduodenectomy only approach 20%. Several large series that have applied multivariate statistical analysis have shown that age is not an independent prognostic factor for survival [61, 62, 92, 93]. In contrast, one large study of a statewide database of 2,230 patients diagnosed with pancreatic cancer found that advanced age at diagnosis was an independent risk factor for decreased survival (hazard ratio 1.23, CI 1.18–1.29), although this may be a result of elderly patients not undergoing surgical resection [94]. Most analyses find tumor characteristics and stage to be the most influential prognostic factors for survival, such as tumor size, nodal status, margin status, and tumor differentiation.

Numerous single-institution studies have examined long-term outcome after pancreatic resection in the elderly compared to younger patients (Table 75.6). The majority of series found similar 5-year survival rates in elderly patients as those in younger patients [14, 49, 50, 52, 53, 56, 57, 95]. In contrast, a review performed at the Memorial Sloan-Kettering Cancer Center, the 5-year survival rate for patients ≥ 70 who underwent pancreatic resection ($n=138$) was significantly lower than the 5-year survival of patients under age 70 ($n=350$) (21% vs. 29%, $p=0.03$) [45, 47, 55]. As with short-term outcomes, hospital volume is an important determining factor in long-term outcome after pancreatic resection. High-volume, single-institution series report postresection 5-year survival rates as high as 29%, while population-based studies report rates of 15–16% [47, 95]. A study by Birkmeyer and colleagues investigated the relationship between hospital volume and 5-year survival after major cancer surgery. This study showed that for pancreatic cancer resection, there was a difference in long-term survival between low- and high-volume hospitals (10.8% vs. 15.9%) [96]. These data, like those regarding perioperative outcome, suggest that elderly patients are best served at high-volume institutions.

Failure to Operate on Early Stage Cancer

Unfortunately, most patients with pancreatic cancer (52%) are found to have distant disease at the time of diagnosis.

^aIncludes patients with other periampullary malignancies, islet cell malignancy, and other cancers metastatic to the pancreas

^bActuarial survival

FIGURE 75.13 Failure to operate on stage I pancreatic cancer. Note the role of age in the chances that a patient will be offered surgery. **p*<0.0001 compared to age of patients who underwent surgery (Data from Bilimoria et al. [97]).

The dismal prognosis for these patients has led to an overall pessimism for the aggressive treatment of this disease. Of the 38,000 pancreatic cancer patients in the SEER National Cancer Registry database, 7% have localized disease, and 26% present with regional disease. When these 33% patients with locoregional disease have been studied, only about half of them underwent any form of surgical or radiation treatment [97, 98]. Even among Stage I patients, who are potentially curable with resection, Bilimoria et al. found that 71% did not undergo surgery. Analysis of these patients showed that 6.4% were excluded due to comorbidities, 4.2% refused, 9.1% were excluded due to age alone, and 38.2% were not offered surgery for undetermined reasons [97]. In addition to the 9.1% who were excluded due to age, the average age of patients who were

not offered surgery was significantly higher, 71.7 vs. 62.1 (*p*<0.0001). This study suggests that age has a major influence in the management options that are offered to patients, including referral to a surgeon (Fig. 75.13). Gawron et al. found similar differences, with a much higher percentage of older patients treated nonoperatively [99]. This age-related referral bias did not appear to be related to increased comorbidities in the elderly, since the group of patients who were offered surgery had significantly more comorbid conditions than those who were not offered surgery (*p*<0.0001) [97]. Furthermore, the pattern of not offering surgery to elderly patients did not change over the time period of the study (1995–2004) despite significant decreases in surgical morbidity/mortality during that time and multiple reports of successful pancreatic

resection in elderly patients. This unfortunate trend is true for cancer-directed surgery in other diseases as well, with underutilization in elderly populations [100].

Management of Benign and Premalignant Neoplasms

Diagnosis

The diagnosis and management of benign pancreatic neoplasms has become an increasingly frequent problem over the last decade. This is in part due to the increased detection of asymptomatic lesions due to the widespread application of cross-sectional imaging studies. The challenge is determining which lesions are malignant, benign but premalignant, or benign with no malignant potential. The majority of the asymptomatic lesions is cystic and includes mucinous cystic neoplasm (MCN), intraductal papillary mucinous neoplasm (IPMN), and serous cystadenoma (SCA). Cross-sectional imaging (with or without pancreatography), endoscopic ultrasound, and cyst fluid analysis are the principal methods for evaluating cystic lesions of the pancreas.

Multidetector CT scan is generally the first technique used, whether it reveals an incidental, asymptomatic lesion, or has been obtained in the workup of abdominal symptoms. CT can often help discern between several types of cysts, based on specific characteristics. For example, the presence of multiple small-diameter microcysts, stellate scar, and sunburst calcifications is characteristic of SCAs and distinguishes these lesions from mucinous cystic tumors (Fig. 75.2). In addition to aiding in classification of cysts, several findings on cross-sectional imaging can predict the likelihood of malignancy of a cystic pancreatic lesion: peripheral calcification, dilated pancreatic duct, and presence of a solid component [101]. A noninvasive alternative to CT is MRCP, as this technique can determine if the lesion communicates with the pancreatic ductal system. IPMNs typically communicate with the pancreatic ductal system, whereas MCNs do not. MRCP or ERCP, as an invasive procedure, can classify IPMN into main duct type, branch duct type, or mixed type IPMN, which has important implications with respect to management [6, 102]. Endoscopic ultrasound with fine-needle aspiration (EUS-FNA) has also become an important method used to differentiate between cyst types. The viscosity of aspirated fluid is the first clue to diagnosis, as mucinous neoplasms have a higher fluid viscosity than serous ones. Fluid analysis revealing a high mucin content and high carcinoembryonic antigen (CEA) is diagnostic of a mucinous neoplasm, with an accuracy of 79% [11]. This differentiation between

mucinous and nonmucinous is essential, as serous tumors are very rarely malignant and in most cases can be managed without surgery.

Estimating the Malignant Potential

When a pancreatic cystic lesion has been classified as mucinous, whether it be MCN or IPMN, the clinician must then determine the likelihood of malignancy. Certain clinical and morphologic features of mucinous cystic lesions are associated with a higher likelihood of malignancy. When cross-sectional imaging of MCN or IPMN reveals a tumor size >3 cm, calcification, or presence of a solid component, there is an increased chance of malignancy [6, 102]. In patients with IPMN, a main-duct subtype, side branch tumors with a dilated main pancreatic duct, elevated serum CEA or CA19-9, presence of jaundice, and new-onset diabetes have all been shown to be predictors of malignancy [2, 7, 101]. In addition, cyst fluid analysis revealing markedly elevated levels of CEA or PGE₂ is associated with malignancy [103, 104]. Cytology of the cyst aspirate may also be used, which has a specificity of 83%, but the high false-negative rate creates a low sensitivity (34.5%) [105]. Finally, advanced age is also associated with increased likelihood of malignancy, as most series find the average age of patients with malignant lesions to be 5–6 years older than patients with benign tumors [106].

Indications for Resection

In elderly patients, the decision to proceed with surgical resection must take into account the patient's symptoms, the likelihood of malignancy, the patient's general medical condition, and the expected morbidity and even mortality of the procedure. In patients with serous cystadenoma, the likelihood of malignancy is less than 1%, so surgery should only be offered to symptomatic patients in relatively good health or for tumors demonstrating significant growth. In the case of mucinous cystic neoplasms (MCNs), resection is indicated in symptomatic patients and in cases with a high suspicion of malignancy. Because it is impossible to determine malignancy preoperatively with absolute certainty, many surgeons advocate surgical resection for all patients with MCN who are suitable operative candidates [6]. For patients with branch duct IPMN, malignancy is extremely rare in asymptomatic patients with lesions less than 3 cm. Therefore, only those patients who are symptomatic or have large (>3 cm) lesions should undergo resection. In contrast, main-duct IPMN has a malignancy rate of 60–92%, leading to most authors recommending resection for all patients [2, 7, 107].

Resection

When the decision is made to resect a benign or premalignant tumor of the pancreas, most resections are performed using traditional pancreaticoduodenectomy or distal pancreatectomy. However, in recent years, multiple new minimally invasive and/or pancreas-sparing techniques have become popular options for surgical management. These include laparoscopic distal pancreatectomy with or without splenic preservation, central pancreatectomy, and enucleation of the lesion. For lesions of the body and tail of the gland, laparoscopic distal pancreatectomy, with or without the spleen-preserving procedure, has gained favor with many surgeons [108, 109]. The laparoscopic technique has become widely applied for benign tumors or small tumors of undetermined malignant status. In patients considered to have a high probability of malignancy, splenectomy should be considered. For benign small lesions in the midpancreas, a central pancreatectomy may be an appropriate choice, as it preserves as much pancreatic tissue as possible to ensure maintenance of endocrine and exocrine function. An even less invasive option for benign neoplasms is enucleation, in which the lesion is essentially 'cored' out from the pancreatic parenchyma. This procedure is most appropriate for lesions that are not in communication with the main pancreatic duct [110].

Outcomes

Theoretically, the long-term survival after resection of a benign or premalignant pancreatic tumor should be comparable to age-matched controls. However, patients with

IPMNs are at risk for recurrent disease in the remnant gland after partial pancreatectomy. The extent of surgical resection of IPMNs should be determined by the extent of disease (especially the presence of multifocal lesions) and intraoperative frozen section of resection margins. After resection, patients with even benign or noninvasive IPMNs require careful follow-up for recurrent disease, which has been reported in approximately 10% of patients [2]. Survival for patients with resected invasive IPMNs is substantially better than for pancreatic ductal carcinoma and in some series approaches 50% at 5 years [10]. The role of postoperative adjuvant therapy for invasive IPMN has not been specifically determined but in general has been applied similarly to ductal carcinoma.

Conclusions

Tumors of the exocrine pancreas are a significant issue in the elderly. In general, older patients should be treated aggressively with similar indications for surgery and similar procedures as in younger patients. The morbidity and mortality of major pancreatic resection have decreased among all age groups over the last three decades, making safer surgery an option. Great care should be taken, however, in assessing an older patient's preoperative risk factors, potential for increased life expectancy, and hospital volume before proceeding with major surgical resection. In patients with malignant tumors, primary-care physicians and surgeons alike must recognize that surgical resection offers the only chance for cure and must not be withheld based on age alone.

CASE STUDY

Mr. Smith is an 80-year-old man who presented with painless jaundice, dark urine, clay-colored stools, and pruritus. His workup at an outside hospital consisted of a CT scan, which showed a potentially resectable 2.5 cm mass in the head of the pancreas, and an ERCP, which demonstrated pancreatic and biliary ductal obstruction. A biliary endostent was placed. Finally, an endoscopic ultrasound was performed, which showed a pancreatic mass with no evidence of visceral vessel invasion. Fine-needle aspirate performed at the time of EUS was positive for pancreatic cancer. The patient was referred for surgical evaluation.

The patient's past medical history is significant for a 40-year smoking history, although he stopped smoking 20 years ago. He has long-standing atrial fibrillation and has been on anticoagulation with warfarin. The patient has an internal cardiac defibrillator in place. He has type II diabetes managed with oral medications. He has a history of prostate cancer treated with radiation therapy, which has resulted with neuropathic bladder, which requires self-catheterization. He also has a history of a left hip replacement.

After determining that the patient was indeed a potential candidate for surgical management, follow-up with his cardiologist was obtained where echocardiogram revealed an ejection fraction of 20–25%, likely due to a

(continued)

CASE STUDY (continued)

nonischemic cardiomyopathy. His medications included avandia, corgard, glucosamine, iron, lasix, metformin, and norvasc. On review of systems, he denied chest pain, but exercise tolerance was limited with shortness of breath at one block or one flight of stairs. He had no history of cerebral vascular accident or stroke. He had lost a total of 10 pounds since the presentation. He denied nausea, vomiting, or blood in his stool.

The patient was evaluated preoperatively by cardiology as well as in our preoperative assessment and testing center and was brought to the operating room for a planned pancreaticoduodenectomy. His warfarin was stopped five days before surgery and on the morning of admission, he had a normal INR. General anesthesia was induced following placement of an epidural catheter for intraoperative anesthesia and perioperative pain control. After general anesthesia was obtained, the patient underwent a diagnostic laparoscopy, which showed no evidence of metastatic disease. A classic pancreaticoduodenectomy was then performed with an estimated blood loss of 400 ml and no intraoperative complications. After the reconstruction, a feeding jejunostomy was placed. At completion of the surgical procedure, the patient was extubated and transferred to the ICU. He was maintained in the ICU overnight and then transferred to a progressive care unit in the morning following surgery. On postoperative day two, tube feeds were initiated, and on postoperative day three, the patient was started on a clear liquid diet. The patient was maintained with perioperative prophylaxis with lovenox, and on postoperative day four, with no evidence of bleeding in the drains, the patient

was started on therapeutic heparin for the remainder of his hospitalization. On postoperative day five, he developed an episode of atrial fibrillation with rapid ventricular response, and cardiology follow-up was obtained. His heart rate was eventually controlled with digoxin and beta blockers which were not associated with hemodynamic instability. Perioperatively, he had some confusion, thought to be due to intervenous narcotic PCA, but this cleared, and his pain was eventually well controlled with tylenol. He was able to tolerate a diet although oral intake was only marginal, and he was, therefore, maintained on cycled tube feeds throughout the remainder of his hospitalization. The patient was discharged to a rehab center on postoperative day 10 with drains removed and on therapeutic lovenox until his anticoagulation was adequate on oral warfarin.

The patient was seen in follow-up on 1 month after discharge. He has recently been returned to his home where he lives independently with family nearby. He tolerates a diet although we are still using the feeding jejunostomy for daily boluses of tube feeds but felt that his oral intake was adequate. He had no new cardiac events and was therapeutically anticoagulated with warfarin. His feeding tube jejunostomy was removed. His incision was well healed.

Final pathology revealed a 2.7×2.2×1.6 cm ductal carcinoma of the pancreas. All margins were negative. One of 13 pancreatic lymph nodes showed direct invasion by the cancer, but all other lymph nodes were negative. (A.J.C.C. State pT3, N1, M0). After consultation with the patient and his family, it was felt that his recovery was adequate for referral to medical oncology for consideration of postoperative adjuvant chemotherapy.

Chapter 76

Benign and Malignant Tumors of the Liver

Anita Kit Wan Chiu and Yuman Fong

A decade ago, one eighth of the population of the United States was over the age of 65, and this small portion suffered one half of all cancers diagnosed [1]. It is projected by the U.S. Census Bureau that by the year 2030, more than 20% of the U.S. population will be over the age of 65. This demographic change alone will increase the number of cancers in America by approximately 30% [2, 3], making no other single factor as important as age for cancer incidence.

Advanced age has also long been associated with higher risk during surgical therapy. Brooks in 1937 reported operative results of 287 patients over the age of 70 years who underwent surgical procedures that today would be considered minor [4, 5]. The mortality rate was remarkably high (19%), with approximately one third of the patients who had undergone abdominal operations having in-hospital deaths. Brooks foretold that with a rapid increase of the elderly population, surgeons would increasingly be confronted with surgical problems among the elderly and should strive to improve their results by becoming more accustomed to the physiologic changes associated with aging. It has been approximately seven decades since his paper, and with improvements in anesthetic and surgical technique, there has been substantial improvement in surgical outcomes of elderly patients after routine surgical procedures [5]. High-risk procedures such as cardiac operations and liver resections are now being routinely performed on the elderly population with good outcomes [6]. Advances in surgical technology have also increased the potential for curative cancer surgeries in older patients [7]. However, although elderly patients do favorably when carefully selected, they generally are wrought with more preoperative comorbidities, which can cause an increase in morbidity and mortality. Turrentine in 2006, in an institutional review of ACS NSQIP data, acknowledges that increasing age itself remains an important risk factor for postoperative morbidity and mortality [8]. In 2007, Finlayson

commented on population-based outcomes after high-risk cancer operations in the elderly to be worse than previously reported in the literature with a point that patients in this population need to be carefully selected [9].

Surgical extirpation is the only curative therapy for malignant disease of the liver. Although thermal destruction techniques such as radiofrequency ablation are utilized, resection is still the gold standard for potential cure. In approximately 50,000 cases of hepatic colorectal metastasis encountered annually in the United States, and the more than one million cases of primary hepatocellular carcinoma seen worldwide, surgical excision has been shown to result in long-term survival for more than one third of patients [10]. Because the number of elderly persons in the United States is growing and the incidence of many liver tumors increases with age, increasing numbers of patients are presenting for consideration for resection of primary or secondary liver cancers. This chapter summarizes the current data on morbidity and mortality after liver operations in the elderly and the pathophysiology that may underlie the increased risk of complications in this age group. The current approaches for the most common tumors seen in the elderly are then summarized.

Perioperative Outcome After Liver Resection in the Elderly

The past four decades have seen a dramatic decline in mortality rates after liver resection [11–14]. Major liver resections are routinely performed at major centers with perioperative mortality rates less than 5%. In the past, elderly patients were thought to be at particularly high risk for perioperative complications (Table 76.1). Studies published during the late 1980s still reported mortality rates of 11–41% [15–17]. Extensive resections consisting of trisegmentectomy were associated with operative mortality of more than 30% [17]. The higher operative mortality and morbidity rates in elderly patients can be explained partly by associated conditions in elderly patients such as diabetes mellitus, cardiopulmonary

disease, and renal disease [18]. Other studies have implicated high American Society of Anesthesiologist grades, intraoperative transfusions, tumor size, and gender to be predictors of overall survival [6, 19]. A more important factor for such high complication and mortality rates in these series is the high incidence of the concomitant hepatic disorders of hepatitis and cirrhosis [5, 15, 20–22]. Several studies suggest that if these factors were excluded, there would be no difference in morbidity and mortality between old and young patients [20]. In more recent studies, in predominantly noncirrhotic elderly patients, the perioperative mortality mirrored that expected in a younger population [5, 6, 20, 21, 23–26].

We have reported two large series where resections in the elderly were performed with an operative mortality less than 4% and a complication rate less than 35% [5, 25]. The major cause of mortality continues to be postoperative hepatic insufficiency; therefore, elderly patients with cirrhosis should be scrutinized closely before an operation is performed. Chronologic age alone should not be considered a contraindication to liver resection. In fact, many studies suggest that an aggressive surgical policy in the elderly is associated with low perioperative morbidity and mortality, as well as good long-term outcomes [27]. However, because associated medical conditions are more frequently encountered in patients with advanced age, we routinely refer patients of age 65 and over for cardiopulmonary evaluation prior to liver resection. Contrary to recommendations of others [17, 24], we do not believe that trisegmentectomies carry prohibitive risk in the elderly, and routinely offer such extensive resections to medically fit patients of advanced age. Postoperative medical monitoring is based on objective evaluation of medical fitness and not on age alone. In a series of 128 patients undergoing liver resection for metastatic colorectal cancer, only 7% required intensive-care unit (ICU) admission at any time during the

hospitalization, and the median hospital stay was only 13 days [5]. Liver resection in the elderly can, therefore, be performed with low mortality and morbidity and with expenditure of health-care resources similar to that for resections performed in a younger age group. In fact, the long-term survival of elderly patients undergoing liver resection for malignancy mirrors that of younger patients (Fig. 76.1).

Pathophysiologic Basis of Liver Complications in the Elderly

The liver undergoes physiologic changes during aging, such as a decrease in size and blood flow [1, 2, 28]. There is an observed increase in mean cellular and mitochondrial volume and a decrease in cell number. There is also a decrease in mitochondrial DNA [29]. Under normal conditions, these changes do not seem to be clinically significant, as hepatocyte functions such as detoxification, demethylation, conjugation, and hepatic extraction remain normal. However, during periods that require increased hepatocyte function, the liver of an older patient may not be able to respond by increasing synthetic or metabolic function, and hence, hepatic insufficiency may result [1, 3, 30]. One clinically important scenario requiring increased hepatocyte function is the immediate postresection period, when a reduced hepatocyte mass must perform the physiologic tasks of the preoperative liver until such time as regeneration may restore the liver to preoperative capacities. The reduced hepatocyte protein synthesis in the elderly may be a factor contributing to postoperative hepatic insufficiency [31, 32]. This may help explain the higher incidence of liver failure, particularly in cirrhotic elderly patients after liver resection [16, 20]. Elderly patients with cirrhosis should therefore be considered discriminantly for surgical resection.

Postoperative liver insufficiency may also be explained by a reduced “regenerative” capacity in the aged. The basis for major liver resection is the potential for the liver to undergo compensatory hypertrophy and hyperplasia, or “regeneration,” as it is more often termed. Resection of up to 80% of the hepatic mass is followed by liver regeneration, such that within a 3-week period, a liver of approximately the same size as the preresection liver can be expected, with normalization of liver functions usually within 6 weeks. This regeneration, however, may be altered by the processes of aging. Numerous animal studies have demonstrated retarded liver regeneration in aged animals, as measured by mitotic index, tritiated thymidine uptake, and restoration of liver mass [33, 34]. Such alterations in liver regeneration and function in aged animals are particularly dependent on the nutritional status of the animal [32], making nutritional support particularly important in this age group. One possible mechanism of such retardation of regeneration is a reduction of thymidine

FIGURE 76.1 Survival after liver resection for colorectal metastases for patients age 70 years or older ($n=128$) compared with that of patients younger than age 70 ($n=449$; $p=NS$) (from Fong et al. [5] with permission from Lippincott Wilkins & Williams).

kinase expression in aged animals [34]. In addition, levels of DNA polymerase- α , a key enzyme for DNA synthesis, are diminished in aged animals [35]. These and other enzymes are necessary for maintenance of DNA synthesis in animals. There is also decreased fidelity of DNA synthesis by DNA polymerase- α [36], which may very well be related to the alterations in histone function that have long been recognized [37, 38]. Whether such cellular changes are seen in human regenerating livers is not known, as studies evaluating cellular alterations during liver regeneration in the elderly patient are sparse. For the noncirrhotic patient, the alterations in liver regeneration seen in animals cannot be clinically relevant in humans, as most reports suggest that there is little difference in the hepatic regeneration rate measured by size when the old patient is compared to young individuals. In patients with cirrhosis, it is this parenchymal abnormality that has the greatest influence over the regenerative capacity.

Treatment of Liver Tumors

In the following section, we discuss the most commonly encountered liver tumors in the elderly patient, beginning with benign tumors. The latter usually do not require therapy but are discussed because patients of advancing age are more likely to be subjected to the wide variety of imaging modalities now available. Benign liver tumors are often discovered incidentally and lead to emotional distress and diagnostic confusion. Our discussion then concentrates on the two malignant tumors most commonly encountered: metastatic colorectal cancer and hepatocellular carcinoma.

Benign Liver Tumors

Most benign liver tumors are asymptomatic and are discovered incidentally at the time of laparotomy or detected on an imaging examination done for other indications. When a patient presents with an incidentally discovered liver mass, a workup should begin as always with a thorough history and physical examination. A history of previous cancers is elicited, as are any symptoms suggestive of gastrointestinal malignancy. Patients should be questioned for a history of hepatitis, alcohol abuse, and familial history of liver disease. Most patients are asymptomatic. It is a highly unusual situation when a patient presents with definable symptoms from a benign tumor, which are usually related to encroachment on adjacent structures or the stretching of Glisson's capsule by a large tumor. On physical examination, signs of portal hypertension such as caput medusae and ascites are sought, and a stool guaiac test is done for occult blood. Serum transaminase levels are sometimes elevated as a consequence of tissue

necrosis in hepatic cell adenomas. Alkaline phosphatase levels may be elevated because of impingement of tumor on the biliary tree. Most liver function tests, however, are normal in patients with benign tumors. Hepatitis screen – hepatitis B surface antigen (HBsAg) and hepatitis C antibody – is assayed along with α -fetoprotein (AFP) and carcinoembryonic antigen (CEA). The most common imaging test employed is computed tomography (CT) scanning because it is the most commonly available and most uniform in quality. Ultrasonography is performed if cystic lesions are suspected, but for most other lesions, it is not specific enough for a confident diagnosis [39]. Magnetic resonance imaging (MRI) is currently the most accurate noninvasive diagnostic tool used for differentiating various benign lesions including adenomas, fibronodular hyperplasia (FNH), and hemangiomas, and with the recent addition of MR cholangiography, MR techniques have proven to be even more powerful for evaluating liver tumors [40]. Occasionally, angiography is still called on to diagnose a hemangioma, adenoma, or FNH more confidently.

Bile Duct Adenomas

Bile duct adenomas are sometimes referred to as bile duct hamartomas and are presumed to be developmental defects. They are usually small lesions that rarely exceed 1 cm in diameter. Often discovered at the time of laparotomy and confused with metastatic cancers, they are grayish white and firm to palpation. Microscopically, they are composed of fibrous stroma surrounding bile ducts. It is estimated that approximately one third of the population has these lesions [41]. Bile duct hamartomas are universally asymptomatic and require no therapy.

Hepatocellular Adenomas

Hepatocellular adenomas are soft and fleshy with a yellowish-tan color. They are sometimes quite vascular and can grow to an enormous size. These rare tumors have been associated with the use of oral contraceptives. Liver enzyme abnormalities are nonspecific, and tumor markers are usually negative. On CT scan, the adenoma is typically a low-density solid mass. Even with imaging by MR and angiogram, and occasionally even after biopsy, these lesions are still not distinguishable from a well-differentiated hepatocellular cancer.

Management of the asymptomatic patient presents an interesting and slightly controversial conundrum. There are growing concerns about leaving adenomas in situ, with recent reports suggesting that adenomas are premalignant lesions [42]. Adenomas may also rupture, and the resultant hemorrhage is associated with high mortality [42]. In young individuals, we almost always resect adenomas for fear of rupture

and malignant transformation. Oral contraceptives should also be discontinued. In the elderly individual, enthusiasm for resection must be moderated by the medical risks of surgery. Certainly, if the tumor was symptomatic, the decision would be easier. Asymptomatic tumors in a patient with significant associated medical illnesses may warrant observation.

Hemangiomas

Hemangioma is the most common benign tumor of the liver. Cavernous hemangiomas in most autopsy series have a reported incidence of approximately 7% [43]. The age range associated with hemangiomas is usually 55 years or above in most clinical series, although it is probably due to the higher chance for abdominal imaging in patients with advanced age.

Hemangiomas usually present as a solitary lesion but are multiple in about 10% of cases. They usually measure less than 2 cm in diameter but occasionally grow to enormous

size and in some cases even replace an entire lobe of the liver. Most of the lesions remain asymptomatic, and hemangiomas <4 cm in diameter rarely become clinically relevant. Sixty percent of patients with large tumors present with abdominal pain or discomfort, digestive problems, and the sensation of an abdominal mass or distension [44]. Rarely, platelet trapping in the large tumors results in thrombocytopenia, which may manifest as ecchymoses and purpura.

Liver function is almost always normal, and tumor markers are consistently negative. On CT scans, hemangiomas present as low-density areas within the liver parenchyma which upon intravenous injection of contrast show early peripheral opacification followed by variable degrees of enhancement of the central portion. Even though ultrasonography and CT scanning are usually the first imaging tests used in the investigation of hemangiomas, MRI scans have been shown to improve specificity. A combination of T1-weighted, T2-weighted, and gadolinium-enhanced dynamic scans provide the diagnosis of hemangioma with an accuracy of more than 95% (Fig. 76.2) [40]. MRI has

FIGURE 76.2 Gadolinium-enhanced magnetic resonance imaging (MRI) scans of a hemangioma. The peripheral nodular enhancement pattern seen is diagnostic of a hemangioma.

replaced the tagged red blood cell (RBC) scan as the modality of choice for evaluating patients with suspected hemangiomas. MRI can provide information for diagnosis of other liver lesions and provide anatomic details not possible on tagged-RBC scans. Percutaneous needle biopsy should be avoided, as it is associated with severe, sometimes fatal, hemorrhage.

In the elderly, asymptomatic hemangiomas require no treatment. Indications for treatment include pain, discomfort, early satiety, rapid increase in size, thrombocytopenia, or evidence of bleeding intraperitoneally or intraparenchymally [45, 46]. There are a few documented reports of significant reduction in tumor size with the use of external beam radiation, but those results are inconsistent [47, 48]. Hepatic artery embolization has also been attempted but has only occasionally been successful [49]. Symptomatic lesions should be resected. Because hemangiomas are usually surrounded by compressed hepatic parenchyma, lesions are often amenable to enucleation, though deep lesions are usually best treated with a formal resection along anatomic planes.

Malignant Liver Tumors

Hepatic cancers may be subdivided into primary and metastatic cancers. Primary hepatic cancers arise within the liver and include hepatocellular carcinoma (HCC) and cholangiocarcinoma. Metastatic cancers are derived from a variety of primary sites, with metastatic colorectal cancer being predominant and few other types being appropriate for surgical therapy. The challenges of treating elderly patients with HCC or metastatic colorectal cancer are discussed.

Hepatocellular Carcinoma

Hepatocellular carcinoma is the most common solid organ tumor worldwide and comprises approximately 90% of all primary liver cancers in the elderly population. Most of these tumors are associated with chronic liver disease, such as viral hepatitis or alcoholic cirrhosis. HCCs may be unifocal or multifocal. Most patients are relatively asymptomatic until the tumor reaches an advanced stage when it causes symptoms, usually right upper quadrant pain. It is then found as a highly vascular, large tumor that is susceptible to rupture and intraperitoneal hemorrhage. The most common physical finding is hepatomegaly with tenderness. Bile duct obstruction and invasion with tumor embolus may cause jaundice.

FIGURE 76.3 Portal vein invasion and intraportal extension by hepatocellular carcinoma (HCC) as demonstrated by intraoperative ultrasonography (*arrows*). HCC has a great propensity for intraluminal growth and extension along major blood vessels and bile ducts.

At an advanced stage, these tumors cause a host of other symptoms, including abdominal distension, weight loss, fatigue, anorexia, and fever. Occasionally, hepatic decompensation, ascites, Budd–Chiari syndrome, variceal bleeding, severe jaundice, or encephalopathy is the presentation of HCC in a previously well-compensated cirrhotic patient [50]. Not infrequently, the cause of such decompensation is portal vein invasion and thrombo-occlusion by the tumor (Fig. 76.3).

Diagnosis

The triad diagnostic of HCC consists of hepatic mass by imaging, positive serologic markers for hepatitis B or C, and a strongly positive AFP level [50]. At presentation, patients should be evaluated for a history of chronic liver disease or a familial history of liver disease. Questions and the examination should be directed at uncovering signs and symptoms of hepatic insufficiency. Blood tests should include liver function tests, renal functions, hepatitis screen, AFP, and CEA. An AFP > 500 ng/dl is diagnostic of HCC.

The goals of diagnostic imaging are to distinguish primary liver cancer, metastatic cancers, and benign liver tumors, to assess the extent of spread of the tumor, and to define local resectability. The patient is usually evaluated by CT scan before referral. CT scanning is a widely available test that allows examination of hepatic and tumor anatomy, as well as the presence of cirrhosis or fatty infiltration in uninvolved segments of the liver [51]. Of note, a noncontrast CT is essential for evaluating HCC in addition to the contrast-enhanced scans. This is because an HCC often is isodense to the liver parenchyma on contrast-enhanced images and requires noncontrast scans for imaging.

If the portal veins and hepatic veins are well visualized, a CT scan alone may be sufficient for evaluating the liver tumor. Most often, though, an ultrasound examination or MRI should be performed because of the propensity for HCCs to invade and grow along major vasculature, even when they are small tumors. We prefer abdominal ultrasonography for this evaluation because of the lower cost and the accuracy of this test in experienced hands, acknowledging that the results are highly dependent on the skill of the ultrasonographer. In general practice, MRI is of more uniform quality and should be the test performed. MRI with magnetic resonance angiography (MRA) and magnetic resonance cholangiopancreatography (MRCP) [52] allows not only characterization of various tumors, assessment of the tumor extent, and proximity to vascular structures but also proximity to biliary structures. Hepatic angiography is now rarely used because of the quality of current noninvasive imaging studies; it is reserved largely for patients requiring embolization as treatment of the HCC.

Surgical Treatment

Surgical resection is the only potentially curative treatment for patients with HCC. However, because small HCCs are usually asymptomatic, most patients do not present until the disease is far advanced, and only 30% of patients with suspected HCC are candidates for surgical exploration. In the elderly, surgical therapy is further restricted because liver transplantation is not an available option. In the general population, liver transplantation is considered for those patients with small tumors but with liver reserve considered too risky for partial hepatectomy. However, most transplant centers do not give liver transplants to patients aged 65 or more, and therefore, total hepatectomy and liver transplantation are not an option for this age group.

Technical aspects of partial hepatectomy are largely as for patients of a younger age group, and the reader is referred to

textbooks of liver surgery for a general discussion [53]. The differences are modifications to suit not only elderly patients but also cirrhotic patients who usually comprise the population undergoing HCC resection. Bilateral subcostal incisions are usually employed with a xiphoid extension although we advocate a midline incision with a right transverse extension. This high incision and the likelihood of a right pleural effusion after liver resection are the main reasons elderly patients should be evaluated carefully for pulmonary status. Respiratory compromise and pneumonia are frequent complications in patients undergoing liver resection, compounded in the elderly patient by the normal loss of pulmonary reserve with advancing age. At exploration, the entire liver should be mobilized from its ligamentous attachments to evaluate resectability. Exposure is constantly maintained with a retractor fixed to the table, enabling excellent exposure and decreasing the chances of needing to enter the chest. Intraoperative ultrasonography is performed to determine the relation of the tumor to the major vascular structures and to identify additional sites of disease in the liver not appreciated by conventional preoperative imaging [54]. Inflow and outflow vasculature to the section of liver to be removed is usually controlled. We avoid total vascular exclusion (TVE), in general, but are even more adamant about it in the elderly. The hemodynamic changes often associated with TVE are particularly poorly tolerated in elderly patients who may have cardiopulmonary disease. The porta hepatis is controlled to allow application of the Pringle maneuver. A Pringle maneuver is performed to decrease bleeding when dividing the liver parenchyma [55]. We prefer use of the Pringle maneuver intermittently, releasing the Pringle every 5 min to allow reperfusion of the liver.

Operative mortality in cirrhotic patients of any age undergoing liver resection in a major center continues to be in the 10% range [56]. In elderly cirrhotic patients, the mortality rate has been reported to be as high as 19–41% [16, 20] and as low as 5% [15, 21]. Most of the complications following liver resections are usually cardiopulmonary (angina, arrhythmia, myocardial infarction, transient ischemic attacks, pneumothorax, pulmonary embolism) [2]. Patient selection is key to a favorable outcome. Although many sophisticated tests have been proposed for preoperative evaluation of liver function, none has been demonstrated to be better than Child's criteria. We routinely consider Child's A patients for surgical resection. Patients with Child's B liver functional status are considered for resection only if the lesion is peripheral and requires resection of little functional liver. Elderly Child's C patients are offered only supportive care, as transplantation is generally not an option in the elderly, and even ablative therapies are associated with prohibitive risk in patients with such little liver functional reserve [57].

Unfortunately, only 30% of patients explored have resectable lesions. Among patients who undergo resection, long-term survival is achieved in up to 76% (Table 76.1), though most series of HCC resections report long-term survival in one third of patients.

Nonsurgical Treatment

Many ablative therapies have been developed for the treatment of nonresectable HCC. Transarterial embolization or chemoembolization has had the most extensive record. It involves use of a foam, gelatin particles, thrombin-soaked foam, plastic particles, or metallic coils injected into the hepatic artery to selectively occlude blood flow to the tumor (Fig. 76.4) [58]. Others have also attempted to increase antitumor efficacy by soaking the various particles in a

chemotherapeutic drug [59], though such chemoembolizations have not been demonstrated objectively to have improved efficacy over plain particle embolization. Embolization is associated with low morbidity and mortality and with 2- to 3-year survival rates of up to 30% [60]. This compares favorably with resection results; enthusiasm to supplant potentially curative resection in otherwise healthy patients of advanced age should be tempered. Prospective randomized trials to compare these modalities with surgical resection are ongoing.

Ablative therapies have recently increased in popularity among surgeons as treatment for HCC. The most used forms at present for HCC are alcohol injection and radiofrequency ablation (RFA) [61]. Alcohol injection involves chemical killing of tumor by percutaneous or operative injection. This method is very safe but suffers from the fact that multiple treatments are necessary for effective ablation.

Percutaneous ethanol injection ablates tumor by using CT- or ultrasound-guided direct injection of ethanol into the tumor. This technique is limited by the size and number of tumors that can be treated. Few investigators treat tumors >4 cm and more than four in number. For small tumors, however, such ablation can be highly effective [62]. The morbidity associated with such treatment includes pain, fever, and infection of the dead tumor. Mortality rates are low. Approximately 40% of these lesions are not detectable on CT scan at 6–12 months. Although this treatment is effective, there is a significant recurrence rate associated with the technique. Recent efforts have combined this technique with transarterial embolization, a combination that appears to be complementary in action. These ablative techniques should be considered for patients who are medically unfit or anatomically unsuitable for partial hepatectomy. Irradiation and systemic chemotherapy are of limited value for treating HCCs [63].

RFA kills tumors by generation of heat to ablate the malignancy. Reports with thousands of patients have shown this to be a safe and effective therapy. This technique has great potential for managing high-risk elderly patients with concomitant medical problems or cirrhosis (or both) who might not tolerate a resection. Several preliminary reports suggest that RFA may be as effective as liver resection for small tumors, though it has not been formally compared to other therapies. When a patient clearly has an unresectable tumor, we prefer nonsurgical ablative approaches that do not require anesthesia, abdominal incisions, and the associated risks. When patients are explored for resection, we usually have the RFA instrument prepared in case more tumor than is resectable is encountered, since in such cases, the risks of general anesthesia and laparotomy have already been incurred [64].

FIGURE 76.4 Embolization as ablative treatment for hepatocellular carcinoma. A large solitary right lobe HCC in a 91-year-old woman is seen on CT before (a) and 3 months after (b) embolization.

Metastatic Colorectal Cancer

There are an estimated 150,000 new cases of colorectal cancer diagnosed annually [10]. Of these patients, 25% are over the age of 70, and 6% are over 80 years old. It is believed that 40–45% experience recurrence within 5 years. About 75–80% of these patients have the liver as one of the involved sites of recurrence and 15–20% have the liver as the first or only site of recurrence [65]. Advances in liver surgery and an increasing proportion of elderly patients have encouraged hepatic resection in this ever-growing segment of the population. Early studies on hepatic resection in the elderly reported significant mortality rates, with cirrhosis and concomitant medical problems being the most commonly identified associated factors [17]. Later studies in predominantly non-cirrhotic patients, however, reported mortality rates in the elderly population similar to those reported in younger patients [5]. There is little doubt now whether liver resection is a potentially curative option for treating metastatic colorectal cancer of the liver and such resections can be performed safely in the elderly and with good long-term results.

Natural History

Several studies have analyzed in a retrospective fashion patients who were not treated for metastatic colon cancer to the liver [66]. In most of these series, even when patients had liver metastases that were solitary and clearly resectable by radiologic criteria, fewer than 40% of untreated patients were alive at 3 years, and nearly all of the patients were dead at 5 years. Chemotherapy, whether based on 5-fluorouracil [67, 68] or irinotecan (CPT-11) [69, 70], improves survival but is not curative. The demonstration that resection can provide 10-year disease-free survivors for this disease [71] has led to acceptance of surgical resection as the treatment of choice for liver metastases.

Preoperative Evaluation

Preoperative evaluation of the elderly patient with colorectal metastases to the liver should address several concerns. As with any major operation, a comprehensive initial examination is paramount. Particular attention should be directed to the cardiopulmonary status of the patient, as nearly 50% of all postoperative deaths that occur in the elderly are related to cardiovascular or pulmonary disease. There have been several predictive risk indices and functional assessments reported that can identify with fairly accurate certainty

the elderly patients at increased risk for cardiopulmonary complications [72]. As stated above, the elderly patient undergoing liver resection is at particularly high risk for pulmonary complications because of decreased pulmonary reserve with aging, a high abdominal incision and increased discomfort with the respiratory effort, and postoperative pleural effusion. In series that have examined liver resection for metastatic colorectal cancer, the risk of pneumonia is 2–8% [73, 74].

Generally, patients undergoing evaluation for resection of hepatic colorectal metastases do not have associated cirrhosis. In the noncirrhotic patient, there is enormous liver reserve, and resections of up to 80% of liver parenchyma can be performed with confidence of full recovery. In patients with associated liver parenchymal disease such as from alcohol abuse or viral hepatitis, thorough evaluation with a physical examination, liver function tests, coagulation studies, and nutritional assessment for degree of baseline hepatic insufficiency may identify patients intolerant of a liver resection. No test of greater sophistication than these have proved to be clinically useful for distinguishing patients at high risk for liver failure. Tests such as bromosulfophthalein retention, indocyanine green retention, and hepatic wedge pressure [76] have advocates but are not accepted universally.

Selection of patients is also based on clinical details of the colorectal cancer. Risk factors for recurrence after liver resection include regional lymph node involvement by the primary tumor [65, 76, 77], symptomatic liver tumors [65, 66], synchronous presentation of liver metastases with the primary tumor [12, 76, 78], large numbers of tumors [12, 76], the presence of satellite nodules [12, 78], high preoperative CEA level [78], and the extent of liver involvement of more than 50% [77, 79]. Whereas none of these criteria alone is a complete contraindication for resection, increasing numbers of these criteria, particularly in a patient with medical problems, should lead one to be circumspect when recommending resection. The two criteria considered by most liver surgeons to be absolute contraindications to resection are the presence of extrahepatic disease and the presence of the technical inability to clear all of liver tumor. The preoperative evaluation must therefore include adequately imaging areas with the highest likelihood of disease spread and adequate imaging for the distribution of tumors within the liver. The radiologic techniques available are the same used for evaluating primary liver cancer. Before surgery, the extent of disease workup should include chest radiography, abdominal and pelvic CT scans, and colonoscopy. CT portography is also highly recommended as the most sensitive test for imaging metastatic tumors within the liver. MRI or sonography is used occasionally if proximity to the vena cava or hepatic veins is a major concern. Routine

use of angiography has declined with the increasing use of MRI technology.

Surgical Treatment

The technical concerns are as for resection of HCCs, except liver failure is less of a concern in this predominantly non-cirrhotic population, and up to 80% of the liver can be resected with confidence for recovery. Following entry of the abdomen with bilateral subcostal incisions with xiphoid extension, a complete abdominal exploration is performed. If extrahepatic disease is identified, resection is not justified by the data. Intraoperative ultrasonography is performed to identify lesions missed on preoperative scans and to confirm the relations of known lesions to vascular structures. Resection is then performed using standard inflow and outflow vascular control and low central venous pressure as previously described [80]. In a series of 128 consecutive resections in patients aged over 70 with metastatic colorectal cancer, the operative mortality was 4% [5]. This was no different from a cohort of patients less than 70 years of age operated on during the same time period. Of particular note, long-term survival was also no different between the two groups (Fig. 76.5). In fact, among six series of patients analyzing long-term outcome after liver resection for metastatic colorectal cancer [13, 71, 73, 77, 78, 81], only one demonstrated a more adverse outcome for elderly patients [13]. Thus, resection of metastatic colorectal cancer in the elderly is safe and can result in long-term survival.

For metastatic colorectal cancer, large resections can be undertaken with safety and potential eradication of the tumor.

FIGURE 76.5 Survival of patients of age 70 or more undergoing liver resection for metastatic colorectal cancer compared to those less than 70 years of age (from Fong et al. [5] with permission from Lippincott Wilkins & Williams).

Thus, unlike the situation with HCCs, where enthusiasm for resection is tempered by the risks of such resections, ablative techniques do not have established roles in metastatic colorectal cancer. Cryoablation has been performed with safety but has not been shown to have an advantage. We reserve cryoablation for the rare patient with widely scattered disease isolated to the liver that is not resectable or for the patient with an unresectable recurrence. In otherwise fit patients regardless of age, we routinely resect up to ten tumors even if they are bilateral. Medically fit patients who can have complete extirpation of disease are offered potentially curative resections.

Minimally invasive liver therapies have advanced greatly in the last decade with the improvements in the field of laparoscopic surgery. Initially, laparoscopic liver resections were described for small, benign peripheral lesions, but as the field has evolved, experienced teams are performing anatomic resections for cancer [82]. Buell's group at the University of Louisville conducted a retrospective review at their liver center with data supporting that laparoscopic hepatic resection is a viable alternative to open resection with superior results compared to radiofrequency ablation for the treatment of cancer [83]. However, as exposure is limited compared with an open surgical approach, certain groups advocate careful selection of patients based on various factors, such as tumor location [84, 85]. Our record is that we find approximately 5–10% of patients to be candidates for laparoscopic resection.

Conclusions

The aging process generally does not lead to clinically evident compromised liver function under normal conditions, and age alone is not a contraindication for most surgical procedures. For liver resections, clinicians have long feared that the physiologic decrease in liver function with age and a decrease in regenerative capacity would compromise recovery. In clinical practice, these fears have not been substantiated except in the cirrhotic patient. Liver resection remains the only potentially curative therapy for liver tumors of any type. In our advancing technological age, minimally invasive liver therapies are becoming safer and more widespread as an alternative at some centers. In the noncirrhotic patient, associated medical conditions, measured physiologic function, and clinical case history should be the criteria for patient selection for surgery, not simply chronologic age. A much more cautious approach is recommended in the cirrhotic patient, and ablative therapies are often chosen for physically resectable liver tumors.

CASE STUDY

The patient is an 80-year-old male with a past medical history significant for atrial fibrillation on anticoagulation and digoxin, scarlet fever, coronary artery disease, diabetes mellitus, hypertension, arthritis, and DVT who was referred by his primary-care physician for evaluation and management of a right-sided liver mass. The patient had undergone a routine physical exam entailing basic laboratory tests and X-rays, which were suggestive of a liver mass. A CT scan at that time revealed a large 10-cm mass in the right aspect of his liver. A biopsy was performed prior to referral that was read as a well-differentiated hepatocellular carcinoma versus adenoma. His past surgical history included tonsillectomy, appendectomy, hydrocele repair, knee replacement, and laparoscopic cholecystectomy. At the initial consultation, a right hepatic lobectomy was offered to the patient as the lesion occupied the right posterior sector all the way up to the right hepatic vein and the right anterior sectoral vessels were on the tumor. The options of resection, embolization, radiofrequency ablation, chemotherapy, and biologic therapies were all discussed. The risks of liver surgery including liver failure, bleeding, and death were discussed as well. The patient was then referred to cardiology for clearance because of atrial fibrillation and coronary artery disease. At the time, the patient was clinically alive with disease, Karnofsky's score 100.

He was evaluated by cardiology 2 days after initial consultation. A recent ECHO and a prior Persantine stress test were reviewed. He was deemed an intermediate-to-high-risk patient given his advanced age, well-controlled arrhythmia, and insulin-dependent diabetes for the upcoming liver resection, approximated to take 2 h. No further cardiac testing was thought to decrease his risk. No anticoagulation bridging was recommended. The proposed plan was to monitor postoperative telemetry, to start low-molecular-weight heparin with warfarin as soon as possible postoperatively, and to continue digoxin for rate control up until the morning of surgery. Perioperative beta blockade was recommended. He was

received again in the clinic 5 days after cardiac evaluation and clearance for consenting and preadmission testing and anesthesia evaluation. He was deemed ASA III.

The patient was taken to the operating room for a right hepatic lobectomy 1 week after initial consultation with no complications and an estimated blood loss of 300 cc. In the immediate postoperative period, he was also assessed by respiratory therapy for ventilator management as well as hospital chaplaincy services. He was extubated without difficulty in the PACU. Postoperatively, the patient did well. He was followed by the cardiology service. He was advanced to clears on POD#1. FFP was administered for an elevated INR of 1.47. Pain was controlled with a fentanyl PCA pump. He was noted by hospital staff to be confused at times but easily oriented. He was maintained on fall precautions. On POD#2, the patient was evaluated by physical therapy services. That evening, he was confused and pulled out his triple lumen catheter and arterial line. He was placed on 1:1 precautions for his own safety. He was cleared from telemetry by cardiology. Additional FFP was administered for an elevated INR of 1.7. POD#3 was uneventful. PT recommended that he be discharged to a subacute rehabilitation facility or with home PT and concurrent 24-h care. He was advanced to a regular diet on POD#4 with return of bowel function. PCA was discontinued, and he was converted to oral pain medications. Reassessment by PT recommended home PT with home-care services. The Foley catheter was discontinued on POD#6. The patient was evaluated by the hospital dietitian for a low-nutrition risk assessment, and recommendations were made for a discharge diet. On POD#8, he was discharged with VNS for RN and PT services. His daughter was present and was also given discharge medications and instructions.

The patient returned for a postoperative visit in the clinic 4 days following discharge. He was tired but otherwise oriented and doing better. He was sent for routine blood work. He was clinically with no evidence of disease, with a Karnofsky's score of 70.

Final pathology was consistent with hepatocellular carcinoma confined to the liver.

Section X
Urogenital System

Chapter 77 Invited Commentary

George W. Drach

Genitourinary Surgeons Are Mostly Geriatricians

All surgeons in the United States (and indeed other countries) will encounter more elderly patients during future years of practice. Thus, texts like this one serve a very important need by providing references that are valuable in management of such patients. And, for those disciplines that deal with the genitourinary system, the need is greater. Why? Because the average urologist now encounters about 50% of all office patients in the over-65 age (Medicare) category. And, because of the population growth in the older age decades described previously in this text, the urologist will see even more and more elderly patients in his or her office. For example, prostate cancer is now the eighth most common diagnosis amongst Medicare patients, and most of these patients receive their ongoing care from urologists [1]. Added to these activities is the malady of female urinary incontinence which continues to be a major life problem for older women, diagnosed and treated by urologists and gynecologists alike. Independent health surveys of these older women estimate that 9.2–27.6% has some degree of incontinence [2], and most do not mention this to their physicians. Some men also develop incontinence, often related to treatment for that increasing disease condition, prostate cancer. Improvement or cure of incontinence results in significant increases in quality-of-life scores for elderly patients.

Another serious problem for the elderly patient is bladder cancer. As America fought its way through World War II, it gave millions of cigarettes to our soldiers. And, at the same time, millions of women working at factories took “cigarette breaks,” under the dubious assumption that a smoke improved alertness and productivity. This WWII cigarette culture

passed the habit along to its “Baby Boomer” children, who now reach us in their sixtieth to eightieth decades with fully developed smoking-related invasive bladder cancer. It is of interest that cancer survival data does not even show any significant death rate owing to bladder cancer until after 80 years of age. But, if we take this over-80 group only, cure often requires radical cystectomy and fashioning of some type of urinary diversion, perhaps the most serious and challenging operation performed by urologists [3]. Urologic oncologists must, therefore, have a much more precise understanding of the challenges of treating these elderly surgical patients if they are to have successful outcomes.

Carcinoma of the kidney represents another problem encountered more often in the elderly patient, as does ovarian carcinoma [4]. In both instances, surgical intervention is noted to be less likely than if these diseases occur in a younger patient. It is unclear if this decrease in rate of surgery is related to degree of invasiveness of the disease at time of discovery or simply due to unwillingness to operate on the older patient, a prejudice known as agism. Perhaps part of the reluctance to remove a kidney from or operate on geriatric patients rests in the well-known loss of renal function with aging. At age 85, the average patient has lost 40% of overall renal function so that removal of one kidney could cause them to approach the margin of renal failure. One result of this risk of renal failure is the recent trend toward treatment of smaller renal carcinoma lesions by partial resection only [5].

So where does the genitourinary system fit into the overall provision of care system for our older surgical patients? According to 2005 Medicare statistics, the most active surgical specialty is ophthalmology, having provided over 60 million “allowable” Medicare services during that year. Orthopedics followed with 38 million and urology with 32 million. Gynecology had a much lower number at about 17 million [6]. But, as noted, gynecology and urology share the large geriatric population with incontinence, so their combined provision of services could approach a total of 49 million, second only to ophthalmology. Like it or not, we are evaluating and managing many geriatric patients.

Department of Surgery/Urology, Hospital of the University of Pennsylvania, 3400 Spruce Street, Philadelphia, PA 19104, USA
e-mail: George.Drach@uphs.upenn.edu

The point is this: those of us involved in the care of the elderly genitourinary patient will be exposed to the multiple problems that they bring with them, and we must learn the basic geriatric principles necessary to lead to excellent outcomes when we treat them, either medically or surgically, within the milieu of these problems.

Chapter 78

Change in Renal Function, Fluids, and Electrolytes

Juan F. Macías-Núñez and Manuel Martínez-Maldonado

Renal Structure and Function

Renal aging is not a pathological process since the aging kidney is able to maintain the homeostasis of the internal medium in conditions of health despite the fact that its resources and ability to adapt to challenges of restriction or overload are limited. It should be understood by the reader that we have based the findings in this chapter mostly on the relatively few studies carried out in healthy aged persons in whom biochemical and clinical findings, including holistic geriatric evaluation, have been done before inclusion in the study protocol. The majority of published studies have been, unfortunately, performed in “apparently healthy” aged individuals in home care institutions, aged persons attending outpatient clinics, or hospitalized individuals whose baseline status was not well evaluated.

In this chapter, we describe the structural and functional changes that occur in the kidney with aging. We also review the senescent kidney’s mechanisms for handling fluid, electrolyte, and acid–base derangements, especially during the perioperative period. Clearly, successful management of the elderly patient requires a knowledgeable appreciation of the changes occurring in the senescent kidney that result in: (1) increased tendency for volume depletion and dehydration; (2) decreased ability to tolerate a volume load; (3) increased propensity for potassium disturbances (hypo- and hyperkalemia); (4) diminished production of renin and blunted physiologic response to the effects of aldosterone, and antidiuretic hormone (ADH); (5) increased tendency to lower the levels of phosphate; (6) tendency for the development of hypocalcemia and hypomagnesemia. A brief assessment of the role of extracellular fluid volume (ECFV) depletion and other factors contributing to acute renal failure in the elderly is also presented.

Histopathology of the Aging Kidney

Autopsy material, biopsy material from kidney donation, and nephrectomy for tumor and trauma from elderly subjects have revealed the presence of glomerular sclerosis [1], a condition that leads to a loss of filtration capacity.

The cause of sclerosis of the aged glomerulus is confusing. It is sometimes difficult to distinguish whether the changes are due from the aging process itself or from common diseases of the elderly, such as hypertension, diabetes, and atherosclerosis. It appears that even in the absence of these diseases such changes occur. Probably the cause of the changes is intraglomerular hypertension resulting from afferent arteriole vasoconstriction in an attempt to raise the glomerular filtration rate (GFR) [2].

Elderly individuals who have hypertension or diabetes may have more deterioration of renal function than elderly people who do not have these underlying medical problems. Glomerular senescence may begin during the fourth decade of life and progresses linearly with age, reducing the GFR by ~1 ml/min for every year over 40 years of age [3]. This predictable reduction of the GFR is one of the main factors responsible for morbidity in the elderly surgical patient.

In addition to glomerular changes, tubular senescence occurs with advancing age [4]. Tubular length decreases, interstitial fibrosis between tubules occurs, and the properties and anatomy of the tubular basement membrane change. Atherosclerosis of nutrient peritubular capillaries contributes in part to these changes. The consequence of tubular senescence is reduced tubular reabsorption and secretion.

Renal Plasma Flow

Healthy Young Individuals

The kidneys only represents 0.5% of the body mass, yet they receive about 20% of the cardiac output, approximately 1,200 ml/min on average at a rate of 4 ml/min/g which is

considerably greater than that received by other organs such as the brain, heart, or liver. Renal plasma flow (RPF) is the amount of blood going to the kidneys minus the hematocrit (Hct). Therefore, assuming an Hct of 45%, humans have a RPF of approximately 660 ml/min, which leads to a GFR of 125 ml/min and a filtration fraction (the ratio of GFR to RPF) of 0.19. This means that 19% of the plasma entering the kidney every minute is filtered. RPF in young people (below 30 years old) averages 592 ± 153 ml/min/1.73 m² in woman and 654 ± 153 ml/min/1.73 m² in man [5]. After the age of 30, RBF progressively decreases [6].

Aged Healthy Individuals

Diodrast clearance (a measure of RBF) decreases from a mean of 613–290 ml/min in the ninth decade of life [7], a fall of over 50% [8]. An exhaustive analysis of the available literature has revealed that the rate of reduction in RPF is approximately 10% per decade of life. Prospective PAH clearance (another measure of RBF) studies confirmed the drop (361 ml/min/1.73 m² in the aged vs. 618 in the young) [9]. Filtration fraction increases with age [7], indicating that more filtrate in milliliter per minute is formed (suggesting that, indeed, the increase in glomerular pressure that would result is the cause of sclerosis). Radioactive xenon wash-out curves reveal that the largest drop in renal blood flow occurs in the cortex, while medullary blood flow is relatively well preserved [10].

Glomerular Filtration Rate

Inulin clearance (the gold standard for GFR measurement) increases from approximately 20 ml/min at birth to 120 ml/min by age 30. Thereafter it begins a slow descent reaching a mean of 65 ml/min at 90 years of age [7]; however, the lower limit of inulin clearance (mean \pm 2SD) for a population of apparently healthy 80 years old individuals is 40 ml/min/1.73 m². Moreover, the difference between the sexes seen in the young disappears for those 75 years or older [11]. Inulin clearance is inconvenient for routine clinical use because its measurement in blood and urine is cumbersome, requires 3–4 h to perform, and is available in very few institutions. As a result, endogenous creatinine clearance has become the most widespread technique for GFR estimation in clinical practice.

Renal Handling of Creatinine

Creatinine is derived from the metabolism of creatine in skeletal muscle and from dietary meat intake. It is freely filtered across the glomerulus, reabsorbed, and secreted by the renal tubule. Studies of the tubular secretion of creatinine

in humans are controversial, some indicating that secretion is negligible, yet others suggesting that 15–30% of the creatinine present in the urine derives from tubular secretion. Studies of dehydration have shown that humans can reduce creatinine clearance by approximately 30% and rehydration can raise it back to normal and by as much as 20% above the baseline normal values [11]. This dramatic increase upon rehydration may represent increase in tubular secretion and decrease in tubular reabsorption of creatinine. Thus, low extracellular volume resulting from any maneuver in conjunction with (vide infra) reduced renal capacity to regulate sodium reabsorption and the low-thirst sensation of the elderly will almost certainly imperil renal function.

In studies comparing creatinine and inulin clearances, the ratio of creatinine clearance to inulin clearance reached 1.4 suggesting that 28% of the total creatinine collected in the urine is secreted by the tubules [12]. We have evaluated the difference in GFR between young (<65 years) and old (>65 years) healthy persons of either sex [13] by the clearance of creatinine or Cr⁵¹-EDTA and found them to be lower in the aged than in the young. In addition, the ratio of creatinine clearance to Cr⁵¹-EDTA is higher in nine out of ten tested healthy young individuals, whereas this is the case in only one subject, and lower than one in five, out of 13 healthy aged individuals, indicating that tubular handling of creatinine differs among healthy young and aged individuals and its clearance is not always a reliable measure of GFR [13, 14].

GFR in Healthy Aged Persons

GFR ranges between 95 ± 20 ml/min in healthy adult female and 120 ± 25 ml/min in young healthy males, but it declines with age (around 40 years of age), regardless of the marker used to assess it. However, the decline in GFR is neither universal nor inevitable since longitudinal studies have revealed some individuals whose GFR remains constant with age, even though the mean GFR of the aging population falls. Importantly, nutritional status of the subjects at the time of measuring GFR influenced the results, particularly when using creatinine clearances. Elderly subjects eating more than 1 g/day of protein per kilogram had a creatinine clearance in the range of 90–100 ml/min/1.73 m² while those with a lower protein intake had a lower creatinine clearance [15, 16]. In cross-sectional data [7], inulin clearance in aging subjects fell from a mean of 122 ml/min to a mean of 65 ml/min between ages 30 and 90.

The Cockcroft–Gault and Other Formulae

The urinary elimination of creatinine diminishes with age [13]. Therefore, attempts have been made to estimate GFR without the need for urine collection. Cockcroft and Gault in

deriving their formula to measure GFR used hospital patients that included individuals from 18 to 92 years old regardless of the level of renal function [15]. Others have conducted cross-sectional, except for some data in the study of Rowe et al. [17], rather than longitudinal studies. In an important extended longitudinal study, some patients were followed with repeat measurements for more than 30 years [18]. Despite a mean calculated reduction in creatinine clearance of 0.75 ml/min/year for the whole group, 92 of the 254 subjects showed no reduction in creatinine clearance; a few evidenced increased clearances. Larsson et al. [19] also found no decline in GFR in individuals between the ages of 70 and 79, although plasma creatinine increased from 0.91 to 96 mg/dl in women and from 1.00 to 1.07 mg/dl in men. Despite this evidence of falling GFR as a function of age, there are no dramatic or clear cut increases in plasma creatinine with age. Thus, the normal value of plasma creatinine is statistically the same at the ages of 30 and 90 years.

Because of the uncertainties in the assessment of GFR using creatinine clearance, formulas and nomograms have been developed that theoretically allow a better estimation of GFR in clinical practice. Using plasma creatinine concentration, age, gender, body weight, and height, Cockcroft and Gault's [14, 16] formula is the most used, although it may overestimate the decline in GFR, at least in persons older than 80 years. However, a good correlation in 18 individuals aged 66–82 years between GFR calculated by the Cockcroft–Gault formula $[(\text{GFR}) = ((140 - \text{Age}) \times \text{Weight (kg)}) / 72]$ and the clearance of [$^{99}\text{Tc}^m$] diethylenetriamine penta-acetic acid (DTPA) has been found [19]. The simplest formula to estimate the expected mean creatinine clearance in milliliter per minute from 25 to 100 years of age in persons with normal blood creatinine (≤ 1.3 mg/dl) is: $[130 - \text{Age (in years)}]$ [20].

Other formulas have been developed to predict GFR based on blood creatinine level including those of the modified diet in renal disease (MDRD) group [21, 22], but have not been formally validated for persons aged over 70 years, diabetic nephropathy or pregnancy, and the very ill and healthy individuals. Formula-calculated GFR may provide a reasonable estimate of renal function compared with clearance of markers such as creatinine and Cr⁵¹-EDTA, the variation may be considerable [22] (Table 78.1).

Clinical Implications

Despite the controversy surrounding GFR measurement or calculation, it is clear that “normal” values of serum creatinine do not represent a normal GFR in the vast majority of healthy aged persons. An effort must be made to adjust drugs regime to estimate GFR in the case of all drugs primarily handled by the kidney (vide infra). On the other hand, low GFR in the aged does not automatically means renal disease since it is influenced by many factors.

Two such factors, reversible and common, are depletion of ECFV and poor nutrition (particularly poor protein intake). Aged persons with low GFR (compared with younger adults) in the absence of clear signs of renal insufficiency should be tested for these two reversible findings. Measurement of urine sodium will show low concentrations despite patient-provided history or self-assessment of “normal intake” unless the patient is on diuretic therapy. In that case, other clinical tests, such as postural hypotension and rapid feeble pulse, may be present. Low serum albumin, and a very low (<10 mg/dl) blood urea nitrogen, and a BUN to creatinine ratio of <10 will be clues to the presence of malnutrition. These findings have an important role in the presurgical evaluation of the elderly patient and must be taken into consideration for fluid replacement during and after surgery. Isotonic (0.9%) saline is the fluid of choice for all patients, since it provides the most physiological and metabolically sound approach to the problem of ECFV depletion. Even if the immediate cause of ECFV depletion is corrected in the elderly, it is still wise to adjust drugs regime to the calculated GFR until a new post surgical steady state has been achieved.

Drug Dose Modification in the Elderly

Drugs that are eliminated from the body by renal excretion require dose modifications in the aged. Because the serum creatinine does not accurately reflect reduced renal functioning in the elderly, the doses of toxic drugs, such as the aminoglycosides, require adjustments based on creatinine clearance and calculated by the 24-h urine collection or by the estimate of creatinine clearance using the urine-free

TABLE 78.1 GFR in young and old healthy people measured by CrCl and Cr⁵¹-EDTA, and estimated by the MDRD formula

	Age [mean \pm SD (years)]	Blood creatinine [mean \pm SD (mg/dl)]	Urine creatinine [mean \pm SD (mg/dl)]	GFR CrCl [mean \pm SD (mg/dl)]	GFR Cr ⁵¹ -EDTA [mean \pm SD (mg/dl)]	GFR MDRD equation [mean \pm SD (mg/dl)]
Young (N=10)	35.8 \pm 11.8	0.81 \pm 0.08	122 \pm 83	127 \pm 25	101.6 \pm 13.4	114 \pm 15.6
Old (N=13)	74.4 \pm 3.7	0.86 \pm 0.1	84.4 \pm 25.4	91.7 \pm 29	81.3 \pm 11.3	83 \pm 12.8

Source: Modified from [46]

formula described above. The dose interval (DI) can be calculated from the following:

$$DI = \left(\frac{100}{\text{Estimated creatinine clearance}} \right) \times \text{Usual interval.}$$

In a 68-year-old woman with a calculated creatinine clearance of 17 ml/min and requiring a course of gentamicin, a loading dose would be given at the usual 2 mg/kg. Then 1 mg/kg would be given every $(100/17) \times 8$ h. Thus, the interval would be every 47 h, a regimen that would lessen the likelihood of an elevated trough level, which has been associated with aminoglycoside toxicity in several studies [23, 24].

Tubular Functions

Proximal Tubule

Over 60–80% of the filtered sodium and water, bicarbonate and other electrolytes, glucose, uric acid, phosphate, amino acids, and small molecular weight proteins are reabsorbed in this segment.

Healthy Aged

No differences have been detected in proximal tubule function when young (<60) are compared with elderly healthy aged individuals (older than 60) in clearance studies performed in healthy persons [25]. Moreover, the handling of lithium, a well-known marker of proximal tubule sodium reabsorption and general function [26] does not differ between young and old. Nevertheless, although the renal reabsorption threshold for most compounds handled by the proximal tubule is not different between young and old, the maximal tubular reabsorption capacity (T_m) is diminished in aged persons, a finding that may be important in the postsurgical period in patients receiving glucose solutions.

Glucose

A lower T_m for glucose will lead to persistent glucosuria and osmotic diuresis resulting in ECFV depletion. Since, as already mentioned, a normal glucose threshold of reabsorption exists in elderly people normal levels by much, at which time the reduced T_{m_{glucose}} will become apparent and large amounts of glucose may appear in the urine. T_m has been demonstrated to fall in parallel with the reduction in GFR [27]. The apparent T_{m_{glucose}} averaged 359 mg/min/1.73 m² in the third decade, and only 219 mg/min/1.73 m² in the ninth.

It is therefore critical to follow closely for the presence of glucosuria and the levels of plasma electrolytes to assess the state of homeostasis in the postsurgical elderly patient receiving glucose solutions [28].

Thick Ascending Limb of Henle's Loop

This water and urea impermeable segment sustains the transport of Na⁺ from the lumen to the interstitium; thus, resulting in dilute urine emerging into the early portion of the distal nephron. Since it is also responsible for increasing the tonicity of the interstitium, in the presence of ADH, it is also responsible for the reabsorption of water from the urine as it traverses the collecting duct and determines the excretion of concentrated urine (low volume and high osmolality) as fluid ascends in the thick ascending limb, electrolytes pass to the interstitium, but water remains in the lumen. In essence, the ascending limb and the early part of the distal convoluted tubule (DCT) is the site in the nephron where solutes are reabsorbed without water in a process leading to “free water formation,” and thus have been named the diluting segment [26].

Healthy Aged

The diluting segment loses some of its capacity to reabsorb Na⁺ leading to a higher delivery of Na⁺ to the most distal segments of the nephron, which has been shown to be statistically higher in the healthy elderly than in the healthy young [26]. This reduction in Na⁺ reabsorb in the thick ascending limb of Henle's loop found in all tested subjects in situations of normal salt diet or salt restriction and at any age [29] does not seem to be the result of obvious structural changes, but results from the normal aging process and, particularly, the fall in GFR [29, 30].

Clinical Implications (see Table 78.2)

Loss of sodium reabsorptive capacity in the thick portion of Henle's loop leads to Na⁺ and water spillage make the aged very sensitive to easily becoming dehydrated and desalinated. It is common to find elderly patients in everyday practice who exhibit copious natriuresis and diuresis leading to Na⁺ depletion and/or hyponatremia. Particularly vulnerable to these Na⁺ abnormalities are aged subjects on low salt diet plus diuretics. Failure of awareness of this effect of aging on renal function and failure of timely replenishment of Na⁺ and water deficits may lead to instauration of acute renal failure [31, 32]. It is clinically incorrect to routinely restrict salt intake in the aged unless they suffer from illnesses managed in part by

TABLE 78.2 Key parameters of renal function in healthy adults, old, and very old individuals

	Adult (18–64 years) (mean ± SD) N=22	Old (>65 years) (mean ± SD) N=30	Very old (>80 years) (mean ± SD) N=22
Hemoglobin (g/l)	14.7 ± 1	14.1 ± 0.8	14.3 ± 1
Erythropoietin (U/l)	14 ± 2.7	13 ± 4.8	17 ± 9.4
Creatinine clearance (ml/min)	111 ± 14.4	71 ± 19.8	47 ± 13
Fractional excretion of sodium (%)	0.5 ± 0.1	1.3 ± 0.6	1.4 ± 1
Fractional excretion of urea (%)	30 ± 2	59 ± 3	61 ± 6

Erythropoietin is an indirect measure of functional renal mass. It did not differ statistically in any of the groups

Source: Modified from [46]

salt restriction such as liver, heart, and renal diseases in which edematous syndromes (other than malnutrition) and/or hypertension are manifest. Even under those circumstances, it is advisable to periodically monitor plasma electrolytes, particularly if diuretics are a mainstay of the therapeutic regime. Both hypo- and hypernatremia are dangerous situations in the elderly and should be avoided at all costs.

Despite the reduction in sodium reabsorptive capacity by the loop of Henle with aging, the aged take much longer to eliminate sodium overloads than the young, most likely due to the diminution of GFR. Because of these differences in sodium handling by the elderly kidney, it is important to be cautious in describing hypertension in the aged as “salt dependent” or “salt sensitive.” The elderly hypertensive patient may retain a larger portion of an amount of salt, compared with younger individuals, not because their hypertension is salt dependent but because of the low GFR that, despite the reabsorptive defect in more distal segments of the nephron, leads to salt retention.

Collecting Duct

The amount of Na⁺ reabsorbed in the collecting duct is approximately 3% of the sodium filtered (plasma sodium concentration multiplied by the GFR). Yet, despite the apparently low sodium capacity of the collecting duct, its normal function is of paramount importance for overall sodium balance to be kept and for ECFV to remain within normal limits [32, 33]. Under the influence of aldosterone, the collecting duct is also responsible for the final control of urinary Na⁺ excretion. The synthesis of aldosterone by the adrenal cortex is controlled by angiotensin II, plasma concentration of Na⁺

TABLE 78.3 Blood and urine aldosterone levels in healthy young and aged persons under normal diet conditions and after salt restriction

	Young (N=10)	Elderly (N=12)	p Value
Normal diet			
Blood	19.6 (9.6) ng/dl	5.56 (4.2) ng/dl	<0.05
Urine	10.95 (8.8) μg/24 h	4.2 (2.8) μg/24 h	<0.05
Salt restriction			
Blood	30.58 (4.8) ng/dl	8.6 (3.9) ng/dl	<0.05
Urine	29.3 (19.6) μg/24 h	9.6 (3.8) μg/24 h	<0.05

and K⁺, and ACTH. The level of plasma Na⁺ is the least potent stimulus on aldosterone synthesis. In contrast, aldosterone-secreting cells in the adrenal cortex are very sensitive to the concentration of K⁺ in the extracellular fluid. The increase in potassium intake increases extracellular potassium, which directly stimulates the production of aldosterone in the adrenal cortex. The increase in plasma aldosterone concentration stimulates sodium reabsorption and K⁺ secretion in the cortical collecting duct (CCD). This affects final control of sodium reabsorption and excretion and helps eliminate potassium excesses and prevent hyperkalemia.

The collecting duct is unable to reabsorb greater quantities of Na⁺ delivered to it from previous tubular segments, such as the ascending limb of the loop of Henle. Thus, decreases in sodium reabsorption in prior segments will lead to natriuresis and could enhance potassium secretion into the tubular urine and cause hypokalemia and volume depletion.

Aldosterone in the Healthy Aged (see Table 78.3)

It has been proven that aged persons in unrestricted diets of salt and water have lower aldosterone plasma levels (a result of lower renin production by the juxtaglomerular apparatus, therefore less production of angiotensin II) and respond slower (continue to excrete sodium) to salt restriction than healthy young persons [31, 34, 35]. Therefore, the elderly may be susceptible to having a higher plasma potassium level because of inability to secrete the hormone, partial insensitivity to it, and lower the rates of sodium–potassium exchange.

Clinical Implications

The most common and life threatening clinical consequences is the development of hyperkalemia in circumstances where the aged are treated with aldosterone blocking agents such as spironolactone, or angiotensin-converting enzyme inhibitors

(ACE inhibitors) and angiotensin receptor blocking (A II RB) agents, which diminish aldosterone secretion by blocking either A II production (ACE inhibitors) or its actions (A II RB). Elderly patients with cardiac failure or other comorbidities treated with antialdosterone agents should be periodically investigated for blood potassium and at least every 3 months if they are simultaneously treated with drugs interfering with the renin–angiotensin system such as ACE inhibitors or Angiotensin II receptors blockers [33, 35].

Metabolic Acid–Base Disturbances in the Elderly Surgical Patient

Alkalosis

The reduced GFR in the geriatric patient reduces the body's ability to excrete an alkaline load [34, 36]. Renal tubular damage during the perioperative period resulting, for example, from hypotension or drug injury may further damage the kidney's ability to excrete bicarbonate. The commonest causes of metabolic alkalosis during the perioperative period are prolonged nasogastric suctioning or vomiting. In patients with prolonged vomiting (e.g., secondary to gastric outlet obstruction), the resultant acid–base disturbance is a hypokalemic hypochloremic metabolic alkalosis. The kidney compensates for the chloride loss by reabsorbing excess amounts of that anion and excreting bicarbonate in the urine. Initially, sodium is the cation that accompanies bicarbonate in the urine, but as fluid loss increases, the body excretes potassium and hydrogen in preference to sodium in order to preserve intravascular volume. This results in paradoxically acidic urine in the presence of a metabolic alkalosis and compounds the disturbance.

The elderly patient is less well able to tolerate metabolic alkalosis and may, in this setting, experience the development of rapid, dangerous hypokalemia, as the body preferentially conserves sodium (under the influence of aldosterone) and hydrogen (which is titrated by the excess bicarbonate to carbon dioxide and excreted by the lungs) [36]. The resultant hypokalemic alkalosis is a risk for cardiac dysrhythmias in the elderly surgical patient, especially in those with coronary artery disease, those taking digitalis, or those who may be taking long-term potassium-losing diuretics.

Lactated Ringer's solution is commonly administered as the maintenance intravenous fluid intraoperatively. This lactate is metabolized to bicarbonate. Because of the impaired renal excretion of alkali in the elderly, the serum bicarbonate may accumulate to an unacceptable level. In this case, it is preferable that a balanced salt solution such as normal saline be used. Potassium chloride can be added to this solution as

needed and the plasma level followed by intraoperative monitoring of potassium levels.

Acidosis

The elderly are prone to metabolic acidosis. Western potash diet leads to the daily production of 1 mEq of hydrogen ion per kilogram of body weight. Buffering of this acid load is accomplished by bicarbonate. This produces CO_2 , which is then excreted by the lungs [36, 37]. To correct for this loss of bicarbonate, the distal tubule secretes H^+ formed from the conversion of CO_2 to H_2CO_3 (catalyzed by carbonic anhydrase) and, under the influence of aldosterone, the newly regenerated bicarbonate is delivered with sodium back to the circulation. This makes hydrogen ion available to be pumped into the urine, where it lowers the urinary pH. To enhance hydrogen ion excretion, ammonia, filtered phosphate, and filtered sulfate accept hydrogen ions in the urine and the urine becomes maximally acidified. Ammonia is produced in the renal tubular cell from glutamine, and phosphate and sulfate are generated during metabolism of the potash diet. This releases sulfate and phosphate as sulfuric and phosphoric acids, which promptly release their hydrogen ion, leaving the phosphate and sulfate to be filtered and become part of the composition of urine. In the elderly, these tubular processes are less efficient and have less capacity. Moreover, the lower aldosterone levels lead to decreased ability to excrete an acid load and to regenerate bicarbonate. The ability of the kidney to compensate for metabolic acidosis is thus diminished [36].

Metabolic acidosis in the surgical setting is caused by the accumulation of fixed acids (e.g., lactic acid) or from the loss of bicarbonate (e.g., through diarrhea, pancreatic or small bowel fistulas, or renal tubular damage). Any significant period of circulatory failure results in the accumulation of lactic acid, reflecting anaerobic metabolism. In the geriatric patient, the impaired GFR leads to less direct filtration of lactic acids. In addition, the reduced tubular function and lower aldosterone levels lead to less regeneration of bicarbonate. Thus, the elderly patient is more at risk to develop perioperative disturbances of acid–base balance and, compared with the younger patient, has decreased mechanisms of compensation.

Water Balance

Water balance is controlled by the regulation of thirst, neurohypophyseal function (ADH secretion), and the renal capacity for water excretion [38]. Both perception of thirst and spontaneous intake of liquids diminish with age [39]. When healthy active elderly volunteers were water restricted for

24 h, the threshold for thirst was increased and water intake was reduced in comparison to a control group of younger individuals. Despite the reduction in water intake and thirst, a considerable increase in blood osmolality, plasma sodium concentration, and in circulating vasopressin (ADH) occurred during water deprivation [39]. In fact, osmotic release of ADH in response to intravenous hypertonic saline in elderly people is greater than in the young, but the vasopressin response to volume depletion is blunted [40]. The lack of normal thirst sensation in elderly people despite an increase in plasma tonicity remains unexplained. Dryness of the mouth and a decrease of taste with age may contribute to the diminution of thirst [41]. It has also been suggested that a reduction in the sensitivity of the osmoreceptors responsible for thirst regulation may play a part in water-handling alterations in elderly persons. A contrary view has arisen from studies in which an increase in the sensitivity of the osmoreceptors that regulate the release of vasopressin release was observed. Thirst diminution may also result from an inappropriate response to hypovolemia. Age diminishes the sensitivity of baroreceptors and their capacity to influence the release of vasopressin [41, 42]. Finally, plasma concentration of angiotensin II, a powerful generator of thirst, is diminished in elderly people. Therefore, severe hypovolemia and/or hypotension may be required to trigger stimulation of thirst and overcome water deficits [41]. Since there is no difference in the plasma concentration of vasopressin between young and elderly persons before or after water deprivation, this finding cannot be the explanation of poor water conservation in the elderly [37].

The Healthy Aged

Body Water

Total body water is slightly diminished with age and comprises only 54% of total body weight, probably because old people have a greater proportion of their body weight as fat than the young. The diminution seems to be predominantly of intracellular water [43].

Plasma Volume

Cross-sectional and longitudinal studies have revealed that plasma and blood volume do not change solely as a result of age alone in healthy adults [44]. Some investigators [45] have found that elderly women have a significantly greater plasma volume than young women and, as a consequence, variations in plasma potassium. We have found that plasma and blood volume measurements using radiolabeled albumin do not

differ between young and elderly healthy volunteers and that males have a greater volume than females, regardless of age [46]. Thus, a diminished plasma volume in an elderly individual is almost always the result of disease [46].

Clinical Implications

When oral fluid intake is prescribed to aged patient for volume replacement, prevention of dehydration, or with other purposes, it should be realized that the aged lose taste recognition and dislike drinking water; they will never drink the amount prescribed. In fact the clinical experience indicates that one of the most difficult tasks for the geriatric nurse is convincing aged patients to drink water.

Immobility (see Table 78.4)

In 40 elderly nursing-home patients (>64 years old), the 20 that were immobilized had a significantly higher total body water (BW) than aged controls who could move [47, 48].

Clinical Implications

Control of BW influences the distribution volume and the pharmacokinetics of water-soluble drugs. It is essential that this state of BW balance, as inferred from plasma sodium concentration and urine sodium excretion, be known in order to properly design therapeutic regimes of drugs whose solubility in water will determine their action and bioavailability.

Mental impairment, particularly deterioration of verbal learning, in the aged can occur as a result of alterations of BW balance. Yet a recent study found that water metabolism in a group of demented elderly patients was not significantly different from controls [48]. Moreover, acute confusion

TABLE 78.4 Water metabolism in mobile and immobile elderly patients

<i>N</i> =40	Mobile [Mean (SD)]	Immobile [Mean (SD)]	<i>p</i> Value
Plasma sodium (mEq/l)	143 (1.28)	140 (5.16)	0.014
Plasma osmolality (mOs/l)	281 (5.22)	270 (10.00)	0.025
Antidiuretic hormone (pg/dl)	4.2 (3.56)	3.4 (2.60)	NS
Body water (%)	50 (9.8)	61 (7.7)	0.0003

Source: Modified from [48]

syndromes may result from water or electrolyte imbalances that are dissipated by correction of their presence, upon which the confused patients recover the previous mental status. Clearly, measurement of plasma electrolytes and urea is mandatory in confused elderly individuals before other diagnoses are entertained.

Urea

Healthy Aging Kidney

The old healthy aged exhibit a higher fractional excretion of urea than young controls, a phenomenon not clearly understood, but that may result from (less reabsorption) diminished function of urea transporters. Moreover, the elderly eat less protein which contributes to the lower blood and kidney urea.

Clinical Implications

It is possible that the impairment in urinary concentration and dilution observed in the healthy aged may be partly the result of the increased urea excretion rather than its accumulation in the renal interstitium. Low interstitial urea would reduce the favorable osmolar gradient for water reabsorption from lumen to blood. Consequently, the steep interstitial osmolar gradient necessary for urinary concentration cannot be maintained.

Urinary Concentration and Dilution

Healthy Young

The generation and maintenance of the hyperosmolar interstitium is equally necessary for both the concentration and the dilution of urine. The former will occur in the presence of hypertonic interstitium, ADH, and maximal increase in permeability of the collecting duct, while the latter will occur with a hypertonic interstitium in the absence of ADH and ADH-mediated collecting duct water permeability. In both processes, normal function of the thick ascending limb of the loop of Henle is mandatory in order to establish the interstitial to lumen gradient. Transport of electrolytes from the lumen to the interstitium makes it hypertonic. The special loop configuration of the vasa recta, that confer counter current flow of tubule fluid is able to sustain the hyperosmolar profile of the interstitium.

Healthy Aging Kidney

Concentration

Aged persons have a reduced renal capacity to maximally concentrate the urine [49] and lose 5% of this capacity with every 10 years of age [50]. From a maximum urinary specific gravity of 1.030 at 40 years of age, they fall to 1.023 at 89 years of age. Rowe et al. [40] found a mean maximum osmolality of 1,109 mOsm/kg in individuals aged 20–39 years, with a minimum urine flow rate of 0.49 ± 0.03 ml/min; 1,051 mOsm/kg in 40- to 59-year-olds; and only 882 mOsm/kg in those aged 60–79 years. In this group, the minimum urinary flow rate of 1.03 ml/min was more than double that of the young. Other groups have recorded that even healthy individuals aged 60–80 years showed a greater excretion of water, sodium, and potassium during the night than younger individuals [51]. The origin of the decreased concentration ability is multifactorial. It has been related to the decrement in GFR that occurs with age in most studies, although some data do not reveal a close relation between the reduction in the GFR and the capacity to concentrate urine in elderly persons [16]. The relative increase in medullary blood flow is unlikely to contribute to the impairment of renal concentration capacity [10, 51, 52]. As already discussed, inappropriately low ADH does not seem to be a factor in the genesis of the defect since the elderly secrete as much hormone as the young. The defect in sodium chloride reabsorption in the ascending limb of the loop of Henle, which is the basic mechanism for the operation of the countercurrent concentration mechanism, may be the most important factor for the decrease in the capacity to concentrate urine seen in aged individuals.

Clinical Implications

Impaired urine concentration may play some role in the frequency of nocturia in the elderly, although this alteration in circadian rhythm does not depend upon inability to concentrate the urine alone, but also reflects the defects in sodium handling and the decreased aldosterone secretion and sensitivity already discussed.

Dilution

Few data in a few numbers of papers are available to explain the change in the capacity of the aging kidney to dilute urine. Nevertheless, it has been found to be decreased [50, 52]. The minimum urine concentration of only 92 mOsm/kg in elderly individuals is almost half of that (52 mOsm/kg) achieved in

TABLE 78.5 Renal handling of potassium

	Young Mean (SD)	Elderly Mean (SD)	<i>p</i> Value
Plasma potassium	3.6 (0.24)	3.6 (0.16)	NS
Urinary potassium output/24 h	43.2 (9.1)	30.5 (9.7)	<0.05
Fractional excretion of potassium (%)	8.6 (3.1)	9.3 (3.4)	NS

Data is mean (SD)

Source: Modified from [70]

the young. Maximum free water clearance (CH_2O) was also reduced in elderly individuals from 16.2 to 5.9 ml/min. This is, probably, mostly dependent on the reduced GFR, but when CH_2O was factored by GFR to normalize it as a percent of filtration rate, it was still somewhat reduced in the older participants (9.1 vs. 10.2%). Again, the functional impairment of the diluting segment (diminished sodium reabsorption) of the thick ascending limb described above seems to account for the remainder of the diminution in the capacity to dilute urine observed in aged persons.

Potassium (see Table 78.5)

Measurements of total exchangeable body potassium by various isotopic dilution methods all agree that total body potassium is 15% lower in elderly than young people [53, 54]. The reasons for these differences are not altogether clear, but one major factor is that muscle mass, a major site for potassium storage, is diminished in the aged. Despite the spontaneous ingestion of lower amounts of potassium by the elderly (<60 mmol/24 h) because of a low diet in meat, fruit, and vegetables, plasma potassium concentrations in aged persons do not differ from those of the younger population [55]. The basal urinary excretion of potassium is also lower than in the young [53–55]. These results have been postulated to result from physiological changes, such as low aldosterone and tendency to retain K associated with age that predisposes the elderly to hyperkalemia (see Table 78.7 below). However, when diuretics are taken, the elderly develop hypokalemia much more rapidly and frequently than the young.

Renal Handling of Divalent Cations, Phosphate, and Uric Acid (see Table 78.6)

Magnesium

The normal range of serum Mg^{2+} is 1.7–2.3 mg/dl, and no difference between the healthy young and the elderly have been discovered. Magnesium is the main intracellular divalent

TABLE 78.6 Fractional excretion of calcium, phosphorus, magnesium, and uric acid in basal conditions and after hyposaline volume overload in healthy young and old-old volunteers

		Young [mean and (range) (mg/dl)]	Old [mean and (range) (mg/dl)]	<i>p</i> Value
Calcium	Basal	0.8 (0.1–1.3)	0.8 (0.2–1.4)	NS
	Expansion	1.6 (1.3–2.3)	2.3 (1.7–4.1)	0.013
Phosphate	Basal	7.5 (1–10.5)	9.5 (0.3–19)	NS
	Expansion	9.6 (2.3–35)	9.8 (2.4–100)	NS
Magnesium	Basal	4.1 (2.6–5)	2.8 (2–4.6)	NS
	Expansion	3.2 (2.5–6.2)	5.1 (2.2–15)	0.02
Uric acid	Basal	7 (3.5–10.4)	6.2 (3.9–22)	NS
	Expansion	12 (9–14)	10 (1.9–31)	NS

cation and 99% is found in the intracellular space [56]. Under basal conditions, the small intestine absorbs 30–50% of the dietary magnesium, a figure that can rise to 80% in cases of severe magnesium deficit [57].

Renal Handling

Approximately 20% of serum magnesium is bound to albumin, and in spite of the fact that 80% of this cation is filtered at the glomerulus only 3% of it is finally excreted in the urine [58]. Renal excretion is determined largely by filtration and tubular reabsorption rates. Tubular Mg^{2+} secretion does not appear to play a significant role in its balance. Between 10 and 15% of the filtered Mg^{2+} is reabsorbed in the proximal convoluted tubules [59], and between 60 and 70% is passively reabsorbed in the thick ascending limb of the loop of Henle via paracellular channels facilitated by a lumen-positive transepithelial gradient generated by the luminal Na–K–2Cl cotransporter and potassium recycling into the lumen [60]. In addition, this nephronal segment contains calcium sensitive receptors on the basolateral pole sensitive to increased plasma calcium or magnesium concentration. Mg^{2+} is still significantly reabsorbed in the DCT, a mechanism responsible for the final control of its excretion. Urinary Mg^{2+} excretion is increased by high natriuresis, osmotic load, and metabolic acidosis; it is reduced by parathyroid hormone, metabolic alkalosis, and perhaps, calcitonin action. Vitamin D seems to have no influence on its renal handling [57].

Healthy Aged

Fractional excretion of magnesium (FE Mg^{2+}) does not differ from the one in a healthy young population. However, in the setting of volume expansion, old people are prone to develop a significant increase in FE Mg^{2+} leading to a reduction in their serum magnesium level, whose normal values are

around 2.1 (1.9–2.3 mg/dl) [60]. Since most of the filtered Mg^{2+} is normally reabsorbed in the thick ascending loop of Henle and this segment shows some degree of incompetence for the reabsorption of Na^+ , the handling of Mg^{2+} in the elderly may be less effective than in the young.

Calcium

Healthy Young

Calcium is critical for many metabolic functions. Although 99% of body calcium is found as part of the structure of bone and teeth, the remaining 1% found in plasma and body cells is crucial for many functions such as blood clotting, nerve impulse conduction, and muscle contraction. The homeostasis of calcium is a complex process that integrates the function of the gastrointestinal tract, the bones, and the kidneys, all required for normal calcium balance. The normal total serum calcium concentration oscillates between 9 and 10.5 mg/dl; approximately 50% of serum calcium is bound to albumin. A small amount of it is complexed to anions, and the remainder of serum calcium is in the form of free ionized calcium [61].

Renal Handling

The kidney is critically important for the maintenance of overall Ca^{2+} homeostasis in mammals by partly controlling the excretion of Ca^{2+} and by conversion of vitamin D to its active metabolite, 1,25-dihydroxyvitamin D₃ [$1,25(OH)_2D_3$]. To maintain a net Ca^{2+} balance, 98% of the Ca^{2+} filtered at the glomerulus must be reabsorbed along the nephron [62]. The main percentage of Ca^{2+} reabsorption takes place along the proximal tubule and the thick ascending limb of Henle's loop through paracellular pathways. The remaining 15% of Ca^{2+} reabsorption occurs in the DCT, connecting tubules (CNT), and the initial portion of the CCD. The relative contribution of these individual segments to active Ca^{2+} reabsorption appears to differ among species [61].

Healthy Aged

In healthy old people, plasma calcium levels and fractional excretion of calcium (FE Ca^{2+}) do not differ from those of a healthy young population. However, when the healthy aged undergoes volume expansion, they develop a significant increase in their FE Ca^{2+} . This increased FE Ca^{2+} induces a significant reduction in blood calcium levels. Healthy elderly people under the conditions of an adequate diet and sun exposure have normal levels of blood calcium, blood phosphate, vitamin D, PTH, and urinary calcium and phosphate excretion

[63]. However, since this population frequently has a deficient dietary content of Vitamin D, reduced sun light exposure, and low serum levels of sexual hormones, they have a tendency to develop hypercalciuria. The latter phenomenon together with a poor calcium intestinal absorption may account for the senile secondary hyperparathyroidism (reduced serum Ca^{2+} and high levels of PTH) communicated by some authors [64].

Phosphate

Healthy Young

Serum concentration ranges between 2.5 and 5.0 mg/dl. Approximately 1% of total body phosphorus is in the extracellular space. Homeostasis of phosphorus is maintained by the transport of phosphate (Pi) across renal and intestinal epithelia [65]. The majority of body phosphorus is absorbed from the digestive tract, mostly in the duodenum and jejunum. Normally, the amount of phosphate in the diet exceeds 1,000 mg/day and its net absorption is more than 60% of the intake.

Renal Handling

Approximately 80% of renal phosphate reabsorption takes place in the proximal tubule by means of sodium-dependent phosphate transporter [65, 66]. Two transporters [Na-Pi-IIa (SLC34A1) and Pi-IIc (SCL34A3)] are specifically expressed in the brush border membrane of the proximal tubular cells. Both are stimulated by serum phosphate depletion, although severe phosphate depletion can reduce the electrolyte reabsorption capability of the proximal and distal tubules [65]. About 5–10% of filtrated phosphorus is reabsorbed by the distal tubules.

Healthy Aged

There is no significant difference in neither the serum phosphorus level or in its fractional excretion between the young and the healthy aged in basal conditions or following volume expansion.

Uric Acid

Healthy Young

The normal plasma uric acid level is 2.2–7.5 mg/dl in adult males, being slightly lower (2.1–6.6 mg/dl) in premenopausal females [67]. Normally, two-thirds of uric acid is eliminated

TABLE 78.7 The clinical manifestations of the principal functional derangements observed in the aged relate to the anatomical site of dysfunction with advance age

Renal site	Tubular dysfunction	Clinical manifestation
Cortex		
Proximal tubule	↓ Reabsorption of glucose Na ⁺ , HCO ₃ ⁻ , PO ₄ ⁻³ , and urate	Renal glucosuria: osmotic diuresis leading to volume depletion; tendency for acidosis and hyperkalemia; hypophosphatemia (muscle weakness and potential for muscle injury or rhabdomyolysis)
Distal tubule acidosis	↓ Secretion of: H ⁺ , K ⁺	Hypouricemia
	↓ Reabsorption of: Na ⁺	Distal tubular Hyperkalemia Hypokalemia Salt wasting (volume depletion and hyponatremia) Hypomagnesemia
Medulla	↓ Concentrating ability ↓ Reabsorption of: Na ⁺	Distal tubular Nocturia (increased water loss: dehydration; salt wasting and volume depletion); hyponatremia or hypernatremia

Source: Data from [32, 36, 69–71]

by the kidney and one-third by the gut [68]. Only 4% of this substance is bound to plasma proteins, thus most of it is freely filterable [67]. Approximately 10% of the filtered urate is finally excreted in the urine [69, 70]. This process is usually greater in males than females: fractional excretion of uric acid (FE UAc) is around 12 and 8%, respectively

Healthy Aged

In healthy old people, serum uric acid levels and FE UAc do not differ from those of a healthy young population. Moreover, when healthy old people undergo volume expansion, they show no significant difference in their renal uric excretion before and after the procedure (Table 78.6).

Acute Renal Failure and Its Prevention in the Elderly

Acute renal failure is a disastrous complication of surgery in the elderly patient. In one series, major surgery was the second most common cause of acute renal failure in the elderly [71]. Mortality rate was 57.3% in this group of 122 patients. The causes of death were pneumonia, myocardial infarction and cardiac arrest, pulmonary embolus, and septicemia in decreasing order of frequency. Infection (bronchopneumonia and septicemia, combined) was the leading cause of mortality in the elderly patient with acute renal failure.

There are several types of acute renal failure in the elderly, but the most common (as in other age groups) is acute tubular necrosis [32]. The tubular necrosis results from ECFV depletion leading to circulatory disturbances and ischemia; it

can also be caused by nephrotoxicity (aminoglycoside antibiotics, chemotherapy drugs, or intravenous contrast agents). The diagnosis is made by microscopic analysis of the urinary sediment in which desquamated tubular cells or their degenerative products are observed. The cells degenerate into pigmented granular casts, often called “dirty brown” casts. In addition, there is evidence of tubular dysfunction in the form of impaired sodium conservation. As already mentioned ECFV depletion and circulatory instability in the elderly must be avoided. Early detection and rapid therapy with physiologic saline is of the essence.

In summary numerous electrolyte and acid–base disturbances can occur in the aged that facilitate the development of volume depletion and conditions that can lead to acute renal failure. Table 78.7 summarizes the disturbances already described above and provides the anatomical site and defect that generates them.

Acknowledgments The authors are grateful to Drs. Joaquin Alvarez Gregori, Paula Scibona, and Carlos Musso for their help in the preparation of the manuscript.

Chapter 79

Urinary Incontinence in the Elderly

Pat O'Donnell

Urinary incontinence (UI) is one of the most personally devastating diseases of the elderly. It has humiliating social consequences that touch every facet of the quality of life of the old person. One of the most debilitating consequences of UI in the elderly is a loss of self-esteem, which results in self-imposed social isolation. Elderly incontinent persons become prisoners in their own home due to the behavioral changes that occur from the personal fears and shame of UI. Many elderly people believe they are a victim of a disease without having any control over the personal and social consequences. As a result, they suffer in silence because of the shame and lack of awareness of successful treatment options. Because of the loss of self-esteem, treatment of UI in old people is usually deferred until the disease has become severe and the progressive symptoms have compromised many years of the life of the individual. Personal decisions about the treatment of UI often derive from feelings of desperation and shame rather than a careful consideration of the treatment options that meet the quality-of-life needs of the patient. Many elderly people have a strong reluctance to seek treatment or participate in treatment for incontinence because of personal feelings.

Most treatment programs for UI in the elderly require patient involvement and participation, which is important for long-term success of therapy of UI in old people. The requirement to be personally involved in both surgical and nonsurgical treatment programs gives elderly people a feeling of control over their own lives and control over the devastating personal consequences of UI they experience.

Elderly people experience a feeling of loss of control in all areas of their environment and loss of importance to family and society as they become older. They are no longer essential for “the job to get done” in their occupation or essential to “the existence of the family” as they once were when they were younger. The personal feelings of self-esteem

and value to society they once experienced in their occupation are no longer present and they no longer feel important or needed. Their importance to the family is different because their role has changed drastically, and it does not provide the same feeling of being needed by the family. The many personal and social changes associated with aging have a collective effect of lowering self-esteem. The ultimate loss of self-esteem for the elderly person is the humiliation of loss of bladder control.

Loss of bladder control is the most profound reminder to elderly persons that they are not able to control even the most basic body functions of normal life. Particularly in the elderly population who have lost a personal feeling of value within themselves and in society, UI has an unusual capacity as a disease to render the individual emotionally paralyzed to seek treatment. The greatest obstacle to successful treatment of UI in the elderly is getting the individual to consult a physician and subsequently to become involved in a treatment program. Successful treatment of UI can restore to the patient essential control over a basic normal body function necessary to restore self-esteem, which has an enormous impact in all other areas of their life.

Although UI is not a life-threatening disease, it is one of the most serious “quality of life” threatening diseases of elderly people. The economic, social, medical, and psychological impact on the lives of elderly people who have UI is immense [1]. Among the elderly people who are community dwelling and live independently, approximately 38% of women and 19% of men experience UI. Of the old people who live in chronic care facilities, approximately 55% experience UI. The total direct health care cost of UI in the USA during 1987 was approximately \$10.3 billion and is estimated to be more than \$15 billion at the present time. The annual cost of managing UI in old people is more than the combined annual cost of all coronary artery bypass surgery and all renal dialysis in the USA. Although the economic cost to old people and to society is enormous, the greatest cost by far is the personal distress of the elderly person through self-imposed social isolation and loss in self-esteem resulting from UI.

Urinary Incontinence in Elderly Women

Clinical Assessment

Elderly women are twice as likely to be incontinent as elderly men in a similar age group. The assessment of incontinence in an elderly patient is essential to ensure that any therapeutic program is based on an accurate diagnosis of urinary bladder and urethral dysfunction. UI in the elderly is much more complex than UI in younger people; and clinical trial and error treatment programs that are not based on a complete diagnostic evaluation of the patient are unlikely to be successful and can be potentially harmful to the patient. The immense importance of the impact of UI on quality of life of the older person must be a factor in every decision including the complexity of the clinical management of UI. Therefore, the incontinence assessment is important and involves many aspects of the pathophysiology of incontinence and the life style of the individual.

Incontinence History

Many elderly women believe that UI is a normal consequence of aging or of being female. Sometimes the patient has been told by a physician that UI is a normal condition associated with becoming older and that nothing should be done about it. The reluctance by the patient to see a physician about the symptoms of UI may be due to personal embarrassment, lack of knowledge of treatment options, fear of surgery, a sense of hopelessness about UI, and low expectations of treatment success. Therefore, the clinical history of old women with UI should always include direct questions about the occurrence of incontinence episodes, the symptomatic characteristics of urinary incontinence, and the severity of urinary incontinence. Typically, incontinence severity can be estimated by a clinician by asking patients how many times they change pads each day. It is important for the clinician to know if the major component of incontinence is urge urinary incontinence (UUI) or stress urinary incontinence (SUI). Typically, SUI is associated with involuntary loss of urine with coughing, straining, and movement [2]. UUI usually is associated with an intense desire to void with an inability to prevent urine loss voluntarily because the patient cannot physically get to the bathroom in time to prevent an incontinence episode [3].

A urinary diary is an essential part of the initial clinical evaluation of urinary incontinence in old women [4]. The diary helps document the severity of incontinence, determine if associated irritative symptoms are present, establish if there is a pattern to the incontinence, identify precipitating events, and assist in planning the treatment approach.

The assessment of symptom distress and quality of life are increasingly important when evaluating the severity of health conditions, such as UI and the impact of the disease on the daily life of the individual.

Although UI in the elderly is a personally devastating disease, it is not a fatal disease for most patients. Successful treatment of UI in elderly women does not prolong survival, so the goal of treatment of UI is to make the life of the person better. Therefore, quality of life assessment is important when determining the success of treatment. Finally, it is essential to determine the functional status of the older patient. Both mental status and physical status of the patient are important when planning treatment so it is specific to the needs of a particular old person. In addition, comorbid medical conditions may have a significant impact on the treatment decisions of UI in older patients.

Physical Examination

The physical examination of the incontinent elderly woman requires more attention to nuances than in the younger woman. For example, atrophic changes in the vaginal epithelium may indicate that similar changes are present in the urethral mucosa [5]. The general body habitus of the elderly woman is important, as is her agility when planning therapy. A pelvic examination is always performed when possible, including an assessment of the perineal skin, the pelvic floor, and the vaginal wall. It is important for the clinician to identify evidence of anatomic incontinence due to prolapse of the bladder and urethra in old patients. In addition to anatomic changes in the urethra, atrophy of the vaginal epithelium may be associated with poor urethral function, which can contribute to intrinsic sphincter deficiency (ISD) being an etiology of the incontinence. ISD is characterized by the failure of urethra to function properly regardless of the anatomic position of the urethra [6]. ISD can exist in old women who have stress incontinence with an associated anatomic abnormality as well as those who have no evidence of anatomic changes or prolapse. Clinically, it is essential to identify elderly women who have ISD as an etiology of SUI so as to counsel the patient about specific therapy for it. ISD is intrinsic failure of the urethra to function normally and requires a therapeutic approach different from that for anatomic SUI.

Urodynamic Studies

Urodynamic studies of bladder function in elderly patients are necessary for the diagnosis and treatment of UI. Such studies consist of a sequence of bladder and urethral function measurements that often seem confusing to elderly patients and to the referring physician. Because UI in elderly women

is considerably more complex than that in young women, the value of complete urodynamic studies is especially important in the old patient. Complete urodynamic studies can be performed in elderly patients with minimal discomfort, and the studies provide invaluable clinical information essential to the diagnosis and treatment of incontinence in this group of patients.

The urinary flow rate is usually the initial bladder function measurement, and it can be performed in the physician's office without significant inconvenience or discomfort to the patient. To perform a urinary flow study, the patient is positioned on a specially designed commode chair, and she voids into a urinary flow unit. The urinary flow rate is inexpensive, relatively easy to interpret, and provides valuable clinical information about bladder function. The uroflow parameters include the voiding time, peak urinary flow, mean urinary flow, and voided volume of urine. Usually, the residual urine volume is measured after the patient voids for the urinary flow rate. The residual urine volume can be measured with an ultrasound scan of the bladder or with a catheterized residual volume determination. Although the uroflow studies are valuable clinically, they alone do not provide the necessary information to establish the presence of such disorders as bladder outlet obstruction; further urodynamic evaluation is required here, including a pressure-flow study.

Cystometry is one of the most important studies of bladder function in elderly women. It is performed by continuous filling of the urinary bladder using a catheter through the urethra to measure the total capacity of the bladder, the sensation of filling experienced by the patient, the pressure-volume relation of the bladder, and the contractility of the bladder. In many elderly women, the capacity of the bladder is small, the bladder may contract involuntarily causing urinary incontinence, or the bladder may not stretch properly, resulting in an abnormal increase in resting pressure during filling. These abnormalities of bladder function are just some of those that occur in elderly patients with UI that can be found on routine cystometric bladder studies, and they must be identified and treated according to the diagnosis provided by routine cystometry.

Pressure-flow studies measure the pressure inside the bladder during voluntary voiding and simultaneously measure the resulting urinary flow rate. This study is essential for assessing the voiding dynamics of the patient who has a low peak flow rate on routine uroflow studies. The clinician must determine if the cause is a low detrusor pressure or a bladder outlet obstruction. Elderly women who have bladder outlet obstruction or low detrusor pressure during voiding may also have incomplete emptying of the bladder. Either of these problems that result in an elevated postvoiding residual urine volume can cause bladder hyperactivity and may be associated with urinary incontinence. A high detrusor pressure

during voluntary voiding with an associated low urinary flow rate is diagnostic of bladder outlet obstruction.

Bladder outlet obstruction in elderly women can have a functional or anatomic etiology; it is usually associated with previous surgical procedures that resulted in obstruction of the urethra. Urethral obstruction that results from previous surgery may produce a fixed outlet obstruction without correcting the etiology of the SUI. In these patients, SUI due to sphincteric dysfunction can coexist with bladder outlet obstruction, as the urethral obstruction is enough to produce bladder obstruction but not enough to produce continence. This is because urethral resistance is a static resistance instead of the normal dynamic functional resistance of the urethra. Bladder outlet obstruction due to fixed resistance within the urethra cannot be identified unless combined bladder pressure and urinary flow rate studies are done simultaneously. The pressure-flow studies represent the most important assessment available to determine the dynamics of bladder and urethral function of elderly women who have UI.

Another critical part of the evaluation of elderly women with UI is the measurement of urethral function [7]. Measuring the pressure of the urethra throughout the functional length is a study called the urethral pressure profile (UPP). The UPP is an important measurement of urethral function, but it is not necessarily a measure of the continence function of the urethra. Simultaneous measurement of urethral pressure and intravesical pressure during coughing provides a differential pressure between the bladder and urethra. This has been called the stress UPP and has added significantly to the clinical applications of the UPP. With the introduction of the concept of ISD, the abdominal leak point pressure (ALPP) measurement has been used much more commonly as a clinical assessment of the continence function of the urethra.

The ALPP is a measurement of the intra-abdominal pressure required to produce leakage of urine from the bladder through the urethra [8]. This study requires fluoroscopic evaluation of the patient during a straining maneuver. Although this study is highly accurate and predictive of the outcome of surgical procedures for SUI in elderly women, the requirement of simultaneous use of fluoroscopy during the study precludes routine use of the test in many clinical environments. ALPP does remain the most clinically important study when evaluating urethral function in elderly women with the symptoms of SUI and is essential for diagnosing intrinsic ISD. In patients who have a low ALPP, a urethral sling procedure is required to correct the symptoms of SUI if a surgical procedure is being considered. The long-term failure rate of any of the numerous bladder suspension procedures in these patients is high, and a urethral sling procedure is the only operative procedure that has a high long-term success rate in these patients. If the ALPP is more than

60 cm H₂O, then ISD is not likely to be a significant factor in the etiology of UI; hence a routine bladder suspension procedure is usually successful in correcting the problem of anatomic incontinence and alleviating the symptoms of SUI in the elderly woman.

Electromyography (EMG) of the striated sphincteric muscles is one of the more difficult clinical diagnostic studies [9]. Among elderly women it is especially important for patients in whom neurologic disease is the etiology of the UI or a contributing factor. Neurologic disease in the elderly as a cause of urinary incontinence may originate in the central nervous system (CNS) in those who have such diseases as a previous stroke. Neurologic disease as a cause of UI also may originate in the spinal cord in old patients who have diseases such as intervertebral disc disease, or a neurologic disease that causes UI may originate peripherally with such diseases as diabetes. EMG is especially important in patients with UI who may not be suspected to have associated neurologic disease but have a history of degenerative disc disease of the spine or multiple previous operative procedures for disc disease of the back.

Pathophysiology of UI in Elderly Women

Urinary incontinence is usually considerably more complex in elderly women than in young women. In general, incontinence in old women can be caused by abnormalities of bladder function, abnormalities of urethral function, or combinations of bladder and urethral dysfunction [10]. Close attention to the clinical characteristics of the symptoms of UI in old women from their incontinence history can be helpful for identifying the etiology of the UI. However, a precise description by the elderly patient of her symptoms usually is not nearly as helpful in the diagnosis as is a description of the characteristics of symptoms in young women. For this reason, urodynamic studies along with endoscopic and fluoroscopic studies have a significance in the diagnosis and treatment of UI in old women. Even with extreme attention to every detail of the assessment by the clinician, there is a greater degree of imprecision when determining the pathophysiology of UI in old women compared with young women.

Urge Urinary Incontinence

A common cause of incontinence in elderly women is an overactive bladder, which is characterized by the symptoms of urgency, frequency, nocturia, and episodes of urge UI. Elderly women who have symptoms of urinary urgency usually have associated nocturia.

A significant clinical difference between elderly women and young women regarding the symptom of urge UI is that

older women frequently complain that they have no warning of the event [11]. Young women usually describe intense urgency with an inability to control the episode of urgency voluntarily. In contrast, the elderly woman often describes the incontinence event as occurring with little or no warning at all. Although the sensation of urgency exists in elderly women, the duration of the sensation prior to the onset of incontinence is often only a few seconds. The etiology of this clinical observation is unclear, but it appears to be associated with aging. The effects of aging on the lower urinary tract function somehow result in bladder overactivity in many elderly women.

Hyperreflexic Contractility

Incontinence associated with true detrusor hyperreflexia is, by definition, caused by some type of associated neurologic disease [12]. Most commonly in the elderly, detrusor hyperreflexia occurs after a stroke or some other CNS disease, such as Parkinsonism. Detrusor hyperreflexia may result from spinal cord disease related to herniated disc disease or previous back surgery in old people. Urinary symptoms due to neurologic detrusor hyperreflexia in elderly patients usually occur both day and at night with a smaller than normal urine volume in the bladder. The cystometrogram almost always shows a reflex detrusor contractile response associated with filling of the bladder to a relatively small volume. In elderly patients with spinal cord disease, the EMG often shows simultaneous contraction of the external urethral sphincter and contraction of the urinary bladder, resulting in extremely high bladder pressures with failure to empty. It is due to the high outlet resistance of the contracted external urethral sphincter and is called detrusor-sphincter dyssynergia. In most of these patients, neurologic disease that affects urinary bladder function also affects other areas of the body; and the associated functional deficits are usually clinically apparent.

Bladder Compliance

Urinary incontinence associated with abnormal bladder compliance is a critical diagnosis that must be excluded in every elderly woman who has symptoms of an overactive bladder. In a normal person, the increase in volume in the bladder is not associated with a significant increase in pressure within the bladder. However, in patients with abnormal compliance, the pressure within the bladder increases as the volume in the bladder increases. This is a serious intrinsic problem of the urinary bladder, as it can result in obstruction of the kidneys due to a high resting pressure within the bladder that does not allow the ureters from the kidneys to drain properly. Abnormal bladder compliance can result from an injury to

the bladder; it can occur following radiation therapy or chemotherapy to the bladder; or it can be associated with systemic diseases such as diabetes. A common clinical etiology of abnormal bladder compliance resulting from injury is due to bladder decentralization caused by peripheral neural injury that occurs at the time of a radical hysterectomy or an abdominoperineal resection. Abnormal bladder compliance can also be induced by prolonged treatment with a Foley catheter or an indwelling suprapubic catheter. Abnormal bladder compliance is diagnosed by cystometrography. Urodynamic studies are essential to the diagnosis and treatment of the elderly woman with UI.

Stress Urinary Incontinence

In a normal person, the pressure within the urethra increases reflexly with increases in intra-abdominal pressure. During episodes of coughing or sneezing, the pressure within the abdomen sharply increases to a high pressure. However, through neurologically mediated reflex mechanisms, the normal resting pressure within the urethra quickly increases to a level higher than the pressure within the abdomen to prevent the leakage of urine from the bladder through the urethra [7]. When this normal compensatory reflex mechanism of the urethra fails to function properly, urine leaks through the urethra from the bladder during episodes of increased intra-abdominal pressure. This condition is called SUI.

In the elderly woman, there is a gradual decrease in the resting pressure within the urethra with advancing age. Part of the change in pressure is due to a loss in the vascularity of the submucosa of the urethra. This soft submucosa in young women serves as a “gasket” by providing a seal within the urethra when changes in abdominal pressure occur. Estrogen-deficient elderly women usually have a large loss of vascularity in the urethral submucosa, resulting in loss of the gasket effect within the urethra. Loss of the gasket effect of the submucosal seal of the urethra results in failure of the compensatory pressure mechanism within the urethra to be effective in containing the urine within the bladder during episodes of increased intra-abdominal pressure. Clinically, this condition results in SUI.

Another effect of aging in women is loss of the normal support of the bladder and urethra. Many elderly women are often told by their physician that their bladder has “fallen down.” With increases in intra-abdominal pressure such as coughing and straining, there is often rotation of the base of the bladder and proximal urethra into the vagina. Such prolapse is associated with the loss of reflex compensatory pressure mechanism of the urethra. This type of SUI is called anatomic SUI. When an anatomic abnormality or prolapse of the base of the bladder and urethra is associated with urinary incontinence, a surgical procedure is usually required to correct the abnormality and so prevent the persistent symptoms of SUI.

Intrinsic Sphincter Deficiency

When the compensatory reflex pressure mechanism within the urethra is inadequate because of abnormal function of the intrinsic properties of the urethra itself, it is called intrinsic sphincter deficiency (ISD). In many cases, the cause of ISD is unclear. It is much more common in elderly women due to the loss of intrinsic function of the urethra associated with the vascular submucosa that provides the gasket seal of the urethra. ISD is diagnosed by the ALPP test [6]. Currently, an ALPP less than 60 cm H₂O is considered to reflect abnormal intrinsic urethral sphincter function. It is more complicated to manage elderly women with ISD clinically than those who do not have ISD.

When ISD coexists with anatomic incontinence or prolapse, a pubovaginal sling procedure is usually the only treatment for successful long-term management of these patients. The short-term postoperative morbidity associated with a pubovaginal sling procedure for the treatment of UI in elderly women is significant in some patients. If an anatomic abnormality does not exist, intraurethral bulking agents such as collagen may be used successfully in some cases.

Mixed Incontinence

Mixed incontinence in elderly women refers to an etiology of UI within the same patient that consists of both an overactive bladder and SUI due to urethral dysfunction [13]. Mixed incontinence is considerably more complex to treat than either SUI or UUI. Usually both components must be treated, and they are usually treated separately. There appears to be some interaction between SUI and UUI. For example, successful treatment of SUI usually results in improvement or resolution of UUI. Often successful treatment of UUI alleviates the symptoms of SUI. Generally, successful treatment of mixed incontinence requires combination therapy that manages both components.

Nonsurgical Treatment of UI in Elderly Women

Pharmacologic Therapy

Although pharmacologic therapy has been effective in many young women with urinary incontinence, the efficacy and side effects have limited its use in elderly women. For patients with UUI symptoms, cholinolytic drugs such as oxybutynin (Ditropan) are among the most common agents used. In general, cholinolytic drugs have not been as effective in the elderly patient with symptoms of an overactive bladder as in the younger woman. Side effects of a dry mouth

and dryness of the eyes in the elderly have frequently limited the use of oxybutynin, but the occasional elderly patient who experiences confusion associated with that drug causes major concern about the use of this drug in old people.

The first group of new drugs available for clinical use for the treatment of the overactive bladder in the elderly is tolterodine (Detrol). Tolterodine is more highly selective for the bladder than for the salivary glands and has been better tolerated in the elderly. In addition, it does not appear that the problem of confusion is as prevalent with tolterodine as it has been with oxybutynin. Tolterodine appears to be a more effective drug for the treatment of bladder overactivity in elderly patients with considerably fewer side effects than are seen with oxybutynin.

α -Adrenergic drugs have produced clinical improvement in young women with mild SUI. One of the most common drugs used is phenylpropanolamine, usually in doses of 75–150 mg daily. Again, the problem of side effects of this class of drugs in the elderly precludes its routine use for SUI. Cardiac problems, including hypertension, are among the many contraindications for the use of α -adrenergic medications in elderly women.

Behavioral Therapy

The most common behavioral therapy used for both SUI and UUI in elderly women is some modification of the Kegel exercises. The original technique of pelvic muscle exercises (PMEs) described by Kegel was a form of biofeedback therapy. However, since the original description by Kegel, multiple modifications of PME have occurred that do not involve any type of feedback. In fact, PME taught by verbal instruction alone is inadequate for the elderly woman to learn to perform the desired muscle contractions for the training program. PME work primarily by a reflex inhibition of bladder contraction when the muscles are contracted.

Biofeedback Therapy

Of the behavioral therapies, the most effective form of training is biofeedback, which is a precise technique for teaching patients to do the PME. It provides feedback regarding the performance of PME to the patient [14]. The performance is usually displayed to the patient by both visual and auditory feedback signals. The patient learns quickly to perform precise muscle contraction activities that allow maximum return of bladder control. PME therapy is useful for both UUI and SUI, although the efficacy of biofeedback for SUI appears to be less than that for UUI. For the elderly woman with UUI,

biofeedback is considered by many to be the therapy of choice. It has the advantages of being effective with no potential side effects.

Timed Voiding

It has been shown that the inability to prevent an involuntary bladder contraction is only part of the aging process affecting bladder function. Another significant symptom is the inability to voluntarily initiate voiding. It is common for elderly women who have UUI to be unable to initiate voiding voluntarily even though a significant amount of urine is present in the bladder. Shortly after an unsuccessful attempt to empty the bladder, the elderly woman may experience an episode of UUI. Although it is unclear that prompted voiding addresses this specific problem associated with aging, a timed voiding schedule usually improves continence in this group. The treatment program is relatively simple. The patient voluntarily voids at fixed time intervals while awake. The interval is usually 2 h during waking hours. This regimen teaches the patient to inhibit the bladder voluntarily during the 2-h interval and to initiate voiding upon command. A timed voiding schedule can be combined with biofeedback therapy as a part of a comprehensive behavioral therapy program.

Surgical Treatment of UI in Elderly Women

Surgical treatment of UI is usually much more complex in elderly women than in young women, primarily because of a component of mixed incontinence exists in many elderly women who have SUI and the unusual complexity of the mixed incontinence that often occurs with aging. The approach to surgical treatment of the elderly woman also depends on the general health of the patient and existing comorbid conditions.

There is no question that UI is a debilitating disease in elderly women, but it is rarely a cause of death. For this reason, it must be recognized that surgical treatment of UI in elderly women has improvement in quality of life, as the major goal of treatment. Therefore, it is not reasonable to risk survival or existing quality of life with a surgical approach for the treatment of UI in these women without reasonable assurance of successful improvement in quality of life resulting from the operative procedure. In properly selected elderly patients, the long-term success of surgery is excellent, but the marked improvement in quality of life resulting from surgery is often denied the older patient on the basis of age alone [15].

Conventional urethral suspension procedures can be used routinely in the elderly woman with uncomplicated SUI [16]. An uncomplicated patient is one who has not failed previous operative procedures for SUI, does not have ISD, does not have significant coexisting UUI, and does not have serious comorbid conditions. In addition, urodynamic studies should demonstrate normal bladder function on cystometry and pressure-flow studies. Transvaginal procedures such as the Raz procedure or the modified Pereyra procedure are often used in the elderly woman because of the low risk of mortality from the surgery. Other considerations for the surgical treatment of uncomplicated SUI in the elderly woman include modifications of the Burch operative technique. However, no operative procedure should be considered in the elderly woman with SUI until a complete evaluation of bladder and urethral function has been accomplished.

For elderly women with ISD and any degree of prolapse of the bladder and urethra, a pubovaginal sling procedure is the only operative technique likely to be successful. This operative technique is slightly more difficult to perform than a urethral suspension procedure and has a slightly higher incidence of associated postoperative morbidity. A pubovaginal sling procedure should not be considered in the elderly woman with SUI unless a complete evaluation is done to determine the status of urethral and bladder function. Assessment of the urethra and bladder allows appropriate selection of the operative procedure and the ability to predict the outcome of the operation.

In the elderly woman with ISD without evidence of bladder or urethral prolapse, intraurethral bulking agents such as collagen can be used [17], which typically works well in these patients. It is common for patients after intraurethral collagen to develop recurrent SUI over a long time; however, requiring repeat intraurethral injections of the collagen material. This problem is usually not significant because the injections can be done in the office with local anesthesia, and the procedure is completed within a few minutes. Complications associated with intraurethral injections are minimal, and the success rate has been particularly good in the elderly woman with SUI due to ISD without an anatomic defect.

Urinary Incontinence in Elderly Men

Clinical Assessment

The assessment of UI in elderly men consists of a precise, complete characterization of the symptoms experienced by the patient. A voiding diary is an important part of the assessment of community dwelling elderly men with UI. Also the American Urological Association symptom score for benign

prostate hyperplasia (BPH) can be useful for identifying patients with bladder outlet obstruction [18]. In the chronic care environment, assessment of the severity of incontinence is more difficult. Usually the number of times each day absorbent pads must be changed is an indicator of the severity of incontinence in both community dwelling and chronic care elderly men. The severity of incontinence includes the frequency of episodes and the volume of involuntary urine loss. Unlike elderly women, SUI caused by sphincteric incompetence is rare in men who have not undergone previous prostate or pelvic surgery. Therefore, incontinence in elderly men is almost always associated with involuntary detrusor contractions, which means that bladder contractions occur without the patient being able to prevent the occurrence of the episodes voluntarily [19]. Elderly men with symptoms of UUI almost always experience involuntary detrusor contractions, which are the cause of the UI. In fact, it is reasonable to assume clinically that the etiology of UUI in elderly men is involuntary detrusor contractions even though the cystometrogram may show a stable bladder during filling.

The initial clinically useful study in elderly men with UI is usual measurement of the urinary flow rate by office ultrasonography or catheterized residual urine measurement. A peak urinary flow rate of less than 15 ml/s is usually associated with bladder outlet obstruction. An elevated residual urine volume of more than 50 ml is also usually associated with bladder outlet obstruction.

A common characteristic of the aging bladder function in men is the inability to initiate voiding voluntarily. Therefore, the elderly man may be unable to void for a urinary flow rate test, and ultrasonography may show that the bladder contains more than 100 ml of urine. The elderly man with UI often experiences an episode of UI shortly after being unable to void voluntarily even when the bladder contains an adequate amount of urine for voluntary voiding. When the elderly man is unable to void, a catheterized urine volume at that time does not represent a postvoiding residual urine volume. An accurately performed postvoid residual urine volume may show variation from one voiding episode to another within the same elderly male patient and may need to be repeated for accuracy when possible. The postvoid residual volume can be obtained only after the patient has voided. Also, the postvoid residual volume is useful only if the patient has voided a significant urine volume, usually considered to be 100 ml or more.

Cystometrography is important in elderly men who have UI to determine if bladder compliance is normal. That is, the resting pressure in the bladder should not show a significant rise during filling to the capacity at which the patient feels the urge to void. Unstable detrusor contractions are considered to be a significant finding on filling cystometry studies, although detrusor instability is not necessarily diagnostic of

an underlying bladder disorder in elderly men, as the instability is seen in otherwise normal elderly men as well. The most significant finding with filling cystometry is determining the capacity of the bladder and establishing that bladder compliance is normal.

The simultaneous measurement of bladder pressure and urinary flow rate during voluntary voiding is the most important study when evaluating bladder outlet obstruction in elderly men due to BPH. A pressure-flow study in an elderly man that shows a high detrusor pressure and low urinary flow rate during voluntary voiding is the diagnostic of bladder outlet obstruction. Therefore, pressure-flow is one of the most important studies in the urodynamic evaluation of the elderly man with UI. Elderly men who have UI and bladder outlet obstruction should be considered for surgical correction of the obstruction. It usually involves transurethral resection of the prostate (TURP). In many elderly men with significant bladder outlet obstruction and associated UUI, the latter resolves within a few weeks to months following surgical correction of the obstruction. If UUI persists after the bladder outlet obstruction has been surgically corrected, cholinolytic drugs such as tolterodine (Detrol) may be used to treat clinical bladder overactivity.

It is clinically necessary to determine if bladder outlet obstruction is present before using a cholinolytic drug in elderly men with UUI. Cholinolytic medications decrease detrusor contractility, which is contraindicated in patients with existing outlet obstruction of the bladder. Elderly men with bladder outlet obstruction due to BPH usually have high bladder pressure during voiding to empty the bladder considering the degree of bladder outlet resistance. If the bladder pressure is decreased by the cholinolytic medications used to treat overactive bladder symptoms, acute urinary retention may result because of a decrease in bladder pressure resulting from the medication. Therefore, surgical correction of bladder outlet obstruction is necessary before implementing cholinolytic drug therapy for bladder overactivity in elderly men who have UI and coexisting bladder outlet obstruction due to BPH.

Pathophysiology of UI in Elderly Men

Although most continent elderly men experience nocturia, those with UI have a higher number of nocturia episodes than continent men. Most old men awaken completely during these events of nocturia and may complain about having difficulty returning to sleep. Poor-quality sleep in old men is common and may contribute significantly to decreased mental alertness during the daytime. Like elderly women, many elderly men who experience episodes of UUI describe the episode as one in which involuntary voiding occurs with little or no warning of an impending incontinence episode.

The ordered biologic systems regulating micturition in normal young men appears to be impaired in elderly incontinent men, and the normal physiology of voiding is disordered. It may be associated with aging or possible localized CNS deficits. Studies have been performed that carefully measured the exact time of an incontinence episode and the exact volume of involuntary urine loss in elderly incontinent men. It was found that within patients the volume of involuntary urine loss had a wide variation, with no predictability regarding volume of urine loss for any given incontinence episode. In addition, the interval between episodes was measured, and it was found that a wide range of variation in interval between episodes occurred with no predictability of the interval. Also, the residual urine was measured following an incontinence episode. The volumes of the urine loss during the incontinence episode and the residual urine were measured. The total volume at the time of the incontinence episode also showed wide variation within patients. It was apparent from these studies that the occurrence of an incontinence episode in elderly incontinent men was independent of the accumulated volume of urine in the bladder at the time of the incontinence episode.

The same group of patients who demonstrated such irregular bladder activity also demonstrated voluntary voiding without incontinence on a routine basis. These clinical observations suggest that elderly men with UUI have random detrusor contractions resulting in urinary incontinence, whereas the neural pathways required for normal voluntary voiding remain intact. This finding suggests that UI may represent abnormal bladder contractions originating from a neurologic mechanism different from the normal bladder contraction that occurs under voluntary control.

This type of UUI is the most common type of incontinence seen in elderly men. As described previously, SUI is rare in men who have not had previous prostate or pelvic surgery. Elderly men who have undergone radical prostatectomy for adenocarcinoma of the prostate may have SUI resulting from sphincteric incompetence. Failure of the urethral sphincter mechanism following radical prostatectomy is usually due to ISD. Urinary incontinence in elderly men due to an abnormality of the urethral sphincter mechanism following a TURP is uncommon. Patients who have persistent UI after a TURP usually have detrusor dysfunction as the etiology of the UI, with the urethral sphincteric mechanism intact. Elderly men with UI following abdominoperineal resections for colon carcinoma rarely experience SUI due to sphincteric incompetence. The etiology of sphincteric incompetence following abdominoperineal resection is unclear. Voiding disorders following such a resection are uncommon and are likely due to a problem with the bladder, possibly due to partial denervation of the bladder during the operative procedure. These patients may also experience UI due to abnormal bladder compliance. Therefore, all patients

who experienced UI following previous pelvic surgery should have complete urodynamic assessment of both bladder and urethral function before considering therapy.

Nonsurgical Treatment of UI in Elderly Men

If bladder outlet obstruction has clearly been excluded as an etiology of UUI in elderly men, nonsurgical therapies can be implemented. They include pharmacologic and behavioral therapies.

Pharmacologic Therapy

Medical management of the overactive bladder in elderly men is similar to that in elderly women. Oxybutynin (Ditropan) has been used to treat the overactive bladder in elderly men for years, but the side effects are poorly tolerated in this patient population. The side effect of most serious concern is confusion, which is of particular concern in those who operate automobiles. For this reason, oxybutynin has not been routinely used in elderly men with UUI.

Tolterodine (Detrol) is a newer drug used to treat the overactive bladder in elderly men. It is highly effective and well tolerated in this group. Because of the ease of administration and the low incidence of side effects, tolterodine is considered the drug of choice for initial therapy of the overactive bladder in elderly men. Before initiation therapy with tolterodine, the clinician must be certain that there is no bladder outlet obstruction due to BPH.

Behavioral Therapy

PMEs can be used in men with UUI that are similar to those used by women. PME programs are typically variations of the original Kegel exercises. It is important to remember that the original Kegel exercises were done by women using a perineometer, which provided visual feedback of performance to the patient. Over a period of time, modifications of the Kegel exercises became various forms of PMEs. The major problem with PME programs is the instruction of the patient. It is difficult to instruct an elderly man in the PMEs. For this reason, more precise techniques (e.g., biofeedback) are considered more efficacious.

Biofeedback is not commonly used for behavioral therapy in elderly men because it requires complex equipment and trained personnel. However, it is extremely effective for treating those with symptoms of an overactive bladder [14].

It is important to select the proper signal source, which is usually perianal EMG activity displayed as visual and auditory feedback of performance.

Biofeedback therapy depends on the functional status of the patient to some extent. It is important that the patient has adequate mental function and reasonable physical function. Because biofeedback is a training program, it requires a level of mental function that allows training to take place; and enough physical function is required to allow contraction of the appropriate muscle groups. Although biofeedback therapy has been used in chronic care patients, it is generally more suitable for community dwelling patients because of the higher level of functional status usually associated with the latter.

A timed voiding schedule is excellent therapy for elderly men with UUI. In general, the patient is required to void every 2 h while awake. He then attempts to prevent voiding during the 2-h interval and voluntarily initiates voiding on command at the end of the 2 h. This regimen teaches the patient to inhibit the bladder voluntarily and to initiate voiding voluntarily, which improves bladder control. As with women, a PME program (which may be biofeedback-based) can be combined with a timed voiding schedule to improve the efficacy of behavioral therapy.

Surgical Treatment of UI in Elderly Men

Surgical treatment of UI in men depends on the etiology of the UI. In patients who have detrusor hyperactivity and bladder outlet obstruction, the bladder outlet obstruction is treated surgically if possible with a TURP. The patient is then observed for resolution of the symptoms of the overactive bladder, which usually occurs in 2–3 months. If urge UI continues, a cholinolytic drug such as tolterodine should be considered. Behavioral therapeutic treatments may also be considered.

With postprostatectomy incontinence following radical prostatectomy for prostate cancer, the damage to the sphincteric mechanism is something that usually cannot be surgically repaired. Intraurethral injections of a bulking agent such as collagen may be used as an initial therapy. Collagen has typically been beneficial in patients having relatively mild SUI. The overall long-term results of intraurethral collagen for severe postradical prostatectomy incontinence have been disappointing. In most patients who have severe SUI following radical prostatectomy, an artificial urinary sphincter is the best surgical treatment. Results with an artificial sphincter are good overall, but in the elderly patient manual dexterity is an important part of the functional status of the patient that is required for satisfactory results. The artificial urinary sphincter has a silicone pump located within the

scrotum and requires manual pumping of the device through the scrotal skin. This activity requires a reasonable level of both mental function and manual dexterity.

Urinary incontinence following TURP is uncommon even in elderly patients. When it does occur, the etiology is likely detrusor hyperactivity. Rarely, sphincteric incompetence due to ISD is the etiology, and in these cases an artificial urinary sphincter is required to achieve continence.

Conclusions

Urinary incontinence in elderly women and elderly men has a devastating impact on the quality of life of the individual. Because UI is rarely fatal in old people and because quality of life issues are profound, treatment of UI must improve quality of life without compromising survival or the existing quality of life.

Urinary incontinence in elderly women and men may have an etiology related to dysfunction of the bladder or of the urethra. In elderly men and women, the age-related abnormalities associated with changes in bladder activity are similar. In elderly women, SUI due to abnormal sphincter function is a common cause of incontinence in this group. ISD is much more common in elderly women than in young women. A combination of urethral function and bladder dysfunction may occur in elderly women and is referred to as mixed incontinence. Mixed incontinence is especially complex and usually much more difficult to treat successfully.

The overactive bladder in elderly men is similar to the overactive bladder in elderly women. Bladder outlet obstruction due to BPH is common in elderly men and can be a cause of bladder overactivity and UUI. If bladder outlet obstruction coexists with UUI in elderly men, surgical management of the obstruction should be considered if feasible. Following surgical management of bladder outlet obstruction, significant symptoms of overactive bladder usually appear but resolve over 2–3 months. If significant symptoms continue, cholinolytic drugs such as tolterodine may be used to control them. These drugs are contraindicated in the presence of existing bladder outlet obstruction due to BPH.

Elderly men who have ISD following radical prostatectomy for the treatment of prostate cancer can be treated with intraurethral bulking agents such as collagen. Intraurethral collagen is usually more successful with patients who experience mild incontinence. An artificial urinary sphincter is usually required for postprostatectomy incontinence that is more severe.

Often elderly patients do not complain about the problem of incontinence because they are embarrassed about it and have lost their self-esteem. It is only after the problem is

corrected that patients recover their self-esteem and are released from their self-imposed social isolation. Such isolation seriously compromises quality of life. For this reason, every reasonable treatment option for managing incontinence in elderly patients should be utilized to achieve maximum improvement in their quality of life.

Chapter 80

Neoplasms of the Kidney and Bladder

Edward M. Uchio, Juan S. Calderon, and Jonathan J. Hwang

The vast majority of human neoplasms appear to be coupled with the biology of aging. Over 70% of all cancers will occur in individuals over the age of 65 by the year 2030 [1, 2]. The age-specific incidence of many different types of cancer begin to rise steadily as we mature, and neoplasms arising from the kidney and bladder are of no exception. Approximately 88,200 men and 40,500 women developed a malignancy of the kidney or urinary bladder in 2009 [3]. The treatment of these malignancies in the elderly population requires careful consideration of factors such as life expectancy, incidence of treatment complications, and quality of life. This chapter reviews the incidence of kidney and bladder malignancies, the appropriate evaluation in the elderly, surgical and medical treatments available to treat the geriatric patient, and the complications associated with treatment.

Renal Cell Carcinoma

Epidemiology and Etiology

Solid neoplastic lesions of the kidney are comprised of both benign and malignant pathology. Most solid lesions derived from the renal parenchyma are malignant in nature and are predominantly renal cell carcinoma (RCC) (80–90%) [4]. The most common benign solid lesions of the kidney include renal cortical adenoma, metanephric adenoma, oncocytoma, and angiomyolipoma. The latter benign lesion is the only benign tumor that can be readily distinguished by radiographic imaging from its malignant counterpart. These angiomyolipomas are a rare benign clonal neoplasm consisting of adipose tissue, smooth muscle, and blood vessels [5, 6]. The presence of even a small amount of adipose tissue (fat) on computed tomography (CT) is diagnostic of this

tumor and can exclude RCC [7]. Since the majority of solid renal masses are malignant and very few benign lesions can be characterized as noncancerous on imaging, it is the clinical assumption that solid lesions of the kidney are malignant until proven otherwise. RCC accounts for 2–3% of all adult malignancies and is considered the most lethal of all urologic cancers [3]. The majority of RCCs are sporadic in origin with hereditary etiologies (von Hippel–Lindau (VHL), hereditary papillary renal carcinoma syndrome, etc.) accounting for approximately 4% of tumors [8, 9]. RCC is a malignant disease of the elderly, occurring most commonly in the sixth and seventh decades of life [2].

Unlike bladder cancer, there are very few accepted environmental risk factors for RCC. Tobacco exposure is the only accepted factor, with an associated risk as high as 2.5, as compared to controls [10]. In contrast, the hereditary forms of RCC have given us an understanding of the genetic basis of renal carcinogenesis. In many instances, the genes responsible for the hereditary renal cancer syndromes play a role in the more commonly seen sporadic counterparts in the elderly. The most common variant of RCC is clear cell carcinoma. This subtype of RCC is often seen in the autosomal dominant inherited tumor syndrome, VHL disease [11, 12]. Molecular investigations have identified the inactivation of the VHL tumor suppressor gene located on chromosome 3p25 as the genetic cause of renal tumorigenesis in this subtype [13, 14]. A high percentage of sporadic clear cell renal cancer seen in the elderly also demonstrates allelic loss of the VHL locus [15, 16]. In a similar fashion, other hereditary renal syndromes have revealed the genetic etiology of various subtypes of renal cancer (Table 80.1).

Natural History

A thorough understanding of the available knowledge regarding RCC behavior is important for treatment decisions in the elderly population. This special group of patients may have numerous confounding factors such as comorbid disease, which can impact life expectancy not related to their

TABLE 80.1 Hereditary renal cancer syndromes – genetic etiology of RCC subtypes

Disease	Locus	Gene	Protein	Renal manifestations
von Hippel–Lindau disease (VHL)	3p25	VHL	VHL	Clear cell carcinoma, simple and complex cysts
Tuberous sclerosis complex (TSC)	9q34 16p13.3	TSC1 TSC2	Hemartin Tuberin	Angiomyelolipoma (most common), renal cysts, clear cell carcinoma, papillary carcinoma, chromophobe carcinoma
Hereditary leiomyomatosis renal cell cancer (HLRCC)	1q42-q44	FH	Fumarate hydratase	Type II papillary carcinoma
Birt–Hogg–Dubé Syndrome (BHD)	17p11.2	BHD	Folliculin	Chromophobe (34%), chromophobe/oncocytoma(50%), clear cell carcinoma (9%), papillary carcinoma (2%)

TABLE 80.2 2010 AJCC TNM staging for renal cell cancer

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 7 cm or less in greatest dimension, limited to the kidney
T1a	Tumor 4 cm or less in greatest dimension, limited to the kidney
T1b	Tumor more than 4 cm, but not more than 7 cm in greatest dimension, limited to the kidney
T2	Tumor more than 7 cm in greatest dimension, limited to the kidney
T2a	Tumor more than 7 cm, but less than or equal to 10 cm in greatest dimension, limited to the kidney
T2b	Tumor more than 10 cm, limited to the kidney
T3	Tumor extends into major veins or perinephric tissues, but not into the ipsilateral adrenal gland and not beyond Gerota's fascia
T3a	Tumor grossly extends into the renal vein or its segmental (muscle containing) branches, or tumor invades perirenal and/or renal sinus fat, but not beyond Gerota's fascia
T3b	Tumor grossly extends into the vena cava below the diaphragm
T3c	Tumor grossly extends into the vena cava above the diaphragm or invades the wall of the vena cava
T4	Tumor invades beyond Gerota's fascia (including contiguous extension into the ipsilateral adrenal gland)

diagnosis of RCC. Therefore, it is imperative to understand the natural history of this tumor in the geriatric population. Although most clinical observations of RCC have been in patients in their late decades of life, these investigations do not specifically relate biology of tumor to age [17–19]. Factors such as tumor stage (Table 80.2) and grade are important prognosticators for RCC and can give insight into its clinical behavior [20–22]. Despite these important clinical parameters, the natural history of RCC in a particular patient can be highly variable. The clinical presentation of

RCC can vary from an incidentally found solid renal mass seen on imaging only to a large rapidly growing mass with systemic metastasis. Prior to the advent of imaging techniques such as ultrasonography (US), CT, or magnetic resonance imaging (MRI), most of these kidney cancers were detected by clinical symptoms associated with RCC due to local tumor growth, hemorrhage, paraneoplastic syndromes, or metastatic disease. One prominent symptom, flank pain, is usually due to tumor hemorrhage and obstruction of the collecting system from clot. But in advanced disease, the symptom of pain may be the hallmark of local invasion. The classic triad of hematuria, flank pain, and an abdominal mass on physical exam is rarely seen in the modern era of advanced imaging [23]. Prior to CT and US, many of these elderly patients would present with one or more of these symptoms, and most were incurable. Patients with advanced disease also complained of constitutional symptoms, such as weight loss, fever, and night sweats. On physical exam, they were often found to have palpable adenopathy, a nonreducing varicocele, and bilateral lower extremity edema. These tumors were often very large, and up to 25% were associated with metastases. Additionally, half of the patients who appeared to have organ-confined RCC manifest asynchronous metastatic spread following an attempt at curative surgical extirpation [24]. This malignancy preferentially spreads to the lungs, lymph nodes, and bone, although metastatic lesions are also found in less common sites such as brain, gallbladder, epididymis, and skin. The increasing use of noninvasive imaging has shifted the presentation of this disease from a symptomatic course to that of a disease found incidentally in the elderly.

The incidence of RCC has steadily increased during the last 3 decades, mainly due to the use of routine abdominal imaging for renal-related and nonrenal-related indications [25]. Now, most RCCs are detected incidentally as small tumors in patients without symptoms. In the early 1970s, the incidental detection rate was reported as 7–13%; most were for cause, but this percentage has increased to greater than 50% in recent years [19, 26]. The incidence of asymptomatic RCCs detected at autopsy has been reported to be 0.47% [27].

The natural history of these neoplasms has not been investigated adequately, especially that of an incidentally found small renal mass. However, retrospective studies by Bosniak et al. suggest that small solid renal masses <3.5 cm at the time of diagnosis grow slowly (0.36 cm/year) and rarely metastasize [17, 18]. More recently, 32 renal masses in mainly elderly patients (median age 71 years) who refused or were deemed unfit for surgery were followed for a median of 27.9 months. The growth rate of these masses did not differ statistically from zero growth. Only one-third of these presumed RCCs were shown to grow if managed conservatively and followed serially. The growth rate is slow or undetectable in the majority of patients [19, 28]. In other series of active surveillance of renal masses in elderly patients with multiple medical comorbidities, investigators found that 43% of tumors exhibited no tumor growth at a median follow-up of 2 years. At the conclusion of the study, 31% of the patients were deceased, none due to RCC [29]. These data would suggest that conservative management of renal masses may be a possibility, especially for an initial observational period in the elderly population. The optimal duration of this observational period still is not known. Although the previous studies have revealed that conservative management of RCC is possible in select elderly populations, the physician and patient assume a calculated risk when following these tumors. All of the conservative management series with longer follow-up had a small but not insignificant risk of metastatic disease and cancer-associated death. This group of patients who did poorly did not have any characteristic such as tumor size that portended an unfavorable prognosis [30]. Current guidelines for small renal masses <7 cm include active surveillance (AS) as an option, but all require careful counseling between the patient and physician, regarding the risks of this approach and the risk for a future intervention if the tumor shows rapid growth [31].

Management

Management of renal cancer in the elderly may be a very complex decision process. Treatments must incorporate concerns about efficacy, comorbid illnesses, and complications, as well as physiologic effects on renal function and competing causes for future mortality. Surgery remains the mainstay for curative management of localized RCC. The foundation of surgical therapy for renal cancer is complete excision of all neoplastic tissue with an adequate surgical margin. This objective may be obtained by either complete removal of the kidney (radical nephrectomy) or via a nephron-sparing surgical approach (partial nephrectomy). In addition, many newer minimally invasive techniques have gained popularity, such as cryotherapy or radiofrequency ablation (RFA). These new

thermal ablative techniques can be applied during standard open or laparoscopic surgery but are better suited to a percutaneous approach under radiologic guidance (CT or MRI). When performed via the latter technique, a potentially curative treatment can be applied to a completely different patient demographic. Those with significant comorbid illnesses that were previously deemed unsuitable for surgical management can now be given treatment with curative intent, under local anesthetic or minimal sedation. Lastly, as described in the previous section, active surveillance may be an option especially for those elderly individuals with significant competing risk factors for non-RCC-related mortality. Renal biopsy may help delineate the natural history of RCC in this nontreatment group, to help identify aggressive renal cancers from those with minimal growth and metastatic potential [30].

Radiologic Evaluation

The current radiologic modalities used to diagnose and evaluate renal masses include intravenous pyelography (IVP), renal ultrasound (US), CT, and MRI. In the past, the standard IVP was a commonly used test for the evaluation of hematuria. However, due to the lack of sensitivity and specificity for the detection of renal parenchymal tumors, this technology has been supplanted by multidetector computed tomography urography (CTU), for the evaluation of hematuria [32]. Many renal masses found today are detected by the widespread use of US and CT scans, for the evaluation of abdominal and gastrointestinal complaints [25]. More than 70% of these asymptomatic renal masses are found to be simple cysts. The prevalence of benign renal cysts increase with age and are found in over 50% of patients older than 50 years of age, thus a significant finding in the elderly [33]. These lesions are easily characterized by US and CT, and the most common “simple” variety requires no further workup or surveillance [34]. A dedicated renal protocol CT, which entails thin-slice images through the kidney with and without administration of contrast, is the single most important radiologic test to evaluate for RCC. Any renal mass with enhancement characteristics of more than 15 Hounsfield units (HU) after administration of contrast material should be considered an RCC, until proven otherwise (Fig. 80.1) [35]. In the past, gadolinium-enhanced MRI was an excellent modality equal to contrast-enhanced CT that was utilized extensively for patients with renal insufficiency, a significant problem in the elderly population. The gadolinium-based contrast agent (GBCA) used in MRI lacks significant nephrotoxicity [36]. Unfortunately, recent evidence has shown an association of nephrogenic systemic fibrosis (NSF), a debilitating and potentially life-threatening disease, with the use of GBCA in renal failure patients [37]. Due to this finding, many centers

FIGURE 80.1 Computed tomography (CT) of renal cell carcinoma. (a) Axial (b) Sagittal (c) Coronal (d) 3D (e) Specimen.

have limited the use of gadolinium-enhanced MRI to patients with a glomerular filtration rate (GFR) >30 mL/min and have avoided gadodiamide, a commonly used type of GBCA [38, 39]. The resulting problem is how to adequately image an elderly patient with poor renal function (GFR <30 mL/min).

Currently, this involves informing the patients regarding the potential risks of gadolinium-enhanced MRI versus performing a standard CT with iodinated contrast media and understanding the risk of contrast medium nephropathy of 5% in patients with a GFR between 15 and 40 mL/min [40].

The use of newer macrocyclic GBCAs may obviate this concern regarding renal function and the development of NSF [41]. These agents by nature of their chemical structure are less likely to release free gadolinium into the tissues, a hallmark of NSF.

Radical Nephrectomy

The radical nephrectomy with en bloc removal of the affected renal unit outside of Gerota's fascia and excision of the ipsilateral adrenal gland, as described by Robson and colleagues, is established as the "gold standard" curative procedure for localized RCC [42]. The procedure also includes removal of the lymphatic tissue in the renal hilar area and immediately adjacent paracaval or paraaortic lymph nodes. Regional lymph node metastasis is an important prognostic factor usually associated with poor survival [43]. The need for a complete regional lymphadenectomy from the crus of the diaphragm to the aortic bifurcation remains controversial. The lymphatic drainage of the kidney is highly variable, and metastasis often occurs through the bloodstream. Only a small percentage (<2–3%) of patients with micrometastatic disease would benefit from this added procedure, and the main benefit is local recurrence without an augment in survival [44–46]. Therefore, the surgeon performing a radical nephrectomy in an elderly patient may consider omission of the extended regional node dissection, to minimize morbidity of the procedure. In addition, another variable in this curative procedure is the choice of surgical incision, which can affect morbidity in the elderly.

The radical nephrectomy can be performed through a variety of surgical incisions. The surgical approach is determined by a variety of factors, which include size and location of the tumor, body habitus, history of previous abdominal surgeries, and morbidity of the patient, which is important in the elderly population. This operation is usually performed through a transabdominal approach, which allows abdominal exploration for metastatic disease and early visualization of the renal vasculature with minimal mobilization of the tumor. The principal disadvantage of this approach is a slightly longer postoperative ileus and possible long-term complications related to adhesions. Other approaches include the flank incision, most commonly at the eleventh and twelfth rib, and a thoracoabdominal incision. The flank incision is an extraperitoneal approach that may be beneficial in the elderly or in patients with poor surgical risk, but exposure of the renal vasculature is limited especially in large tumors. The thoracoabdominal incision extends from the flank anteriorly, involving an incision through the diaphragm. This approach allows excellent visualization of the tumor and vessels but often requires placement of a tube thoracostomy

for management of the consequent pneumothorax. Although large RCCs may be removed from this incision, the postoperative morbidity is high and should be avoided in patients with poor pulmonary function, and is rarely indicated in the elderly.

The cancer-specific survival following this procedure is dependent on a number of variables, with pathologic stage proving to be the single most important prognostic factor for RCC [21, 47]. Approximately 70–90% of patients with organ-confined RCC (TNM stage T1-2) are alive without disease at 5 years [21, 48–50]. Survival decreases significantly once the tumor is locally advanced or when lymphatic and systemic metastases are discovered, with a 5-year survival of <20% [50]. Importantly, the absence of effective chemotherapeutic agents in the adjuvant setting for RCC increases the need for complete surgical excision for cure. Oral tyrosine kinase inhibitors (TKI) targeting the mediators in the VHL pathway are currently being studied in the adjuvant setting for high risk disease [51]. The antitumor effects of these targeted agents in metastatic disease may prove to be a benefit in this setting. The side-effect profile is very favorable when compared to classic chemotherapeutic agents which is important when considering use in the elderly.

Laparoscopic Radical Nephrectomy

The first laparoscopic radical nephrectomy (LRN) was performed by Clayman and coworkers in 1991 on an 85-year-old woman with a right renal cancer [52]. Since that initial report, laparoscopic nephrectomy for both benign and malignant disease has become the standard of care at most centers. This minimally invasive surgery is associated with less postoperative discomfort and improved recovery, and costs compare favorably with the open approach [53]. LRN has emerged as a less morbid alternative to open surgery for most tumors (<10 cm) with no local extension. Outcome data for 5- and 10-year cancer-specific survival are comparable with open radical nephrectomy in the treatment of organ confined RCC [54, 55]. These results are not unexpected given the same technique of open radical nephrectomy is emphasized laparoscopically but with the benefits of decreased postoperative morbidity. A variety of approaches are utilized laparoscopically which include transperitoneal, retroperitoneal, and hand-assist approaches, each dependent on the skill and comfort level of the surgeon.

In the elderly population, this technique is attractive due to the decreased convalescence and pain associated with LRN. The latter benefit results in a substantially diminished requirement for narcotic analgesia, and in some patients, its use can be completely avoided with the addition of ketorolac [56]. These benefits have been shown to result in improved

pulmonary function among patients treated by LRN as compared to the open counterpart, suggesting that this procedure may be particularly useful in patients with poor pulmonary reserve [57]. One exception is the patient with severe chronic obstructive pulmonary disease with CO₂ retention. These patients may develop significant hypercarbia or acidosis and will require close monitoring. Some surgeons avoid this situation by using alternate gases such as helium or argon [58]. Lai and coinvestigators attempted to address the comparative morbidity of the LRN in patients of age 70 and over to those under age 70 [59]. In this series, complications rates were the same in both groups, and the only difference was in hospital stay by 1 day (age >70 group). When this procedure was performed purely laparoscopically (no hand-assist), this difference was mitigated.

Nephron-Sparing Surgical Therapy

Postoperative morbidity of radical nephrectomy includes renal dysfunction in the both the short- and long-term setting. This occurrence has prompted surgeons to investigate alternatives to complete removal of the kidney, especially in the patient with a solitary kidney, impaired renal function, or those that present with bilateral renal masses. In the past, parenchymal-sparing partial nephrectomy was performed only for the above reasons due to concerns about incomplete resection and recurrence. In addition, the renal transplant literature concerning donor nephrectomy (patients with a normal contralateral kidneys) have shown that donors do not have a higher rate of kidney failure during their lifetime [60]. However, distinct differences exist between donors and RCC patients. Renal donors tend to be carefully selected for medical comorbidities and are generally young (age 40 or less) [61]. A recent study by Bijol et al. demonstrated a far greater degree of underlying chronic renal disease in RCC patients undergoing surgery than what has been previously appreciated [62]. Only 10% of patients had completely normal adjacent renal tissue in the kidney tumor specimen; most had evidence of significant intrinsic renal abnormalities (diabetic nephropathy, glomerular hypertrophy, mesangial expansion, and diffuse glomerulosclerosis). These changes are reflected in the renal function of RCC patients who choose complete nephrectomy. A landmark study by Huang et al highlighted the impact of radical nephrectomy on future renal function. The incidence of chronic kidney disease (stage 3) was much higher in patients who underwent radical nephrectomy (65%) than after partial nephrectomy (20%) [63]. These data highlight the importance of considering partial nephrectomy even with a normal contralateral kidney.

The classic partial nephrectomy for RCC involves removing the tumor with an adjacent 1 cm margin. A margin this

size is easily obtainable for exophytic tumors but is not technically feasible for neoplasms located intraparenchymally or near the renal sinus/vasculature. More contemporary data has shown that a histologic tumor-free margin is more important; the width of the resection margin has no biologic or prognostic significance [64]. Partial nephrectomy is now considered an acceptable therapeutic approach in patients with a single, small T1a (<4 cm) RCC and a normal contralateral kidney. Multiple studies have established that partial nephrectomy for neoplastic lesions <4 cm provides equivalent tumor control compared to radical nephrectomy [65, 66]. In an elderly patient, the choice of a partial nephrectomy is an accepted practice to avoid chronic renal dialysis, as discussed earlier. However, in the setting of a normal contralateral kidney, one must weigh the additional risk of complications unique to this procedure. These include increased bleeding, urinary fistula, positive margins, local recurrence, arteriovenous fistula, and nonfunction of the remaining portion of the kidney. Stephenson et al. attempted to address the issue of comparative morbidity in 1,049 patients who underwent radical nephrectomy or partial nephrectomy [67]. The complication rate when adjusted for other variables was not statistically different between the two groups, but the partial nephrectomy group had more procedural complications due to urinary leak. Overall, the complications of both groups were very minimal. A more recent trend has been to perform partial nephrectomy via the laparoscopic approach. Highly specialized centers have extended this procedure even to the octogenarian population with promising results [68]. The long-term benefit of this more technically demanding procedure for an elderly patient with RCC is uncertain, especially when performed outside centers of excellence.

Thermal Ablative Therapies

In the preceding chapter, nephron-sparing surgery has been shown to be effective in the treatment of RCC while maximally preserving renal function. However, this procedure even when performed laparoscopically requires general anesthesia with its associated risks. Many elderly patients with RCC have significant comorbidities that make them poor surgical candidates. This group of patients is often treated conservatively with active surveillance and not given an option for curative treatment. It is assumed that the patient will most likely have a non-RCC mortality. With improvements in health care, these elderly patients are living longer which would allow a subset of these RCCs to grow and metastasize. In addition, many elderly patients are very anxious about not treating RCC in their kidney, especially for such a chemo-/radiation-resistant tumor. Thermal ablative therapies are a minimally invasive option for curative

treatment of RCC. These modalities include renal cryotherapy, RFA, and high-intensity focused ultrasound (HIFU); all are different forms of ablative energy focused on the renal lesion. HIFU is currently not FDA-approved in the United States but has ongoing clinical trials regarding its use, mainly in prostate cancer. Both cryotherapy and RFA use needles to transmit their energy to the tumor and can be placed percutaneously or through laparoscopic exposure. The percutaneous approach can be performed with local anesthetic alone or with intravenous sedation which would allow most patients who are poor surgical risks a chance at curative treatment. These focused thermal ablative therapies allow RCC treatment with minimal morbidity while maximizing posttreatment renal function.

Percutaneous thermal ablative therapies are performed with image guidance: CT, MRI, and ultrasound. The most important principle in all the described therapies is precise localization and treatment application of the energy. In this regard, cryotherapy has an advantage because the treatment area or “iceball” is easily visualized on imaging unlike RFA. In fact, early reports suggested that tumor kill was not as reliable with RFA when compared to cryoablation [69–71]. The authors have experience with both modalities and are now exclusively using cryoablation for the aforementioned benefit in visualization. Between 2005 and 2009, we have treated 33 consecutive renal masses in a total of 29 patients with percutaneous CT-guided cryoablation performed in an outpatient basis with local anesthetic and minimal sedation (Fig. 80.2). All renal masses were able to be treated despite location; novel techniques were utilized to access lesions in close proximity to adjacent vital organs. At a mean follow-up of 22 months, 96% of lesions were successfully treated in one treatment session, as verified by lack of contrast enhancement on postprocedure CTs. There were no major complications;

the only minor complication was postprocedure site pain in one patient which resolved spontaneously. Elderly individuals who are poor surgical candidates or choose not to undergo surgery can safely be treated with renal cryoablation. Although intermediate-term data looks promising regarding the efficacy of this procedure, longer term follow-up is still needed. The elderly must be counseled carefully when choosing thermal ablative therapies.

Management of Advanced RCC

Up to 30% of patients with RCC have metastatic disease at presentation and recurrence develops in approximately 40% of patients treated for localized disease [72]. These elderly individuals with advanced RCC are unlikely to benefit from surgical therapy unless a radical nephrectomy is performed for palliative intent. Therefore, systemic agents offer the most rational treatment options for older patients with this disease. Although categorical recommendations for the therapy of cancers based on chronologic age are neither appropriate nor reasonable, many decisions for or against administration of systemic therapy are often based on the age of the individual. Variability among aging individuals with regard to physiologic senescence and comorbidities suggests that a more practical approach for the clinician is the use of guidelines and performance scores to assess the elderly patient’s functional and physiologic tolerability for potentially toxic therapy.

First, it is important to define those who are considered elderly. Without readily usable markers of a patient’s physiologic age, Balducci recommended that the clinician consider those individuals over 70 years as elderly and should undergo

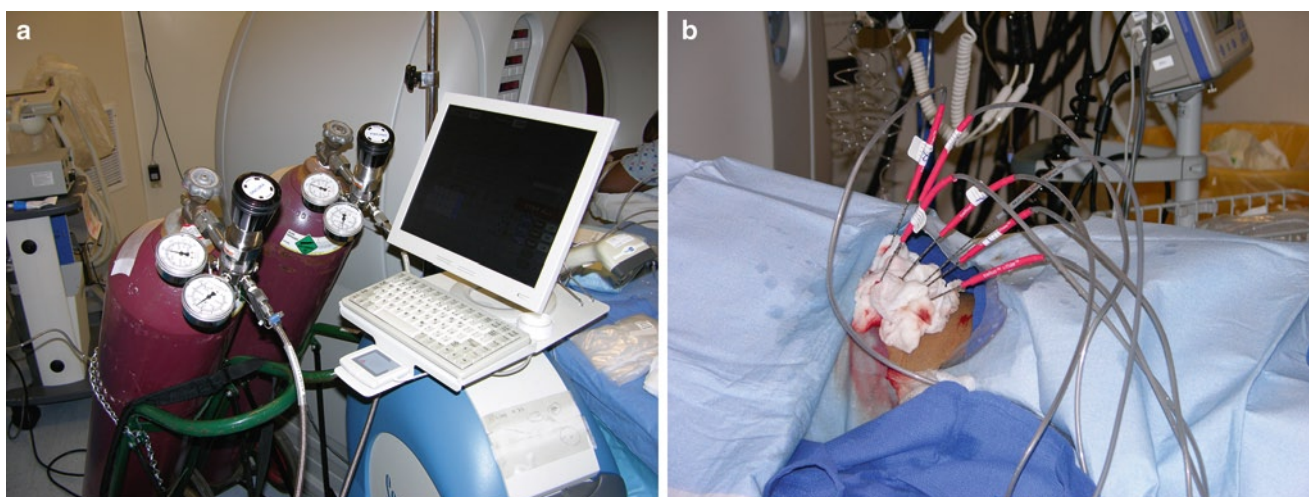

FIGURE 80.2 Percutaneous cryotherapy. (a) Cryotherapy Unit in CT Suite (b) Cryotherapy probes in L renal mass.

some form of geriatric assessment [73]. These individuals have an increased occurrence of the following: decreased musculoskeletal mass, functional limitations, geriatric syndromes (dementia, malnutrition, polypharmacy, incontinence, delirium), and multiple comorbidities. Minimizing the occurrence of side effects from chemotherapeutic drugs in the elderly requires careful clinical assessment for functional ability and preexisting neuropathy, cardiac/hepatic/renal function, bone-marrow reserve, nutrition, polypharmacy, and cognitive function. Interventions should include adjusted doses of renally excretable agents to GFR, use of support agents such as growth factors and cytoprotective agents when indicated, appropriate nutritional support, and the preferential use of safer agents when indicated [74].

Traditional cytotoxic chemotherapeutic agents and hormonal therapies have been ineffective in the treatment of metastatic RCC. The overall response rate was very low, usually much less than 15% [75]. Milowsky and Nanus reviewed the chemotherapeutic strategies for RCC; they concluded that most single-agent chemotherapy trials have been disappointing. There was modest enthusiasm for combination chemotherapy, especially with gemcitabine and capecitabine [76]. Recently published trials of their use showed minimal response rates of only 11–16% with significant toxicity [77]. These chemotherapeutic agents likely have no role in the elderly patient in light of these findings.

Until recently, systemic treatment for metastatic RCC was limited to cytokine therapy, which has been the standard of care for over 15 years. The basis of this treatment was built on observations that spontaneous remission of RCC occurred, although infrequently, in individuals with metastatic disease who underwent nephrectomy. Cytokine therapy, or immunotherapy for metastatic RCC consists mainly of two agents, interleukin-2 (IL-2) and interferon- α (IFN). Various combinations and dosages of IL-2 and IFN have been studied in randomized trials for metastatic, recurrent, and unresectable RCC. These studies have suggested that high-dose IL-2 results in higher response rates when compared to low-dose IL-2 and other cytokines [78–80]. The benefit of high-dose IL-2, as compared to even current systemic therapies, is that this drug is the only one shown to produce durable complete remissions [80]. Therefore, in the very select elderly patients with excellent performance status and low volume disease who have undergone a cytoreductive nephrectomy, one may consider the use of high-dose IL-2. The use of immunotherapy for advanced RCC in the aged must be approached cautiously due to the significant toxicities associated with its use.

Improved understanding of the biology of RCC, especially through the VHL pathway [9], has led to the many “targeted therapies” for treatment of metastatic kidney cancer. Over the last few years, systemic treatment options have improved dramatically due to the introduction of

broad-spectrum receptor TK, vascular endothelial growth factor (VEGF) antibodies, and mammalian target of rapamycin (mTOR) inhibitors. These agents have shown impressive antitumor activity and improved survival rates when compared to cytokine therapy [72, 81, 82]. Since 2005, two broad-spectrum TKIs (sunitinib malate and sorafenib tosylate), one mTOR inhibitor (temsirolimus), and one VEGF antibody (Bevacizumab) in combination with interferon, have been approved for the treatment of advanced RCC. In addition, another mTOR inhibitor (everolimus) has received FDA approval for patients with advanced RCC after failure of treatment with sorafenib or sunitinib, i.e., second-line therapy [83].

Sunitinib is well tolerated when compared to IFN and has become standard first-line therapy for metastatic RCC. In its phase III trial, treatment-related grade 3 or 4 fatigue was higher with interferon (12% versus 7%), but patients treated with sunitinib had higher rates of diarrhea, vomiting, hypertension, and hand–foot syndrome [72]. In addition, recent data from an expanded access trial has revealed that sunitinib is safe and efficacious in subgroups of patients including those with poor performance status [84]. These findings have made sunitinib standard therapy for metastatic RCC in the elderly. All targeted agents can be used in the elderly metastatic patient with consideration of the caveats mentioned earlier (careful evaluation, GFR dose adjustment, use of growth factors, etc.) to minimize the side effects and improve the tolerability of toxic systemic therapy.

Transitional Cell Carcinoma of the Bladder

Few conditions illustrate the link between cancer and aging better than transitional cell carcinoma of the bladder (TCC). The incidence of bladder cancer peaks at 85 years of age, according to a recent California tumor registry study [85]. As one ages, the risk for higher stage and grade disease increases. This raises the probability of developing invasive cancer and therefore affecting survival [86–88]. The basis for this phenomenon has triggered molecular research aiming to explain the influence of biological changes associated with the aging processes on the development and/or progression of TCC.

Transitional cell carcinoma of the bladder represents a broad spectrum of pathologic processes, extending from indolent low-grade papillomas to invasive poorly differentiated tumors with rapid metastatic capability. Age and performance status play a major role in the election of therapy and outcomes. Therefore, successful management of TCC of the bladder in the elderly patient requires an understanding of the natural history of TCC and the quality-of-life implications of each therapeutic approach.

Diagnosis

Bladder cancer represents an important consideration in the differential diagnosis of voiding complaints in the elderly individual. The presence of a neoplastic lesion within the bladder may be heralded by irritative symptoms such as urinary urgency, frequency, or dysuria. Hematuria, microscopic or gross, may also announce the existence of malignant bladder lesions. It has been estimated that 5–15% of patients, predominantly men, with hematuria harbor unsuspected bladder cancer [89]. Despite this, testing for hematuria cannot be recommended as a screening test for bladder cancer in the elderly population. In a study of 2,356 asymptomatic men aged ≥ 60 years who underwent dipstick testing for hematuria, only 0.7% of the screened population were found to have a bladder tumor [90]. The 2008 US Preventive Services Task Force found no high quality evidence that screening would impact mortality from bladder cancer. Although screening for TCC specifically is not recommended, many patients do routinely have urinalysis for the above symptoms or by their primary-care physician. Any asymptomatic hematuria (>3 red blood cells per high power field) requires urologic evaluation. A standard workup for TCC includes urinalysis, urine cytology, and cystourethroscopy. Additionally, a radiographic evaluation of the upper urinary tract is also indicated with conventional excretory urography or with the more contemporary computed tomography (CT) urography [91]. The cost implications of this approach, given the incidence of voiding symptoms and hematuria, are obvious. In the absence of a clear etiology such as infection, it is difficult at the present time to identify a subpopulation of patients not requiring a cancer evaluation.

Basic Science and Natural History

Epidemiologic and experimental evidence favors a strong role for environmental exposure as an etiology of bladder cancer in the elderly. However, since many cases arise in patients with no obvious exposure, it is important to understand the molecular basis of this disease. Well-recognized DNA alterations, such as the *p53* tumor-suppressor gene, seem to be responsible for the initiation and promotion of many human cancers including bladder cancer [92]. A recent study showed that the *p53* transcriptional activity and *p53*-dependent apoptosis was significantly decreased in older mice compared to younger mice [93]. In addition to *p53*, mutational frequency (*Mf*) studies have also provided new insights on how age-related changes may contribute to the development of bladder cancer later in life. Stuart et al. found a greater rate of *Mf* in the bladder of old transgenic mice

compared to other tissues examined in the same mouse model [94]. Further analysis revealed that this phenomenon was the result of accumulated mutations through replication during the lifetime of the mouse, rather than repeated insults associated with the aging process. Another mechanism that may be affected in the elderly involves gene transcription. Promoter regions of tumor suppressor genes can be silenced through DNA hypermethylation resulting in unchecked cellular replication [95]. This epigenetic alteration has been intensively studied in the past. CpG hypermethylation has been detected in 43% of aggressive bladder tumors and only seen weakly in normal epithelium which increases with age [96, 97]. Finally, a study by Gu et al. reported that advanced age was associated with decreased expression levels of mRNA of the four major mechanisms assuring genomic stability [98]. The protective mechanisms studied were *p53*, ataxia telangiectasia mutated (ATM), telomerase reverse transcriptase (hTERT), and telomeric repeat binding factor-2 (TRF2). These studies support the hypothesis that particular regions of the human genome are more susceptible to age-related DNA damage. And, within those regions, important genes, especially those involved with protection of genomic integrity, may be altered which ultimately results in bladder cancer.

The most important epidemiologic risk factors associated with urothelial carcinoma are chemical carcinogens, which are derived from tobacco products or a spectrum of industrial and environmental agents (see Table 80.3). Transitional cell carcinoma of the bladder represents a broad spectrum of pathologic processes, thus preventing a linear description of the natural history of this disease. To better understand the development and progression of TCC, it is important to make a distinction between superficial or nonmuscle invasive bladder cancer and invasive carcinoma. Superficial TCC exhibits an overall low risk of progression (to a life-threatening cancer), but recurrences are very frequent. A minority of these recurrences may eventually progress into high-grade disease,

TABLE 80.3 Identified and potential etiologic agents for transitional cell carcinoma

Established risk factors	
Cigarette smoking (black tobacco higher than blond tobacco)	[167, 168]
Phenacetin-containing analgesics	[169–171]
Aromatic amines (painters, rubber industry workers)	[172–174]
Leather workers	
Cyclophosphamide (cumulative dose)	[175, 176]
Ionizing radiation	[177, 178]
Chronic cystitis	[179, 180]
Potential risk factors	
Coffee drinking (large amounts, 7–10 cups a day)	[181, 182]
Hair dyes exposure (hairdressers)	[183]
Artificial sweeteners (saccharin, cyclamates, only in rats)	[184]
Chlorinated water	[185]
Arsenic (in drinking water)	[186]

TABLE 80.4 2010 TMN staging system for carcinoma of the urinary bladder: primary cancer

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Noninvasive papillary carcinoma
Tis	Carcinoma in situ: flat tumor
T1	Cancer invades subepithelial connective tissue
T2	Tumor invades muscularis propria
T2a	Tumor invades superficial muscularis propria (inner half)
T2b	Tumor invades deep muscularis propria (outer half)
T3	Tumor invades perivesical tissue
T3a	Microscopically
T3b	Macroscopically (extravesical mass)
T4	Tumor invades any of the following: prostatic stroma, seminal vesicles, uterus, vagina, pelvic wall, and abdominal wall
T4a	Tumor invades prostatic stroma, uterus, and vagina
T4b	Tumor invades pelvic wall and abdominal wall

which can then be locally invasive. A retrospective review of 761 patients with superficial bladder cancer treated with endoscopic surgical extirpation alone found that only 7% died of bladder cancer, while 15% died from other causes [99]. The management of high-grade/invasive disease in the elderly is costly and challenging (over \$35 million per year) [100]. Treatment options for patients with muscle-invasive disease or recurrent high-grade superficial disease include cystectomy (with or without chemotherapy), radiation and chemotherapy (bladder sparing therapy), and a palliative approach. It is important to understand the difference between a superficial and invasive lesion when considering treatment of a geriatric patient with bladder cancer. The staging system for a primary bladder TCC is shown in Table 80.4 [22].

Superficial Transitional Cell Carcinoma

Approximately 75–80% of all bladders TCCs are classified initially as nonmuscle invasive or superficial. This group of lesions encompasses indolent papillary lesions confined to the urothelium with high recurrence frequency (stage Ta), a poorly differentiated flat cancer called carcinoma in situ (CIS) with higher invasive potential (Tis), and neoplasms invading the lamina propria of the bladder wall (stage T1). Information regarding the recurrence and possible progression of superficial TCC is available after a complete transurethral resection of the bladder tumor (TURBT) has been performed. The pathologic specimen allows incorporation of information regarding the depth of invasion, histologic

TABLE 80.5 Features associated with an increased risk of recurrence or progression

Multiple papillary recurrences (two or more in a given year)
More than three lesions or any tumor >3 cm in diameter, sessile or with a thick stalk
Invasion of the lamina propria (T1 tumor) or poorly differentiated histology (grade 3)
Incomplete resection due to diffuse bladder involvement and/or unfavorable location
Diffuse Tis alone or in association with papillary tumors

grade, and presence or absence of multicentric disease. The remainder of this discussion refers to the biologic behavior of each of these lesions in elderly patients.

Stage and histological grade are central determinants of the disease-specific outcome for superficial TCC [101]. In general terms, a stage Ta lesion exhibits a 50–90% recurrence rate at 5 years with a 2–25% rate of progression to muscle-invasive disease [102–104]. Within this same category (Ta), pathologic grade-1 and 2 cancers exhibit a recurrence rate of approximately 30%, whereas grade-3 lesions recur in over 70% of cases, exemplifying the importance of histologic grade. Many studies have analyzed large retrospective series in an attempt to stratify patients according to their risk of disease recurrence and progression [105–107]. The presence of any feature displayed on Table 80.5 is associated with an increased risk of recurrence or progression. This is encouraging for the geriatric patient with comorbidities who does not present with these risk factors, since they can be managed conservatively. This would involve intermittent resection or even fulguration of recurrent lesions without any additional treatments. In this context, patients who do not develop another tumor within 3 months of the initial resection for TCC have an 80% probability of never demonstrating another tumor in the bladder [102]. However, patients who experience ten or more recurrences exhibit a high rate of progression and death from TCC [108]. Therefore, in this instance, the conservative algorithm for stage Ta TCC with endoscopic resection alone should be complemented by intravesical therapy.

CIS presents as a flat formation of poorly differentiated TCC confined to the mucosal surface of the bladder. This CIS lesion (Tis) may appear as a solitary primary lesion or accompanied by another form of TCC. It has been suggested that the presence of Tis in the mucosa adjacent to a Ta or T1 tumor increases the risk for muscle-invasive disease [109, 110]. Tis may also display a diffuse involvement of the mucosa and extend into the distal ureters or prostatic ducts. This pattern of superficial spread is associated with particularly aggressive disease, with 60–80% progressing to invasive cancer [111, 112]. Common presenting manifestations of CIS include severe irritative voiding symptoms and hematuria. But, many of these patients may be relatively asymptomatic

with only an abnormal finding on urine cytology. Tis lesions have demonstrated a recurrence rate ranging from 63 to 92% after resection and intravesical chemotherapy [113]. In addition to recurrence, the literature supports an especially high rate of progression to invasive disease after endoscopic resection [114]. Therefore, patients with primary or concomitant Tis cannot be treated with endoscopic resection alone, regardless of their age. Intravesical therapy should be used in conjunction with TURBT. If this combination therapy fails to control the disease, cystectomy should be considered in the elderly individual with a good performance status [115].

The final type of superficial TCC is a lesion that invades the lamina propria of the bladder wall but not the muscularis propria. This stage T1 lesion exhibits a high rate of recurrence (67–81%) and progression (12–49%). Patients presenting with this stage disease have a cancer-specific mortality ranging from 17 to 71% [114]. Virtually, all of these tumors are of high grade and require therapy beyond standard endosurgical resection due to the risk of progression [116]. T1 tumors are often treated adjuvantly with instillation of chemotherapeutic or immunotherapeutic agents in addition to endoscopic ablation. The intravesical instillation of *Bacillus Calmette–Guérin* (BCG) has been shown to be efficacious in reducing the recurrence rate by 30–40% [117, 118] and may also reduce progression of T1 tumors [119]. In a series of 86 patients with T1 tumors, a complete response of 91% was demonstrated for the combination of TURBT and intravesical BCG [120]. However, chemotherapy (mitomycin, thiotepa, etc.), on the other hand, has not reliably demonstrated an effect on progression [121]. Elderly individuals with significant comorbidities and solitary T1 disease may comprise a subpopulation of patients for whom endoscopic resection may be adequate. One study evidenced curative rates of 40% for stage T1 TCC, particularly grades 1 and 2, with a single resection and confirmation of complete removal of the lesion on a repeat bladder biopsy [122]. Nevertheless, intravesical immunotherapy in addition to TURBT should be standard practice for T1 lesions in the geriatric population given the high risk for progression and recurrence. One must also verify the lesion to be a true T1 lesion by a repeat resection even when muscle is present in the initial biopsy specimen [123]. Patients who present with recurrent T1 disease within 6 months to 1 year after resection or after one or two courses of BCG should be considered for radical cystectomy [124, 125]. Alternatively, an aggressive approach of early cystectomy for de novo T1 disease has been advocated by one study that compared this approach versus cystectomy for a recurrent T1 lesion. The results suggested that immediate cystectomy at the time of initial diagnosis of a T1 cancer can improve survival [126]. The selection of an adequate therapeutic plan for an elderly patient with T1 TCC must involve performance status, comorbid illness, and impact of the treatment on their quality of life.

Intravesical Therapy

Intravesical therapy permits high local concentrations of a chemotherapeutic or immunotherapeutic agent within the bladder to eradicate residual tumor cells that remain viable after TURBT, thus preventing recurrence. Conceptually, this application is provided after complete resection as a specific strategy against recurrence or progression. Less commonly, intravesical therapy is instituted for residual tumor following incomplete TURBT. These instilled agents may cause symptoms of bladder irritation as a side effect. Furthermore, systemic absorption can occur if the bladder mucosa is damaged and results in systemic toxicity. Treatments, therefore, are generally initiated 2–4 weeks after tumor resection, allowing the reepithelialization of the bladder mucosa.

The most commonly used agent for intravesical therapy is *Bacillus Calmette–Guerin* (BCG). A number of other agents also have activity, including mitomycin, the anthracyclines, thiotepa, gemcitabine, interferon, and docetaxel [127]. Many prospective trials have compared these other intravesical agents with BCG, but none has been shown to be superior [121, 128–130]. The remainder of this discussion focuses on the application of BCG as an intravesical immunotherapy for Ta, Tis, and T1 TCC. Characteristics of the optimal candidates for intravesical therapy are listed in Table 80.6.

Bacillus Calmette–Guérin is a live attenuated *Mycobacterium* that has been found to incite an immune response within the bladder, which appears to be responsible for its therapeutic efficacy against TCC. The immune activation may persist for a number of months facilitating an ongoing antitumor response. In a systematic review that included 585 patients with Ta or T1 disease, administration of intravesical BCG as prophylaxis has been found to reduce tumor recurrence by approximately 54% compared to transurethral resection alone [131]. This effect is also associated with a decreased incidence of tumor progression [119]. BCG has also demonstrated effectiveness when administered as therapy for CIS of the bladder (Tis), with complete response

TABLE 80.6 Characteristics of candidates for intravesical therapy

Indications

Solitary Ta lesion	

rates of 60–79% [132]. The optimal strategy for instillation of BCG consists of a 6-week induction course with maintenance therapy. The largest randomized trial evaluating the effectiveness of BCG induction alone versus induction plus maintenance therapy found a median recurrence-free survival time twice as long in the maintenance arm [133]. Interestingly, only 16% of patients received all eight courses of maintenance therapy over 3 years mainly due to toxicity. One would assume that this strategy represents a challenge for elderly patients who often present with a suboptimal nutritional status and comorbid conditions that may limit their immune response (i.e., diabetes), predisposing them to severe BCG toxicity. At the author's institution, BCG maintenance therapy is the standard intravesical regimen, and the majority of elderly patients complete the full protocol duration with reduction doses if necessary. Lowering the dose of BCG for this population of patients still maintains its efficacy. At a median follow-up of 61 months, one study found no differences between standard or reduced dose BCG with respect to disease recurrence, time to recurrence, need for deferred cystectomy, or disease-specific survival [134]. Severe toxicity rates were lower with the reduced dose. Although these results are encouraging, further confirmatory trials are needed before a reduced dose of BCG can be considered standard therapy in the face of no toxicity. In addition, recent trials have suggested that increased age may confer a less durable response to BCG with earlier recurrences and a shorter cancer-free survival time [135]. These findings highlight the need to investigate the optimal regimen of BCG induction and maintenance in the elderly.

In summary, superficial TCC presents frequently in the aged population often with a protracted natural history and a low risk of progression. Most stage Ta lesions may be managed with endoscopic resection with subsequent outpatient follow-up utilizing cystourethroscopy and urine cytology. Surveillance protocols for such patients often involve cystoscopy every 3 months for 2 years, every 6 months for 2 years, and then every year thereafter. The intensity of this approach may be reduced for individuals in ill health or with favorable lesions at low risk for recurrence and progression. Patients who present with Tis or T1 cancers will benefit from a course of intravesical immunotherapy with BCG, following surgical resection. Again, these patients should be carefully followed with an organized surveillance protocol. Individuals with recurrent or refractory Tis or T1 lesions should be considered for curative radical cystectomy.

Muscle-Invasive TCC of the Bladder

The concept of muscle-invasive disease refers to lesions that have invaded beyond the lamina propria into the muscle

wall of the bladder (stage T2). The literature suggests that approximately 50% of individuals who present with stage T2–T4 TCC will develop distant metastasis within 2 years [136]. Most patients who develop T2 lesions of the bladder present initially with this muscle-invasive disease *de novo* rather than from a previous superficial cancer (Ta–T1). It appears that the proportion of patients with muscle-invasive TCC increases with age. Approximately 18% of patients aged 40–44 years have locally advanced TCC at presentation, whereas 39% of patients over 84 years of age present with this stage disease [137]. As a result, the elderly patient more often faces a life-threatening cancer compared to their younger counterparts. Unfortunately this elderly patient will have a higher surgical risk due to comorbidities. Data extracted from SEER database found that individuals of 75 years of age and older with muscle-invasive bladder cancer had a higher prevalence of cardiac disease, prior cancer diagnosis, chronic anemia and poor American Society of Anesthesiologists Physical Status Classification (ASA) [86]. These factors have a direct impact on treatment choices, especially when surgical options may involve significant morbidity. The evaluation and treatment of this patient with locally advanced TCC will be discussed further.

Locally Advanced Transitional Cell Carcinoma of the Bladder

Radiologic Evaluation

Once the diagnosis of a stage T2 TCC has been established through transurethral biopsy or resection, the patient should be thoroughly examined for evidence of lymphatic or hematogenous spread, as well as invasion into adjacent tissues. The primary sites for the dissemination of TCC include the pelvic lymph nodes (within the obturator and hypogastric regions), lung, liver, and bone. Pertinent radiologic studies include a chest radiograph and an abdominal/ pelvic CT or MRI scan. A bone evaluation with skeletal scintigraphy (bone scan) is indicated in individuals with complaints of musculoskeletal pain or an elevated alkaline phosphatase level [50]. Approximately 5–15% of patients with invasive TCC harbor metastatic bone lesions, which obviate an attempt at curative (surgical) therapy.

Computed tomography is about 80% accurate in differentiating locally advanced tumors involving perivesical fat or surrounding structures from those with less invasive tumors. However, since CT is often performed after a transurethral resection, interpretation of perivesical fat invasion becomes involved. It may be difficult to distinguish inflammatory or postsurgical edematous changes from true extravesical tumor extension. Another important limitation of CT is that it may

miss tumors <1 cm in size, particularly those in the bladder trigone or dome. Tumors located in these areas may be better evaluated by gadolinium-enhanced MRI, which may also be superior to CT in detecting extravesical tumor extension and surrounding organ invasion [138–140]. The use of positron emission tomography (PET) in the evaluation of patients with localized TCC remains investigational, largely due to confounding factors from urinary excretion of the glucose-labeled tracers. MRI may ultimately be the preferred study over CT in the older patients since they often present with a suboptimal creatinine clearance. A discussion of contrast-induced nephropathy is detailed in the radiologic section of renal cell cancer.

Treatment

Therapeutic approaches to muscle-invasive TCC of the bladder are determined by the presence or absence of clinically detectable lymphatic or hematogenous metastases. Multimodality curative therapy should be applied only in individuals whose cancers are confined to the bladder wall or associated with minimal-volume regional lymphatic disease. We discuss next the therapeutic alternatives for patients with locally advanced TCC and the use of radical surgery in elderly patients.

Surgical Therapy

The perioperative morbidity associated with radical cystectomy and the substantial impact of urinary diversion on the quality of life has led to the use of less radical approaches for the management of muscle-invasive bladder cancer in the elderly. Alternatives to radical cystectomy include radical transurethral resection (TURBT), partial cystectomy, or chemotherapy/radiation, which combines radical TURBT followed by external-beam radiation therapy with concurrent chemotherapy (cisplatin used as a radiation-sensitizing agent). In general, bladder preservation approaches are considered by many to produce inferior oncologic outcomes compared to radical cystectomy, although this has not been proven in randomized trials. It appears that solitary tumors confined to the muscle wall are ideal candidates for these alternative treatments with intermediate and long-term cancer-specific survival rates approaching that of radical cystectomy. An attempt at complete endoscopic resection of a solid muscle-infiltrating lesion within the bladder represents the most conservative surgical treatment approach. The role of definitive TURBT was illustrated by a retrospective series where 10-year cancer-specific survival rates were similar to those seen with radical cystectomy (76% versus 71%) [141]. However, radical TURBT is applicable only to a small

minority of patients with muscle-invasive disease and demands intensive, long-term cystoscopic follow-up due to local recurrence. This follow-up may represent a challenge for the geriatric population which according to the SEER data has shown suboptimal adherence to surveillance recommendations [142]. Another surgical option, the partial cystectomy, allows complete pathologic staging of the primary tumor with an extended pelvic lymph node dissection. This technique preserves urinary function and avoids the need for diversion, therefore minimizing the impact on the elderly patient's quality of life. As with the radical TURBT, only a few patients are optimal candidates for this partial resection, and the risk of recurrent tumor in the residual bladder remains.

Complete surgical extirpation with radical cystectomy remains the treatment of choice for locally advanced TCC in patients of all age groups. The contemporary surgical approach includes thorough pelvic lymph node dissection followed by complete removal of the bladder, uterus, and anterior vaginal wall in women or bladder with the prostate and seminal vesicles in men. A urinary diversion with either an ileal conduit (noncontinent) or a continent reservoir (orthotopic or nonorthotopic) is constructed following the cystectomy. Skinner and Lieskovsky reported a series of 197 patients in 1984 who had 5-year survival rates of 75% with pT2–T3a disease, 44% with pT3b, and 36% with stage pT4 or positive pelvic lymph nodes [143]. Importantly, the postoperative survival was not affected by application of preoperative radiation therapy. In addition, radiotherapy prior to surgery increases the risk of operative complications and makes the creation of an internal urinary reservoir using irradiated bowel more difficult [144, 145]. Therefore, radical cystectomy alone has become established as satisfactory monotherapy for most patients with locally advanced TCC of the bladder. The impact on survival from a radical cystectomy performed in a healthy surgical patient is clear. The benefit of this extensive surgery, as we age, depends largely on competing risks for death.

In the elderly individual, who typically carries a high burden of comorbid diseases and disability, the benefit of radical cystectomy versus radiation therapy is less dramatic. The largest case series involving contemporary data evaluated the benefit of cystectomy in different age groups (<60, 60–69, 70–79, >79), without correlating outcomes to physiologic measures, such as performance status [146]. A total of 8,034 patients underwent cystectomy, while 2,077 had radiation therapy as their primary treatment for muscle-invasive TCC. They found that older patients were less likely to have a cystectomy and that a sizeable survival advantage was seen with cystectomy in all age groups except for the octogenarian (15 versus 18 months). The small benefit of cystectomy was lost when the elderly patient had a limited or no pelvic node dissection, highlighting the importance of a full lymph node

dissection in locally advanced TCC. Another multicenter trial evaluated 888 patients over a 19-year period [147]. Thirty percent of the patients were 70–80 years of age, but only 6% were over 80. Age was an independent predictor for adverse outcomes. Currently, only two small studies have utilized functional geriatric assessment as it relates to radical cystectomy outcomes. Weizer et al. correlated a Karnofsky Performance Status (KPS) score with cystectomy in one hundred and six patients with muscle-invasive disease. Patients with a KPS score below 80 had an overall 4-year survival of 14% versus 33% for those with a KPS score above 80 [148]. This functional assessment tool was validated as the only independent predictor of overall survival in a multivariable analysis that included age, marital status, treatment type, mobility, and stage. In another retrospective study of 44 patients over 80 years of age, the 6-month rehospitalization rate was higher when accompanied by a drop in KPS score from 70 to 65 at 1 and 3 months following surgery [149]. These findings demonstrate the importance of functional age of the patient in contrast to their chronologic age when dealing with muscle-invasive TCC. It is, therefore, not justified to withhold a potentially curative therapy such as radical cystectomy on the basis of age alone.

Historically, many individuals are willing to undergo intensive therapy and endure significant morbidity if the likelihood of cure from a disease is high. As discussed earlier, the ability to eradicate bladder cancer is directly related to the stage at presentation, particularly the presence or absence of lymphatic metastasis. Most reports demonstrate that lymph node metastasis at the time of radical cystectomy is associated with a 6–23% 5-year survival [150]. For the elderly patient with an otherwise asymptomatic stage T2–T4 bladder cancer with borderline nodal enlargement on CT, an accurate identification of lymphatic disease could dissuade them from undergoing radical cystectomy and make more palliative approaches attractive. In this regard, minimally invasive laparoscopic techniques can be employed for accurate pelvic lymph node staging. Accumulating evidence has shown that the standard template for pelvic node dissection (distal common iliac, obturator, hypogastric, and external iliac nodes) is inadequate [151]. Lymph nodes proximal to the origin of the inferior mesenteric artery and presacral lymph nodes have been included in an extended template dissection. This minimally invasive technique with an expanded dissection may identify those patients harboring metastatic deposits within the lymphatic drainage of the bladder, thus avoiding the morbidity of radical cystectomy for a cancer with poor prognosis.

Finally, minimally invasive alternatives such as laparoscopic radical cystectomy or robotic-assisted radical laparoscopic cystectomy, with the potential for reduced morbidity and more rapid convalescence, are being adopted in many centers worldwide. Reports have demonstrated the technical reproducibility and safety of these techniques, although

extensive experience with these procedures is required to achieve optimal results. Advantages include faster reactivation of gastrointestinal motility and shorter hospital length of stay. Although this appears as a promising alternative for the geriatric population, data regarding the long-term oncologic outcomes is lacking at the present time, especially with regard to the adequacy of the pelvic lymph node dissection by these techniques [152, 153].

Multimodality Therapy for Advanced TCC of the Bladder

Chemotherapy is widely used for therapy in advanced or metastatic bladder cancer and remains an area of active research as an adjuvant or neoadjuvant treatment with definitive local therapy. Further applications of systemic chemotherapy include the development of multimodality treatment protocols for curative therapy with bladder preservation. Since Sternberg et al.'s original report of a 72% response rate in metastatic bladder cancer patients using methotrexate/vinblastine/doxorubicin/cisplatin (M-VAC) [154], the incorporation of newer and highly active agents, such as gemcitabine and paclitaxel, has led to the development of new combination regimens. Multiple randomized studies have demonstrated the superiority of the M-VAC regimen versus other combination regimens positioning M-VAC as the standard first-line regimen [155–157]. However, the regimen employs agents whose excretion and distribution can be affected by age-related physiologic changes. Age alone should not preclude the use of M-VAC; careful evaluation of nutritional state, cardiac and renal function, and screening for underlying neuropathy is paramount to the safe delivery of this combination of drugs.

Gemcitabine has been identified as a highly active single agent in nonrandomized studies for untreated patients with metastatic urothelial carcinoma [158]. This drug was further combined with cisplatin in the GC regimen, showing response rates as efficacious as the ones achieved by the M-VAC regimen. These studies have made GC the new standard first-line therapy especially in regard to tolerability. However, elderly patients may not be fit for intensive cisplatin-based chemotherapy regimens. A retrospective review of 381 patients with advanced urothelial carcinoma who were treated with one of several platinum-based regimens identified 116 who were ≥ 70 years of age [159]. The elderly experienced more frequent neutropenia and renal toxicity compared to patients < 70 years of age. However, toxic death rates were similar in both age groups, and median survival did not differ significantly. Single-agent regimens with gemcitabine or paclitaxel and various two-drug combinations in which carboplatin, whose dose can be adjusted for individual variation in renal function, is substituted for cisplatin have been found to be feasible and have activity in

older populations [160–162]. The efficacy of these systemic agents have stimulated investigations into neoadjuvant or adjuvant protocols for locally advanced TCC associated with poor prognostic factors. Multiple large randomized clinical trials and individual patient data meta-analysis have demonstrated a survival benefit for neoadjuvant cisplatin-based regimens, shifting the algorithm of treatment from cystectomy alone [163, 164]. In contrast, definitive recommendations on the use of adjuvant chemotherapy for patients with locally advanced urothelial bladder cancer still require the completion of large randomized trials.

The clinical response of metastatic TCC to systemic chemotherapeutic agents has stimulated the design of investigational protocols with the intention to eradicate locally advanced TCC while preserving bladder function. These bladder-sparing approaches combine the efficacy of an aggressive transurethral resection with external beam radiation therapy and systemic chemotherapy. Although irradiation has demonstrated only modest efficacy as monotherapy, several investigators have advocated its role in a multimodality approach [165]. One study of 94 patients with T2–T4 TCC treated with endoscopic resection followed by two or three cycles of M-VAC or CMV with subsequent 6480 cCy radiation to the bladder was reported in 1995. The 5-year relapse-free survival was 84% for T2, 53% for T3, and 11% for T4 cancers. Importantly, only 18% of the surviving patients had an intact bladder [166]. Bladder preservation is an admirable goal for the healthy individual with an early invasive T2 lesion within the bladder, but it appears that most patients who are cured by this approach ultimately require a radical cystectomy. The older

patient must be prepared to submit to the toxicity of the combined therapy while maintaining the potential requirement of a radical cystectomy. Therefore, multimodality therapy for TCC must be considered experimental for patients of all ages, particularly for the person over 70 years of age.

Conclusions

Improvements in diagnostic imaging, surgical techniques, advanced instrumentation, and systemic chemotherapy have been combined to offer older individuals a wide array of treatment options for renal and bladder malignancies. However, the myriad issues confronting these people serve only to complicate the choice of therapy. The literature suggests that aging may affect negatively the treatment response of superficial disease and the outcomes of curative surgery. Comprehensive geriatric assessment tools that incorporate not only age but also physiologic and biologic considerations, such as comorbidities, functional status, renal function, and hemoglobin are necessary to help stratify the elderly into “fit” and “frail” populations, allowing tailoring of appropriate therapy. Clinicians must avoid the unconscious bias against curative treatment for an elderly individual and thoroughly address all potential options and the impact of these in the patient’s context of quality of life. Age-specific investigations in conjunction with comprehensive assessment tools are needed before the best treatment options for geriatric patients are identified.

CASE STUDY

Mr. M who initially presented as a 75-year-old male with multiple medical problems including a history significant for coronary artery disease, on ultrasound for right upper quadrant pain, was found to have a 3-cm solid mass in the right lower pole of the kidney. This mass was verified as “enhancing” by a gadolinium-enhanced magnetic resonance imaging (MRI), which was substituted for computed tomography (CT) due to a history of chronic renal insufficiency with a glomerular filtration rate (GFR) of 35 mL/min. All other testing including chest radiograph and blood laboratories were negative for evidence of metastatic disease. Preoperative cardiology evaluation placed him at high risk for a post-surgical event due to his coronary artery disease. The patient was counseled regarding the options for this likely malignant renal mass which included conservative

management (surveillance with serial imaging), surgical removal (radical/partial nephrectomy), and new minimally invasive techniques (cryotherapy, radiofrequency ablation). Although the patient was at high risk for open surgery, he was not comfortable following this lesion and wished to have curative treatment. Percutaneous cryotherapy was performed (Fig. 80.2) under local anesthetic with no sedation. The lesion was biopsied during the procedure which revealed a clear cell renal carcinoma – intermediate grade. The procedure was uneventful, and the patient was discharged on the same day.

Mr. M is currently 80 years old with stable coronary artery disease and still very active. All posttreatment imaging since the procedure show “no enhancement” which is consistent with successful treatment. This case highlights the many factors that must be considered when treating genitourinary malignancies in the elderly population.

Chapter 81

Benign and Malignant Diseases of the Prostate

John A. Taylor III and Peter C. Albertsen

CASE STUDY

An 82-year-old gentleman presents to his urologist with worsening LUTS in spite of combined medical therapy with Flomax and Proscar. His symptoms have become more of an obstructive nature with decreased force of stream, intermittency and need to strain. He is relatively healthy otherwise with only a-fib and HTN managed medically.

His evaluation reveals a flow rate of 6 ml/s with a post-void residual of 250 cc. His rectal exam reveals a very large prostate, which is benign in nature. His PSA, which had been stable at 3.4 ng/ml, has risen in the past year to 5.0 ng/ml. Urodynamic evaluation shows decreased detrusor contractility with borderline obstructive values. He is counseled on options including conservative

management or a TURP. He is very concerned about his PSA results and has heard that Proscar can lead to high-grade prostate cancer. Prostate biopsy is discussed, which he chooses to proceed with in light of his desire to pursue aggressive treatment for his urinary symptoms.

He undergoes a 12 core transrectal biopsy which reveals <5% of one core with Gleason 3+3=6 disease. He is counseled on active surveillance, hormone ablation therapy, and external beam radiation in light of his advanced age. He is interested in discussing a robotic prostatectomy as his son just had one at 60. After a long discussion, he agrees to active surveillance. He ultimately undergoes a TURP for his progressive LUTS with good results and all benign tissue found pathologically. He eventually passes from a CVA 10 years later at 92.

Introduction

Benign prostatic hyperplasia (BPH) and prostate cancer are two common neoplastic processes that occur in elderly men. Both of these conditions are rare before the age of 50, but by age 80 more than 80% of men have pathologic evidence of benign hyperplasia and more than 50% have at least microscopic foci of prostate cancer [1, 2]. While BPH associated urinary symptoms will impact quality of life in most elderly men, the likelihood of prostate cancer resulting in significant morbidity remains low [3, 4]. This chapter reviews the incidence of these two diseases, the appropriate evaluation of elderly men and surgical options available to the geriatric patient as well as expected outcomes.

General Anatomical Considerations

The prostate is a glandular organ situated in the pelvis. The base of the prostate is in continuity with the bladder and the apex rests on the pelvic floor. It is composed predominantly of glandular elements with an investing fibromuscular stroma. The latter forms a capsule around the gland which is a unique feature of the human prostate [5]. The urethra runs through the gland with anterior angulation at the veru montanum, representing the exit site of the ejaculatory ducts. The prostate can be defined by anatomical zones (Fig. 81.1) or surgical lobes (Fig. 81.2), which have relevance to both BPH and prostate cancer.

Distinct zones are described based predominantly on the ductal drainage site within the urethra. The transition zone consists of periurethral tissue situated proximal to the veru montanum. The central zone surrounds the ejaculatory ducts, extending posteriorly to the bladder base. The posterior zone encompasses the remainder of tissue posterior to these two

FIGURE 81.1 Zonal anatomy of the prostate as described by McNeal. (From McNeal JE. Normal histology of the prostate. *Am J Surg Pathol* 1988;12:619–633).

FIGURE 81.2 Surgical anatomy of the prostate. (Adapted from Gillenwater JY, ed: *Adult and Pediatric Urology*. St Louis: Mosby Yearbook, 1991:1214).

areas adjacent to the rectal vault and makes up the bulk of the nonpathologic gland. The anterior fibromuscular stroma is devoid of glandular elements and runs from the anterior bladder neck to the pelvic floor.

While BPH arises almost exclusively from the transition zone, 70% of prostate cancers originate in the posterior zone,

with approximately 25 and 5% of cases stemming from the transition and central zones, respectively. Surgical lobes have also been described in relation to BPH. Lateral lobes are typically seen on cystoscopy as bilaterally bulging elements impinging on the prostatic urethra. A middle or central lobe represents the hyperplastic component that protrudes

superiorly into the floor of the bladder, sometimes creating a perceived ball-valve effect on voiding.

Benign Prostatic Hyperplasia

Terminology

In order to understand the diagnostic and treatment dilemmas facing practitioners caring for the elderly gentleman with BPH, it is important to have working knowledge of the historical terminology used to describe the clinical symptoms. "BPH" represented an acronym for benign prostatic hypertrophy, as the majority of men with urinary symptoms were found to have enlarged prostates. However, from a histologic standpoint, the growth of the gland represents a hyperplastic process with increase in both glandular and stromal elements. Two problems with this new terminology were: (1) hyperplasia has been noted in prostates from men in their third decade of life who exhibit no urinary symptoms and (2) a linear correlation between prostate size and degree of urinary symptoms does not exist. Several other acronyms can be encountered that represent attempts to circumvent these issues. BPE (benign prostatic enlargement) and BOO (bladder outlet obstruction) represent such examples. Although BOO is pathophysiologically correct with regards to the underlying process, it remains a urodynamically defined element thus requiring a semi-invasive and costly test typically not viewed as necessary for treatment or diagnostic purposes. In order to get back to the clinical picture which leads patients to seek treatment yet another acronym was coined being LUTS (lower urinary tract symptoms). This covered the constellation of symptoms (urgency, frequency, hesitancy, intermittency, straining, sense of incomplete emptying, and nocturia) that were associated with the original "BPH." However, LUTS may be resultant from a diverse list of diagnoses not limited to the obstructive processes of an enlarged prostate [6]. Today ICD-9 coding includes both BPH with and BPH without LUTS.

Epidemiology

The prostate is small at birth, enlarges rapidly at onset of puberty, and then remains at a constant size during the next several decades of life. The average weight of the prostate slowly increases after 50 years of age with an associated increase in the incidence of symptomatic BPH (Fig. 81.3). Although the development of pathologic BPH is almost a universal phenomenon in aging men, the cause and

FIGURE 81.3 Development of human benign prostatic hyperplasia (BPH) with age: age-related changes in the weight of the prostate removed at autopsy in 925 men, prevalence of BP hyperplasia at autopsy in 1,075 men, and the weight of the adenoma removed at simple perineal prostatectomy in 707 men. Long dashed line indicates the mathematically extrapolated range in this group (From Berry et al. [1] with permission. Copyright Elsevier 1984).

pathogenesis of this disorder are poorly understood. While genetic susceptibility may play a role in younger patients, the relevance dramatically diminishes for those over 60. Androgens are recognized as necessary for the development of pathologic BPH; however, they are not the cause of BPH. While individuals castrated prior to puberty do not develop pathologic BPH, prostate size can continue to increase with age when androgen levels typically decline, suggesting little correlation between the two [7]. Several researchers have suggested that estrogen may contribute to the pathogenesis of BPH, but the alterations in estrogen and androgen production that occur with aging appear to be minor and occur after the onset of this disease [8]. Several other risk factors have been proposed, but to date there is no evidence to suggest that BPH can be attributed to any specific factor [9]. Researchers have investigated sociocultural variables including celibacy, specific blood groups, the use of alcohol or tobacco, and diseases commonly found among geriatric men such as coronary artery disease, peripheral vascular disease, hypertension, and diabetes.

Pathophysiology

The pathophysiology of symptomatic BPH is complex involving both static and dynamic components (Fig. 81.4). BPH is a true hyperplastic process with histologic studies demonstrating an increase in cell numbers throughout the gland. Hyperplasia occurs in the form of nodules that consist of stromal and epithelial elements. In addition, many nodules contain smooth muscle. Prostatic hyperplasia increases

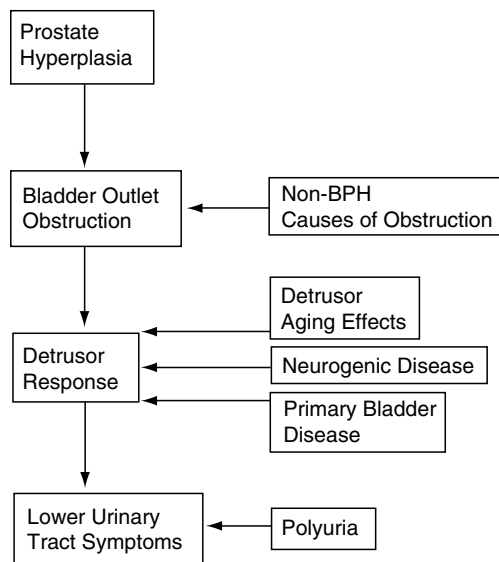

FIGURE 81.4 The pathophysiology of symptomatic BPH involves complex interactions between urethral obstruction, detrusor function, and urine production. (From McConnell JD (1998) Epidemiology, etiology, pathophysiology and diagnosis of BPH. In: Walsh RC, Retik AB, Vaughan ED Jr, Wein AJ (eds) Campbell's Urology, vol 2, 7th edn. WB Saunders, Philadelphia, 1437. Copyright Elsevier 1998.).

urethral resistance due to mechanical obstruction from tissue expansion. Presumably, the confinement created by the capsule transmits pressure to the urethra leading not only to increased resistance but also compensatory changes in bladder function. How the smooth muscle tissue contributes to symptomatic BPH is unknown, but the muscle fibers are regulated by the adrenergic nervous system. Receptor binding studies indicate that α receptors are the most abundant type of receptor in the human prostate and partially explain the ability of α -blocking medications to relieve BPH-associated LUTS.

In addition, age-related functional changes in the bladder and nervous system have been reported to contribute to LUTS. At the ultrastructural level, normative aging and BOO both result in muscle loss and axonal degeneration with increased collagen deposition [10]. This can lead to both hyperactivity and impaired contractility, which manifest with clinical symptoms associated with symptomatic BPH. It is interesting to note that clinical LUTS are as common in age-matched women as they are in men.

Diagnosis and Evaluation of Prostate Disease

Benign Prostatic Hyperplasia

Physicians evaluating elderly men for obstructive urinary symptoms should begin with a detailed history that focuses on the urinary tract, previous surgical procedures, general

health issues, and fitness for possible surgical procedures. Specific areas to discuss include a history of hematuria, urinary tract infection, diabetes, neurologic disorders such as Parkinson's disease or previous stroke, urethral stricture disease, urinary retention, and aggravation of symptoms by cold or sinus medications. Physicians should check all current prescription medications to determine whether the patient is taking any anticholinergic drugs (which impair bladder contractility) or α -sympathomimetics (which increase outflow resistance). A history of lower urinary tract surgery suggests the possibility of urethral or bladder neck stricture.

The etiology of LUTS is multifactorial, and specific symptoms may be a poor indicator of underlying pathophysiology. This is particularly true in the elderly patient. While LUTS are most often attributed to prostatic obstruction, only two-thirds of men with LUTS meet the accepted diagnostic criteria for obstruction. Obstructive symptoms (hesitancy, weakened stream, intermittency, straining, and sense of incomplete emptying) do not reliably predict outlet obstruction. Researchers' have shown that many aspects of detrusor performance decline with aging and progress to detrusor underactivity (DU) in many older individuals [11–14]. DU can influence the clinical picture and may impede the therapy of many LUT disorders including BPH.

Other contributing processes include detrusor overactivity, sensory urgency, sphincteric incontinence, polyuria, or nocturnal polyuria [15]. Nocturia may also result from a wide range of other pathologic conditions, including cardiovascular disease, diabetes mellitus, lower urinary tract obstruction, anxiety, sleep disorders, and other behavioral and/or environmental factors [16]. The use of certain drugs is also associated with increased risk for LUTS. A community-based cross-sectional study that included 2,115 men between 40 and 79 years found that daily use of antidepressants or antihistamines was associated with an increase in symptoms [17].

A tool for symptom assessment has been established and permits objective data for evaluation that can be followed in a longitudinal manner. This is the International Prostate Symptom Score (IPSS) [18] (Table 81.1). This instrument consists of a series of seven questions, correlating to common LUTS that have five-graded responses. Symptoms are considered mild, moderate, and severe with scores between 0 and 7, 8 and 19, and 20 and 35, respectively. The IPSS should not be used to diagnose symptomatic BPH, but rather to evaluate treatment response or disease progression. Symptom scores alone do not capture the morbidity of a prostate problem as perceived by the patient. The impact of symptoms on a patient's life style must be considered as well. Intervening with medical or surgical therapy may make more sense in a patient with moderate symptoms he finds relatively troublesome compared with a patient with severe symptoms who is able to manage them fairly well. Thus, the

TABLE 81.1 International prostate symptom score (I-PSS)

Criterion	Not at all	Less than 1 time in 5	Less than half the time	About half the time	More than half the time	Almost always	Your score
Incomplete emptying: Over the past month, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0	1	2	3	4	5	
Frequency: Over the past month, how often have you had to urinate again less than 2 hours after you finished urinating?	0	1	2	3	4	5	
Intermittency: Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5	
Urgency: Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5	
Weak stream: Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5	
Straining: Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5	
Nocturia: Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	0	1	2	3	4	5	
Total I-PSS score							

critical question for all patients is how much bother these symptoms create and what are they willing to do to improve them. In addition, use of a voiding diary may help to identify patients with polyuria or other nonprostatic disorders.

The physical examination should include a digital rectal examination (DRE) and a focused neurologic examination. The rectal examination establishes the approximate size of the gland and can help to guide which surgical approach is most appropriate should this be warranted. Because prostate size does not correlate with symptom severity or treatment outcomes, and DRE typically underestimates size by 50%, size by DRE should not be used to make a diagnosis and proceed with treatment. The DRE is helpful only for guiding management. A focused neurologic examination can be used to exclude neurologic problems that may cause the presenting symptoms and should include an assessment of rectal sphincter tone.

Diagnostic tools that should be considered when assessing men with moderate or severe urinary symptoms include urinalysis, measurement of serum creatinine, and possibly a prostate specific antigen (PSA) assay. Urinary cytology should be considered in men with severe irritative symptoms and those with hematuria, especially if they have a history of smoking. Patients with renal insufficiency have an increased risk for postoperative complications: 25 versus 17% for patients without renal insufficiency [19]. More important, patients with renal insufficiency have a sixfold increase in

mortality when undergoing surgical treatment for their disease [20]. Although localized prostate cancer typically does not produce urethral obstruction, it can coexist with BPH. Consequently, physicians may wish to consider assessing the serum PSA level should a diagnosis of prostate cancer alter the proposed management. Many patients advised to undergo surgical treatment may have cystoscopy and or a transrectal ultrasound. These examinations are not recommended to determine the need for surgery, but rather to help the surgeon determine the most appropriate technical approach based on prostate size. Finally, formal urodynamic evaluation should be considered in elderly gentlemen who maintain high postvoid residuals, have a known or suspected neurologic disease that may affect the urinary tract or have persistent symptoms after an invasive procedure.

Treatment of Benign Prostatic Hyperplasia

Most men with moderate-to-severe BPH-associated LUTS are advised to consider medical therapy. Those failing medical treatments are then usually offered surgery. Absolute indications for surgery include refractory urinary retention, recurrent urinary infections, recurrent gross hematuria, bladder stones, renal insufficiency caused by obstruction, and the concomitant presence of a large bladder diverticulum.

Urologists have developed several surgical procedures to manage BPH. Open surgical excision, known as a simple prostatectomy, was developed more than 100 years ago. Although surgeons still utilize this approach to remove large glands, most urologists now favor transurethral resection of the prostate (TURP). In 1986, it was reported that 96% of the more than 350,000 men requiring surgical therapy for BPH had a TURP. The advent of medical therapies and less invasive office-based procedures to treat BPH have decreased the frequency of this procedure, so fewer than 200,000 men in the Medicare age group now undergo TURP annually.

Although TURP is considered the standard surgical procedure for treatment of BPH, the associated historical morbidity and related costs of hospitalization have prompted the development of several alternative surgical procedures. The majority involve a form of thermal energy transfer to the tissue which causes necrosis and desiccation with time.

Transurethral Resection of the Prostate

TURP is usually considered the treatment of choice for patients with glands less than 100 g in size. The procedure is typically performed under a spinal or general anesthetic with the patient placed in the lithotomy position. Because urinary tract infections are found in 8–24% of men with symptomatic BPH, many are initially treated with antibiotics and most receive a prophylactic dose prior to initiating surgery. The resection is normally conducted in a fluid medium. Water can be used, but it increases the risk of hemolysis; hence nonhemolytic solutions such as 1.5% glycine, sorbitol, or mannitol are more commonly employed.

The resection technique varies according to the size and configuration of the prostate. The ventral tissue is usually resected first unless the patient has a large median lobe in which case this is done first. Resection is carried out in a circumferential manner from the bladder neck to just proximal to the veru montanum. Resection beyond this point risks damage to the external urinary sphincter. The majority of hyperplastic tissue exists between the 3 and 9 o'clock position with less noted anteriorly. The amount of intraoperative bleeding depends on the size of the prostate, the length of time required to resect the hyperplastic tissue, and the skill of the surgeon. Arterial bleeding is controlled by electrocoagulation. Venous bleeding may be apparent at the end of the procedure, when on irrigating the catheter the returning fluid initially clears but then turns dark red. Venous bleeding can be controlled by inserting a catheter and placing it on traction for several minutes. Extravasation occurs in approximately 2% of patients, usually following capsular penetration. The symptoms associated with extravasation and fluid absorption include nausea, vomiting, and abdominal pain. Most of these patients can be managed simply by

terminating the procedure and placing a urethral catheter. Patients who absorb large amounts of fluid can become severely hyponatremic and may require treatment with hypertonic saline and diuretics.

Over the past 50 years, there has been a steady decline in postoperative complications and mortality associated with TURP. These improvements can be attributed to several factors, including better medical management, better anesthesia, and better surgical equipment including improvements in optics and light sources. Wasson et al. reported that 91% of men undergoing TURP in the Veterans Affairs health care system experienced no complication during the first 30 days after surgery [21]. The mortality rate due to surgery was less than 1%. The most frequent complications reported included the need for catheter exchange (4%), perforation of the prostatic capsule (2%), and hemorrhage requiring transfusion (1%). Long-term complications at 3 years associated with TURP include vesicle neck contracture requiring endoscopic surgery (3%), urethral stricture requiring dilation (3%), and secondary transurethral resection (3%).

Results can be immediate or delayed and are the criteria against which all other treatment options are compared. Improvement in flow rates can be on the magnitude of 120% with decreases in IPSS of 85%. Patients with acute (AUR) or chronic urinary retention (CUR) may not fare as well. TURP can fail to restore spontaneous voiding in 10% of patients with AUR, 38% of those with CUR, and 44% with AUR or CUR. This is of particular concern in the elderly when the presence of DU is known to occur.

Simple Prostatectomy

Open prostatectomy is usually considered when the prostate gland is approximately 100 g or larger. This procedure should also be considered when other concomitant bladder conditions are present, such as a large diverticulum or a large, hard bladder calculus. The advantage of open prostatectomy is a complete removal of the adenomatous tissue under direct vision without the risk of dilutional hyponatremia, which is often associated with a prolonged transurethral resection. The disadvantages include the need for a lower abdominal incision, a longer hospitalization, and an extended convalescence period. In addition, there may be an increased potential for intraoperative hemorrhage from the prostate fossa. Contraindications to this operation include a small prostate gland, a previous prostatectomy, previous pelvic surgery, and prostate cancer.

An open prostatectomy can be accomplished using one of two approaches: retropubic or suprapubic. With the retropubic approach, the anterior prostatic capsule is incised and the hyperplastic adenoma enucleated. Advantages to approach include excellent anatomic exposure of the adenoma,

precise transection of the urethra distally, clear and immediate visualization of the prostate fossa to control hemorrhage, and minimal trauma to the urinary bladder. The disadvantages of this approach include the inability to access the bladder and difficulty dealing with a large median lobe.

A suprapubic prostatectomy is accomplished through an extraperitoneal incision in the lower anterior bladder wall. The bladder neck and prostate capsule are scored under direct vision and the adenomatous tissue enucleated. The urethra at the apex of the adenoma is transected sharply under surgeon feel. The major advantage of this procedure over the retropubic approach is that it allows better visualization of the bladder neck and bladder including the ureteral orifices. As a result, this operation is ideally suited for patients with a large median lobe protruding into the bladder, a concomitant symptomatic bladder diverticulum, or a large bladder calculus. It also may be the preferred approach in obese men when it is difficult to gain direct access to the prostate capsule and the dorsal vein complex. The major disadvantage of this approach is the inability to visualize the apical portion of the prostate directly. Contemporary series shows a 60% improvement in obstructive symptoms and approximately 50% improvement in irritative symptoms [22].

Minimally Invasive Surgical Techniques

TUIP

Transurethral incision of the prostate capsule results in significant alleviation of the outflow obstruction, despite the fact that the volume of the prostate remains the same. This involves either unilateral or bilateral incisions, at the 5 and 7 o'clock positions, starting distal to the ureteral orifice ending just proximal to the veru. The depth of the incision is generally described as down to the prostatic capsule. This has been considered an alternative to formal resection in elderly patients who are not deemed medical candidates for more invasive procedures. A meta-analysis of available studies reported similar outcomes as for TURP with a trend toward lower complication and mortality rates [23].

Multiple minimally invasive therapies have been developed. The majority of these involve energy transfer to the prostate causing tissue heating. Treated areas are either vaporized due to high temperatures or develop coagulation necrosis and slough after several days to weeks. Heat generating elements include lasers (Green light, holmium, Nd-Yag, and interstitial), high-intensity focused ultrasound (HIFU), or transurethral microwave thermotherapy (TUMT). Most of these procedures involve delivery of energy through a catheter placed transurethrally or under direct vision cystoscopically. The treatment area can be as long as 40 mm, as wide as 10 mm, and as deep as 10 mm.

Thermotherapy can alleviate voiding symptoms by utilizing a wide range of temperatures. As the intraprostatic temperature rises with the use of higher power devices, more tissue is destroyed, cavities are produced, and more sedation and analgesia are required. Up to 80% of patients experience urinary retention after thermotherapy at high temperature settings. Usually a catheter is placed and may be needed for up to 3 weeks. Patients undergoing these procedures appear to have some reduction in their voiding symptoms, but results are usually less dramatic than are achieved by transurethral resection. Greater symptom improvement usually occurs following treatment with devices delivering higher temperatures. Unfortunately, long-term results are unavailable for many of these procedures. Their role in the treatment of geriatric patients with symptomatic BPH remains to be defined.

Prostate Cancer

Epidemiology

Prostate cancer is now the second most common cancer diagnosed in men. The incidence of this disease increased dramatically following the introduction of testing for prostate-specific antigen (PSA), but has declined somewhat since 1993 to rates that are about twice those recorded prior to the introduction of PSA testing (Fig. 81.5) [24]. Researchers estimated that in 2008, approximately 186,520 men would be diagnosed with this disease and 28,660 men would die from prostate cancer [25]. Prostate cancer is primarily a disease of old men. The probability of developing prostate cancer is about one in seven for men aged 70 and older as compared to one in 15 for men aged 60–69 and one in 39 for men aged 40–59 [25]. The majority of prostate cancer deaths (53%) occur among men age 80 and over [25]. Prostate cancer occurs much more frequently among African-American men than in white Americans. Although the incidence rates are parallel for Whites and African-Americans, the mortality from this disease is almost twice as high for African-American men as for white men.

Despite the significant mortality from prostate cancer, many men never experience symptoms from their disease. Many prostate cancers are indolent. Autopsy data from several countries have confirmed a high incidence of prostate cancer histology, suggesting that less than 1% of men with histologically identifiable cancer die from this disease [26]. There is little geographic or ethnic variability in the rate of small latent carcinomas even when comparing populations with markedly different clinical prostate cancer incidences and mortalities [27, 28]. Numerous studies have demonstrated that as many as 50% of men over the age of 50 years

dying of causes other than prostate cancer have microscopic evidence of disease. These studies also demonstrated that the presence of these cancers increases with age. By age 75 years, more than 80% of men have microscopic evidence of prostate cancer at autopsy. Most of these tumors are microscopic foci fulfilling the criterion for prostate cancer, but it is not unusual for an 80-year-old American man dying of heart disease to have an intraprostatic tumor measuring 2–4 cm [29].

The etiology of prostate cancer is unknown. The similar prevalence of latent disease among racial and ethnic groups at autopsy and the vast difference in the incidence of clinically significant disease suggest that the initiation of prostate cancer occurs frequently, but only some groups are susceptible to prostate cancer promoters. Known risk factors include familial inheritance. Several families have been identified with an apparent Mendelian pattern of inheritance, and several prostate oncogenes have been isolated [30]. A man with one first-degree relative with prostate cancer has a two- to threefold risk of being diagnosed with prostate cancer compared with the general population. A man with a first-degree and a second-degree relative may have a sixfold risk of developing prostate cancer [31].

Screening for prostate cancer remains controversial especially among older men. A greater understanding of the

natural history of screen detected prostate cancer suggests that as many as half of the screen detected prostate cancers found among men age 70 and older are not clinically significant [32]. These findings have led the US Preventive services Task Force to recommend against routine PSA testing among men 75 years and older [33].

Pathophysiology

Adenocarcinoma of the prostate is frequently diagnosed as a result of an elevation in PSA. In many cases, tumors cannot be palpated on rectal examination. Among men with clinically localized prostate cancer, the tumor is often multifocal and most of the tumor mass is usually located in a peripheral location near the posterior edge of the prostate [34].

As prostate cancer grows, cancer cells invade the soft tissue surrounding the prostate directly and along the perineural pathways. Penetration of the capsule usually occurs posteriorly and posterolaterally, which may lead to extension into the seminal vesicles. The most frequent sites of metastatic spread are the pelvic lymph nodes and bone, especially the pelvis and vertebral bodies.

In general, the size of a prostate cancer correlates with its extent [35]. Tumors <0.5 ml are usually incidental findings. Capsular penetration is uncommon in tumors <4 ml, whereas larger tumors usually have metastatic elements. The likelihood of developing metastatic prostate cancer depends on the grade of the tumor. The Gleason scoring system is the most common method of estimating malignant potential [36]. The Gleason system is based on the glandular pattern of the tumor as identified at relatively low magnification (Fig. 81.6). The primary (most predominant) and secondary

FIGURE 81.5 Prostate cancer incidence and mortality in the USA, 1990–1995. Estimates were obtained by multiplying the age-specific incidence rates for the 11 SEER registries in the US population for each year (from Stanford et al. [24]).

FIGURE 81.6 Gleason grading system. (From Walsh PC, Retik AM, Vaughan ED JR, Wein AJ (eds) (1998) Campbell's urology, 7th ed. Saunders, Philadelphia, with permission. Copyright Elsevier 1998).

(second most prevalent) architectural patterns are assigned a grade from 1 to 5, with 1 representing the most well differentiated and 5 the most poorly differentiated. A Gleason score is determined by summing the primary and secondary patterns. Men with high-grade disease (Gleason score 8–10) generally have a poor prognosis, whereas men with low-grade disease (Gleason score 6) have an excellent prognosis. Men with Gleason score 7 tumors have a prognosis between these two extremes [37]. Gleason 2–5 scores are rarely assigned to newly diagnosed prostate cancer in contemporary practice [38].

Diagnosis and Evaluation

Unlike BPH, prostate cancer rarely causes symptoms early in the course of the disease because most prostate cancers arise in the periphery of the gland distant from the urethra. Symptoms in men with prostate cancer suggest locally advanced or metastatic disease. Growth of prostate cancer into the urethra or bladder neck can result in obstructive or irritating voiding symptoms. Metastatic disease that involves the bones can cause pain and anemia.

Aggressive screening efforts have reduced the proportion of men with prostate cancer detected because of symptoms suggestive of advanced disease [39]. Because of the significant risk of prostate cancer, transrectal ultrasonography and prostate biopsy are recommended for all men who have an abnormality on DRE regardless of the serum PSA level. Unfortunately, in both screened and nonscreened populations, DRE misses 23–45% of prostate cancers that are subsequently found following prostate biopsy because of elevated serum PSA [40]. Routine use of the serum PSA assay increases the detection of prostate cancer over that achieved by a DRE alone. The use of serum PSA testing increases the lead time for prostate cancer diagnosis and the likelihood of detecting prostate cancers confined to the prostate. Recognizing that PSA elevations are common in aging men because of the high prevalence of BPH, investigators have focused on methods of improving the ability of the PSA test to distinguish between men with BPH and men with cancer. Recommendations include adjusting serum PSA levels for patient age, prostate volume, and the rate of change of PSA values [41–43]. With the advent of specific assays quantifying PSA molecular forms, the measurement of free, unbound PSA has been evaluated as a method of distinguishing between BPH [44].

Imaging studies are frequently employed to evaluate the extent of prostate cancer progression. Bone scans and computed tomography (CT) scans are the most common, but other studies include pelvic magnetic resonance imaging (MRI) and endorectal coil MRI. Unfortunately, most of these

studies are insufficiently sensitive to identify microscopic metastases. A prospective analysis of more than 3,600 men demonstrated that imaging studies are positive in fewer than 10% of cases when the serum PSA level is less than 20 ng/ml or the Gleason score is less than 8 [45]. Only men with serum PSA levels higher than 50 ng/ml are likely to have evidence of metastatic disease that can be identified on bone scan, CT scan, or MRI. Unfortunately, more than half of the men with newly diagnosed prostate cancer who have a serum PSA level over 10 ng/ml already have disease extension beyond the confines of the prostate [46]. Men with serum PSA levels over 20 ng/ml are usually poor candidates for surgical therapy because of the high rate of tumor recurrence within 5 years of surgical therapy.

Surgical Treatment of Prostate Cancer

The appropriate treatment of prostate cancer among old men remains controversial. Studies concerning the long-term outcomes of men treated conservatively for their disease have documented the relatively modest disease-specific mortality among men with low and moderate grade tumors [47–49]. A recently published competing risk analysis of men aged 55–74 at diagnosis demonstrated that men with Gleason score 2–4 and five tumors have a 4–7% and 6–11% chance, respectively, of dying from prostate cancer [50]. These data were recently updated to include 20-year outcomes [37]. Older patients had a much greater chance of dying from competing medical hazards (Fig. 81.7). Conversely, men with Gleason score 7 and 8–10 tumors have a 42–70% and 60–87% chance, respectively, of dying from prostate cancer, if it is treated with hormone therapy alone. Men with Gleason score 6 tumors face an intermediate risk (18–30%) of dying from prostate cancer within 15 years, if the tumors are treated with hormone therapy alone. Based on these results, it appears that men over 70 years at diagnosis with Gleason score 2–5 disease face a minimal risk of dying from prostate cancer and therefore may not be good candidates for surgical therapy. Men whose biopsy specimens show Gleason score 7–10 disease face a high risk of death from prostate cancer when treated with hormone therapy alone, even when cancer is diagnosed as late as 74 years. These men may wish to consider surgical treatment in an attempt to cure their disease. Alternatives to surgery include external beam radiation therapy and implantation of radioactive seeds, often referred to as brachytherapy.

When choosing therapy for an individual patient with clinically localized prostate cancer, the age and general health of the patient remain critically important because of the indolent progression of many prostate cancers. Death from a localized cancer left untreated is not likely to occur

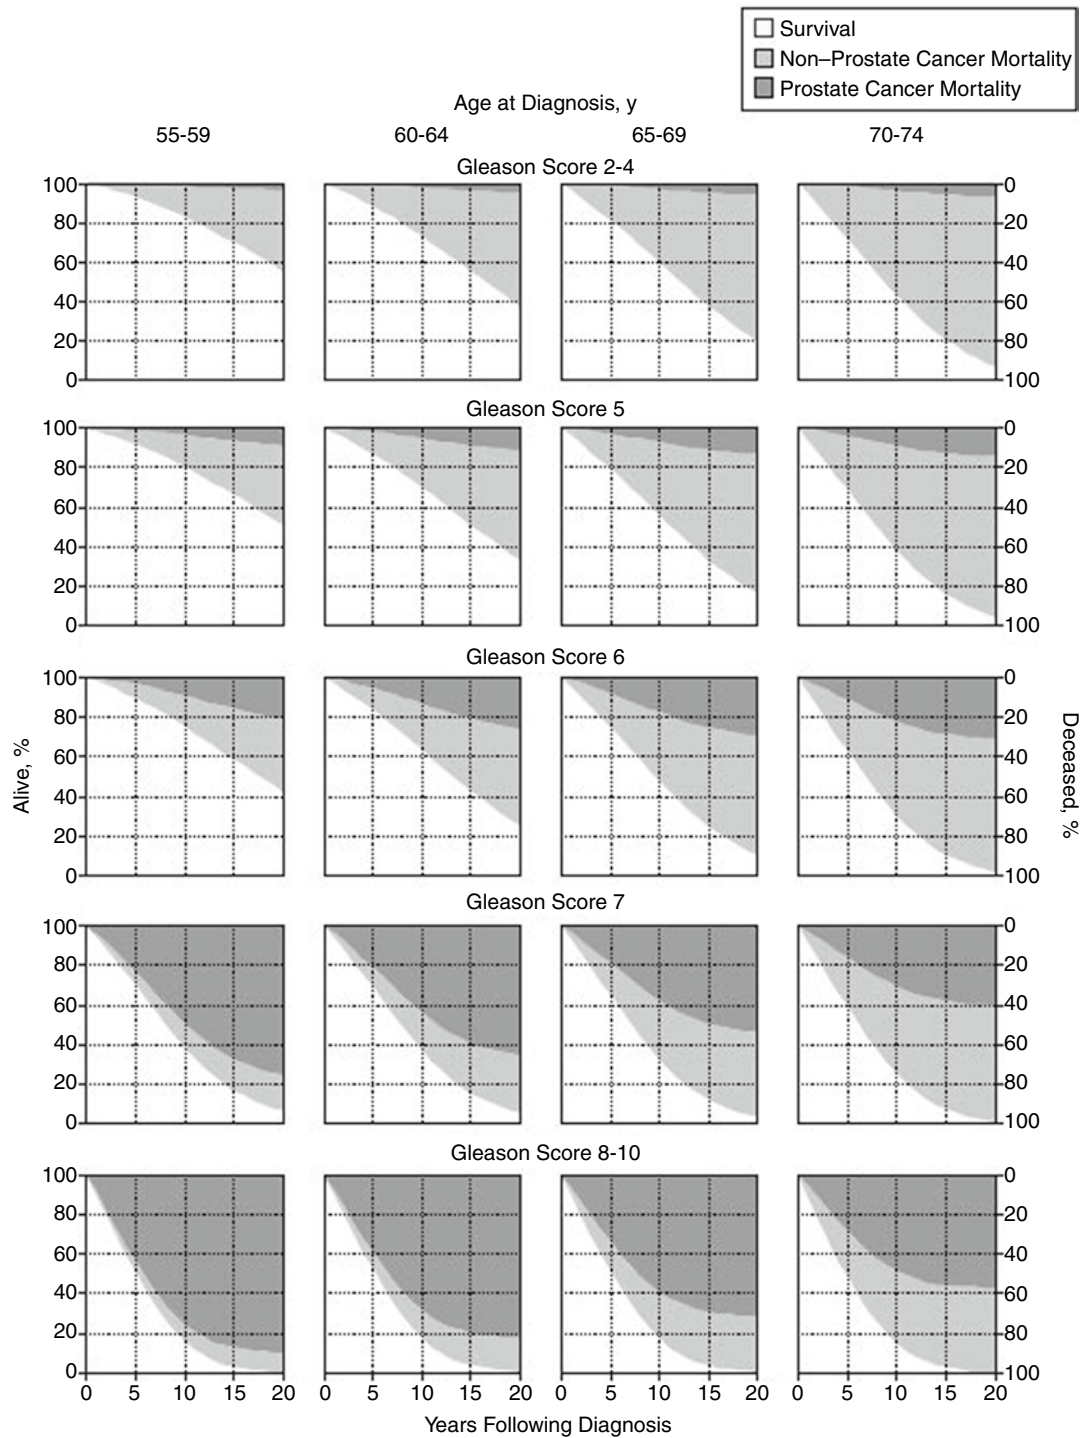

FIGURE 81.7 Survival (white lower band) and cumulative mortality from prostate cancer (dark gray upper band) and other causes (light gray middle band) up to 20 years after diagnosis stratified by age at diagnosis and Gleason score. Percentage of men alive can be read from

the left-hand scale, and percentage of men who have died from prostate cancer or other causes during this interval can be read from the right-hand scale (From Albertsen et al. [37], with permission. Copyright © 2005 American Medical Association. All rights reserved).

for 8–10 years, yet the risk of death from prostate cancer continues to increase for at least 15 years (Fig. 81.7). In 1989, the average life expectancy of a man aged 70 was 12.1 years, and for a 75-year-old man it was less than 10 years

(Table 81.2). Thus, the potential benefits of surgical intervention decreases rapidly as men age.

Chronologic age is only one factor that influences life expectancy. Prostate cancer occurs frequently in elderly men

TABLE 81.2 Life expectancy at single years of age for men, all races

who have associated comorbid conditions. Conversely, some old patients are in excellent physical condition and have a life expectancy longer than average for their age group. The impact of comorbid conditions on long-term outcomes among men with localized prostate cancer has been assessed [51]. Men with significant comorbid disease, measured using one of several instruments, have a much higher probability of dying from causes other than prostate cancer compared with those men with no or relatively few competing medical hazards (Fig. 81.8). Elderly patients must carefully assess the risks and benefits of surgical management compared with those of conservative management before making a decision concerning which therapy is the appropriate management for their localized prostate cancer.

Radical Prostatectomy

Surgical excision of prostate cancer can be accomplished using one of several surgical approaches: a retropubic approach, a perineal approach, a laparoscopic approach, or a robot assisted approach. Each approach has its advantages and disadvantages, but all appear to offer the same probability of controlling spread of disease. Furthermore, each of these approaches appears to have similar outcomes including length of hospital stay and long-term recovery. The rate of complications associated with each of these techniques appears to be similar.

Radical retropubic prostatectomy done open is performed with the patient in the supine position and laparoscopic or

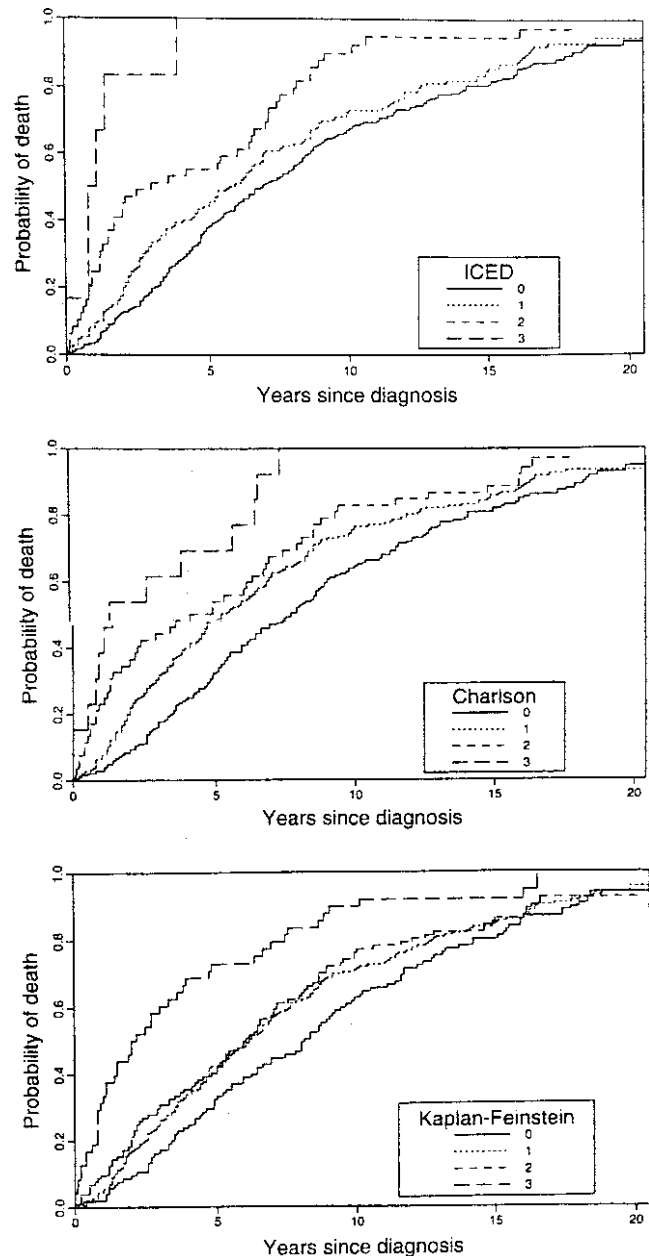

FIGURE 81.8 Cumulative mortality from all causes of death stratified by severity of comorbidities at diagnosis as measured by each of three instruments tested. Data are not adjusted for patient age or Gleason score, ICED, index of coexistent disease (From Albertsen et al. [50], with permission. Copyright Elsevier 1996).

robotic with relatively steep Trendelenberg to increase exposure to the prevesicle space. The procedure is usually performed under general anesthesia, although regional techniques using an epidural catheter are popular because they decrease the need for narcotics during the procedure and the postoperative period. Usually a pelvic lymph node dissection is performed as the first step. The lymphadenectomy is not therapeutic but does provide additional pathology to stage the cancer more accurately. The procedure is performed by entering the

prevesicle space either directly through a lower midline incision or transabdominally, when a laparoscope or robot is employed. The open radical retropubic approach begins by incising the endopelvic fascia, controlling the dorsal vein complex, and then dividing the urethra at the level of the prostate apex. The laparoscopic or robotic approach usually approaches the prostate from the posterior, developing the plane between the seminal vesicles and the rectum. The prostate is separated from the bladder neck prior to controlling the dorsal vein complex and dividing the urethra at the level of the prostate apex. In young men, care is taken to preserve the neurovascular bundles that lie on either side of the prostate apex. Unfortunately, among older men, there is a high probability of impotence associated with this procedure. Once the prostate and seminal vesicles have been removed, the bladder neck is repaired and secured to the stump of the urethra. Careful dissection around the apex of the prostate to avoid injury to the pelvic floor musculature should minimize the chance of incontinence.

All techniques for performing a radical prostatectomy are associated with complications, which increase with the patient's age. An analysis of more than 100,000 Medicare claims has demonstrated that approximately one in four patients suffers a major or minor complication associated with these procedures [52]. The radical retropubic approach had higher risks of respiratory complications and miscellaneous medical complications and a lower risk of miscellaneous surgical complications. The perineal approach resulted in a 1–2% incidence of rectal injury, but this appears to be offset by the medical complications of the gastrointestinal tract with the retropubic approach. Short-term mortality following radical prostatectomy is low; approximately 0.5% for men under age 70 and about 1.0% for men aged 75 and older. Table 81.3 demonstrates that the risk of mortality increases sharply with age.

Long-term complications associated with radical prostatectomy include impotence and incontinence. Although modern surgical techniques have decreased the incidence of postsurgical incontinence, reported rates of this complication vary widely. Patient reports of incontinence have been as high as 31%, whereas reports from tertiary medical centers suggest rates under 10% [53–55]. The age of the patient and whether an anastomotic stricture develops influence the recovery of continence. Patients over age 65 have a greater risk of incontinence compared to men under age 65.

TABLE 81.3 Thirty-day mortality following radical prostatectomy by age and surgical approach

Age (years)	30-Day mortality, by surgical approach (%)	
	Retropubic approach	Perineal approach
65–69	0.45	0.22
70–74	0.60	0.36
75+	1.04	0.95
Overall	0.56	0.37

Return of erectile function has also been correlated with patient age. Quinlan et al. evaluated 503 potent men between the ages of 34 and 72 who underwent radical retropubic prostatectomy [56]. Among men under the age of 50, about 90% were potent if one or both neurovascular bundles were preserved [57]. Among men age 65–69, only 27% recovered sexual function. Recovery of sexual function is likely to be even lower among men 70 years and older.

Only one randomized trial has been conducted to evaluate the efficacy of radical prostatectomy in the treatment of localized prostate cancer. Recently Bill-Axelsson et al. published 11-year outcomes from a randomized trial comparing radical prostatectomy against surveillance for men with clinically localized prostate cancer [58]. They found that all cause survival was not significantly different between the two arms of the study, although there was a modest decrease in prostate cancer mortality from 18% in the watchful waiting arm to 13% in the radical prostatectomy arm. Interestingly, this benefit was only seen in men less than 65 years at the time of diagnosis and was achieved primarily during the first 5 years following treatment.

Conclusions

Prostate diseases cause significant morbidity and mortality among elderly men. Both BPH and prostate cancer are relatively rare before age 50 but become increasingly common as men age into their 60s and 70s. For many patients with mild or moderate symptoms of bladder outlet obstruction, watchful waiting or various medical therapies may be sufficient therapy. As symptoms worsen, however, surgical treatment may offer the best chance of relieving symptoms of urinary frequency, hesitancy, and slow stream. Most patients with symptomatic BPH should be offered therapy with an α -blocker or a 5 α -reductase inhibitor before proceeding to transurethral prostatectomy. Only patients with large prostates should be considered for open prostatectomy. Minimally invasive thermal therapies are available but both short- and long-term efficacy appear to be inferior to standard surgical techniques.

Prostate cancer poses a much more difficult problem for elderly men, especially men with well or moderately differentiated tumors. Prostate cancer in these men is frequently a slow-growing tumor, and other medical hazards may become the dominant medical problem long before the cancer metastasizes.

Patients must carefully assess the relative risks and benefits of a surgical approach compared with other less invasive options, such as delayed hormone therapy or irradiation before proceeding with radical prostatectomy. Men with high-grade prostate cancers (Gleason scores 8–10) face a

significant risk of dying from their disease even when it is diagnosed as a localized disease as late as age 74. These men may want to consider radical prostatectomy as the preferred treatment option. Fortunately, in 2008, the primary risk associated with radical prostatectomy is impotence. Incontinence is less common, while mortality from surgery is a relatively rare event.

Chapter 82

Benign Gynecologic Disorders in the Older Woman

Kimberly A. Gerten, W. Jerod Greer, C. Bryce Bowling, Thomas Wheeler II, and Holly E. Richter

Introduction

Nonmalignant genital tract conditions and pelvic floor disorders including pelvic organ prolapse and incontinence are common gynecologic problems encountered by the older woman. With the rapidly increasing population of active older American women, physicians can expect to provide evaluation and treatment of these conditions with increasing frequency. These conditions are typically amenable to both medical and surgical therapies making individualization of treatment approaches important. An anatomically directed survey of nonneoplastic conditions of the lower and upper genital tract conditions is presented along with a discussion of pelvic floor support disorders common in the older woman. Evidenced-based evaluation and treatment suggestions are provided.

Menopause

Menopause is defined as 12 months of amenorrhea secondary to cessation of ovulation. It can also be induced by surgical oophorectomy, chemotherapy, or radiation [1]. The transition into menopause (perimenopause) typically begins 4 years prior to the last period [2] and starts with irregular cycle lengths during which estrogen levels can be normal or elevated. Ultimately, estrogen and progesterone levels decrease with subsequent increase in follicle-stimulating hormone (FSH) levels. Postmenopausal estradiol levels, the most potent estrogen, are typically <20 pg/mL, while FSH is most often >70 mU/mL. Testosterone production, however, is maintained by the ovaries and adrenal glands maintaining

serum levels of testosterone at 2–40 mg/dL. Even though estrogen production declines dramatically with menopause, a small amount of production continues via peripheral conversion of androgens by aromatase in adipocytes [2]. The natural process of aging results in increased fat body mass and decreased lean body mass such that obese postmenopausal women can manifest conditions due to estrogen excess, such as endometrial hyperplasia and carcinoma. In the USA, the mean age of menopause is 51 years [2] with cigarette smoking and low socioeconomic status being risk factors for premature (<40 years old) menopause [1].

Symptoms attributed to menopause include vasomotor symptoms (hot flashes and night sweats), vaginal atrophy symptoms (itching, dryness, and painful intercourse), urinary incontinence, sleeping difficulty, depression, anxiety, mood changes, cognitive decline, and somatic complaints. However, only vasomotor symptoms, atrophy symptoms, and trouble sleeping are consistently related to menopause in longitudinal studies [1–3]. A hot flush is the sudden feeling of warmth of the chest, neck, and/or face. It lasts for about 4 min, usually no longer than 5 min, and may have concurrent perspiration followed by a chill [1, 2]. Hot flushes occur most commonly in the late perimenopause (~65% of women). Symptoms decrease in intensity over time with up to 90% of women having complete resolution in 5 years [1]. The physiology behind hot flashes is poorly understood, but theories center around hypothalamic control in relation to hormonal changes with the transition to menopause [1, 2].

Estrogen therapy is the most effective treatment for vasomotor symptoms [4]. However, use of systemic estrogen has been complicated by results from the Women's Health Initiative (WHI), which found that systemic estrogen alone increased the risk of stroke (relative risk 1.39), while the addition of progestin increased the risk of coronary events (relative risk 1.28), breast cancer (relative risk 1.26), and pulmonary embolism (relative risk 2.13) [2]. The absolute increase in risk for these events is lower in the younger menopausal women [2]. A description of the criticisms and various organizational guidelines regarding hormone replacement therapy is beyond the scope of this chapter.

e-mail: kimgerten@hotmail.com

The American College of Obstetricians and Gynecologists and the North American Menopause Society recommend that the lowest effective dose of systemic estrogen (plus progestin if the uterus is present) should be used, and estrogen replacement should not be used for disease prevention [1, 2, 4]. Alternative medicines for the treatment of vasomotor symptoms, especially when estrogen is contraindicated, include paroxetine, clonidine, and gabapentin [1, 2].

Connective tissue, in general, is sex-hormone-sensitive. Therefore, menopause may also be associated with a loss of skin elasticity and strength of bone because of the estrogen sensitive collagen of these structures. Postmenopausal women who are given a combination of estrogen and testosterone have been reported to have greater skin collagen content and greater skin thickness than do untreated women [5]. In untreated women, skin collagen content is inversely proportional to the amount of time since menopause. It also has been shown that oral or transdermal estrogen given together with medroxyprogesterone acetate significantly increases skin collagen content in postmenopausal women [5].

Lower Genital Tract

Vulva

The vulva includes the portions of the genitalia that are externally visible: the mons pubis, labia majora and minora, clitoris, and vestibule. Within the vestibule are the hymen, vaginal orifice, urethral meatus, and the openings of Skene's and Bartholin's ducts [6]. The vulva is covered by keratinized stratified squamous epithelium with the exception of the vestibule which, like the vagina, is not keratinized.

Skin changes that occur with menopause and the accompanying decrease in ovarian estrogen production are evident on the vulva as they are on all skin surfaces. These changes include dryness, roughness, wrinkling, and loss of turgor. Structurally, there is flattening and decreased thickness of the epidermis and dermis, an overall decrease and change in distribution of subcutaneous fat, and loss as well as depigmentation of hair. These changes lead to functional loss of the skin's barrier function, elasticity, mechanical protection, and wound healing [7].

Lichen Sclerosus

Lichen sclerosus is a chronic, benign epithelial condition associated with characteristic skin changes as well as vulvar pain and pruritus. The vulva is the most common site at up to 96% of cases, but lesions can be seen on any skin surface [8].

The condition typically occurs in postmenopausal women, with a mean age of 52.6 years at time of diagnosis in one study, but can also be seen in children, premenopausal women as well as men [9]. The etiology is unknown, but possible mechanisms include genetic and/or local vulvar factors as well as immunologic abnormalities [10, 11].

Patients typically complain of vulvar pruritus, the hallmark symptom of the condition, along with pain or irritation; however, some women are asymptomatic. Other common symptoms include dysuria and painful defecation if fissures are present, and dyspareunia associated with introital stenosis. On physical examination, the classic features of the disease are thin, pale, wrinkled (often described as "parchment paper") skin on the labia (Fig. 82.1). Excoriations may be present secondary to scratching, and fissures can be seen perianally or between the labial folds and around the clitoris. More advanced disease can lead to the destruction of labial and clitoral architecture, with nearly complete midline fusion of the labia. One important distinctive feature of lichen sclerosus is that the vagina and cervix are not involved [12].

Diagnosis is based on high-clinical suspicion and confirmatory 3 mm punch biopsy, as other vulvar dystrophies can have a similar appearance. Women with lichen sclerosus also have an increased risk of invasive squamous cell cancer of the vulva [13]. High-potency topical corticosteroids are the mainstay of therapy for lichen sclerosus, typically with clobetasol or halobetasol propionate 0.05% ointment nightly for at least 4 weeks followed by a slow taper when symptoms resolve. Approximately 95% of patients will have complete or partial resolution of their symptoms with this regimen [14, 15].

FIGURE 82.1 Lichen sclerosus. Note the destruction of normal architecture and "parchment paper" skin.

Maintenance therapy with twice weekly dosing may decrease flares or recurrent symptoms, though some experts recommend stopping therapy with resolution of symptoms and only retreating for recurrences [16]. It is unclear whether maintenance therapy reduces the chance of malignant evolution, so any recurrent or persistent lesions should be rebiopsied to rule out cancer [17]. Topical immunosuppressants have shown some promise in lichen sclerosus, but are currently considered second-line therapy for disease that is unresponsive to high-potency corticosteroids [12].

Lichen Simplex Chronicus

Lichen simplex chronicus is an eczematoid disease of hyperkeratotic, scaling plaques of varying pigmentation that is associated with severe vulvar pruritus. It may commonly be seen in conjunction with a number of other vulvar skin disorders and is ultimately brought about by chronic scratching and irritation from both environmental and dermatologic processes [18]. Lichen simplex chronicus has been found to be associated with a history of atopic disease in up to 75% of patients, and typically presents later in adult life though it can be seen in children. Initiating events range from chronic heat and excessive sweating to candidal infection or other dermatoses such as lichen sclerosus [12].

Diagnosis of lichen simplex chronicus is based on a history of vulvar irritation, pruritus, and typical hyperkeratotic lesions on examination. Ulcers and excoriations are sometimes seen due to chronic scratching. Biopsy may be done to identify the underlying disease (e.g. lichen sclerosus), and vaginal yeast cultures may also be helpful in this regard [12]. First-line therapy involves treatment of any underlying conditions, and topical corticosteroids may be used for symptomatic relief of inflammation and itching. Additionally, hygiene measures are important in controlling chronic vulvar wetness and avoiding potential irritants (strong soaps, perfumes, or detergents) that might exacerbate or prolong the condition.

Lichen Planus

Lichen planus is another inflammatory disease involving the genital mucosa that is thought to be caused by a cell-mediated autoimmune mechanism [19]. Unlike other vulvar dermatoses, lichen planus is more commonly found on nonvulvar skin or the mucosal membranes, especially the buccal mucosa [20]. Oral lichen planus is present in approximately 1% of the population, and up to one-fourth of women with oral disease will also have genital disease. The condition generally presents from 30 to 60 years, and the typical lesions seen are

white reticulate striae on the buccal mucosal surface (Wickham's striae). Vulvar and skin lesions tend to consist of shiny, pruritic, violaceous papules; vulvar lesions can be less well demarcated and may even appear as white patches that are difficult to distinguish from lichen sclerosus [12]. The erosive form of lichen planus can lead to extremely painful erosions of the posterior vestibule and labia minora, with eventual architectural destruction, scarring and narrowing of the introitus; patients with such advanced disease complain of dyspareunia and difficulty voiding [12].

Diagnostic biopsy specimens are usually nonspecific, but classic findings in lichen planus include liquefactive degeneration of the basal cell layer and a band-like lymphocytic dermal infiltrate [21]. However, biopsy does help to rule out immunobullous diseases as well as cancer. There are a number of treatment options for lichen planus; unfortunately, though, response is typically poor and therapy goals should focus on long-term maintenance of symptoms rather than complete control. Patient education, behavioral modification, and emotional support are all important components of any treatment plan. Medication options include topical and/or systemic high-potency corticosteroids, topical and oral cyclosporine, as well as a number of other immunomodulators [12]. In our experience, Tacrolimus (Protopic) 0.1% ointment applied twice daily has been used with some success.

Bartholin's Cysts and Abscesses

Bartholin's glands are located near the 4 and 8 o'clock positions on the posterolateral aspect of the vaginal opening. The ducts from Bartholin's glands empty into the vestibule, and obstruction of these orifices from chronic inflammation can lead to Bartholin's cysts, which are typically asymptomatic unless they become large. These ducts and cysts may also become infected and evolve into polymicrobial abscesses, which generally present with exquisite pain and swelling. The incidence of Bartholin's cysts or abscesses is up to 2% over a woman's lifetime, but tends to be less common during the postmenopausal years [22]. Due to the possibility of underlying Bartholin's gland carcinoma, cysts and abscesses in women over the age of 40 should be drained and biopsied at the first occurrence, followed by complete excision of the gland for recurrent disease [23].

Vulvodynia

Vulvodynia is defined as chronic pain in the vulvar area lasting at least 3–6 months [24]. In 2003, the International Society for the Study of Vulvovaginal Disease classified vulvar pain

into two categories: (1) vulvar pain related to an underlying disorder (infection, inflammation, neoplasm, or neurologic disease) and (2) vulvodynia, defined as vulvar burning or discomfort in the absence of any identifiable cause [25]. The true prevalence is unknown, but has been reported to be between 10 and 16% over a woman's lifetime, and tends to be more common in older patients [26, 27]. The etiology of vulvodynia is also unclear, but is thought to have a neuropathic basis related to long-term tissue damage; it may also be related to changes in hormonal status, possibly explaining its temporal association with menopause [28].

While all patients present with complaints of pain, their descriptions may be widely variable with respect to location, timing, character, and provocations. Many patients believe that they have – and may have been treated for – chronic, recurrent yeast infections. Vulvodynia has been associated with co-existing conditions such as depression, interstitial cystitis, fibromyalgia, irritable bowel syndrome and frequent urinary tract, and yeast infections [27]. The diagnosis of vulvodynia is one of exclusion, and many times vulvar erythema, tenderness to palpation and/or allodynia may be the only physical exam findings; vaginal pH, wet mounts, and yeast cultures may help to exclude other causes.

Vulvodynia can also be a frustrating treatment dilemma, as specific triggers for the pain patients experience are often difficult to identify. General measures should include education, emotional support, hygiene measures, and behavioral therapy; referral to a pain specialist may be helpful, and physical therapy involving pelvic floor muscle rehabilitation can be effective in patients with vaginismus and pelvic floor hypertonicity [29]. First-line pharmacologic therapy consists of tricyclic antidepressants (e.g., amitriptyline 10 mg nightly, increasing by 10 mg weekly until symptoms improve) with or without a topical anesthetic. Topical lidocaine gel may be used on a scheduled basis up to six times a day, or on an as needed basis for intercourse. With the tricyclic antidepressants, care must be taken to watch for anticholinergic side effects as they may be more pronounced in the geriatric population. Other pharmacologic options include gabapentin, duloxetine, and the addition of topical estrogen if atrophy is present. For pain unresponsive to these therapies, local nerve block with a corticosteroid and lidocaine has been found to provide temporary relief, and referral to a pain management specialist may be appropriate in this case [30].

Cervix

In the geriatric patient, the appearance of the cervix changes in comparison to that of premenopausal patients as the transformation zone is usually found high within the endocervical

canal. The cervix may also atrophy and become flush with the vaginal vault. While problems arising from the cervix are rare, two of the more common conditions in menopausal women are cervicitis and cervical stenosis.

Cervicitis in postmenopausal females is typically related to atrophic changes rather than an infectious process and can be a common cause of vaginal bleeding in this patient population. If there is no evidence of sexually transmitted or superimposed infection, treatment with vaginal estrogen should be started. A wet mount slide and/or cultures should be performed to evaluate any associated suspicious discharge, and appropriate antibiotics prescribed for any infectious process.

In addition to cervicovaginal atrophy, the menopausal decrease in estrogen also induces changes in the endocervical canal that may lead to the agglutination of the cervix, ultimately resulting in complete stenosis. This can obstruct the outflow of secretions and debris from the atrophic endometrial cavity, leading to hematometria or hydrometria; pyometria can occur if this accumulation of debris becomes infected.

Urogenital Atrophy and Vaginitis

During the menopause, the vagina, in particular, thins and loses elasticity. In addition, the vagina undergoes a decrease in blood flow and secretions. For a third of women, this results in dryness, discomfort, itching, and/or painful intercourse early in menopause and is often referred to as atrophic vaginitis. Unlike vasomotor symptoms, atrophy symptoms continue or worsen and the prevalence increases to about half of women with aging. Additionally, lack of estrogen changes the vagina from an acidic to a more basic environment, which favors colonization with enteric potentially uropathic bacteria [1–3]. Low doses of transvaginal creams, pessaries, tablets, and rings are likely equally effective in treating symptoms of vaginal atrophy and are not associated with significant systemic absorption [3]. Reversing vaginal atrophy before vaginal surgery is often performed (Fig. 82.2).

Other less common forms of vaginal irritation in the older women include bacterial vaginosis (BV) and candidiasis. In the atrophic vagina with a higher pH, lactobacilli, and yeasts are less commonly found likely explaining the decreased incidence of candidiasis [31]. Differentiation between these causes of vaginal irritation is important. Increased vaginal pH is found with both BV and atrophy. The discharge with BV is malodorous, thin, homogenous, grayish, and adherent to the vaginal walls. Candidiasis is odorless and “cottage cheese” like in appearance; the labia

FIGURE 82.2 Vaginal atrophy treated with estrogen cream. (a) A thin vaginal epithelium (0.075 mm) where the estrogen sensitive superficial cell layer (flatter cells with smaller nuclei) composes a smaller propor-

tion of the epithelium. (b) Epithelial changes after nightly treatment with 50 μg of estrogen cream. The thicker epithelium (0.4 mm) contains a larger proportion of superficial cells.

can be erythematous and edematous with satellite lesions. BV also has a characteristic fishy odor with the application of potassium hydroxide. On saline wet mount, BV has clue cells (epithelial cells stippled with bacteria), while candidiasis has pseudohyphae [32]. With atrophy, the wet mount is predominantly intermediate and parabasal epithelial cells with few or no superficial cells [33]. Antibiotic treatment for BV and anticandidal regimens is effective and routinely prescribed by practitioners caring for older women [32].

The lower urinary tract is also estrogen sensitive, as estrogen receptors are found in the bladder and urethra. Symptoms of dysuria, urethral discomfort, overactive bladder (OAB), hematuria, urinary tract infections (UTIs), and urinary incontinence (UI) are associated with aging. Estrogen had been a mainstay of treatment of urinary tract symptoms, generally based on small observational studies [34]. However, a 2003 Cochrane review called into question the routine use of systemic estrogen as a therapeutic agent for UI. Fifteen of the 28 trials in this review favored estrogen use to treat UI, but the results from the Heart and Estrogen/Progestin Replacement Study (HERS) swayed the analysis towards estrogen worsening UI [35]. This review was followed by the negative findings in the Women's Health Initiative which showed increased or worsening of UI in women taking estrogen and progesterone or estrogen alone [34]. It is important to note that the influence of different estrogen formulations and route of delivery, in particular transvaginal estrogen, have yet to be elucidated. However, it is clear that systemic estrogen has not been shown to improve OAB or urinary incontinence and may actually worsen them [1, 34]. There is a role for transvaginal estrogen in preventing recurrent UTIs [36].

Urethra

Urethral Prolapse

The female urethra is typically 4 cm in length and is distally lined by nonkeratinized squamous epithelium. This epithelium and its spongy submucosa are estrogen sensitive and intrinsically remain sealed to each other. Two adherent smooth muscle layers are also present, an inner longitudinal layer and an outer circular layer. A circular disruption in this distal anatomy can result in prolapse out of the external meatus [37].

Urethral prolapse is relatively rare in the menopausal women but is associated with a lack of estrogen as it is found in prepubertal girls and postmenopausal women. Bleeding is the most common symptom, followed by voiding symptoms such as dysuria, urgency, frequency, and nocturia. If strangulated, suprapubic pain can occur. Concurrent infection is common [37].

Since urethral prolapse is rare, careful examination is needed to confirm the diagnosis, as the more common urethral caruncles and rare malignancy are in the differential diagnosis. Urethral prolapse is distinguished by the circumferential prolapse with a central opening, which can be catheterized to confirm the presence of the urethra. Significant swelling can lead to anatomical distortion, strangulation, and potentially necrosis and may necessitate examination under anesthesia to confirm the diagnosis with possible surgical correction. Imaging studies are seldom necessary once the diagnosis has been confirmed with catheterization; otherwise, malignancy should be considered. Histologically, inflammatory infiltrates are seen in the underlying connective tissue.

Treatments include warm sitz baths, transvaginal estrogen cream, topical steroids to reduce inflammation and antibiotics for infection [38, 39]. Estrogen has been reported to resolve the prolapse within 6 weeks [39]. If conservative management fails or if strangulated, surgical excision, and short-term catheterization (less than a week) should be performed [40]. Long-term transvaginal estrogen should be included in the postoperative care.

Urethral Caruncles

Urethral caruncles are benign, usually small, asymptomatic reddish exophytic lesion coming off of the posterior urethra. Often they are an incidental finding but can present with dysuria, tenderness, or bleeding especially if they enlarge to 1–2 cm (Fig. 82.3). The etiology likely starts with incomplete urethral prolapse, which becomes chronically irritated and takes a polypoid form. Like urethral prolapse, its origins are attributed to estrogen deficiency but are more common in older women being rarely found in premenopausal women or prepubertal girls. Cystoscopy is generally unnecessary. Treatment of symptomatic urethral caruncles is conservative and consists of sitz baths, transvaginal estrogen therapy, and anti-inflammatories when necessary. When clinical differentiation from cancer is difficult, such as a large (1–2 cm) lesion, there is a failure of medical therapy, or in the presence of severe symptoms, surgical excision biopsy should be considered [41].

FIGURE 82.3 Urethral caruncle. Note it is a reddish, exophytic lesion off of the posterior urethra.

Urethral Diverticulum

A urethral diverticulum is an outpouching of the urethra into the anterior vaginal wall and is uncommon past 60 years of age. It is thought to be the result of obstruction of periurethral glands and is most commonly found in the distal urethra. Symptoms include dysuria, dribbling, urgency, frequency, and dyspareunia. On examination, it feels like a suburethral mass that is tender and can be hard if a stone is present. Urine or purulence may be expressed from the meatus when massaged. The differential diagnosis includes vaginal wall cysts from an embryologic remnant or local gland, ectopic ureterocele, and, rarely, malignancy. Magnetic resonance imaging (MRI) is the diagnostic imaging modality of choice to confirm the diagnosis, location, and size. Surgical excision is recommended treatment [42].

Upper Genital Tract

Uterus

Many of the changes evident in the postmenopausal uterus are a direct result of decreasing estrogen levels. There is an estimated 95% decline in blood estrogen concentration from the premenopausal to postmenopausal state [43]. The postmenopausal uterus undergoes involution and gradually becomes smaller with age. Benign abnormalities of the uterus, especially abnormalities of the uterine cavity, may result in postmenopausal bleeding, and endometrial cancer must be ruled out when it occurs in this age group. The primary causes of postmenopausal bleeding include vaginal atrophy with friability, endometrial atrophy, endometrial hyperplasia, endometrial and cervical polyps, and invasive cancer. The workup of all postmenopausal bleeding should consist of an endometrial biopsy either in the office or in the operating room when confronted with cervical stenosis or difficulty with patient discomfort. The use of ultrasound may be a useful first step in determining the existence of a thickened endometrium.

Endometrial Atrophy

Endometrial atrophy is a frequent cause of postmenopausal uterine bleeding. The surface epithelium of the uterine cavity, otherwise known as the endometrial layer, is known to undergo cellular and glandular loss, likely as a result of lowered estrogen levels [44]. This ultimately thinned endometrial surface is subject to bleeding, especially as a result of trauma. The collapsed, atrophic endometrial surfaces contain little or no fluid to prevent intracavitary friction [45]. Microerosions of the surface epithelium then develop that are prone to light bleeding or spotting.

The diagnosis of endometrial atrophy is confirmed by endometrial biopsy or by ultrasound (double layer thickness

less than 4 mm). Adequate estrogen therapy is nearly always effective in relieving symptoms of both endometrial and vaginal atrophy. Although many oral preparations are available for the treatment of endometrial atrophy, local vaginal estrogen therapy has also been shown to be effective and well tolerated in the treatment of endometrial atrophy, but should be accompanied by a progestin for doses greater than 50 µg [3, 46].

Endometrial Polyps

Endometrial polyps, which are hyperplastic overgrowths of endometrial glands and stroma, develop from the endometrial basalis layer and are likely the result of estrogenic stimulation. The known association of large endometrial polyps with tamoxifen [47], a selective estrogen receptor modulator, strengthens this likelihood. The incidence peaks in the fifth decade of life; fortunately for most postmenopausal women, the incidence of endometrial polyps greatly decreases after menopause. They may be solitary or multiple and are usually pedunculated. Most are benign, with an estimated 1.5% being malignant [48]. In addition, while most are asymptomatic, they account for 12–25% of cases of postmenopausal bleeding [49, 50].

Endometrial polyps are diagnosed only by microscopic evaluation of the specimen postremoval, although they can be further evaluated and characterized using sonohysterography (Fig. 82.4). Saline infusion sonography has been shown to be more accurate than ultrasound alone in diagnosis, with a sensitivity and specificity of 93 and 94%, respectively, compared to 65 and 76%, respectively, for ultrasound alone [51].

FIGURE 82.4 Saline infusion sonohysterogram of a perimenopausal patient with abnormal uterine bleeding. A polypoid lesion is seen extending near the anterior fundal region. This measures 10.2×6.7 mm (calipers). At the time of D&C with hysteroscopy, a polyp was identified and confirmed by pathology (reprinted with permission from Goldstein SR (2008) Abnormal uterine bleeding. In: Gibbs RS, Karlan BY, Haney RF, Nygaard IE (eds) Danforth's Obstetrics and Gynecology, 10th ed. Lippincott Williams & Wilkins, Philadelphia, p 668).

Treatment is removal by dilatation and curettage (D&C) or hysteroscopic guided polypectomy. Excision is essential to rule out carcinoma. Treatment decisions based on ultrasonography and hysteroscopy provide little utility as neither can adequately distinguish between benign and malignant polyps [48, 52].

Leiomyomas (Fibroids)

Benign uterine leiomyomas, otherwise known as fibroids, are hormonally responsive and typically decrease in size after menopause [53]. Although leiomyomas tend to atrophy as the woman ages, their presence can cause concern during bimanual exams or with their appearance on imaging studies. Medical therapy to decrease fibroid size is generally not indicated in the older postmenopausal woman. Additionally, surgical interventions for simple uterine fibroids in the postmenopausal female usually are not indicated. However, while most uterine masses ultimately prove to be benign fibroids, a rapidly enlarging pelvic mass may represent a uterine leiomyosarcoma. These are relatively uncommon, accounting for only 1–2% of postmenopausal uterine masses [54]. With any enlarging or persistent uterine mass, evaluation in the form of ultrasonography, computed tomography, and referral to a gynecologic specialist is warranted to exclude sarcoma.

Endometrial Hyperplasia and Cancer

Endometrial hyperplasia, or excessive proliferation of the uterine endometrium, can occur from many conditions, almost all associated with long-term unopposed estrogen stimulation. Risk factors for endometrial hyperplasia, other than direct unopposed estrogen stimulation include obesity, nulliparity, diabetes, early menarche, late menopause, polycystic ovarian syndrome, and tamoxifen therapy for greater than 2 years [55].

Endometrial hyperplasia is classified as either atypical hyperplasia or hyperplasia without atypia. These classes are further subdivided into two categories: simple and complex, with complex and atypical classifications having higher risks for malignancy. The diagnosis of endometrial hyperplasia is made from direct tissue sampling in the form of an office endometrial biopsy sampling or D&C. Treatment strategies center around the use of progestins. Progestins can be used for both simple and complex hyperplasia, both with and without atypia. Untreated endometrial hyperplasia can progress to endometrial carcinoma, so early treatment is paramount. Endometrial cancers are covered in Chap. 83.

Ovary

As women progress into menopause, there is a marked depletion of ovarian follicles resulting in decreased synthesis of

circulating estrogen. The ovaries become atrophic becoming smaller in size than those of the premenopausal woman and are typically not palpable on bimanual examination. This may present a problem as the gynecologist or primary care physician attempts the examination, however, yearly examinations are paramount for the early detection of ovarian neoplasms. In the older woman, a combined rectovaginal examination may assist with the routine pelvic exam in detecting ovarian abnormalities. The incidence of ovarian neoplasms in the postmenopausal patient rises rapidly and plateaus until the age 70 and then rapidly declines.

Benign ovarian enlargement or benign cysts are rarely found in the postmenopausal female, as the ovary is inactive. Benign teratomas missed at an earlier age are sometimes found, but in general, most postmenopausal ovarian masses are suspect for malignancy. Management of ovarian tumors is discussed in Chap. 83.

Pelvic Floor Disorders

The national prevalence of symptomatic pelvic floor defects including pelvic organ prolapse (POP), urinary incontinence (UI), and fecal incontinence (FI) has been estimated to be 23.7%, regardless of age. Older women are far more affected, with rates up to 49.7% in women 80 years old and older [56]. The prevalence of anatomic stage II–IV POP using the Pelvic Organ Prolapse Quantification (POPQ) [57] (see Table 82.1 and Fig. 82.5) examination in the general population was reported to be 37%; prevalence in an older population of women with a mean age of 68 years was 64.8% [58]. Clearly, these are highly prevalent conditions and contribute significantly to older women's overall quality of life. Despite the availability of effective evaluation and treatment methods, women continue to suffer needlessly, with nearly 50% of affected women neglecting to inform their healthcare providers about their symptoms [59].

The etiology of POP and incontinence is complex, involving potential injury to, or attenuation of the many ligaments, muscles, connective tissue, and innervation of the pelvis. These conditions are associated with several risk factors including age, parity, abdominal circumference, and body mass index. Vaginal support defects as defined by DeLancey include Level I apical support defects (the cardinal–uterosacral ligament complex), Level II defects including cystocele, rectocele, or paravaginal defects (a defect in vaginal support at the level of the arcus tendineus fascia pelvis), or a Level III defect, detachment of the perineal body (Fig. 82.6) [60].

It is common for the older woman to be affected by more than one pelvic floor condition. POP can be associated with urinary as well as bowel dysfunction/incontinence. Women with advanced POP may experience voiding dysfunction, caused by urethral obstruction. Older women are at risk for

TABLE 82.1 Stages of pelvic organ prolapse

Stage 0	No prolapse is demonstrated. Points Aa, Ap, Ba, and Bp are all at -3 cm, and point C is between total vaginal length (TVL) and $-(TVL - 2$ cm)
Stage I	The most distal portion of the prolapse is >1 cm above the level of the hymen
Stage II	The most distal portion of the prolapse is <1 cm proximal or distal to the plane of the hymen
Stage III	The most distal portion of the prolapse is <1 cm below the plane of the hymen but no further than 2 cm less than the total vaginal length
Stage IV	Complete to nearly complete eversion of the vagina. The most distal portion of the prolapse protrudes to $>+(TVL - 2)$ cm

FIGURE 82.5 Six sites (points Aa, Ba, C, D, Bp, and Ap), genital hiatus (gh), perineal body (pb), and total vaginal length (tv) used for pelvic organ support quantification (from Bump et al. [57]). Reprinted with permission from Elsevier.

coexisting urinary and fecal incontinence. A thorough history will elucidate these associated symptoms. An evaluation for occult incontinence may be warranted in cases of advanced prolapse, as an incompetent urethra may be masked by the urethral kinking associated with advanced organ descent.

The diagnosis of POP is made during a pelvic examination. The full extent of tissue prolapse may not be appreciated unless the patient stands or uses a strong valsalva force. Bladder and bowel dysfunction may require the use of further diagnostic testing such as urodynamics, anal manometry and ultrasound, or electromyography of the pelvic floor.

Urinary incontinence (UI) is defined as the complaint of any involuntary leakage of urine [61]. Diagnostic categories

FIGURE 82.6 Vaginal support defects as defined by DeLancey include Level I apical support defects (the cardinal–uterosacral ligament complex). Level II defects including cystocele, rectocele, or paravaginal defects (a defect in vaginal support at the level of the arcus tendineous fascia pelvis), or a Level III defect, detachment of the perineal body (From De Lancey [60]. Reprinted with permission from Elsevier).

of UI include stress incontinence (leakage associated with episodes of increased intra-abdominal pressure), urge urinary incontinence (leakage associated with urgency and involuntary detrusor muscle contractions), overflow incontinence (seen when bladder emptying is insufficient), and mixed incontinence (any combination of the above).

Initial evaluation techniques center on the treatment of reversible causes of UI, for example, infection, inappropriate medication use, and mobility issues. After a thorough history, the examination focuses on pelvic/bladder anatomy and neurologic status. Bladder physiology and function may be further characterized using a stress test or urodynamic assessment, a diagnostic means of observing bladder neurologic and motor/muscle physiologic function.

Medical/Nonsurgical Treatment of POP and UI

Nonsurgical therapy of POP and urinary incontinence includes behavioral management (pelvic floor muscle rehabilitation and for incontinence the teaching of stress and urge incontinence strategies), medications, as well as the use of mechanical devices. A conservative treatment approach is usually considered in older women who do not desire a surgical intervention or where surgery may not be an ideal choice due to medical comorbidities causing increased surgical risk.

Pelvic floor muscle exercises may limit the progression of mild prolapse and related symptoms; however, less response has been noted with prolapse beyond the vaginal introitus

[62]. This method of treatment is often employed to treat accompanying urinary and/or fecal incontinence. Results are generally dependent on patient motivation and adherence to the exercise program.

The use of a mechanical device such as a pessary is an excellent option to nonsurgically treat POP and UI. Several different types of pessaries have been described made with numerous types of material; according to Mylex Products, Inc. (Chicago, IL) brochures, there are six to nine sizes of 13 pessary models used for stress urinary incontinence and/or POP, the majority of which are made of silicone or inert plastic. Pessaries provide pelvic organ support within the vaginal vault. Two categories of pessaries exist for prolapse: support and space filling. The ring pessary (with diaphragm) is a commonly used support pessary and the Gelhorn pessary is a commonly used space-filling pessary. (See Fig. 82.7) The ring and other support pessaries are recommended for Stage 1 and 2 prolapse, whereas the space-filling pessaries are for Stage 3 and 4 prolapse [63].

Possible complications associated with pessary use include vaginal discharge and odor. There may be failure to retain the pessary or conversely, the pessary may be too large, which could lead to excoriation or irritation. There may be de novo or increased stress incontinence [64] with the reduction of vaginal prolapse and in rare instances more severe complications such as fistula development.

The mainstay of treatment for overactive bladder and urge incontinence includes a combination of pelvic floor muscle rehabilitation and use of an anticholinergic medication. Patients refractory to these conservative therapies may be candidates for intra-vesical botulinum toxin A injections or neuromodulation techniques.

Surgical Treatment of POP

The decision for surgical versus conservative intervention for the treatment of pelvic floor disorders should not be based on chronologic age alone. Prior to the selection of a specific treatment or procedure, all existing pelvic floor defects should be evaluated. The older woman can expect similar operative risks as well as subjective and objective anatomic and quality-of-life outcomes as that of younger women undergoing pelvic floor disorder treatment.

Over 200,000 inpatient and outpatient surgeries are performed yearly for the treatment of urinary incontinence (UI) and POP in US women [65]. Demand for the care of pelvic floor disorders has been projected to increase significantly in the coming years due to significant shifting of American age demographics. Women aged 80 years and older are the most rapidly growing segment of the older US population. A woman's lifetime risk of having surgery for either POP or UI up to

FIGURE 82.7 (a) Ring pessary without support in place; patient with cervix and uterus. Note that the pessary rests at the level of the bladder neck anteriorly and behind the cervix posteriorly. (b) Gelhorn pessary in place; patient with cervix and uterus. Note that the disk of the Gelhorn

pessary rests at the level of the bladder neck anteriorly, and behind the cervix posteriorly (similar to the position of a ring pessary and that the knob rests behind the perineal body) (From Weber and Richter [62]. Reprinted with permission from Lippincott Williams & Wilkins).

the age of 80 years is 11.1% [66]. Women who have undergone a procedure for UI or POP are at risk for recurrence [67].

The ideal procedure in the older woman would robustly repair symptomatic pelvic floor defects, be performed efficiently, allow for rapid postoperative recovery including return to baseline or improved functional status, and conform with the sexual activity desires of the patient. Although many studies have included older women when examining outcomes after pelvic floor surgery, most studies have not specifically addressed POP surgery outcomes in the older woman. However, based on the information we do have, older women undergoing elective pelvic floor surgery face risks similar to patients of all ages undergoing elective general surgery. Pelvic floor surgery is considered an intermediate risk procedure with a perioperative mortality rate <5%. A review of recent studies that examine outcomes of the older woman undergoing pelvic floor surgery show mortality rates from 0.0 to 4.1% and complication rates from 15.5 to 33.0% [68]. Complication rates vary and may be due to the heterogeneous definitions of complications throughout the studies. However, the majority of complications were related to urinary tract infections, febrile morbidity, and blood loss requiring transfusion. Presurgical preparation should include optimization of the urogenital epithelium. In order to prepare the tissue for surgery and optimize healing, vaginal application of estrogen cream several weeks prior to the procedure and in the postoperative period is recommended.

Perioperative management of the older gynecology patient may demand attention to multiple medical considerations. Suggested prophylactic interventions are presented in Table 82.2. Surgery to correct POP and UI should address the specific pelvic floor defects that are present including the anterior vaginal wall (cystocele), posterior vaginal wall

(rectocele), and apical vaginal support defects (enterocele) (see Figs. 82.8 and 82.9).

Surgical techniques to address anterior defects are the anterior colporrhaphy and paravaginal repair. Symptomatic anterior wall prolapse repair outcomes were compared at a 21-month average (12 months minimum) follow-up between 31 patients aged 80 years or more and 234 younger patients. They demonstrated similar rates of symptomatic failure between the groups, 6 versus 5%, respectively. Recurrence of any vaginal support defect in the older group was 10% [69].

The most efficacious technique to repair posterior defects is the traditional midline colporrhaphy [62]. Perineorrhaphy should be performed when there is separation of the perineal muscles. The posterior rectovaginal connective tissue should be reattached to the perineal body if separated. However, careful attention should be paid to avoid excessive vaginal narrowing (unless desired) as postoperative dyspareunia is a common complication. Anatomic success is high with this procedure; however, functional success rates may be considerably lower regardless of age.

Surgical techniques to address apical vaginal defects include the abdominal sacrocolpopexy (ASC), uterosacral ligament suspension (USS), ileococcygeus fixation, and sacrospinous fixation. The ASC employs graft material to suspend the anterior and posterior walls of the vagina to the anterior longitudinal ligament of the sacrum. Published ASC apical cure rates range from 78 to 100% [62]. However, this surgery requires a laparotomy, has a longer operative time, a longer recovery period, and higher postoperative complications when compared with vaginal approach surgeries. A recent RCT demonstrated similar perioperative complication rates as well as subjective and objective outcomes in women aged 70 years and older compared to a younger

TABLE 82.2 Perioperative clinical management of the older woman undergoing gynecologic surgery

Issue	Background	Clinical recommendation
Cardiovascular	Perioperative MI associated with 50% mortality rate [79]	Perioperative beta-blocker use in the high and moderate risk patient
Delirium	Abrupt change in cognition or consciousness- Post-surgical prevalence estimate 37% [80] At risk for long-term cognitive deficiencies and increased mortality Under diagnosed	Avoid meperidine and anticholinergic agents including promethazine, minimize hospital stay, allow a companion to stay at bedside, maintain circadian pattern
DVT/thromboembolic events	Older patients have 20–40% risk of DVT due to advanced age (>60 years) and length of surgery [82]	Perioperative use of sequential pneumatic compression devices and selective use of heparin prophylaxis, early ambulation
Hypothermia	Decreased immunologic response, prolonged wound healing, [82] increased perioperative cardiac events	Intraoperative forced warm air blanket use, warmed intravenous fluids
Infectious disease	Clean contaminated procedures: mixed flora of the vagina	Perioperative dose of first-generation cephalosporin [83]
Neuropathies	Neurologic injuries due to nerve compression and ischemia as a result of patient positioning	Careful patient positioning with attention to the peroneal, femoral, ulnar, and sciatic nerves with padded stir-ups, avoid hyperflexion or extension of the lower extremities
Pulmonary	Increased perioperative morbidity and mortality rates with development of pneumonia	Pulmonary toilet with deep cough, incentive spirometry, early ambulation
Urinary tract infection	Pelvic floor surgery postoperative rates up to 44% [84]	Screen if new onset bladder/voiding symptoms

group undergoing ASC [70]. ASC may be safely performed laparoscopically, even in the older woman; however, this requires significant surgical skills. Furthermore, there are few studies and no randomized trials looking at outcomes between the open versus laparoscopic approaches, especially in the older woman.

The USS is an intraperitoneal technique that attaches the vaginal vault to the uterosacral ligaments near the ischial spine bilaterally (Fig. 82.10). Published anatomic cure rates range from 65 to 98% depending on the definition of cure and the length of follow-up in an unselected patient population [71]. Sacrospinous fixation and ileococcygeus fixation are extraperitoneal techniques that attach the vaginal vault to the sacrospinous ligament or coccygeus muscle, respectively. Anatomic success for the sacrospinous fixation range from 29 to 98% and 53 to 96% for the ileococcygeus fixation [62].

Colpocleisis or colpectomy (narrowing or closure of the vaginal tissue and introitus) may be offered to the older woman who has no desire for vaginal function. These obliterative procedures have been shown to have shorter operative times and have fewer perioperative complications as compared to reconstructive repair [72]. Patient satisfaction is high and prolapse recurrence is low [73]. Preoperative assessment and operative treatment for occult stress incontinence may help avoid this unwanted postoperative complication.

Little information is available to guide us about which procedure should be considered in the older woman versus the younger woman. The ultimate decision on which approach and which procedure to employ in the treatment of POP in the older woman should take into consideration the patient's overall health and physical activity status, her specific pelvic floor defects and her future sexual activity desires, as well as the surgeon's training, skills, and preference.

Surgical Treatment of Urinary Incontinence

Common surgical approaches for the treatment of stress urinary incontinence include the midurethral sling (retropubic or transobturator), colposuspension, and the pubovaginal sling (autologous, synthetic, or allograft).

Older woman undergoing incontinence surgery can expect continence rates that in general compare favorably to those of younger women. The choice of incontinence surgery will depend upon surgeon experience as well as patient history and whether other concomitant procedures will be performed. Similar favorable short- and long-term outcomes have been demonstrated using the midurethral sling, colposuspension, and pubovaginal sling in the older woman.

Outcomes were compared between 123 women aged 70 years and older (mean 74.8) versus 208 younger women (mean 57.2) undergoing a retropubic midurethral sling (TVT Gynecare). Mean follow-up was 30 months (minimum 12). Persistent SUI was found in 7 versus 6%, respectively, and postoperative complications were similar between groups [74]. Review of current literature demonstrates SUI cure rates in older women who underwent midurethral slings (TVT) range from 45–93% compared to 73–95% in younger cohorts of women in the same studies [68].

A recent secondary analysis of data from the Stress Incontinence Surgical Treatment Efficacy Trial (SISTER), a randomized trial of Burch colposuspension versus autologous rectus fascial sling addressed 2-year outcomes in older women (≥ 65 years of age) versus those younger [75]. Older women had a slightly longer time to normal activities (50 days compared with 42 days, $P=0.05$), but there was no difference in time to normal voiding (14 days compared with 11 days, $P=0.42$). Older women were more likely to have a positive stress test at follow-up (odds ratio [OR] 3.7, 95% confidence interval [CI] 1.70–7.97, $P=0.001$), less subjective improvement in stress (eight point lesser decrease, 95% CI 1.5–14.1, $P=0.02$), and urge incontinence (seven point lesser decrease, 95% CI 1.5–12.2, $P=0.01$) as measured by the Medical and Epidemiologic Social Aspects of Aging questionnaire and were more likely to undergo surgical retreatment for SUI (OR 3.9, 95% CI 1.30–11.48). Perioperative adverse events and length of stay did not differ between groups.

Periurethral bulking injections have been employed in the treatment of SUI in the older woman. Regardless of the agent, cure and improvement rates are poor and appear to decline with time. However, given that the risk of the procedure is low and requires no specific anesthesia, this may be a reasonable option in the medically compromised patient or in the patient who has failed other approaches.

Aging is associated with decreased detrusor contractility and decreased urinary flow rates, which may explain the slightly increased occurrence of postoperative voiding dysfunction, irritative urinary symptoms, and UTIs seen in some older women. However, older women who have preoperative irritative lower urinary symptoms demonstrate decreased rates of these symptoms after surgery [76].

Bowel Incontinence

Treatment of bowel or fecal incontinence in the older woman should include evaluation for possible functional, anatomic and neurologic deficiencies in the lower gastrointestinal tract. Behavioral therapies that include diet modification with fluid and fiber balance as well as pelvic floor muscle

FIGURE 82.10 Diagrams illustrating open vaginal apical area with (a) exposure of site for suture placement or lateral pelvic side wall and (b) suture placement through ligament then through the posterior and anterior paravaginal tissue where they are locked to enable pulley action to the ligaments when tied. (Reprinted with permission from Berek JS (ed) (2006) Berek and Novak's Gynecology, 14th edn. Lippincott Williams & Wilkins, Philadelphia, pp 923–926.)

rehabilitation should be considered. If an anatomic defect such as a sphincter disruption is identified, anal sphincter repair could be considered. No specific studies address the efficacy of this approach in the older woman, however "good" short-term outcomes in all age ranges are achieved in approximately 70% of patients. Unfortunately, long-term

results may not be as robust, with one study reporting only 23% of patients with "good" results at 10 years follow-up [77]. Other surgical approaches to consider for the treatment of refractory FI include stimulated muscle transposition, artificial anal sphincter implant, sacral nerve neuromodulation, and colostomy.

Research Involving the Older Woman

Given the growing geriatric population along with the high prevalence of pelvic floor disorders, there is a pressing need for information on the nonsurgical and surgical treatment outcomes in this unique population of women. There is a relative paucity of literature that addresses the older woman and the treatment of pelvic floor disorders. In fact, older women have been excluded from many of the trials that have examined the outcomes of pelvic floor surgery. A systematic

review found the median percentage of women aged 70 or older who participated in surgical trials for SUI was 3.8%, while the number of surgeries for SUI performed on this population of women is estimated at 16% [78]. As the outcomes of surgery may be different in this population, the older woman should be encouraged to participate in clinical studies. Further investigation is required to understand the impact that surgery for pelvic floor disorders has on anatomic, physiologic, and functional outcomes in older women.

CASE STUDY

Ms RR is a 78-year-old white female from Eastern Europe seen in Urogynecology clinic with her daughter. Both speak English well, however, the daughter did help clarify some issues during the interview. Ms RR complained of an increasing feeling of protrusion and pressure that has markedly worsened over the past 6 months. She does describe problems emptying her bladder and denies significant urinary leakage. She is a widow and not sexually active. The patient had used a pessary for a while and did not wish to continue this nonsurgical treatment approach. Her medical history is significant for a renal transplant approximately 2.5 years previously secondary to a history of polycystic kidney disease; she takes prednisone and Cellcept for this. Other medical conditions include recurrent urinary tract infections, hypertension, coronary artery disease, and hypercholesterolemia. She has had a previous cholecystectomy, back surgery, and a heart catheterization. Other medications include furosemide, amlodipine, augmentin, atenolol, prograf, ASA, and a multivitamin; she has no known drug allergies. Other review of systems was noncontributory.

Physical examination revealed the abdomen to be soft, nontender, no mass effect; genitourinary examination revealed an evident uterine procidentia with total vaginal vault eversion (see Fig. 82.11a). On bimanual examination, there was the appreciation of a mass, just right of midline that was slightly tender to palpation. The urine dip was positive for nitrates and leukocytes and was sent for culture and sensitivities. All surgical options were discussed and it was decided that a vaginal obliterative procedure (colpocleisis, leaving the uterus in situ) would be performed.

The patient was started on some intravaginal estrogen cream to help thicken the vaginal epithelium, an oral antibiotic to treat the urine and dates for a urodynamic evaluation and surgery were set up. A CT scan would be set up to characterize the mass thinking that it may be her pelvic kidney. The urine culture was positive for *E. coli* sensitive to intravenous antibiotics. The renal transplant service subsequently admitted her for treatment and while she was in the hospital, she underwent a noncontrast CT of the abdomen and pelvis. Significant findings included extensive diverticular disease and an air-filled uterus and left fallopian tube. Further evaluation with the placement of transrectal contrast revealed a fistula tract between the sigmoid colon and the left adnexa (Fig. 82.11b). On further discussion with the patient, she did relate a several months history of lower abdominal–pelvic pain and some occasional discharge from the cervix. The patient was transferred to the Urogynecology service, gentle hydration and antibiotic therapy was continued and a colorectal surgery consult obtained. The patient remained afebrile throughout her hospital course. Perioperative medication management was discussed including holding the furosemide and amlodipine the day before surgery; she would take her beta-blocker and receive stress dose steroids the day of surgery. One week after admission, after a gentle bowel preparation and medication management, she underwent a TAHBSO and sigmoid resection. As there was concern about using a mesh to elevate the vagina, the planned colpocleisis was also performed.

Her postoperative course was unremarkable. Her daughter stayed with the patient the majority of the time. Pain was well controlled with initial patient controlled anesthesia, with conversion to oral medications once bowel function was assured. All of her medications

CASE STUDY (continued)

FIGURE 82.11 (a) Total uterine procidentia. (b) CT shows gas in tubular fallopian tube and adjacent stranding. There are numerous diverticula in the sigmoid colon. (c) Water soluble enema shows linear contrast in the tract. The round structure is a calcified fibroid.

were reinstated and she was discharged home with her daughter on POD#4.

This is a case where clinical suspicion for other potential contributing processes resulted in findings that markedly changed the initial surgical plan. Older patients, particularly older patients who are chronically immuno-

suppressed, often do not manifest with typical signs and symptoms of infectious and other pathologic processes. Once the diagnosis was made, careful perioperative planning under nonemergent conditions allowed this complex clinical scenario to be resolved in a very satisfactory manner resulting in markedly improved quality of life.

Chapter 83

Gynecologic Malignancies in the Elderly

Dan-Arin Silasi, Peter E. Schwartz, and Thomas J. Rutherford

Pelvic reproductive organ cancers include those that arise in the vulva, vagina, cervix, uterus, fallopian tubes, and ovaries. In the United States, the number of persons over 65 years of age has been increasing at a disproportionately higher rate than that of the general population. According to the U.S. Census Bureau, the percentage of women 65 years of age and older has increased from 13.1% in 1980 to 14.6% in 1990.

The risk of gynecological cancers increases with age. It is important that the medical community is aware of the unique aspects of clinical care of older cancer patients.

This chapter presents the epidemiology, presenting symptoms, diagnosis workup, and treatment of pelvic malignancies in elderly women. It also notes the alternative therapies that can be applied to elderly patients when they are unable to tolerate standard treatment due to associated medical comorbidities.

Vulvar Cancer

The vulvar skin can present with a variety of dysplastic and malignant changes that vary from mild dysplasia to carcinoma in situ to invasive cancers involving other pelvic organs or have distant metastases. Vulvar cancer is an uncommon occurrence, representing approximately 4% of genital tract malignancies. Cancer statistics estimated that 3,970 patients were newly diagnosed in the United States in the year 2004 and that 850 deaths occurred [1, 2].

Dysplastic changes of the vulva may be unifocal or multifocal. The disease tends to be unifocal in the elderly population, whereas in women of younger age it tends to be multifocal [3].

Elderly patients, particularly those over 70 years of age, are less likely to have an associated human papilloma virus (HPV) infection [4, 5].

Dysplastic and malignant squamous cell changes are the dominant histologic patterns seen in vulvar neoplasias.

In addition to squamous cell changes, extramammary Paget's disease (EMPD) is most commonly seen in the vulva of postmenopausal Caucasian women but may also be seen in the axilla, male genitalia, eyelid, and ear. It is sometimes associated with an underlying vulvar carcinoma [6]. Patients with EMPD in the anogenital region most commonly present with pruritus, hyperpigmented or hypopigmented lesions, ulceration, and/or areas of leukoplakia and can frequently be mistaken for an inflammatory or infectious process [7].

Squamous cell carcinomas account for approximately 90% of newly diagnosed cancer cases. The second most common malignancy is melanoma [8], and the third most common is adenocarcinoma, arising in a Bartholin's gland or in skin appendages [9].

The etiology of vulvar carcinoma is unknown. The association of vulvar cancer with preceding vulvar intraepithelial neoplasia (VIN) and Human Papillomavirus infection (HPV) is controversial, as is its relationship with vulvar dystrophies. Other authors, however, have reported progression of VIN to invasive cancer [10, 11]. The association of HPV subtypes with oncogenic potential and smoking with invasive vulvar cancers is frequently found in women of relatively younger age [12].

However, vulvar cancer is encountered mostly in elderly patients and appears to be unrelated to smoking and HPV infection, while concurrent VIN is uncommon. This patient population has a high incidence of dystrophic lesions, like lichen sclerosus [13].

Staging of vulvar malignancies is surgical in nature and depends on the extent of the local disease and the presence or absence of inguinal lymph node metastases (Table 83.1).

The diagnosis of vulvar cancer starts with inspection. It is important to distinguish atrophy from dysplasia. Elderly patients often have atrophic changes of the vulva. Lesions that are symmetric in distribution, white, and nonraised are

TABLE 83.1 Carcinoma of the vulva [175]

Stage I	Tumor confined to the vulva
IA	Lesions ≤ 2 cm in size, confined to the vulva or perineum and with stromal invasion ≤ 1.0 mm ^a , no nodal metastasis
IB	Lesions > 2 cm in size or with stromal invasion > 1.0 mm ^a , confined to the vulva or perineum, with negative nodes
Stage II	Tumor of any size with extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with negative nodes
Stage III	Tumor of any size with or without extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with positive inguino-femoral lymph nodes
IIIA	(i) With 1 lymph node metastasis (≥ 5 mm), or
	(ii) 1–2 lymph node metastasis(es) (≤ 5 mm)
IIIB	(i) With 2 or more lymph node metastases (≥ 5 mm), or
	(ii) 3 or more lymph node metastases (≤ 5 mm)
IIIC	With positive nodes with extracapsular spread
Stage IV	Tumor invades other regional (2/3 upper urethra, 2/3 upper vagina), or distant structures
IVA	Tumor invades any of the following:
	(i) Upper urethral and/or vaginal mucosa, bladder mucosa, rectal mucosa, or fixed to pelvic bone, or
	(ii) Fixed or ulcerated inguino-femoral lymph nodes
IVB	Any distant metastasis including pelvic lymph nodes

^aThe depth of invasion is defined as the measurement of the tumor from the epithelial–stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion

usually atrophic in nature. Dysplastic lesions and malignancies tend to be asymmetric in distribution and may be friable.

Most commonly, patients present with the complaint of a vulvar lump or mass. A long history of vulvar burning or pruritus is frequently elicited. Most lesions occur initially on the labia majora and less frequently on the labia minora, clitoris, or perineum. Only approximately 5% of cases are multifocal.

There is little consensus regarding the optimal method of management. There has been a gradual trend toward conservation in the management of dysplastic lesions (vulvar intra-epithelial lesion, VIN grade 1–3). Current treatment modalities include carbon dioxide (CO₂) laser vaporization or ablation and surgical excision. Recurrence rates after treatment have been reported to range from 10 to 50% and are thought to be related to the grade of VIN and margin status along with the multifocal nature of the condition and its relationship with HPV [14].

In the elderly, if chosen, surgical excision may be performed under local anesthesia. Generally, a 1-cm margin is adequate for noninvasive lesions. For extramammary Paget's disease of the vulva, however, even 2-cm margins are often insufficient [15, 16].

For extramammary Paget's disease of the vulva, it is sometimes necessary to perform extremely wide local excisions with skin grafts or advancement flaps to cover the defect [17]. Microscopically, positive margins following surgical excision of vulvar Paget's disease is a frequent finding, and disease recurrence is common regardless of surgical margin status. Long-term monitoring of patients is recommended, and repeat surgical excision is often required [18].

The standard surgical management of women with invasive carcinomas of the vulva is a radical vulvectomy with bilateral inguinal–femoral lymphadenectomies [19]. The inguinal lymph nodes are the primary lymphatic drainage for the vulva and lower one-third of the vagina. The lymph node sampling is performed by removing an ellipse of skin in continuity with the underlying fat pad above the cribriform fascia present in the inguinal–femoral subcutaneous tissue. However, the cribriform fascia is difficult to identify in some women or may not be anatomically intact. This treatment can be modified if the tumor is unilateral, in which case a modified radical vulvectomy, effectively a unilateral radical excision of the labia in association with ipsilateral lymphadenectomy, is performed [20].

Data suggest that a woman with a unilateral vulvar cancer having negative ipsilateral inguinal lymph nodes is highly unlikely to have contralateral inguinal lymph node involvement [21].

If the lesion is less than 2 cm in diameter and is associated with minimal invasion (usually < 2 mm), the chance of inguinal lymph node metastases being present is virtually nil. For an elderly woman with significant medical problems that presents with a superficial lesion (< 2 mm invasion), wide local excision may be adequate management. Such surgery can be accomplished under local anesthesia if the patient is not a candidate for general or regional anesthesia [22–24].

Further modifications in the management of vulvar cancer include inguinal lymph node sampling, rather than a formal inguinal–femoral lymphadenectomy. The sentinel inguinal lymph node is the node most likely to be involved if metastatic disease from the vulvar lesion is present. Inguinal lymph node sampling reduces the likelihood of the postoperative complication of a lymphocyst. Sentinel lymph node technology [25–27] has provided the means for identifying the sentinel lymph node draining a tumor bed, and it can be excised with a minimally invasive approach. Inguinal sentinel lymph node (SLN) dissection in vulvar cancer patients has been shown to be feasible and highly sensitive for the detection of metastatic disease to the inguinal nodal basin. Clinical studies have shown a nearly 100% identification rate of a SLN when lymphatic mapping with a radioactive tracer (Tc-99m sulfur colloid) is used in combination with blue dye. The negative predictive value of a negative sentinel lymph node in these studies has been shown to be 100%.

The utilization of a sentinel node dissection allows for an in-depth pathologic examination of the one or two sentinel lymph nodes. In this approach, pathologic ultrastaging can detect micrometastases [28–30].

If the sentinel lymph node is free of disease, it is unlikely that other lymph nodes would be involved. Particularly in an elderly patient, this technique may reduce the extent of lymphadenectomy [31, 32].

Patients with advanced vulvar cancer (stage III and IV) that are managed with primary surgery tend to be older patients that have smaller lesions but positive lymph nodes, whereas patients treated primarily with chemoradiation are younger and have larger volume disease but fewer lymph node metastases. Despite these differences, patients treated with surgery or primary chemoradiation have no differences in overall survival, progression-free survival, or recurrence rates. Age is the most powerful predictor of survival when size, lymph node status, stage, and treatment are accounted for [33].

The combination of postoperative irradiation with or without chemotherapy is used routinely for managing patients with vulvar cancer following a radical vulvectomy and inguinal–femoral lymphadenectomy if lymph node metastases are identified [34]. The most common cytotoxic drug used for concurrent chemoradiation is cisplatin.

The vulvar tissue is supplied with an end-arterial blood supply. The skin and subcutaneous tissue are quite sensitive to the radiation effect. Dry desquamation followed by moist desquamation is a routine problem associated with irradiating the vulva [35].

Nevertheless, relatively low-dose fractions of radiation therapy combined with 5-fluorouracil and mitomycin C have been employed for managing advanced vulvar cancer and cancer in elderly patients who are unable to tolerate a radical vulvectomy [36–40].

Survival of women with vulvar cancer is related to the presence of lymph node metastases. Patients with no lymph node metastasis have approximately an 80% 5-year survival. Those with evidence of lymph node metastasis have a 54% 5-year survival. Patients with unilateral lymph node metastases have a 60% 5-year survival, whereas those with bilateral lymph node metastases have a 23% 5-year survival [41].

Key Points in Vulvar Cancer Affecting Elderly Patients

- It is predominantly a disease of the elderly patient.
- It has a lesser association with HPV infection.
- Squamous cell carcinoma is the most common histology followed by melanoma.
- Vulvar Paget's disease is frequently associated with carcinoma.
- Staging is surgical.
- Tumor size and inguinal lymph node status are the most important predictors.

Vaginal Cancer

Primary cancer arising in the vagina is rare. It constitutes approximately 2% of all gynecologic cancers. It is primarily a disease of older women. Most patients are diagnosed with vaginal cancer in their seventh to eighth decade of life [42, 43].

The histology of these lesions is predominantly squamous cell cancer, although adenocarcinoma can arise de novo within the vagina [44].

Less common histologies include melanoma and the rare paravaginal sarcoma [45].

It is appreciated that 84% of vaginal involvement is secondary from cancers of the cervix, uterus, rectum, ovary, vulva, or bladder [46].

The etiology of vaginal cancer is associated with that of cervical cancer, and many of the precancerous changes of the vagina occur after patients have been treated for squamous cell carcinoma in situ of the cervix or invasive cancer of the cervix. However, primary vaginal cancers do occur in elderly women without previous or concurrent cervical disease [47]. Vaginal cancer is associated with HPV infection [48, 49].

By convention, the classification and staging of the International Federation of Gynecology and Obstetrics (FIGO) requires that if a cancer is present in the vagina and reaches the cervix, the cancer is considered a cervical cancer because cervical cancer is much more common than vaginal cancer.

Women with vaginal cancers present with vaginal discharge and sometimes burning or pain. The discharge may be bloody or purulent when the lesion becomes secondarily infected by vaginal flora.

The diagnosis is made by inspection, palpation, and biopsy. Dysplastic changes of the vagina may be confined to the vaginal apex, particularly in women with a history of cervical dysplasia or malignancy. However, multifocal dysplastic lesions of the vagina do occur, usually in association with HPV infection [50–53]. The diagnosis is confirmed by biopsy. The staging of vaginal cancer is presented in Table 83.2.

TABLE 83.2 Carcinoma of the vagina [176]

Stage 0	Carcinoma in situ, intraepithelial neoplasia grade 3
Stage I	The carcinoma is limited to the vaginal wall
Stage II	The carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall
Stage III	The carcinoma has extended to the pelvic wall
Stage IV	The carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum; bullous edema as such does not permit a case to be allotted to stage IV
IVA	Tumor invades bladder and/or rectal mucosa and/or direct extension beyond the true pelvis
IVB	Spread to distant organs

Source: Reprinted from Odicino et al. [176], with permission

Management of vaginal cancer is based on the stage of disease, the volume of tumor present, and its location within the vagina. No consensus exists regarding the management of different presentations of vaginal cancer. The low incidence of the disease precludes the organization of large randomized trials and comparison of different treatment modalities. Vaginal cancers that involve the upper one-third of the vagina and are limited in extent (i.e., stage I or stage II) can be treated with a radical hysterectomy in continuity with a radical vaginectomy. Tumors involving the lower third of the vagina can be treated surgically in the form of a wide local excision that includes the adjacent vulvar tissue or by a vulvectomy in continuity with a partial vaginectomy [54, 55].

Most vaginal cancers, however, occur in older age women, and the treatment of choice is radiation therapy. The combination of brachytherapy and external beam radiation therapy is often employed for the management of vaginal cancer. Chemoradiation for vaginal cancer appears appropriate, an approach derived from the treatment of cervical cancer. Reports of experience with chemoradiation in the treatment of vaginal cancer are limited. Most commonly, the cytotoxic drug is cisplatin, administered as a radiation sensitizer concurrently with external beam radiation [56].

Complications of radiation therapy include radiation mucositis and subsequent vaginal stenosis. Vaginal necrosis may occur and lead to vesicovaginal or rectovaginal fistulas, the treatment of which are urinary or colon diversions.

The survival of women with vaginal cancer is based on the stage of the disease at presentation. The overall 5-year survival rate for vaginal cancer is approximately 44%. The 5-year survival for stage I disease was 73.4%, stage II, 51.4%, stage III, 32.5%, stage IVA, 20.4%, and stage IVB, 0% [57].

Most recurrences occur in the pelvis. Management of recurrent disease is similar to that for cervical cancer (i.e., exenterative surgery for a centrally localized tumor and chemotherapy for disseminated disease) [54].

Key Points in Vaginal Cancer Affecting Elderly Patients

- It is predominantly a disease of the elderly patient.
- Vaginal involvement with carcinoma is mostly from the surrounding pelvic organs.
- The presenting symptoms are vaginal discharge and sometimes burning or pain.
- The treatment of choice is chemoradiation.

Cervical Cancer

Cervical carcinoma represents the second most common cancer that develops in the female reproductive organs. Data published by the American Cancer Society estimate that 11,070 new cases of cervical cancer were diagnosed in the

year 2008 in the United States and that 3,870 deaths occurred as a result of this disease [58].

The median age for cervical cancer is 53 years, which is the lowest median age for all pelvic reproductive organ cancers. Cervical cancer is predominantly a disease of younger age women; nevertheless, 13.1% of all cervical cancers present in women 70 years of age or older.

The most common histology for invasive cervical cancers is the squamous cell variety. The second most common subtype is adenocarcinoma of the cervix [59].

A spectrum of changes can occur in the cervix, from mild dysplasia through carcinoma in situ, all of which may be treated in the office using simple treatments that mechanically destroy the surface epithelium and allow healthy tissue to grow in. However, when a woman goes through menopause, the site at which most cervical cancers begin, the transformation zone (i.e., the junction of the exocervical squamous epithelium with that of the endocervical columnar epithelium) recedes into the endocervical canal. Dysplastic changes often cannot be seen within the endocervical canal, especially in elderly women, in whom often there is an associated invasive cancer.

Other invasive cancers that occur in the cervix are adenocarcinomas arising in the glandular epithelium of the endocervix [60].

Adenosquamous carcinomas, a combination of malignant glandular and squamous elements, also arise in the cervix but to a much lesser extent than squamous cell carcinoma and adenocarcinoma [61].

A variety of risk factors have been associated with the development of cervical cancer. They include having multiple sexual partners, sexual intercourse at a young age, cigarette smoking, HPV infections or other sexually transmitted disease infections, immune suppression, genital warts, and multiparity. Human Papillomavirus (HPV) infection is the number one etiologic agent in the development of cervical neoplasia. At least 90% of invasive cervical cancers have evidence of HPV infection [62, 63].

The diagnosis of cervical dysplasia is based on a biopsy of the cervix. It must be remembered that in the elderly patient, the transformation zone is within the canal, so if the elderly patient has an abnormal Pap smear, the endocervical canal must always be biopsied. An office endocervical curetting of the endocervical canal is extremely useful for determining the nature and extent of the lesions. If such a change is present in the endocervical canal, it is the authors' recommendation that the patient should undergo a cone biopsy. A cone biopsy removes a large segment of the cervix and allows the pathologist to determine more accurately the extent and margins of the dysplastic or malignant changes present. Loop electrical excision of the transformation zone (LEETZ) is an alternative method for evaluating the cervix. In the elderly, with the transformation zone in the endocervical canal, the

LEETZ procedure often causes cautery artifacts, so the endocervical and ectocervical margins cannot be interpreted.

In an elderly patient diagnosed with high-grade cervical dysplasia, it is wisest to consider a hysterectomy. If the patient has significant medical comorbidities and is diagnosed with an early cervical cancer, a large cone biopsy of the cervix can be curative [64].

The FIGO (International Federation of Gynecology and Obstetrics) staging system for invasive cervical cancer is presented in Table 83.3. Although advanced imaging modalities are not used when determining the clinical stage of patients

TABLE 83.3 Carcinoma of the cervix uteri [175]

Stage I	The carcinoma is strictly confined to the cervix (extension to the corpus would be disregarded)
IA	Invasive carcinoma which can be diagnosed only by microscopy, with deepest invasion ≤ 5 mm and largest extension ≥ 7 mm
IA1	Measured stromal invasion of ≤ 3.0 mm in depth and extension of ≤ 7.0 mm
IA2	Measured stromal invasion of >3.0 mm and not >5.0 mm with an extension of not >7.0 mm
IB	Clinically visible lesions limited to the cervix uteri or preclinical cancers greater than stage IA ^a
IB1	Clinically visible lesion ≤ 4.0 cm in greatest dimension
IB2	Clinically visible lesion >4.0 cm in greatest dimension
Stage II	Cervical carcinoma invades beyond the uterus, but not to the pelvic wall or to the lower third of the vagina
IIA	Without parametrial invasion
IIA1	Clinically visible lesion ≤ 4.0 cm in greatest dimension
IIA2	Clinically visible lesion > 4 cm in greatest dimension
IIB	With obvious parametrial invasion
Stage III	The tumor extends to the pelvic wall and/or involves lower third of the vagina and/or causes hydronephrosis or nonfunctioning kidney ^b
IIIA	Tumor involves lower third of the vagina, with no extension to the pelvic wall
IIIB	Extension to the pelvic wall and/or hydronephrosis or nonfunctioning kidney
Stage IV	The carcinoma has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum. A bullous edema, as such, does not permit a case to be allotted to stage IV
IVA	Spread of the growth to adjacent organs
IVB	Spread to distant organs

Source: Reprinted from FIGO Committee on Gynecologic Oncology [175], with permission

^aAll macroscopically visible lesions – even with superficial invasion – are allotted to stage IB carcinomas. Invasion is limited to a measured stromal invasion with a maximal depth of 5.00 mm and a horizontal extension of not >7.00 mm. Depth of invasion should not be >5.00 mm taken from the base of the epithelium of the original tissue – superficial or glandular. The depth of invasion should always be reported in mm, even in those cases with “early (minimal) stromal invasion” (~ 1 mm) The involvement of vascular/lymphatic spaces should not change the stage allotment.

^bOn rectal examination, there is no cancer-free space between the tumor and the pelvic wall. All cases with hydronephrosis or nonfunctioning kidney are included, unless they are known to be due to another cause

with cervical cancer, in the developed world, CT, MRI, and 18-F FDG PET scans are routinely ordered and help in planning for the most appropriate treatment modality [65, 66].

Management of invasive cancer of the cervix is by radiation therapy or surgery. Surgery is performed in women with early-stage disease who can tolerate a radical hysterectomy with bilateral pelvic lymph node resection [67].

Patients with microinvasive cancer (<3 mm) can undergo a type II radical hysterectomy in which the tissue that is removed includes the parametria medial to the ureters and the proximal one-third of the vagina. However, if an invasive carcinoma is present, a type III or a Meigs–Wertheim radical hysterectomy is indicated. This procedure removes the parametrial tissue lateral to the ureter and removes approximately one-half of the vagina in continuity with the cervix and uterine corpus. While traditionally these operations have been performed by laparotomy, conventional laparoscopic and robotic techniques are equally effective and carry less morbidity [68–70].

For the elderly patient with more advanced disease or who is unable to tolerate a radical hysterectomy, radiation therapy using intracavitary and external beam techniques is effective for managing an invasive cancer of the cervix. The efficacy of the treatment depends on the stage of the cancer and the tumor volume [71–75].

The overall survival for women with cervical cancers correlates with the stage of the disease. Stage I patients have an 81.6% 5-year survival, stage II 61.3%, stage III 36.7%, and stage IV 12.1% [76].

Treatment of recurrent cervical cancer is based on the extent of the disease present and the primary treatment modality.

Tumor recurrence after surgery for cervical carcinoma is associated with high fatality and morbidity, posing a major therapeutic challenge. Salvage radiotherapy with concurrent chemotherapy for recurrent cervical carcinoma following surgery may result in 40–50% long-term disease-free survival and an acceptable risk of severe treatment complications even in patient with recurrences extending to the pelvic wall [77].

Patients who develop central recurrence (i.e., at the vaginal apex) that does not extend to or reach the pelvic side wall may be treated with exenterative surgery [78–80].

In the past, we used 70 years of age as a cutoff for those eligible for exenterative surgery. As improvements in postoperative care have evolved, we are now able to offer exenterative surgery to women over the age of 70 years if they are otherwise in good health. Exenterative surgery includes anterior pelvic exenteration, which removes the uterus in continuity with the bladder via a radical hysterectomy, radical cystectomy, and urinary diversion. Posterior pelvic exenteration involves a radical hysterectomy in continuity with resection of the sigmoid colon and rectum, and it requires a colostomy. Total pelvic exenteration removes the bladder,

uterus, and rectosigmoid colon. The creation of a continent pouch at the time of exenterative surgery avoids the need for continuous collection of urine in an ostomy bag. However, experience at the Yale-New Haven Medical Center suggests that patients who have been heavily pretreated with radiation and are over 65 years of age do poorly with continent pouches and probably are best served by an ileal conduit.

Patients who have extensive recurrent disease not limited to the center of the pelvis are offered chemotherapy. Chemotherapy for the management of recurrent cervical cancer is palliative. Overall response rates to combination chemotherapy of 46.3% have been reported. Responses were higher in patients with disease in nonirradiated sites [81].

Key Points in Cervical Cancer Affecting Elderly Patients

- Only 13% of all cervical cancers occur after the age of 70.
- The evaluation of the endocervical canal can be difficult secondary to stenosis and atrophy.
- Although advanced imaging modalities are not included in the WHO recommended diagnostic workup, MRI, CT, and 18-F FDG PET scans are routinely used.
- Surgery and chemoradiation are equally effective. Surgery is limited to stage IIA and earlier.

Uterine Cancer

In the United States, the uterine corpus is the most common site for cancer in the female reproductive tract, with an estimated 40,100 new cases and 7,470 deaths occurring in the year 2008 [58].

SEER data from 1992 to 2002 state that uterine cancers were diagnosed in 31% of patients between 65 and 74 years of age, 20% between 75 and 84 years of age, and 4% between 85 and 95 years of age [83].

The most common histologic types of uterine cancer arise from the endometrium and are of endometrioid type (Table 83.4). Other subtypes are adenosquamous, clear-cell carcinomas, and uterine serous cancers. Grade 3 endometrioid, clear cell, and serous cancers have an aggressive behavior and require more than a hysterectomy to achieve cure [83, 84].

Uterine sarcomas are a group of rare and usually aggressive soft-tissue cancers. The three major subtypes of uterine sarcomas (listed in decreasing order of incidence) are carcinosarcoma, leiomyosarcoma, and endometrial sarcoma. Most patients with uterine sarcomas are middle- to older-aged women who present with abnormal uterine bleeding or a pelvic mass [85, 86].

Uterine cancers are usually diagnosed after an obvious early signal, postmenopausal bleeding, occurs. Women must

TABLE 83.4 Carcinoma of the endometrium [175]

Stage I ^a	Tumor confined to the corpus uteri
IA ^a	No or less than half myometrial invasion
IB ^a	Invasion equal to or more than half of the myometrium
Stage II ^a	Tumor invades cervical stroma, but does not extend beyond the uterus ^b
Stage III ^a	Local and/or regional spread of the tumor
IIIA ^a	Tumor invades the serosa of the corpus uteri and/or adnexae ^c
IIIB ^a	Vaginal and/or parametrial involvement ^c
IIIC ^a	Metastases to pelvic and/or paraaortic lymph nodes ^c
IIIC1 ^a	Positive pelvic nodes
IIIC2 ^a	Positive paraaortic lymph nodes with or without positive pelvic lymph nodes
Stage IV ^a	Tumor invades bladder and/or bowel mucosa, and/or distant metastases
IVA ^a	Tumor invasion of bladder and/or bowel mucosa
IVB ^a	Distant metastases, including intraabdominal metastases and/or inguinal lymph nodes

^aEither G1, G2, or G3

^bEndocervical glandular involvement only should be considered as stage I and no longer as stage II

^cPositive cytology has to be reported separately without changing the stage

be informed that whenever vaginal bleeding occurs after menopause, they must be promptly evaluated [87].

If the vulva, vagina, and cervix appear unremarkable on inspection, an endometrial biopsy should be obtained. Rarely, women are found to have endometrial cells on a routine Pap smear. The presence of such cells from postmenopausal women may be associated with endometrial hyperplasia or malignant changes of the endometrium [88]. This cytologic finding is another indication to perform an endometrial biopsy. An endometrial biopsy can usually diagnose the presence of hyperplasia of the endometrium or carcinoma [89, 90].

Endometrial hyperplasias are categorized into simple and complex hyperplasia. The hyperplasias are further subdivided into those with or without atypia. It is unusual for simple hyperplasia to be associated with cytologic atypia, whereas complex hyperplastic changes are often associated with cytologic atypia. Simple hyperplasia rarely progresses to invasive cancer. Retrospective studies reported that complex hyperplasia without atypia can progress to invasive cancer in approximately 2% of patients over a 12-year period, whereas complex hyperplasia with atypia is associated with an up to 30% chance of developing invasive cancer over an 8-year observation period [91].

Management of simple hyperplasia in the elderly consists of observation. The treatment of complex hyperplasia without atypia is progestin therapy (medroxyprogesterone acetate, megestrol acetate). Repeat endometrial sampling is indicated

after 3 months. Persistent hyperplasia is an indication for hysterectomy and bilateral salpingo-oophorectomy. Atypical hyperplasia in an elderly woman should be treated with hysterectomy and adnexectomy [92, 93]. If the patient cannot tolerate surgery, progestin therapy in the form of daily oral medroxyprogesterone acetate or megestrol acetate may be used to revert the endometrium back to an atrophic state.

Uterine cancer is staged surgically (Table 83.3). Patients should routinely undergo a total hysterectomy, bilateral salpingo-oophorectomy, and pelvic and paraaortic lymph node sampling. Omentectomy or omental biopsy is indicated for uterine clear cell and serous carcinomas, and uterine sarcomas [94–97]. Conventional laparoscopic or robotic approaches have less perioperative morbidity [98–101].

Additional therapy is based on the findings of the surgical staging. Patients with histologically low-grade endometrial cancers that do not deeply infiltrate the myometrium require no additional therapy. Patients with high-grade endometrial cancers are usually treated with vaginal apex irradiation alone to prevent local recurrences. Some centers prescribe external beam radiation therapy of the pelvis [102]. Chemotherapy is indicated for clear cell and serous uterine cancers.

Patients with disease that has extended beyond the uterus and cervix are usually treated with chemotherapy in combination with vaginal apex radiation. A Gynecologic Oncology Group Phase III trial has demonstrated that chemotherapy for advanced endometrial carcinoma significantly improves both progression-free survival and overall survival when compared with whole abdominal irradiation. Adverse effects of treatment tended to be more frequent and more severe on the chemotherapy arm, but the majority of acute toxicities were expected and manageable [103–105].

The 5-year survival of women with uterine cancer confined to the uterine corpus (stage I) is approximately 85%. Those who have only superficial invasion without any negative prognostic factors have survivals of 95–100%. Those patients with deep penetration of the uterine wall (i.e., stage IC) have survivals of 70–80%. As the stage of the cancer increases, the likelihood of cure decreases. The 5-year survival for women with stage II disease is 70%, stage III disease is 49%, and stage IV disease is 19% [106].

Elderly patients often are found to have more aggressive histologic types of endometrial cancer and may have medical comorbidities that preclude surgery. Published data show that elderly women with uterine cancers who have severe medical problems can have their cancers controlled with intracavitary radiation therapy administered with or without external beam radiation, particularly if the disease is confined to the uterus [107].

Experience at the Yale-New Haven Medical Center suggests that this approach is effective. Most inoperable patients die of other medical diseases rather than of their

cancer. Fifty-four patients treated at Yale deemed medically inoperable had a significantly shorter overall survival than the 108 control patients with stage I or II disease ($p < 0.0001$). Deaths in the inoperable group were more likely to be due to intercurrent disease (28 of 32 cases) compared to the controls (3 of 15) ($p < 0.0001$). Inoperable patients who did not die of intercurrent disease had a median 5-year survival approaching that of the operable patients. The average age of the stage I patients was 72.0 years (range 44–93 years) and stage II patients 70.0 years (range 51–82 years) [108].

The majority of patients with uterine cancer has disease confined to the uterus and has an excellent overall prognosis. However, some patients present with advanced primary disease. The management of metastatic disease is variable, depending on factors such as medical comorbidities, tumor grade, performance status, and prior treatments. Management options include hormonal therapy, cytotoxic chemotherapy as well as targeted therapies that inhibit angiogenesis and the cellular signaling pathways involved in cell growth and proliferation. Hormonal therapy and cytotoxic chemotherapy have traditionally been used in the treatment of metastatic endometrial cancer. Advances in molecular biology have led to multiple potential targeted therapies to be used in the treatment of metastatic endometrial cancer [109].

Patients with more advanced disease, particularly with extrapelvic disease, may be treated with neoadjuvant chemotherapy [110]. Using this approach, the tumor bulk is reduced, allowing a less extensive surgical procedure with less perioperative morbidity. Patients tend to stop bleeding promptly after the initiation of chemotherapy.

Pelvic irradiation can be administered for elderly patients with multiple medical comorbidities for locoregional control and palliation. Using this approach, vaginal bleeding ceases shortly after the initiation of treatment [111].

Radiation therapy is a regional technique that has no significant impact on overall survival for women with advanced-stage endometrial cancers. In contrast, neoadjuvant chemotherapy may potentially have an impact on overall survival and accomplish the same control of bleeding as that offered by radiation therapy [112].

The management of recurrent uterine cancers is based on the cancer's histology and the extent of disease [113].

Patients with well-differentiated endometrial cancers may respond to progestin therapy. We have used progestin therapy to control recurrent endometrial cancer for prolonged periods of time, although most, but not all, women who have recurrent disease treated with progestin therapy will have further recurrences. Patients with the less well-differentiated or more aggressive histologic subtypes typical in elderly patients are usually treated with chemotherapy to control advanced and recurrent disease.

Three forms of sarcoma involve the uterus: leiomyosarcomas, carcinosarcomas, and endometrial sarcomas [114–117].

Surgery, including hysterectomy and resection of disease, serves as the main treatment modality. Adjuvant therapies, including radiation, chemotherapy, and/or hormonal therapy, have limited benefit on overall survival. Few large randomized controlled trials were conducted because of the uterine sarcomas' rare and aggressive nature. For patients with metastatic or recurrent disease, multimodality therapy is limited by low response rates and limited duration of response [86, 118].

Uterine leiomyosarcomas are treated with hysterectomy. Sarcomas arising within the center of well-delineated leiomyomata and have not penetrated beyond the pseudocapsule of the leiomyoma often are cured with hysterectomy alone [117].

Leiomyosarcomas arising de novo in the muscular wall of the uterus tend to be more aggressive, and surgery alone is insufficient [119]. Currently, a debate remains as to whether such patients should receive chemotherapy at the time of diagnosis or treatment should be delayed until the leiomyosarcoma recurs. The infrequent occurrence of uterine leiomyosarcomas has limited the opportunity for a prospective randomized trial to address this issue. Patients that present with metastatic uterine sarcomas are treated with surgery and chemotherapy. Their prognosis is poor [120–122].

Carcinosarcomas of the uterus histologically contain carcinomatous and sarcomatous elements. The carcinomatous element of a carcinosarcoma is often uterine serous cancer, although poorly differentiated endometrioid carcinoma can also be found or, rarely, a squamous cell carcinoma. The sarcomatous elements have been categorized as homologous elements (tissues normally found in the uterus) and heterologous elements (not normally found in the uterus). An example of a homologous element is a leiomyosarcoma. Heterologous elements include rhabdomyosarcoma, chondrosarcoma, and osteosarcoma.

The management of uterine carcinosarcomas is surgical, including a total hysterectomy, bilateral salpingo-oophorectomy, omentectomy, and pelvic and paraaortic lymphadenectomies. Surgery is followed by combination chemotherapy and irradiation of the vaginal apex or whole pelvis. This approach has been most effective for early-stage disease, but it has not been effective when the disease has spread outside the uterus (i.e., stage III or IV disease) [123–125].

Endometrial stromal sarcomas are low-grade malignancies. They are sensitive to progestin therapy. Following a hysterectomy for a low-grade endometrial stromal sarcoma, patients should be placed on an oral progestin, either megestrol acetate or medroxyprogesterone acetate. Endometrial sarcomas, formerly referred to as high-grade endometrial stromal sarcomas, are high-grade cancers and often are at an advanced stage when diagnosed. Their management is by cytoreductive surgery and postoperative combination chemotherapy [126].

Key Points in Uterine Cancer Affecting Elderly Patients

- The most common presenting symptom is postmenopausal vaginal bleeding.
- Endometrial cells present on a cervical cytology specimen (Papanicolaou smear) require evaluation of the endometrial cavity.
- Uterine cancers in the elderly are frequently of the type II variety: papillary serous carcinomas, clear cell carcinomas, and high-grade endometrioid carcinomas. Even stage I cancers are treated with chemotherapy and radiation following surgery.
- Conventional or robotic laparoscopy is the preferred surgical modality.

Fallopian Tube Cancer

The fallopian tube is the least common site for primary cancers to develop in the female reproductive tract. The age-adjusted incidence rate for fallopian tube carcinoma is 3.72 per million in the United States. The median age for women with fallopian tube carcinomas is 64 years. Fallopian tube cancers are mostly adenocarcinomas, and serous carcinomas are the most common diagnosed histologic type [127]. If the fallopian tube carcinoma involves the ovary, by convention, it is considered to be an ovarian cancer, as ovarian cancer occurs more frequently than fallopian tube carcinoma.

The etiology of fallopian tube carcinoma is unknown. Symptoms associated with fallopian tube carcinoma include lower abdominal pain and pressure and a profuse, clear vaginal discharge (hydros tubae profluens) [128]. Physical examination often confirms the presence of a mass. Imaging studies may be performed using ultrasonography or computed tomography (CT) scans to identify an adnexal mass. Most fallopian tube carcinomas are found when patients undergo surgery for a pelvic mass or presumed ovarian cancer.

Surgical staging and chemotherapy follow the concepts used in epithelial ovarian cancer (EOC). Surgery consists of total hysterectomy, adnexectomy, pelvic and periaortic lymphadenectomy, omentectomy, and resection of any metastatic disease. The goal of the surgery is to remove all visible and palpable cancer (i.e., cytoreductive surgery) [129].

Postoperative treatment for fallopian tube carcinoma is combination chemotherapy using platinum-based protocols [130]. CA 125 determinations are routinely used for follow-up of patients with fallopian tube cancers [131].

Recurrent disease is managed with combination chemotherapy. Surgery may be employed to resect recurrent tumor if the disease is limited to a few sites rather than diffuse in nature.

The overall survival rate for patients with fallopian tube carcinoma is approximately 30–50%. As in EOC, residual disease after initial surgery is a significant prognostic factor. These figures have not changed significantly with time, indicating the need for further research [132]. Stage of disease at the time of diagnosis is the most important factor affecting prognosis. The calculated 5-year survival rates from six literature series were 62% for stage I, 36% for stage II, 17% for stage III, and 0% for stage IV [133].

Ovarian Cancer

Ovarian cancer is the sixth most commonly diagnosed cancer among women in the world, accounting for nearly 4% of all female cancers. In the United States, ovarian cancer is the eighth most common cancer and the fifth leading cause of cancer death, after lung, breast, colorectal, and pancreatic cancer [134].

Ovarian cancer represents the second leading gynecologic cancer, following cancer of the uterine corpus, and causes more deaths per year than any other cancer of the female reproductive system. An estimated 1 in 70 women in the United States will develop ovarian cancer in their lifetime. In 2007, approximately 22,500 new cases of ovarian cancer were diagnosed, and 15,500 ovarian cancer-related deaths occurred in the United States [135, 136].

Mortality is high with an overall 5-year relative survival rate of 45% because women typically present with late-stage disease. Thus, the public health burden is significant [137]. The incidence of ovarian cancer increases with age, with a median age at diagnosis of 65 years. Over 80% of ovarian cancers occur after 45 years of age.

One of the most significant risk factors for ovarian cancer is a family history of the disease. It is estimated that approximately 7% of women with ovarian cancer have a positive family history for this disease [138–140].

First-degree relatives of ovarian cancer probands have a threefold to sevenfold increased risk, especially if multiple relatives are affected and at an early age at onset [141].

It is clear that a subset of ovarian cancers occur as part of a hereditary cancer syndrome that is inherited in an autosomal dominant pattern. The majority of hereditary ovarian cancers can be attributed to mutations in the *BRCA1* and *BRCA2* genes [142]. According to data from the Breast Cancer Linkage Consortium, the risk of ovarian cancer through 70 years of age is up to 44% in *BRCA1* families and approaches 27% in *BRCA2* families [143–145].

Ovarian cancer lacks early warning symptoms and is not usually diagnosed until it spreads beyond the ovary and the pelvis (i.e., stage III or IV disease). Approximately 70% of women present with advanced disease (Table 83.5) [146].

TABLE 83.5 Carcinoma of the ovary [176]

Stage I	Growth limited to the ovaries
IA	Growth limited to one ovary: no ascites present containing malignant cells. No tumor on the external surface; capsule intact
IB	Growth limited to both ovaries: no ascites present containing malignant cells. No tumor on the external surfaces; capsules intact
IC ^a	Tumor either stage IA or IB, but with tumor on surface of one or both ovaries, or with capsule ruptured, or with ascites present containing malignant cells, or with positive peritoneal washings
Stage II	Growth involving one or both ovaries with pelvic extension
IIA	Extension and/or metastases to the uterus and/or tubes
IIB	Extension to other pelvic tissues
IIC ^a	Tumor either stage IIA or IIB, but with tumor on surface of one or both ovaries, or with capsule(s) ruptured, or with ascites present containing malignant cells, or with positive peritoneal washings
Stage III	Tumor involving one or both ovaries with histologically confirmed peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes. Superficial liver metastases equal Stage III. Tumor is limited to the true pelvis, but with histologically proven malignant extension to small bowel or omentum
IIIA	Tumor grossly limited to the true pelvis, with negative nodes, but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces, or histologic proven extension to small bowel or mesentery
IIIB	Tumor of one or both ovaries with histologically confirmed implants, peritoneal metastasis of abdominal peritoneal surfaces, none exceeding 2 cm in diameter: nodes are negative
IIIC	Peritoneal metastasis beyond the pelvis >2 cm in diameter and/or positive retroperitoneal or inguinal nodes
Stage IV	Growth involving one or both ovaries with distant metastases. If pleural effusion is present, there must be positive cytology to allot a case to stage IV. Parenchymal liver metastasis equals stage IV

Source: Reprinted from Odicino et al. [176], with permission

^aIn order to evaluate the impact on prognosis of the different criteria for allotting cases to stage IC or IIC, it would be of value to know if rupture of the capsule was spontaneous or caused by the surgeon, and if the source of malignant cells detected, peritoneal washings or ascites

The most common presenting symptoms are abdominal bloating and distension, often in association with vague non-specific abdominal complaints. Frank pain is unusual. Gastrointestinal dysfunction is seen in about 20% of women with ovarian cancers, and less commonly, postmenopausal bleeding is observed. The diagnosis is based on physical examination and diagnostic imaging, which reveals pelvic and/or abdominal masses and ascites. The tumor marker

CA-125 is frequently elevated especially in patients with metastatic disease.

The ovary forms cancers from a variety of structures. The most common cancer, representing approximately 90% of all ovarian cancers, arises from the surface epithelial cells. These cells give rise to the common epithelial cancers of the ovary, including serous, mucinous, clear-cell, endometrioid, Brenner, transitional, and undifferentiated cancers. Mixed epithelial cancers also occur.

The germ cell is the second most common source for ovarian cancer and represents approximately 5% of all ovarian malignancies [147]. Ovarian germ cell malignancies occur most frequently in teenagers and women in their twenties. They are not found after menopause.

Sex cord-stromal tumors are the third most common cancers developing in the ovary [148]. They may be functional in nature (i.e., produce hormones). The most common functional tumor is the granulosa cell tumor, which produces estrogen. The Sertoli–Leydig cell tumor produces androgens. Mixed tumors and sex cord-stromal tumors are rare and are called gynandroblastomas. Elderly patients, in particular, may present with pure Sertoli cell or pure Leydig cell tumors, and their symptoms are related to the excess hormone production [149–151].

Sarcomas and tumors with sarcomatous elements, such as fibrosarcomas, leiomyosarcomas, and carcinosarcomas, are rare and most often occur in women over 70 years of age. They are a particularly virulent form of ovarian cancer and are usually diagnosed as stage III or IV disease [152].

The ovary is a frequent site of metastasis, particularly from breast and colon cancer. In addition to CT imaging, breast examination, mammograms, and colonoscopy can be useful adjuncts when evaluating women with tumors involving the ovaries [153–156].

The staging of ovarian cancer is surgical (Table 83.5). The conventional treatment for ovarian cancer is maximum cytoreductive surgery followed by combination platinum-based chemotherapy [157, 158]. The surgical treatment consists of total hysterectomy, adnexectomy, pelvic and periaortic lymphadenectomy, total omentectomy, and tumor debulking [159].

Survival is directly related to the stage of the cancer. For women with advanced disease, survival is correlated with the amount of residual tumor left at the time of the initial surgery. Resection of all visible tumors with only microscopic residual disease left at the completion of the procedure confers the best prognosis [160, 161].

In addition to residual tumor volume, age, performance status, and tumor histology are independent prognostic factors in patients with metastatic disease [162].

Surgery is followed by chemotherapy (adjuvant treatment). The most common regimen prescribed is the combination of carboplatin and paclitaxel [163].

The 5-year survival for stage I patients is 81%, stage II patients is 57%, stage III patients is 30%, and stage IV is 14% [164].

While conventional treatment of patients with ovarian cancer consists of cytoreductive surgery followed by chemotherapy, more recently, a shift has occurred in this treatment philosophy. Patients who present with widely metastatic disease and who on preoperative evaluation are not considered candidates for optimal tumor debulking, may be treated with neoadjuvant chemotherapy [165, 166]. The patients eligible for this approach will have a CT scan showing advanced disease and cytologic evidence or biopsy confirming ovarian epithelial cancer. Laparoscopy and biopsies can be used as an alternative approach to determine resectability. Neoadjuvant chemotherapy can also be used to treat patients that are unable to tolerate the lengthy and extensive tumor debulking procedures because of significant medical comorbidities [167, 168]. Patients treated with neoadjuvant chemotherapy have the same survival rates as those treated in a conventional fashion for stage IIIc or IV disease. Retrospective reviews showed no difference in survival [169, 170]. Patients who received neoadjuvant chemotherapy had a much quicker return to their normal status than those women who underwent conventional surgery followed by adjuvant chemotherapy. The rapid improvement in performance status among women who underwent neoadjuvant chemotherapy was impressive despite the fact that their performance status was statistically worse than that of women who underwent conventional treatment. In addition, the median age of patients who were treated with neoadjuvant chemotherapy was significantly older than of those who received conventional treatment [171].

Two-thirds of the women who underwent neoadjuvant chemotherapy for ovarian cancer management also underwent cytoreductive surgery. The survival of the women who underwent cytoreductive surgery was statistically better than the survival of those who did not. More women who underwent cytoreductive surgery after neoadjuvant treatment had no visible residual tumor at the completion of surgery compared to those who underwent conventional therapy [172].

One-third of the neoadjuvant-treated patients were unable to undergo surgery. Chemotherapy alone can be used to palliate women who are elderly and medically unable to undergo surgery. Patients who do not have a complete response to neoadjuvant chemotherapy invariably die of ovarian cancer or intercurrent disease.

Most women who initially present with metastatic ovarian cancer will develop recurrence [173]. Treatment is based on whether the cancer recurs locally or diffusely throughout the abdominal cavity. Isolated recurrent cancers are usually treated by secondary cytoreductive surgery followed by single-agent or combination chemotherapy [174]. Patients whose lesions are optimally cytoreduced at the time of secondary cytoreductive surgery appear to have a longer survival than those whose lesions could not be completely resected. Once ovarian cancer recurs, it acts like a chronic disease that invariably leads to the patient's demise.

Key Points in Ovarian Cancer Affecting Elderly Patients

- It is predominantly a disease of the elderly patient.
- Only 5% of ovarian cancers are caused by inherited mutations, and these patients are affected at younger ages.
- Most patients present with metastatic disease.
- Resection of all visible tumors confers the best prognosis.
- In patients with advanced disease, neoadjuvant chemotherapy increases the rate of optimal tumor debulking and decreases perioperative morbidity without affecting overall survival.

CASE STUDY

MG is an 82-year-old Caucasian patient with medical history significant for well-controlled hypertension who presented to the Emergency Department with sudden onset of palpitations and severe dyspnea. The workup included a CT scan, which showed a massive pulmonary saddle embolus, large ascites, and numerous pelvic and abdominal masses. On further inquiry, the patient stated that she noticed her waist getting wider; however, she attributed this to “getting fat” since she experienced no pain or any changes in her bowel or bladder function. The patient underwent a paracentesis, and the cytologic examination revealed metastatic ovarian adenocarcinoma. She was treated with six cycles of combination neoadjuvant chemotherapy consisting of paclitaxel and carboplatin every 21 days. After two cycles, the ascites resolved; she was able to leave her wheelchair, and she no longer required oxygen therapy. After four cycles, she was her usual self, and the serum levels of CA-125 went from over 1,500 U/mL to normal. Her nutritional status returned to normal. She underwent surgery with successful resection of all visible tumors. The intraoperative findings showed a notable decrease in size of the tumor burden. Her postoperative course was uneventful. Postoperatively, she was treated with six cycles of the same cytotoxic drugs. She remained without evidence of recurrent disease for 12 months after which she was treated with several chemotherapy regimens. Three years after her initial diagnosis, she remains an active person leading a normal life.

Discussion

The concept of neoadjuvant therapy with cytotoxic agents is one of the most important contributions to the treatment of ovarian cancer in the last two decades. Most patients with ovarian cancer have no or minor symptoms until metastases develop. Currently, there is no effective screening test for epithelial ovarian cancer. These factors impede the diagnosis in early stages, and most patients present with stage III or IV disease.

It is well recognized that the best survival is assured when all visible tumors are resected. However, the surgical procedures to accomplish the destruction of all metastatic implants do not carry a trivial morbidity.

Approximately 85% of epithelial ovarian tumors respond when treated with neoadjuvant platinum-based therapy. The results can be dramatic sometimes, with the ascites disappearing and the tumors shrinking or disappearing completely. This effect facilitates a higher rate of optimal tumor debulking, and the perioperative morbidity is much reduced.

This treatment concept is also applicable to patients who are not suitable for an extensive operation because of advanced age, medical comorbidities, or poor nutritional status. The overall survival for patients with ovarian cancer is better when a multimodality approach is used, i.e., chemotherapy and surgery.

Section XI

Nervous System

Chapter 84 Invited Commentary

Dennis Spencer

Prior to the 1980s, advances in neurosurgery were tied to increased surgical competence based on better illumination and magnification of the operative microscope coupled with safer anesthesia and the creation of intensive care units devoted to the special needs of the injured nervous system. Most of the literature in the 1960s and 1970s concentrated on improving outcomes in the most devastating and easily recognized disorders such as those of pediatric development (hydrocephalus and spinal dysraphisms), trauma and, in particular, the vascular anomalies of aneurysms and arteriovenous malformations (AVM). There was little attention applied separately to issues of the elderly since the aforementioned disorders primarily affected a young to middle-aged population.

The most surgically unremediable conditions occurred in the elderly, such as hypertensive intracerebral hematomas and malignant brain tumors, particularly glioblastoma multiforma. The most common diagnostic imaging techniques of pneumoencephalography and arteriography were invasive and held increased risk in the elderly.

The last three decades, however, have seen a revolution in our approach to diseases of the nervous system, primarily because of the computer, which has been the basis of sophisticated noninvasive computerized tomographic (CT) and Magnetic Resonance (MR) imaging of the brain, spinal cord, and bony support elements. Because of the rigid skull, the brain was the first organ precisely navigated utilizing stereotactic coordinates, providing minimally invasive diagnostic and therapeutic potential.

With the continued evolution of high-resolution imaging and intravascular microcatheters, the neurovascular field is changing before our eyes. In a few short years, we have seen the universal application of intracranial aneurysm clipping

giving way to endovascular techniques, which are becoming more sophisticated each year and are sure to decrease the morbidity and mortality of aneurysmal subarachnoid hemorrhage in the elderly.

MRI scanning delivers anatomically precise and often disease-specific diagnoses and when coupled with stereotactic devices and radiation therapy tools, aids in non-invasive pinpoint destruction of a variety of slow growing tumors (meningiomas, vestibular schwannomas), AVM's and cranial nerves producing drug resistant pain (trigeminal neuralgia). All of these disorders have an increased frequency in the aging population and are much more safely treated with modern technology.

Analyzing the aging brain with techniques other than CT and MRI, such as Positron Emission Tomography (PET), MR Spectroscopy (MRS), functional MR (fMR) and Single Photon Emission Tomography (SPECT), and electrophysiology, may be coupled in the near future with genetically targeted molecules and precise delivery techniques to treat neurodegenerative diseases such as Parkinson's and Alzheimer's. These two diseases, specifically, are increasing in number, as nutrition and cardiovascular advancements have lengthened our life span.

With all of these new techniques, the issue, more than ever, will be the thoughtful and ethical application of therapy, particularly in those individuals over 70 years where there is less systemic reserve and quality of life takes on a different perspective than that of the 40-year old. Some clinical decisions should be obvious, such as the use of endovascular techniques to palliate or cure intracranial vascular disease. The other edge of this sword, however, may be the indiscriminant use of intra-arterial TPA for occlusive vascular disease in the aged brain. There is just no clear data to guide such therapy. Also, common sense should prevail in watchful waiting of incidentally discovered but asymptomatic slow-growing tumors such as the pituitary, meningioma, and schwannoma.

The judicious use of Deep Brain Stimulation (DBS) has already made a major impact on improving the quality of life (QOL) in Parkinsonian patients, and early nonrandomized trials of neurostimulation in medically intractable depression

e-mail: dennis.spencer@yale.edu

show promising effects. As neurostimulation becomes more popular and available, we must develop proper utilization criteria for these devices in the older patients.

We are quickly approaching an era where the declining health of the baby boomers may overwhelm an already strained health-care system. Applying our surgical decisions, tools, and techniques to the elderly in the same manner that we might in young and middle-aged patients may not be the most thoughtful or cost-effective, just as is inappropriate in

infants and very young children. Modern medicine has the ability to preserve and prolong life. However, our most important consideration must be the quality of the life that remains. Clinical trials of neuroactive drugs, chemotherapeutic agents, and neurosurgical intervention must include and provide segregated study of older patients. Clinical investigation must carefully examine the physiology and pathophysiology of nervous system disorders before therapies are applied widely or withheld without justification.

Chapter 85

Effects of Aging on the Nervous System

Howard A. Crystal, Pedro J. Torrico, Shefali Gandhi, and Paul J. Maccabee

Anatomic, physiologic, and systems levels changes in the nervous system with age

Parameter	Change with age
Anatomical	
Neuron number	Varies, no change in some brain regions, small decreases in others, possible decrease in number of lower motor neurons in some regions
Synaptic density	Possibly decreased in some regions
Dendritic arborization	Possibly decreased in some regions
Myelin	May be decreased in volume
Muscle mass	Decreased
Muscle fast twitch fibers	Decreased
Neuromodulators	May be decreased
Physiologic	
Speed of conduction over myelinated fibers	Decreased
Synaptic plasticity	Probably decreased
Ability for neuronal assemblies to synchronize and desynchronize	Not known
Neurogenesis	May be decreased
Systems level	
Cognition	
Speed	Decreased
Learning, new episodic memory	Decreased
Recalling old semantic memory	Contradictory data
Recalling old procedural memory	Little data
Learning new procedural memory	Little data
Language	Not decreased
Motor	
Strength	Decreased
Speed	Decreased
Somatosensory perception thresholds	Decreased

An issue in analyzing all human studies of normal aging is separating the effects of highly prevalent diseases such as hypertension and hyperlipidemia from the effects of normal aging. Subjects with chronic degenerative disorders with high prevalence such as Alzheimer's disease that have a very long preclinical phase are often unavoidably included as "normals." The best way to deal with this source of error is to conduct longitudinal studies and only include subjects as "normal" who do not decline over time. Although it is tempting to relate changes on the molecular and cellular level to changes at the system level, correlative data supporting such inferences are rarely available

In this chapter, we will discuss four syndromes that comprise most of the neurological problems encountered by geriatric perisurgical patients: weakness, strokes, seizures, and cognitive impairment.

Weakness

Weakness and particularly the inability to wean a patient from a respirator are common neurological problems in critically ill elderly postsurgical patients. Weaning difficulties are often the first sign of weakness as intubated patients do not move out of bed or sit up and eat. Many surgical patients clearly meet criteria for critical illness and systemic inflammatory

CASE STUDY

An 80-year-old man with a 20-year history of hypertension and diabetes is 6 days post-op from an emergency cholecystectomy. He developed pneumonia on the first postoperative day and was never extubated. Neurological consultation was requested on the sixth hospital day when despite recovering from the surgery and pneumonia, it was difficult to wean him from the respirator.

Neurological evaluation showed a drowsy, modestly cooperative man. Mental status testing was done by asking “yes/no” questions and the patient selected the wrong year, month, and hospital name. Facial muscle strength was difficult to assess with the endotracheal tube in place, but eye closure was near normal in strength. Motor exam

showed that he was barely able to break gravity in most muscles tested. Reflexes were absent. Sensory exam revealed little useful information.

The neurologist suggested a possible acute neuropathy, most likely critical illness or acute demyelinating and recommended nerve conduction studies and electromyography, but also indicated that the areflexia could have been from his long-standing diabetes, and acute myopathies or neuromuscular junction syndromes needed to be ruled out as well.

This case shows that neurological exam in the ICU is often challenging. Communication may be limited because of intubation, sedation, and/or encephalopathy. These factors influence manual motor and sensory testing. Access may also be limited because of the site and nature of the surgery.

response syndrome (SIRS) and are at risk for critical illness neuropathy and critical illness myopathy. Weakness associated with prolonged neuromuscular blockade from pancuronium or other agents is also not uncommon. The differential diagnosis of weakness in an acute ill postsurgical patient is long (reviewed in Howard et al. [1]). In elderly patients, several diseases may be contributing to motor functional impairment in the same patient.

Critical Illness Polyneuropathy and Myopathy

Critical illness polyneuropathy (CIP) and myopathy (CIM) may be identified in 25–63% of patients who are maintained on artificial respiration for 7 or more days and achieves a 70–100% incidence in the presence of sepsis [2–4]. Factors leading to SIRS, CIP, and CIM are summarized in Fig. 85.1.

CIP is frequently preceded by septic encephalopathy [3]. Perisurgical infection increases the likelihood of SIRS [3]. The use of neuromuscular blocking agents and/or steroids increases the likelihood of CIM. Organ failure increases the likelihood of CIP. Upon successful treatment of SIRS and recovery of encephalopathy, the inability to wean from the respirator is often the initial indication of CIP [5]. SIRS in the context of neuromuscular blocking medications and corticosteroids is further implicated in CIM. Combined CIP and CIM is common, suggesting the designation of critical illness polyneuropathy and myopathy (CIPNM).

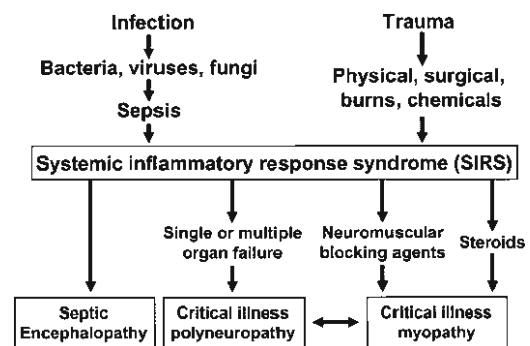

FIGURE 85.1 Factors associated with systemic inflammatory response syndrome (SIRS), critical illness polyneuropathy (CIP), and critical illness myopathy (CIM) (reprinted with permission from Bolton [3]).

Critical Illness Neuropathy

CIP is an acute sensorimotor axonopathy that occurs in patients with multiorgan failure, septic encephalopathy, and systemic inflammatory response syndrome. Hypoalbuminemia and hyperglycemia may further increase risk. Neurological exam typically reveals distal weakness, distal sensory loss, and areflexia, although reflexes may be preserved at the time of the exam, especially early. Facial muscles are usually spared. Weakness is usually more marked than sensory loss. The discrepancy between preserved facial grimace to noxious limb stimuli, with absent or decreased limb movement is “striking” [4]. The main differential diagnosis is preexisting or in-hospital acquired Guillain–Barre syndrome, usually the most common subtype, acute inflammatory

demyelinating neuropathy (AIDP). AIDP may be characterized by very slow motor nerve conduction studies and a CSF pattern of high protein with few cells (albuminocytologic dissociation). In contrast to CIP, facial weakness may often be present in AIDP. Other important diagnostic possibilities include preexisting decompensated Myasthenia Gravis and Lambert–Eaton Myasthenic syndrome.

Diagnosis may be confirmed by detailed electrophysiological studies, and if possible, nerve biopsy. In general, the sicker the patient the more severe the neuropathy; patients with severe neuropathies may show only limited improvement in strength as long as 4 years later. The etiology is not known and signs of inflammation are not present on post-mortem exam.

Appropriate electrophysiologic testing is comprehensive [3]. Studies should include both motor and sensory nerve conductions, F waves, and needle EMG. If respiratory difficulty is present, phrenic nerve conduction studies and needle EMG of respiratory muscles may be critical in establishing the diagnosis [6]. In CIP, the nerve conduction studies indicate a sensorimotor axonal neuropathy, manifest by low amplitude motor and sensory-evoked responses. Decline of motor amplitude responses may be the earliest electrophysiologic finding, following the onset of SIRS but preceding the clinical syndrome [7]. Unlike diffuse axonal sensorimotor neuropathy, demyelinating features in AIDP may include markedly slow motor conduction velocities, extremely prolonged terminal motor and F-wave latencies, absent F waves and H-Soleus reflexes, prolonged distal compound muscle action with potential durations greater than 9 ms, and conduction block. It is important to emphasize that demyelinating abnormalities in AIDP may only be very slight, affecting as few as one or two motor nerves [8, 9].

Neuromuscular Blockade Syndromes

Some patients on neuromuscular blocking agents remain weak for days after the agents are discontinued, long after the blocking agent should have been metabolized and cleared. Several factors increase the likelihood of this syndrome including hypermagnesemia, use of aminoglycoside antibiotics and clindamycin, metabolic acidosis, hepatic or renal failure, and use of high-dose steroids. Hepatic or renal failure will prevent timely metabolism of these agents, resulting in prolongation of neuromuscular block. The syndrome may be distinguished from critical care myopathy by a normal CPK, and a decremental response on repetitive nerve stimulation (see below). This syndrome usually clears over days to 2 weeks, and overall prognosis is good.

It is always necessary to exclude neuromuscular junction disorders by available assays to detect acetylcholine receptor

and muscle-specific kinase (MuSK) antibodies. In the presence of significant weakness, neuromuscular junction disorders are electrophysiologically best assessed by repetitive stimulation of single motor nerves (Jolly test) or single fiber EMG (SFEMG). If the patient is paralyzed or uncooperative, stimulation SFEMG will be required. In Myasthenia Gravis, a post-synaptic neuromuscular junction disorder, repetitive stimulation at slow rates typically shows abnormal decremental evoked responses, usually assessed by comparing the first vs. fifth elicited compound muscle action potential amplitude or area. Repetitive stimulation at fast rates in Lambert–Eaton Myasthenic syndrome, a presynaptic junction disorder, reveals abnormal incremental motor-evoked responses. Characteristic abnormalities of SFEMG in Myasthenia Gravis include prolonged jitter (variation in activation time across the same neuromuscular junction to repetitive discharges and blocking of transmission across the same neuromuscular junction to one or more attempted discharges).

Critical Illness Myopathy

The clinical hallmark of CIM is flaccid weakness, usually diffuse, involving limb muscles, neck flexors, often facial muscles and diaphragm, and occasionally extra-ocular muscles [3]. As in CIP, deep tendon reflexes are usually depressed but may be normal. The diagnosis is rarely suspected until it is difficult to wean patient from the respirator. The true incidence of CIM in patients who have difficulty being weaned from a respirator is not known as such studies require extensive electromyography, muscle biopsy, and nerve biopsy (to distinguish from CIP) and cannot rely on physical exam alone. The few studies that have been conducted suggest CIM is as common as CIP [10–14] or more common than CIP [1]. Prognosis for CIM is better than for CIP. In over 80% of reported cases of CIM, patients have been exposed to both high-dose steroids and neuromuscular blocking agents, but it can occur in any critically ill patient.

The currently proposed three main subtypes of CIM include (1) myopathy with selective loss of thick filaments, also referred to as “acute quadriplegic” myopathy [15]; (2) rhabdomyolysis; and (3) nonnecrotizing cachectic myopathy, also referred to as disuse atrophy. (1) Myopathy with selective loss of thick filaments is typically seen in the context of acute asthma associated with mechanical respiration, neuromuscular blockade, and administration of high-dose steroids, this disorder is also seen following transplant surgery. Serum CPK can be mildly increased. (2) Rhabdomyolysis is also provoked by the administration of neuromuscular blocking medications and high-dose corticosteroids and may be associated with hyperkalemia, hypocalcemia, myoglobinuria,

TABLE 85.1 Neuromuscular conditions associated with critical illness

Condition	Incidence	Clinical features	Electrophysiologic findings	Serum creatine kinase	Muscle biopsy	Prognosis
<i>Polyneuropathy</i>						
Critical illness polyneuropathy	Common	Flaccid limbs, respiratory weakness	Axonal degeneration of motor and sensory fibers	Nearly normal	Denervation atrophy	Variable
<i>Neuromuscular transmission defect</i>						
Transient neuromuscular blockade	Common with neuromuscular blocking agents	Flaccid limbs, respiratory weakness	Abnormal repetitive nerve stimulation studies	Normal	Normal	Good
<i>Critical illness myopathy</i>						
Thick-filament myosin loss	Common with steroids, neuromuscular blocking agents, and sepsis	Flaccid limbs, respiratory weakness	Abnormal spontaneous activity	Mildly elevated	Loss of thick (myosin) filaments	Good
Rhabdomyolysis	Rare	Flaccid limbs	Near normal	Markedly elevated (myoglobinuria)	Normal or mild necrosis	Good
Necrotizing myopathy of intensive care	Rare	Flaccid weakness, myoglobinuria	Severe myopathy	Markedly elevated, myoglobinuria	Marked necrosis	Poor
Disuse (cachectic) myopathy	Common (?)	Muscle wasting	Normal	Normal	Normal or type II fiber atrophy	Good
Combined polyneuropathy and myopathy	Common	Flaccid limbs, respiratory weakness	Indicate combined polyneuropathy and myopathy	Variable	Denervation atrophy and myopathy	Variable

and markedly elevated CPK, with resulting renal failure and cardiac irritability. According to Bolton, the acute necrotizing myopathy of intensive care [16] is a further stage in the progression of rhabdomyolysis. (3) Nonnecrotizing cachectic myopathy occurs in the context of malnutrition and starvation, and may be seen in anorexia nervosa and after gastric-bypass surgery. CPK and electrophysiologic testing are normal.

Nerve conduction studies in pure thick filament myopathy and in rhabdomyolysis may typically show preserved sensory nerve action potentials, low amplitude motor-evoked responses, absence of demyelination findings on nerve conduction, and normal repetitive stimulation at slow and fast rates. Sometimes, it is possible to distinguish CIP from CIM by direct muscle stimulation [17, 18]. In CIP there may be an absent or very low amplitude response to nerve stimulation whereas direct muscle stimulation evokes a significant amplitude response. The hallmark of myopathy on needle EMG is enhanced motor unit recruitment consisting of brief duration, low amplitude polyphasic motor units. Enhancement refers to the demonstration of a full interference pattern often in the presence of weakness; this occurs because in a pure myopathy, the number of voluntarily activated motor units is thought to be full. Active denervation (i.e., the spontaneous presence

of fibrillations and positive sharp waves on needle EMG) may be observed in both CIM and CIP, and therefore does not distinguish either possibility. Another confounding issue is the presence of edema in critically ill patients, which may attenuate sensory nerve action potentials; this can be overcome by direct near nerve recordings at the bedside [19].

Table 85.1 summarizes incidence, clinical features, electrophysiological findings, CPK, muscle biopsy results, and prognosis for the seven neuromuscular syndromes associated with weakness in critical illness.

Strokes and Cerebrovascular Disease

Perioperative stroke is uncommon after general surgery, but incidence can be 8% or higher in patients undergoing heart surgery who also have symptomatic carotid artery disease [20]. Neurologists may be consulted before surgery concerning use or reversal of antiplatelet agents and anticoagulants or management of patients with known or potential carotid artery disease. After surgery, neurologists may be consulted for weakness, difficulty awakening, difficulty weaning from a respirator, or postoperative confusion. A perioperative

stroke is one of several causes for any of these problems. We review (1) epidemiology; (2) etiology; (3) management of antiplatelet drugs and of warfarin; (4) management of carotid artery disease in elective surgery; (5) management of acute strokes in the postoperative period; and (6) timing of elective surgery after a stroke.

Epidemiology

The risk of perioperative stroke depends on many factors including patient age, urgency of surgery, co-morbidities, duration of surgery, and most importantly the type of surgery. Table 85.2 from a recent review [20] summarizes incidences for perioperative stroke after different types of surgery.

Brain surgery also has a relative high risk of associated stroke. The risk of stroke for combined CABG and valve surgery in patients with severe carotid artery disease may be as high as 11% [21]. Factors contributing to the risk of stroke are summarized in Table 85.3.

Etiology

Figure 85.2 illustrates mechanisms of perioperative stroke. The figure emphasizes that decreased cerebral perfusion is a relatively uncommon cause of stroke. A distinction should be made between strokes detected in the first 24 h after surgery that comprise around 45% of perioperative strokes, and those that occur in the second surgical day or later. Mechanisms in this latter group include atrial fibrillation, hypercoagulable state, and myocardial infarction [20]. Interruption of antiplatelet [21] and anticoagulant [22–24] therapy may lead to stroke, possibly by inducing a rebound hypercoagulable state.

Patients who are maintained on cardiopulmonary bypass during surgery are at risk for acute strokes because of microemboli, macroemboli, and hypotension [25]. Macroemboli

TABLE 85.2 Incidence of stroke after various surgical procedures

Procedure	Risk of stroke (%)
General surgery	0.08–0.7
Peripheral vascular surgery	0.8–3.0
Resection of head and neck tumors	4.8
Carotid endarterectomy	5.5–6.1
Isolated CABG	1.4–3.8
Combined CABG and valve surgery	7.4
Isolated valve surgery	4.8–8.8
Double- or triple-valve surgery	9.7
Aortic repair	8.7

TABLE 85.3 Risk factors for perioperative stroke

<i>Preoperative (patient-related) risk factors</i>
Advanced age (>70 years) ^a
Female sex
History of hypertension, diabetes mellitus, renal insufficiency (creatinine, >2 mg/dl [177 μmol/L]), smoking, chronic obstructive pulmonary disease, peripheral vascular disease, cardiac disease (coronary artery disease, arrhythmias, heart failure), and systolic dysfunction (ejection fraction, <40%) ^b
History of stroke or transient ischemic attack
Carotid stenosis (especially if symptomatic)
Atherosclerosis of the ascending aorta (in patients undergoing cardiac surgery)
Abrupt discontinuation of antithrombotic therapy before surgery
<i>Intraoperative (procedure-related) risk factors</i>
Type and nature of the surgical procedure
Type of anesthesia (general or local)
Duration of surgery and, in cardiac procedures, duration of cardiopulmonary bypass, and aortic cross-clamp time
Manipulations of proximal aortic atherosclerotic lesions
Arrhythmias, hyperglycemia, hypotension, or hypertension
<i>Postoperative risk factors</i>
Heart failure, low ejection fraction, myocardial infarction, or arrhythmias (atrial fibrillation)
Dehydration and blood loss
Hyperglycemia

^aAge itself does not predict the risk of stroke, and the 70-year cutoff is arbitrary. However, advanced age is a marker of decreased cerebrovascular reserve and multiple coexisting conditions

^bThe effect of systolic dysfunction on the risk of perioperative stroke is particularly pronounced among patients undergoing left-main-stem revascularization and those with atrial fibrillation

FIGURE 85.2 Mechanisms of perioperative strokes (reprinted with permission from Selim [20] © 2007 Massachusetts Medical Society. All rights reserved).

may come from the aorta or heart. Many heart surgery patients develop atrial fibrillation in the first days after surgery. Microemboli may occur after the release of cross clamping on the aorta, when cardiac ejection is restarting or from the heart-lung machine itself [25]. Post-mortem studies have shown that sometimes millions of microemboli in the brain microvasculature are found.

Hypotension may occur during surgery for several reasons and often it is intentionally induced. If brain cerebral perfusion pressure is kept at 50 mmHg or better hypoxic injury to the brain should not occur [25]. There is no consensus concerning optimal arterial perfusion during surgery, with some experts recommending perfusion pressures around 80 mmHg [20]. Brain regions whose blood supply comes from distal branches of two or more cerebral arteries may suffer borderzone infarction during systemic hypotension. The most common infarcts occur between distal branches of the middle cerebral and anterior cerebral artery (anterior borderzone infarcts), or between branches of the middle cerebral and posterior cerebral arteries (posterior borderzone infarcts). Nonetheless, as indicated above, decreased cerebral perfusion accounts for a small percentage of strokes associated with heart surgery. Indeed, syndromes identical to borderzone infarcts may occur with emboli [26].

Fat emboli can be associated with fractures of long bones. Although most of these emboli usually travel to the lungs and may cause severe hypoxia, in about 2% of cases, the fat emboli enter the arterial circulation and can cause cerebral infarctions [27]. The mechanisms by which the fat emboli enter the arterial circulation are not known. Other uncommon causes of stroke include air emboli from endoscopy, intravascular procedures, or heart-lung bypass, and paradoxical emboli from patients with deep vein thromboses who have a patent foramen ovale [20]. Improper patient positioning may compress or dissect cervical arteries during intubation [21].

Antiplatelets and Anticoagulants in the Perioperative Period

Hundreds of studies have investigated whether antiplatelet agents such as aspirin or clopidogrel should be discontinued prior to surgery so that platelet function returns to normal or whether they can be safely continued up to the time of surgery [28–31]. The risks associated with non-aspirin NSAIDs have also been investigated. In general these studies suggest that although there is a significant increase in bleeding complications associated with these drugs, there is no increase in morbidity or mortality, and that the time to hospital discharge is not prolonged. As discontinuation of antiplatelet agents can be associated with a rebound hyperco-

agulable state and increased risk of infarction, the decision about whether or not to stop antiplatelet agents needs to be weighed carefully. In contrast, there is consensus that antiplatelet agents can be started 6 h after cardiac or carotid artery surgery.

Sixty-five percent of the over 2.3 million patients in the USA with atrial fibrillation are maintained at some time on warfarin. When warfarin is stopped prior to surgery, what is the risk of stroke in these patients? Some surgical procedures have such low risk of major bleeding that it is more risky to stop warfarin. With internal normalized ratios (INRs) of 1.8–2.1, knee or hip replacement, dental procedures, arthrocentesis, and diagnostic endoscopy can proceed without undue risk of major hemorrhage [20]. For surgery with a high risk of bleeding in patients with very high risk of stroke from embolization (such as atrial fibrillation with valvular disease) one expert recommendation is to stop warfarin 4 days prior to procedure, switch to low molecular weight heparin or unfractionated heparin until 12–18 h before the procedure, and restart heparin 6 h after the procedure [32].

In patients who are anticoagulated who require STAT emergency surgery, reversal with fresh frozen plasma, and possibly prothrombin and factor VIII may be indicated. If surgery can be safely delayed for 48–72 h, oral vitamin K supplementation may be sufficient to reduce INR to less than 1.5.

Management of Carotid Artery Disease

Neurological consultation should be considered for presurgical patients with a history of recent TIAs or who have known carotid artery disease. A careful history is required to elicit symptoms of a possible TIA that include unilateral weakness or sensory loss, dizziness, vertigo, language impairment, confusion, diplopia, dysarthria, other visual disturbances, ataxia, and amnesia among others. As these symptoms are not specific, neurological consultation may be useful to assess the likelihood these symptoms were from TIAs in the carotid or vertebral/basilar artery distribution. Prior to elective surgery, imaging of the extracranial arteries with ultrasound, magnetic resonance angiography, or computed tomographic angiography may be indicated. Magnetic resonance imaging of the brain is the most sensitive way to determine whether a patient has had previous strokes. Asymptomatic patients including patients with an audible cervical bruit are at low risk for stroke and probably do not require further evaluation.

A recent study [33] reviewed over 27,000 carotid revascularizations performed between the years 2000 and 2004. Only 3.3% of patients had carotid stenting, and these patients had a lower incidence of stroke or combined stroke and

death. Nonetheless, in-hospital death rates were similar. Randomized clinical trials comparing stenting and endarterectomy are lacking, and there is no consensus on best management [34, 35].

Evaluation and Management of Acute Infarcts

If a stroke is suspected in a perisurgical patient, a STAT neurological consultation should be requested. Although intravenous tPA is contraindicated within 14 days of major surgery, an interventionist neuroradiologist may be able to offer a thrombectomy [36, 37] or possibly intra-arterial tPA [38]. Most Emergency Departments have worked out the logistics for contacting neurologists for “stroke codes.” If a stroke is suspected, it may be most efficient to call the ED physician and tell him or her that you have a stroke code on a hospitalized patient. The stroke team neurologist will then contact the interventionist when appropriate.

How Long Poststroke Is Elective Surgery Permissible?

There are no research studies that address this question, but most stroke experts believe that elective surgery can be scheduled starting 3 months after a moderate- to large-sized acute infarct.

Seizures

In this section, we will discuss four clinical scenarios: (1) patients with epilepsy for years with seizures that are well controlled on antiepileptic drugs (AEDs); (2) patients with known seizures disorder who have poor control or who have stopped taking AEDs; (3) patients with no history of seizures who have seizures in the post-op period; and (4) patients with known epilepsy who have seizures in the post-op period.

Patients with Known Seizure Disorder Stable on AEDs

Seizures disorders are common among geriatric patients with a prevalence of 1–2% [39] and most geriatric patients with seizures are maintained on one or two AEDs with twice or three times a day dosing. In this way, geriatric patients with

epilepsy differ from some younger patients with intractable seizure disorders.

If the duration the patient is expected to have nothing by mouth is 12 h or less, AEDs can be given with a sip of water 2 or more hours before surgery and restarted when clear liquids are permitted. Even if a patient is on three times daily dosing, it is unlikely that AED levels will fall so low that breakthrough seizures will be a problem. If the duration of no oral intake is to be greater than 12 h then either a nasogastric tube can be used or the patient can be maintained on “bridging” therapy with intravenous fosphenytoin/phenytoin, valproic acid, or levetiracetam. If the patient is already on oral monotherapy with these drugs, then the patient should be maintained in intravenous forms of the drug. Measurement of phenytoin and valproic acid levels prior to surgery will be invaluable. Levels of levetiracetam are not available.

It is more complicated for patients who are on gabapentin, carbamazepine, lamotrigine, oxcarbazepine, or topiramate as there are no intravenous forms of these drugs. In these cases, the neurologist will usually recommend temporary monotherapy with intravenous fosphenytoin, valproic acid, and levetiracetam. Fosphenytoin, the proform of phenytoin is completely metabolized to phenytoin within one pass through the liver. Phenytoin has limited solubility in water whereas fosphenytoin is water soluble. Fosphenytoin is preferable to phenytoin for intravenous use because it can be administered more quickly, is less likely to be associated with arrhythmias or hypotension, and is less likely to stick to intravenous tubing. Phenytoin has complicated pharmacokinetics and multiple drug–drug interactions and intravenous forms of valproic acid and levetiracetam are being used more and more for bridging therapies in patients unable to take oral medications.

Patients with Known Seizure Disorders Who Have Stopped Taking Their AEDs

Patients who have gone 2 years without a seizure on AEDs can usually be tapered off their AEDs, particularly if there is no structural lesion on MRI and the EEG does not show epileptiform activity. Accordingly, it becomes a judgment call what to recommend for a patient who has stopped taking AEDs but who has not had a seizure for several months.

Patients with No Previous History Who Have Their First Seizure in the Post-op Period

The first problem is recognizing the seizure. Some movements that are not electrographic seizures may be misinterpreted as

seizures. Conversely, some nonconvulsive seizure activity is often missed.

Myoclonus is defined as “brief, shock-like, large amplitude, irregular movement of a muscle or of muscle groups” [40] and may occur with renal or hepatic failure as well as in many different neurological disorders. However, a common setting for myoclonus in a geriatric surgical population is a patient who has suffered an episode of generalized cerebral ischemia leading to coma. Multifocal or generalized myoclonus starts 2–24 h after the arrest [41]. Neurological exam reveals a comatose patient with limited, if any, response to pain, yet stimuli including tracheal suctioning, positioning limbs, and loud noises may elicit the myoclonus. Pupils are usually spared and eye movements may or may not be impaired. The EEG may show little, if any, electrical activity and usually shows no seizure activity. Despite this, when the myoclonus is nearly continuous it is sometimes called myoclonic status epilepticus. The disorder responds poorly to anticonvulsants and has a very poor prognosis.

Conversely, seizures with minimal convulsive or no convulsive features will usually not be suspected by non-neurologists. Clues to nonconvulsive seizures include confusion, personality change, psychosis, coma, abnormal waxing and waning mental status and possibly unidirectional nystagmus [39].

Etiologies to consider for new onset seizures include a new infarct, metabolic disturbances such as hypo or hyperglycemia, hyponatremia, hypocalcemia, hypomagnesemia, withdrawal from alcohol, and withdrawal from AEDs. Occasionally, history that the patient was maintained on AEDs is unavailable. Seizures occurring in patients acutely withdrawn from AEDs may be difficult to stop until the missing AED is restarted. Frequently, workup will reveal an unsuspected old infarct. Cortically based infarcts are more likely to cause seizures than strokes in other sites.

The general rule in neurology that long-term AED should not be started after a single solitary seizure is less clear among geriatric patients. Patients under 40 who have a single seizure of unknown etiology have only a 40–50% risk of having another seizure even if AEDs are never started. In contrast, patients over 70, have about a 70% of having another seizure [39, 42, 43].

In any patient, if a clear-cut reversible, metabolic etiology can be identified, appropriate treatment is correcting the abnormality, not starting AEDs. However, if it appears likely that it will take several days to correct the metabolic abnormality, many experts would use intravenous AED at least until the metabolic abnormality is corrected, and might taper the patient off oral forms of the AED several weeks after surgery.

Patients with Known Epilepsy Who Have Seizures in the Post-op Period

Management of these patients requires a blending of the approaches #1 and #3.

Cognitive Impairment

Three questions about a patient’s cognitive function are of special importance to surgeons operating on the elderly: (1) What is the prevalence, clinical course, and prognosis for postoperative cognitive impairment (POCD)? (2) Does surgery in older patients increase their risk for Alzheimer’s disease? (3) Special pre-surgical concerns in patients with documented cognitive impairment or dementia.

Postoperative Cognitive Dysfunction

Postoperative cognitive dysfunction (POCD) is extremely common in the elderly with estimates of its prevalence ranging from 10 to 80%. [44–51] Typically, studies distinguish between POCD documented a few days after surgery (typically 5–7 days or around the time of discharge), and POCD present at 3 and 6 months after surgery. The prevalence of POCD at time of discharge or around 7 days post-op ranges from 10 to 80%, with estimates at 3–6 months ranging from 10 to 24% [52, 53]. One study found 80% of post-coronary artery bypass grafting (CABG) patients had abnormal signals on diffusion-weighted MRI sensitive to acute ischemia that were not present prior to surgery [54].

Choice of neuropsychological battery and how change is defined also have big effects on prevalence estimates [55–58]. Many studies used battery of neuropsychological tests covering multiple domains including verbal and non-verbal memory, attention, visuoconstruction, executive function, language, and motor speed [57]. Some data suggest that memory is most likely to be affected [59].

Age, baseline cognitive function, whether surgery was elective or emergency, whether patients are in early stages of Alzheimer’s disease or other dementias, co-morbid illness, nature and duration of surgery, choice of anesthesia, and postoperative complications all influence the prevalence of POCD. Finally, cognitive impairment is so prevalent in older subjects – estimates of the prevalence of AD among those in their early 80s range from 10 to 40% [60–63] – that studies lacking appropriate control groups needed to be interpreted with caution.

A few investigators have continued to follow patients and reassessed them at 1–5 years postsurgery. Newman [53] followed 261 patients who had CABGs. POCD was defined by change from presurgical function of greater than 1 standard deviation in at least one cognitive domain. Prevalence of cognitive dysfunction was 53% at discharge, 36% at 6 weeks, 24% at 6 months, and 42% at 5 years. Because most studies end follow-up at 6 months, this delayed deterioration could have been missed. Unfortunately, a control group was not included so it could not be determined whether a similar course would have occurred in comparably ill elderly patients who did not have surgery.

POCD in the first few weeks after surgery influences discharge planning and suitability for rehabilitation [64]. Patients with POCD may require longer time in rehab [65]. Patients with POCD at 1 week are more likely to require help with living independently. Patients with POCD 1 week after surgery are about three times more likely to be cognitively impaired 1 or 2 years after surgery than patients with normal cognition in the immediate postsurgical period.

Patients and families need be advised that in most patients cognitive function will substantially improve in the weeks following surgery. No data are available whether cognitive rehabilitation is useful in such patients. Often neuroleptics, anti-anxiety medications, antidepressants, or hypnotics are prescribed to try to treat some of the behavioral problems associated with POCD. All of these medications are themselves associated with cognitive impairment and need be used especially judiciously.

Several studies have investigated whether POCD is more common after general anesthesia or after regional anesthesia. In a meta-analysis comparing 1,314 patients with regional anesthesia and 1,395 patients with general anesthesia from 18 unique randomized control trials, Bryson et al. [66] found no difference in frequency of POCD which was around 15–25%.

The etiology of POCD is likely to be multifactorial. Inflammatory processes outside of the CNS may be associated with inflammatory markers within the CNS. For example, hip surgery was associated with increase in CSF interleukin 6 and prostaglandin E₂ [67]. Interleukin-8 and RANTES were elevated post-op in CSF from patients with various kinds of non-brain surgeries [68]. Nonetheless, even if “neuroinflammation” has a role in pathogenesis, it remains unclear why it would affect older but not younger patients. Possible explanations include lack of cognitive reserve and a leakier blood–brain barrier in older patients. Growth factors required for repair may be less efficient in older patients. Embolization, particularly if the heart or carotid arteries were manipulated may be a factor. Global ischemia from decreased perfusion or other causes may also have contributed. Alzheimer’s disease contributes to some POCD. The relationship between surgery/GA and Alzheimer’s disease (AD) is discussed below.

What Is the Risk That Surgery in Elderly Patients “Will Trigger” AD?

Vignette – Mrs. J is a 73-year-old woman with hypertension. Her daughter said that she handled her finances and travelled independently prior to an elective cholecystectomy. At 1 year after surgery, the patient and her daughter are both concerned about impairment in her recent memory. By 18 months after surgery, she has made mistakes paying bills and gotten lost several times. After reviewing her history, performing a cognitive assessment and neurological exam, and obtaining brain imaging, a dementia specialist diagnoses mild Alzheimer’s disease.

Every physician seeing substantial numbers of patients with dementia has encountered the above scenario. Certainly, the data on POCD discussed above would suggest that some patients have sustained cognitive impairment after surgery, but unless the POCD develops a gradually progressive course, there would be no reason to believe there was a relationship between GA/surgery and AD. The findings of Newman et al. [53] are especially provocative because they document such progressive deterioration 5 years after surgery. Nonetheless, the patients in the Newman study had cognitive impairment and did not meet criteria for the diagnosis of AD. Several more years of follow-up would have answered the question of whether they were developing AD.

For years, many dementia specialists maintained with little data that the surgery was only a convenient point in time and that most likely the patient had symptoms of AD for years prior to surgery that went unnoticed by her family. Epidemiological studies have looked at this association with largely negative results. Data from studies with animal models and tissue culture systems have suggested plausible ways that anesthetics might increase the likelihood of AD – although it has to be emphasized that clinical data supporting such an association are equivocal at best.

Epidemiological Studies

In 1991, Breteler et al. [69] performed a meta-analysis of eight case–control studies and found no risk of AD from GA (relative risk=1.0). In another case–control study involving 252 AD cases and matched controls, Bohnen et al. [70, 71] found positive odds ratios for GA that increased with the duration of anesthetic exposure. However, the confidence

intervals were wide and findings were not statistically significant. In a separate analysis, the authors found a significant association between anesthesia exposure before age 50 and earlier onset of AD.

In a study of 502 subjects with vascular dementia and 810 subjects with AD from the California AD centers, Cooper et al. [72] found that GA was overrepresented in the vascular dementia group, a finding confirmed in a larger sample from the same dataset by Corey-Bloom et al. [73]. Both studies lacked a control group to determine whether GA was more frequent in AD than in controls.

Gasparini et al. [74] reviewed hospital records to determine whether GA and surgery up to 5 years earlier were overrepresented in AD. Control groups were patients with Parkinson's disease and patients with nondegenerative neurological diseases – usually peripheral neuropathy or headaches. No association between GA/surgery and AD was found, but the study could not address risks from exposures that occurred more than 5 years earlier.

In a cohort of over 4,000 cognitively normal 65–90-year-olds, Yip et al. [75] studied factors associated with incident dementia at 2 and 6 years after original evaluation. GA was associated with a decrease in risk of dementia (OR 0.6, CI: 0.4–0.9). GA has been associated with both increasing and decreasing apoptosis of brain neurons [76, 77]. If GA actually decreases risk of AD, decreased apoptosis would be one potential mechanism.

In a cohort study involving 9,000 patients, Lee et al. found that the risk of developing AD within 5 years after CABG was 1.7 times higher (CI: 1.02–2.87, $p < 0.04$) than after angioplasty [78]. However, using a case–control design that compared the frequency of prior CABG between a group with dementia and cognitively normal control group, Knopman et al. [79] found no association between CABG and dementia. Among patients who already have AD, CABG may be associated with a slower rate of progression [80].

Animal Studies and Tissue Culture Studies

Transient ischemia increased expression of beta (β)-site APP cleaving enzyme in rats [81]. As this enzyme leads to increased ABeta (β) production, and increased brain amyloid is believed by many to be an early step in the pathogenesis of AD, the work provides another theoretical explanation of why hypoxia associated with surgery/anesthesia could lead to AD.

Bianchi et al. [82] exposed adult transgenic and wild-type mice to either isoflurane or halothane. The transgenic mice exposed to halothane had more brain amyloid than those exposed to isoflurane, but neither agent was associated with cognitive impairment in the transgenic mice. On the other hand, isoflurane did cause cognitive impairment in the wild-type mice that was not associated with amyloid deposition.

This study reemphasizes that cognitive impairment associated with anesthetic exposure, need not be due to AD pathology but may occur by an entirely different mechanism.

Tau protein is a microtubule protein needed to stabilize tubulin networks in the axons of neurons. Abnormally increased phosphorylation of tau protein is a consistent finding in AD. Planel et al. [83, 85] exposed wild-type mice to intraperitoneal pentobarbital or chloral hydrate or isoflurane by inhalation. All three agents were associated with hypothermia and hyperphosphorylation of tau mediated by decreased phosphatase activity. They concluded that the hypothermia, not the agents themselves, led to the increase in phosphorylation, which reverted to normal levels with normothermia. Ikeda et al. [85] found that hyperphosphorylation of brain tau could be induced by ether anesthesia or cold water shock.

Palotas et al. [86] administered intraperitoneal propofol or thiopental to rats and then measured levels of amyloid precursor protein (APP) and APP RNA in rat brain. They found these agents caused no changes in APP. In a similar studies, neither midazolam nor propofol was associated with increase in APP [87].

Eckenhoff et al. [88] studied whether anesthetics might increase oligomerization of A β in a rat pheochromocytoma tissue culture system. Halothane and isoflurane, but not alcohol or propofol (except at very high concentrations) were associated with increased oligomerization. This finding is important because many investigators believe that oligomers are the most toxic form of A β .

Xie et al. [76, 89, 90] exposed human neuroglioma cells that had been genetically engineered to overexpress amyloid to desflurane and hypoxia. Neither desflurane or hypoxia alone were associated with change in amyloid-beta (β)-protein (A β) levels, but the combination was. This combination also was associated with increased caspase-3 activation, which can lead to apoptosis and further production of A β .

Special Pre-surgical Concerns in Patients with Documented Cognitive Impairment or Dementia

All of this research inevitably leads to the question of which anesthetics to use for elderly patients and especially patients with Alzheimer's disease. An expert NIH panel was convened in [91] 2007 to address this and other issues concerning possible neurotoxicity of anesthetics. The panel concluded that there were not enough data to make any recommendations.

Other issues pertain to patients with dementia who are maintained on acetylcholinesterase inhibitors such as donepezil, galantamine, or rivastigmine. There are no data to

suggest these agents are associated with sufficient excess airway secretions to interfere with surgery nor are there data to suggest these agents interfere significantly with the use of succinylcholine [92, 93]. Most anesthesiologists believe that acetylcholinesterase inhibitors do not need to be discontinued prior to elective surgery.

Chapter 86

Geriatric Neurosurgical Emergencies

Toral R. Patel and Joseph T. King Jr.

Introduction

Neurologic illnesses are a leading cause of death and disability in the elderly population. Many of these diseases require surgical evaluation. The US Census Bureau estimates that by 2030, 52 million Americans will be over 70 years of age [1]. The presentation, management, and outcomes of neurosurgical emergencies can be quite different in the geriatric population. It is imperative that practitioners are aware of the unique challenges that exist when caring for geriatric patients with neurosurgical emergencies.

Traumatic Brain Injury

Recent studies report that approximately 1.1 million new cases of traumatic brain injury (TBI) are diagnosed and treated in US hospitals each year, approximately 450 cases per 100,000 people. Subgroup analyses demonstrate that the elderly have a significantly higher rate of TBI. In persons over 85 years of age, there were approximately 1,000 cases per 100,000 people [2, 3]. The majority of these injuries are caused by falls [4]. Multiple studies have demonstrated that despite similar injury severity, older patients have worse outcomes than younger patients [5, 6]. Morbidity and mortality from TBI start to increase in the fifth decade of life, but rise sharply after age 70 [7]. It is postulated that elderly patients have worse outcomes due to diminished cardiovascular reserve and fundamental differences in the aging central nervous system (CNS) and its response to injury [6, 7]. Because of this disparity, the literature suggests that age >70 years should be a criterion for full trauma team activation

and that those patients should also be considered for transfer to a certified trauma center, regardless of the severity of the actual event [8, 9].

Extra-Axial Hematomas

Extra-axial hematomas are defined as hemorrhages within the intracranial space, but outside of the brain parenchyma. They occur almost exclusively in the setting of trauma and can be either acute or chronic in nature. Extra-axial hematomas that form under the dura mater are termed subdural hematomas (SDH), while those that form above the dura mater are termed epidural hematomas (EDH).

SDH may be caused by a variety of conditions, but they most commonly occur as a result of trauma. In the elderly population, SDHs occur in 46% of TBIs, while in younger patients, they occur in only 28% of TBIs [7]. This is thought to be due to the increased adherence of the dura mater to the inner surface of the elderly skull, which in concert with general cerebral atrophy, results in continuous stretching of the bridging veins that connect the cerebral cortex to the dural sinuses. With the added insult of a trauma, these stretched veins are easily injured, resulting in hemorrhage between the dura and brain, otherwise known as a SDH. The clinical manifestations of SDHs are the result of focal or diffuse pressure on the brain, or chemical irritation of the underlying cortex. Signs and symptoms include headache, nausea/vomiting, diplopia, altered mental status, pupillary dilatation, seizures, dysphasia, and hemiparesis/hemiplegia. Acute SDHs can become rapidly symptomatic as blood accumulates in the subdural space and presses on the underlying brain. Chronic SDHs can accrue over time as the result of multiple episodes of bleeding from repeated small traumas. Often times, they are larger than acute SDHs, however, their signs and symptoms are usually milder because the chronology of their development allows the brain to accommodate the mass effect. On CT scan, all SDHs appear as crescent-shaped extra-axial collections, which may cross suture lines but do

FIGURE 86.1 Noncontrast axial head CTs demonstrate (a) acute subdural hematoma – a hyperdense crescent-shaped extra-axial collection and (b) chronic subdural hematoma – a hypodense crescent-shaped extra-axial collection. Both of these lesions are causing significant mass effect and resultant shift of midline brain structures.

not cross midline. Acute SDHs appear hyperdense to adjacent brain tissue on CT scan, while chronic SDHs are hypodense (Fig. 86.1a, b). Chronic SDHs may also have internal septations visible on the CT scan caused by the formation of membranes. Imaging appearance and symptoms are used to determine the need for surgical evacuation. Any symptomatic acute or chronic SDH needs to be evacuated promptly. In addition, acute SDHs >10 mm in maximal thickness or with >5 mm of midline shift are typically removed, regardless of symptoms [10]. The need for surgical evacuation of large asymptomatic chronic SDHs is less clear. Operative intervention for an acute SDH usually requires a generous craniotomy, evacuation of the hematoma, and control of bleeding. Depending on the degree of underlying parenchymal injury and edema, expansion duroplasty and bone flap removal may be necessary to accommodate swelling of the underlying brain and minimize dangerous increases in intracranial pressure (ICP). Operative intervention for a chronic SDH usually involves burr holes and removal of chronic liquefied hematoma via suction and irrigation, often followed by the placement of temporary postoperative subdural drains. A special consideration in the elderly population is the degree of underlying cerebral atrophy. Because the atrophic brain is often unable to expand and fill the subdural space even after the mass effect has been removed, bridging veins remain under tension and at risk for future traumatic injury, and recurrent chronic SDHs often form. Occasionally, craniotomies are performed for chronic SDHs if there is concern for significant membrane formation and therefore inadequate drainage of the loculated subdural hematoma through one or two burr holes.

EDHs also occur as a result of trauma, but are much less common than SDHs, with an estimated incidence of 2.7–4.1% in TBI patients [10]. The increased adherence of the dura

mater to the skull in the elderly serves to tamponade bleeding into the epidural space, thus EDHs are unusual in the geriatric population. When present, EDHs are often associated with skull fractures. Traditionally thought to be of primarily arterial origin, recent studies have indicated that EDHs from venous injuries are quite common as well [10]. Clinically, patients with significant EDHs present with focal and diffuse brain pressure findings similar to those with SDHs. Signs and symptoms include headache, nausea/vomiting, diplopia, altered mental status, pupillary dilatation, seizures, dysphasia, and hemiparesis/hemiplegia. Additionally, some patients present with the classic “lucid interval”, an asymptomatic time period immediately following trauma before the onset of symptoms, attributed to the expansion of the hematoma as it slowly dissects between the skull and adherent dura, gradually increasing pressure on the underlying brain. On CT scan, EDHs appear as hyperdense biconvex extra-axial collections, which do not cross suture lines (Fig. 86.2a, b). Surgical evacuation of the hematoma is indicated for symptomatic lesions. EDH evacuation usually requires a craniotomy, with or without expansion duroplasty and bone flap removal, based on the extent of the underlying parenchymal injury and edema.

Intracerebral/Subarachnoid Hemorrhage

In addition to extra-axial hematomas, patients with traumatic brain injuries often have intra-axial hemorrhages, either within the parenchyma of the brain or in the subarachnoid space. The management of traumatic intracerebral hemorrhages is similar to that of nontraumatic intracerebral hemorrhages. These lesions appear as hyperdense intra-axial collections on CT, which can vary in diameter from under a millimeter to several

FIGURE 86.2 Noncontrast axial head CTs demonstrate (a) acute epidural hematoma – a hyperdense biconvex extra-axial collection and (b) in the same patient, a minimally displaced left frontal skull fracture adjacent to the epidural hematoma, the likely cause of the vascular injury producing the hematoma.

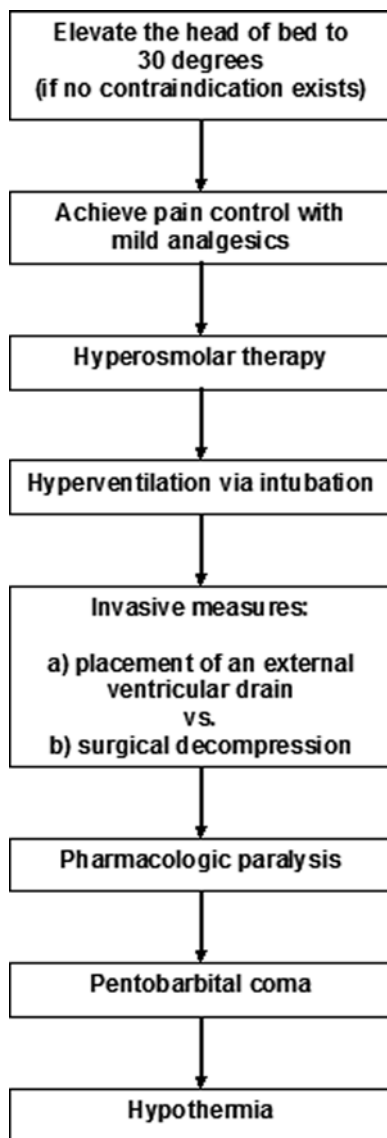

FIGURE 86.3 General schematic for the management of elevated intracranial pressures.

centimeters. Initial treatment should focus on blood pressure control, to prevent rebleeding, and management of ICPs. Frequent neurologic examinations should be performed to assess for acute decompensation and serial imaging studies should be performed to evaluate for rebleeding. In the event of elevated ICPs, medical management should be initiated, and in some cases, surgical decompression is required due to the degree of mass effect (Fig. 86.3) [10, 11].

Subarachnoid hemorrhages are also common sequelae of TBI. Although these hemorrhages seldom require surgical evacuation, they are often associated with seizures, altered mental status, and diffuse axonal injury, all of which can lead to significant morbidity and mortality. On CT, traumatic subarachnoid hemorrhages appear as layered, hyperdense lesions within the subarachnoid spaces, most commonly along the cortical surfaces. Patients with traumatic subarachnoid hemorrhages should be given prophylactic anticonvulsant medications for 7 days posttrauma [12]. Care should be taken in the administration of these medications to the elderly population, as they often have significant side effects including hypotension, cardiac arrhythmias, and confusion. Additionally, for those patients with traumatic subarachnoid hemorrhage and poor neurologic exam in the absence of a focal compressive lesion, placement of an ICP monitor is often required to measure ICPs, which require further management if elevated (Fig. 86.3) [10, 11].

Fractures

The skull is a protective layer meant to absorb high-energy forces and to prevent direct intracranial parenchymal injury. In doing so, the skull is also placed at risk for fracture in the event of a significant trauma. Skull fractures can be loosely categorized into four groups: linear, depressed, skull base, and open, each of which has unique management strategies.

Linear fractures are the most common type of skull fracture and are usually the result of low-energy trauma over a large surface area. These fractures are nondisplaced, seldom require surgical intervention and are treated with observation and expectant management [13].

Depressed skull fractures are usually the result of high-energy trauma over a small surface area. Clinically, depressed skull fractures often manifest with seizures, due to an underlying cortical injury, or as an epidural hematoma, due to laceration of a meningeal artery adherent to the skull. Those fractures that are depressed below the inner table of the adjacent normal bone typically require surgical elevation [13].

Skull base fractures occur in the context of severe trauma and can manifest with a variety of neurologic symptoms [13]. Often, skull base fractures are associated with additional intracranial injuries due to the magnitude of the causative trauma. Most significantly, skull base fractures can cause vascular injuries, commonly to the internal carotid arteries, as well as cerebrospinal fluid (CSF) leaks [14–16]. Therefore, all patients with skull base fractures should undergo computerized tomographic angiography (CTA) to rule out vascular injury [14, 15]. Additionally, they should be monitored closely for the evidence of CSF otorrhea or rhinorrhea. Management of vascular injuries should be deferred to an experienced neurovascular team, which includes both neurosurgeons and neurointerventionalists. Management of CSF leaks includes initial conservative treatment with bed rest and head of bed elevation to reduce the hydrostatic pressure gradient and CSF flow across the dural defect, allowing for the body to seal the breach. If the CSF leak persists despite these conservative measures, CSF diversion using a lumbar drain and/or surgical repair are needed to eliminate the leak to prevent bacterial ingress and subsequent meningitis [16].

Open skull fractures are defined as those lesions with an overlying skin laceration, such that there is a communication between the external environment and the intracranial space. These lesions are at particularly high risk for infection [17]. Open skull fractures often demonstrate significant pneumocephalus on imaging due to the abnormal communication with the external environment. Open skull fractures may be classified as either clean or contaminated. All patients with open skull fractures should receive tetanus toxoid, and those with contaminated fractures should also receive prophylactic antibiotics [17]. In most cases, these injuries require operative exploration for wound cleansing, debridement, and closure [13, 17].

Penetrating Trauma

Penetrating brain injury (PBI) refers primarily to gunshot wounds to the head, although all foreign bodies that invade the cranial vault may be included in this group. The management

of PBI has undergone fundamental changes since initial descriptions in the early twentieth century, which were based primarily on military injuries. The current literature includes accounts of both civilian and military experiences. The former contains mostly reports of low-velocity injuries and self-inflicted wounds, while the later includes a higher percentage of high-velocity and shrapnel injuries [18]. Regardless of injury etiology, studies of both groups have derived similar conclusions, and current management recommendations are based on Class III evidence from both civilian and military case series [18].

The primary goals in the treatment of PBIs are infection prevention and ICP management. World War I trauma surgeons advocated extensive exploration and debridement of PBIs, with removal of all foreign bodies and bone fragments to decrease the risk of infections and seizures. Subsequent military and civilian studies have indicated that extensive exploration and debridement of PBIs is unnecessary and leads to higher rates of morbidity and mortality [18, 19]. Modern studies have demonstrated that the primary cause of PBI-related infections is a persistent CSF leak [18–20]. As such, during the initial management of a PBI, care should be taken to achieve good local debridement, followed by a watertight dural and scalp closure. Extensive brain debridement should be avoided to prevent injury to normal tissues. Additionally, prophylactic anticonvulsant medications should be given to prevent seizures [18]. Surgical evacuation of large intracranial hematomas may be necessary to manage elevated ICPs, and earlier surgery is associated with better outcomes [18, 21]. Additionally, intraparenchymal or intraventricular ICP monitors are often needed to follow the response to treatment.

Increasing age is associated with poorer outcomes in patients with PBIs [22]. However, given that PBIs are relatively uncommon occurrences, and even more uncommon in the geriatric population, analyses of this association have been somewhat limited [22]. Of the studies which have examined the role of age in outcome from PBIs, two have demonstrated that increasing age is associated with higher mortality [21, 23]. It is likely that many of the same mechanisms which contribute to poor outcomes in the elderly from general TBIs play a role in PBIs.

Nontraumatic Vascular Lesions

Neurovascular lesions constitute a broad spectrum of pathologies, yet common to each of these disease processes is precipitous neurologic decline from disruption of vital bloodflow to brain tissue. Population studies indicate that neurovascular diseases are more prevalent among the elderly [24]. Moreover, the geriatric population appears to fare worse from

neurovascular diseases than their younger counterparts [3]. This finding has significantly affected the treatment strategies for the elderly.

Aneurysms

The accepted prevalence of intracranial aneurysms is 5% of the total population, although the prevalence in autopsy series has ranged from 0.2 to 7.9% [25–27]. It is postulated that most intracranial aneurysms develop as a result of combined hypertension, atherosclerosis, cigarette smoking, and congenital predisposition [27]. Most commonly, these lesions develop in the intracranial anterior circulation arterial blood vessels – carotid, anterior cerebral, middle cerebral, anterior communicating, and posterior communicating arteries – although posterior circulation aneurysms of the vertebrobasilar and posterior cerebral arteries account for approximately 15% of all lesions [25]. Ruptured intracranial aneurysms are one of the most devastating and challenging neurosurgical emergencies.

The majority of ruptured intracranial aneurysms cause sudden-onset of worst headache of life, focal neurologic deficits, and symptoms of increased ICPs (nausea, vomiting, headache, and decreased level of consciousness). Brain imaging shows acute subarachnoid hemorrhage (SAH), although intraventricular and intraparenchymal hemorrhages are not uncommon (Fig. 86.4a, b) [25]. The initial management of these patients focuses on the treatment of elevated ICPs and strict blood pressure control to prevent aneurysm

rebleeding [28]. Additionally, the patient must be monitored closely for evidence of neurologic deterioration, which may be indicative of rebleeding, seizures, or hydrocephalus. Systolic blood pressures should be maintained <140 mmHg using short acting, titratable antihypertensive agents, such as labetalol, hydralazine, and nicardipine. However, hypotension must also be avoided as this may lower cerebral perfusion pressure and cause cerebral ischemia. Care should be taken to avoid antihypertensive agents which raise ICPs, such as nitroprusside. If there is clinical evidence for elevated ICPs, these should be treated as previously described (Fig. 86.3) [10, 11].

The incidence of aneurysmal SAH is 6–8 per 100,000 people in most western populations [25]. Approximately 10–15% of patients with aneurysmal SAH incur fatal brain damage and die before reaching medical care [25]. In the early survivors, the initial aneurysm bleeding stops; however, they have a 15–20% risk of rebleeding in the first 2 weeks post-SAH [28, 29]. The 30-day case fatality rate is approximately 50% [30, 31]. Following acute stabilization, decisions must be made regarding aneurysm repair to prevent future bleeding. Several studies regarding the timing of open surgical treatment have been published; however, no definitive conclusions have been drawn [32–34]. Following aneurysmal SAH, patients may develop cerebral vasospasm, during which blood vessels constrict and reduce blood flow to the brain, causing reversible neurologic deficits, stroke, or death. The prevalence of cerebral vasospasm is greatest between days 4 and 10 post-SAH, and patients who undergo aneurysm repair during this interval fare worse than those treated earlier or later [35]. The primary consideration in opting for

FIGURE 86.4 (a) Noncontrast head CT demonstrates diffuse subarachnoid hemorrhage throughout the basal cisterns and bilateral Sylvian fissures, from a ruptured intracranial aneurysm and (b) contrast-enhanced cerebral CT angiogram reveals bilateral middle cerebral artery aneurysms (*single arrows*).

early intervention within the first 96 h after aneurysm rupture is to repair the aneurysm and reduce the risk of rebleeding, an event that can cause stroke or death. Many patients are in poor medical and neurological condition after SAH, and may not be stable enough to tolerate aneurysm repair via open surgery or endovascular techniques. Later aneurysm treatment may allow for the improvement of medical and neurological issues, but exposes the patient to a greater risk of rebleeding from the unsecured aneurysm. Currently, the trend is toward early intervention for all patients with aneurysmal SAH, except for those in extremely poor neurological or medical condition.

Intracranial aneurysms may be treated with either open surgical or endovascular techniques [25]. Open surgical treatment involves craniotomy and placement of a small spring-loaded clip across the neck of the aneurysm, isolating the aneurysm from the parent blood vessel while maintaining vital blood flow to the brain. Endovascular treatment involves femoral artery catheterization and deposition of metal coils within the aneurysm, sealing it off from the parent blood vessel. In a randomized trial comparing endovascular treatment with open surgery for patients with aneurysms deemed treatable with either technique, there were 278 patients age 65 or older [36, 37]. Overall neither of the treatments produced better functional outcomes; however, subgroup analyses based on aneurysm location showed that open surgery was superior for middle cerebral artery (MCA) aneurysms and that endovascular treatment was better for internal carotid and posterior communicating artery aneurysms. The generalizability of these findings is limited, since many aneurysms are not equally treatable by open surgery or endovascular techniques. The durability of endovascular repairs has also been questioned [38, 39]. In current practice, the treatment plan is usually decided by a team of neurosurgeons and neurointerventionalists while considering patient condition, aneurysm location, and angioarchitecture. Despite treatment, only ~1/3 of those patients who survive their initial aneurysm rupture will regain a good functional status, while the remaining 2/3 will have significant deficits or die [25]. These outcomes are strongly associated with the patient's admission neurological exam [25, 40].

Historically, patients with aneurysmal SAH and advanced age (>70 years) have been deemed poor candidates for surgical or endovascular treatment [40–44], based on the worse neurological condition of older patients when compared with their younger counterparts [42]. Elderly patients were traditionally treated conservatively, with only medical management of their SAH symptoms. Not surprisingly, this led to very poor outcomes, with the vast majority (>75%) of elderly patients suffering severe morbidity and mortality [40, 43]. Evidence showing improved outcomes in elderly patients who receive surgical or endovascular treatment when compared with medical management [43] has spurred a recent

trend toward offering geriatric patients with aneurysmal SAH definitive treatment for their aneurysm. However, it is clear that even with treatment, the geriatric population fares worse than their younger counterparts [42]. Using data from a multicenter randomized trial, it was found that with advancing age, patients have significantly worse admission neurological exams, thicker subarachnoid clots, and higher rates of intraventricular hemorrhage, hydrocephalus, and aneurysm rebleeding [42]. Additionally, older patients have higher incidences of preexisting medical comorbidities [42]. Interestingly, in this study, there were no age-related differences in time to presentation, timing of surgery, aneurysm size and location, or surgical complications. After controlling for the above factors, increasing age was still significantly associated with a poorer outcome [42]. This was thought to be related to the impaired ability of the aging brain to recover from acute stress, as well as the overall diminished cardiovascular reserve in older patients, which can lead to suboptimal cerebral perfusion [6, 42]. As endovascular technology evolves, it is likely that it will be used with increasing frequency in the elderly as a means to mitigate the risk of open surgery while still offering definitive therapy [41]. Regardless, it is clear that geriatric patients have better outcomes with definitive treatment than conservative treatment, although outcomes are worse than those in younger patients.

Vascular Malformations

CNS vascular malformations are congenital vascular lesions that fall into four categories: arterio-venous malformations (AVMs), capillary telangiectasias, venous angiomas, and cavernous malformations [25]. Of these, AVMs are most prone to hemorrhages requiring emergency neurosurgical care and will therefore be the focus of this discussion.

The prevalence of intracranial AVMs is not well known; hospital-based autopsy estimates range from 5 to 613 AVMs per 100,000 persons [45]. Anatomically, AVMs represent abnormal tangles of arteries and veins, with an absence of normal intervening capillary architecture, resulting in high-flow arterio-venous shunting [25, 45]. AVMs are congenital and occur throughout the CNS [45]. Although they may cause a variety of neurologic symptoms, the most common presentation is intracranial hemorrhage (ICH), which is a neurologic emergency (Fig. 86.5a–c) [25, 46].

The management of AVM-related ICHs begins with strict blood pressure control to prevent rebleeding. Subsequently, if there is evidence of increased ICPs, medical management should be initiated, as previously described (Fig. 86.3) [10, 11]. If significant mass effect and concern for herniation exists, surgical evacuation of AVM-related ICHs can be

FIGURE 86.5 (a) Noncontrast head CT demonstrates a large left fronto-temporo-parietal intracranial hemorrhage with associated intraventricular hemorrhage, mass effect, and midline shift, (b) contrast-enhanced

cerebral CT angiogram reveals an underlying arterio-venous malformation, and (c) cerebral catheter angiogram confirms the presence of a large arterio-venous malformation.

performed; however, the surgical approach is much different than that for typical ICHs and is beyond the scope of this discussion. If possible, it is preferable to stabilize the patient medically and treat the AVM in a nonacute setting. Treatment options include open surgical resection, radiosurgery, and endovascular embolization.

Most AVMs are diagnosed at an early age (~35 years), and patients who present with hemorrhage are even younger (~31 years) [45, 47]. Prospective data indicate that the patients at highest risk for future hemorrhages are those who have AVMs with deep locations, exclusively deep venous drainage, and a history of previous AVM-related ICH [48]. Additionally, the risk of future hemorrhages increases with age [48]. Given the rarity of this disease, there are no data on specific or different treatment strategies for the elderly population. However, it is likely elderly patients are more often treated with less invasive methods (i.e., radiosurgery and endovascular embolization) when possible, due to the perceived increased risks of open surgery with advanced age.

Stroke

Cerebrovascular accidents, or strokes, are a leading cause of morbidity and mortality, especially among the elderly [3]. Strokes can be either hemorrhagic or ischemic, both of which constitute neurologic emergencies that may require surgical intervention.

Hemorrhagic strokes affect approximately 10–20 per 100,000 people each year [24, 49]. Although these events are

less frequent than ischemic strokes, they have much higher rates of associated death and disability [3]. Specifically, the 1-year mortality rate following hemorrhagic stroke is approximately 62% [24]. The most common risk factor for hemorrhagic stroke is hypertension, which is the focus of this discussion [24]. Amyloid angiopathy is also a significant cause of hemorrhagic stroke and will be discussed in detail later in this chapter. Advancing age, male sex, and alcohol and tobacco use are known risk factors for hypertensive hemorrhagic stroke (HHS). Additionally, blacks have an incidence of HHS that is twice that of whites [24].

HHSs most commonly occur from the rupture of small intracranial perforator arteries in deep regions of the brain (e.g., basal ganglia and brainstem), although cortical and cerebellar hemorrhages occur as well (Fig. 86.6) [24, 25, 50]. The initial management of HHS patients focuses on strict blood pressure control and treatment of elevated ICPs (Fig. 86.3) [10, 11]. The INTERACT randomized controlled trial demonstrated that intensive blood pressure control reduces subsequent hematoma growth, although clinical outcome data are lacking [51]. The role of surgical evacuation in the treatment of HHS is controversial. A recent randomized controlled trial (STICH) evaluated the role of early surgical intervention in supratentorial ICHs and determined that there was no overall benefit from early surgery as compared to initial medical management [49]. Given the deep location of many of these hemorrhages and the need to traverse normal intervening brain to evacuate them, it is not surprising that there was no clear benefit with surgical intervention in this study. On the other hand, anecdotal evidence suggests that superficial supratentorial HHSs with significant mass effect

FIGURE 86.6 Noncontrast head CT demonstrates an acute basal ganglia hemorrhage with mass effect and intraventricular extension.

may respond well to surgical decompression and therefore these patients should be evaluated on a case-by-case basis with the assistance of a neurosurgical team. Alternatively, HHSs in the cerebellum respond much more favorably to surgical evacuation. Cerebellar hemorrhages have a propensity for early hydrocephalus and brainstem compression [24]. Craniotomy and decompression is the definitive treatment for this process and studies have shown that those patients with large cerebellar hematomas (volume greater than 40 mL) have a clear benefit from surgical intervention [24, 52]. Of note, significant research has also been performed to ascertain the role of recombinant-activated factor VIIa (rFVIIa) in the treatment of acute ICHs, including HHSs. The final results of the phase 3 randomized controlled trial (FAST) demonstrated that although rFVIIa reduces the growth of the hematoma, it does not result in any significant improvements in survival or functional outcome, and therefore, the use of rFVIIa for acute ICHs has not become part of standard practice [53].

Ischemic strokes (IS) account for the vast majority of all strokes, with an incidence of 300–500 cases per 100,000 people each year [3]. In general, management of IS should be directed by a neurology team. On rare occasions, IS may require surgical intervention. The role of surgical intervention has been well examined in patients with a “malignant” MCA infarction, where swelling from the damaged brain can cause rapid neurological deterioration and 1-year mortality rates reach up to 80% [54–57]. Several randomized controlled

trials (DESTINY, HAMLET, and DECIMAL) have been performed to evaluate the efficacy of early surgical decompression via hemicraniectomy and durotomy, to relieve the mass effect of the infarcted and edematous brain [55–57]. The pooled analysis of these trials demonstrates a significant reduction in mortality; however, overall patient morbidity and functional outcomes remain unchanged despite surgical decompression [54]. It should be noted that these trials did not include patients greater than 60 years of age and therefore, surgical intervention in elderly patients should be considered on a case-by-case basis.

Amyloid Angiopathy

Cerebral amyloid angiopathy (CAA) is an important cause of nontraumatic ICH, comprising approximately 10% of all ICHs and 30% of all lobar ICHs [25, 58]. Moreover, this pathology has a predilection for the elderly population, making its review particularly germane to this discussion [25, 58]. CAA is characterized by the deposition of beta-amyloid, a fibrillar protein, in the media and adventitia of small- and medium-sized arteries [25, 58]. The exact prevalence of CAA is difficult to determine due to the lack of definitive histopathology in most cases; however, it is well known that the prevalence of CAA increases with age and it is rarely identified in those less than 55 years of age [58]. CAA has an equal predilection for both sexes. Approximately 1/3 of people greater than 60 years of age have evidence of CAA on autopsy, and in individuals over 90 years of age, the prevalence of CAA exceeds 60% [58]. Studies have also demonstrated that those individuals who possess the E2 and E4 alleles of the apolipoprotein E gene have a significantly increased risk of developing CAA [25, 58].

Although CAA can cause progressive dementia, transient ischemic attacks, seizures, and ischemic stroke, arguably the most concerning manifestation is ICH, caused by the rupture of amyloid-laden vasculature [25, 58]. These hemorrhages are most frequently lobar and can be multifocal [25, 58].

The management of ICHs due to CAA is not significantly different from the management of hypertensive ICHs. Most hemorrhages do not require surgical intervention; however, if significant mass effect and neurologic deficits exist, craniotomy for evacuation and decompression can be considered. Unlike cerebral aneurysms and AVMs, ICHs due to CAA do not require treatment of a discrete, underlying vascular abnormality. Although the vasculature is altered in patients with CAA, it does not require unique surgical maneuvers to control bleeding. In contrast with ICHs due to hypertension, CAA-associated ICHs are typically more superficial and therefore more amenable to surgical intervention [25, 58]. Although no specific pharmacotherapy exists for the treatment of CAA,

there is ongoing research into the development of antiamyloid medications and vaccinations [58]. Additionally, as discussed above, the use of rFVIIa has not resulted in a significant clinical benefit in this patient population [53].

Adverse Drug Reactions

As the population ages, the use of antiplatelet and anticoagulant medications such as aspirin, clopidogrel, and warfarin, has increased dramatically. Protocols for managing patients with acute ischemic stroke using thrombolytic therapies, such as intravenous and intraarterial tissue plasminogen activator (tPA), have become more common [59]. Traditional guidelines recommend administration of tPA within 3 h of onset of stroke symptoms; however, many stroke centers now aim to administer tPA in an urgent fashion, within 60 min of onset of symptoms, for embolic stroke [59]. Given the potency of these medications, it is not surprising that some of their primary side effects include undesired bleeding, including ICHs [60, 61]. Patients who receive tPA and have early hypodensities on CT have significantly higher rates of ICH [62]. Patients who develop ICHs secondary to antiplatelet or anticoagulant therapies should have the offending medications discontinued immediately, followed by reversal of the platelet dysfunction and/or anticoagulation with the appropriate blood products and/or medications. The remainder of their management should follow that of other nontraumatic ICHs; strict blood pressure control should be employed and surgical decompression considered on a case-by-case basis for those patients with significant mass effect. In a study of surgical evacuation of ICH following administration of streptokinase for acute myocardial infarction, surgery was beneficial, although survival was dependent upon the time from the initiation of thrombolytic therapy to onset of stroke symptoms, initial Glasgow coma scale score, volume of ICH, and “baseline clinical characteristics” (defined as age, systolic blood pressure, Killip class, heart rate, infarct location, previous myocardial infarction, height, time to treatment, history of smoking, current smoking, diabetes, weight, history of coronary bypass surgery, type of thrombolytic agent, history of hypertension, and history of cerebrovascular disease) [63]. Importantly, all patients who are started on antiplatelet and anticoagulant medications should be counseled about the potential risk of ICH.

Sinus Thrombosis

Intracranial venous sinus thrombosis (VST) is a relatively rare condition that constitutes a neurologic emergency.

There are several factors which predispose individuals to developing VSTs, including: a hypercoagulable state, dehydration, adjacent tumor or infection, pregnancy, vasculitis, systemic inflammatory disorders, and local trauma [25, 64]. Although most intracranial VSTs become evident through headache and other symptoms of increased ICPs, a significant portion of patients develop seizures, intracranial infarcts, ICHs, or focal motor deficits [25, 64]. VSTs cause venous outflow obstruction and subsequent parenchymal edema and infarction [25, 64]. The primary goal in the treatment of VSTs is the prevention of thrombus propagation while allowing for natural thrombolysis and recanalization of the affected vessel. This is achieved with anticoagulation and is typically managed by a neurology team [25, 64]. However, endovascular thrombolysis of the clot/affected vessel using pharmacologic and mechanical techniques is sometimes indicated, and in cases with large ICHs, surgical decompression and evacuation is occasionally performed [64]. As compared to intracranial arterial thromboses, VSTs have an overall better prognosis [64]. In the largest series to date of patients with VSTs, there was a 13% rate of death or dependence at 6 months after ictus [64]. Risk factors associated with poor outcome include advancing age, male sex, altered mental status on admission, deep cerebral venous system thrombosis, ICH, malignancy, and CNS infection [64].

Infection

Infections of the CNS are neurological emergencies, which must be treated in a timely fashion. Generally, CNS infections can be categorized by their location: meningeal, subdural, epidural, intraparenchymal, and intraventricular. Most CNS infections have bacterial, viral, or fungal etiologies; this discussion will focus on bacterial infections, as these most commonly require surgical intervention. Additionally, this discussion will be limited to intracranial CNS infections; a review of spinal CNS infections can be found in Chap. 87.

Infections of the meninges, also known as meningitis, are the most common intracranial CNS infection [25]. Patients typically develop fever, headache, neck stiffness, photophobia, and malaise. Contrast-enhanced imaging studies often reveal diffuse meningeal enhancement, and CSF analysis demonstrates elevations in the nucleated white blood cell count. As meningitis is most often managed medically, without the need for surgical intervention, further discussion of its management is beyond the scope of this discussion.

Infections of the epidural space, also known as epidural abscesses (EA), comprise approximately 2% of intracranial CNS infections [65]. These infections present with fever, headache, neck stiffness, photophobia, periorbital swelling,

scalp tenderness, ear pain, nausea, vomiting, and lethargy. Imaging studies reveal an extra-axial, biconvex lesion with peripheral enhancement. Imaging studies may also reveal evidence of underlying osteomyelitis, sinusitis, or mastoiditis. Cranial EAs typically occur via direct extension of an adjacent sinusitis, although they may also be the result of hematogenous spread from infections located throughout the body. They most commonly occur in adolescent males, though all age groups may be affected [65]. Treatment of cranial EAs involves surgical evacuation, followed by prolonged antibiotic therapy. If the adjacent bone appears to be involved, it must also be debrided and/or removed [65]. The most commonly isolated organisms in cranial EAs are microaerophilic or hemolytic streptococci; however, staphylococci may also be involved in cases of postoperative or posttraumatic infections [65].

Subdural infections, also known as subdural empyemas (SE), occur in 12–25% of intracranial CNS infections [65]. These infections present similarly to cranial EAs; however, focal neurologic deficits are more common given the direct contact with the cortical surface [65, 66]. Imaging studies reveal extra-axial, crescent-shaped collections with peripheral enhancement. As with cranial EAs, there is often evidence of adjacent osteomyelitis, sinusitis, or mastoiditis. Intracranial SEs typically occur in the setting of sinusitis, via direct extension or hematogenous spread, but may also occur as a result of trauma or neurosurgical intervention [65, 66]. Treatment involves prompt surgical evacuation, followed by prolonged antibiotic therapy [65, 66]. The most commonly isolated organisms in intracranial SEs are aerobic and anaerobic streptococci species, as well as staphylococci species [65, 66].

Intraparenchymal intracranial CNS infections, also known as brain abscesses (BA), are occurring with increasing frequency as the prevalence of immunocompromised individuals rises [65]. These infections cause fevers, headache, meningismus, malaise, seizures, and focal neurologic deficits – and they most often have a rapid progression of symptoms. On contrasted imaging studies, BAs appear as intra-axial lesions with marked peripheral enhancement and restricted diffusion on MRI (Fig. 86.7a–c). They can occur in the setting of sinusitis and mastoiditis, but are also commonly the result of bacteremia in the setting of congenital heart defects, bacterial endocarditis, dental abscesses, pulmonary infections, and acute diverticulitis [65]. Treatment consists of abscess drainage, often with the use of intra-operative stereotactic navigation systems, followed by prolonged antibiotic therapy [65]. The most commonly isolated organisms include aerobic and anaerobic streptococci and bacteroides species, staphylococci species, and fungal organisms in the immunocompromised [65].

Intraventricular CNS infections are rare entities. They commonly cause signs and symptoms of obstructive hydrocephalus: headache, nausea, vomiting, lethargy, and coma [25, 65]. Most often, intraventricular infections are caused by parasites (i.e., neurocysticercosis) [25]. Imaging studies reveal an intraventricular mass with a variable enhancement pattern and evidence of obstructive hydrocephalus. Surgical management of these lesions is usually curative. Medical management using antihelminthics remains controversial and should be discussed with an infectious disease specialist [25]. Of note, bacterial ventriculitis may also develop in the setting of a prolonged intracranial bacterial infection.

FIGURE 86.7 (a) Contrast-enhanced head CT demonstrates multiple hypodense ring-enhancing lesions, (b) T1-weighted contrast-enhanced brain MRI demonstrates multiple hypodense ring-enhancing lesions

with surrounding edema, and (c) diffusion-weighted brain MRI reveals restricted diffusion throughout the enhancing lesions, consistent with multiple brain abscesses.

As with intraventricular parasitic infections, individuals with bacterial ventriculitis typically develop symptoms of hydrocephalus. Imaging studies reveal diffusely enhancing ventricular walls. Management includes CSF diversion for elevated ICPs and prolonged antibiotic therapy.

With the exception of meningitis, most CNS infections require neurosurgical intervention. Risks of prolonged, untreated CNS infections include VST, osteomyelitis, hydrocephalus, seizures, and catastrophic intraventricular BA rupture. Importantly, in the management and initial work-up of CNS infections, lumbar puncture is often considered. Although this can be performed safely in most patients with simple meningitis, for those patients with intracranial mass lesions, lumbar puncture should be deferred due to the risk of causing cerebral herniation [25]. Additionally, significant controversy exists regarding the use of steroids in the context of CNS infections [25]. This issue is best dealt with on a case-by-case basis, after careful review of the particular clinical scenario.

Most CNS infections tend to occur in the young; however, the elderly population deserves special consideration for several reasons. First, geriatric patients often have nonspecific signs and symptoms in the setting of infection [3, 67]. This increases the need for vigilant physical examination and CNS imaging studies in this population. Additionally, the elderly population has a relative immunosenescence, therefore, their clinical course and response to therapy may be worse than a younger counterpart with a similar illness [67]. Finally, the elderly tend to have more frequent and more severe adverse drug effects, especially from antibiotics, and this should be taken into account when choosing the appropriate drug regimen [67].

Peripheral Nerve Injury

Traumatic peripheral nerve injuries (PNIs) are relatively rare occurrences and are treated by a variety of specialists, including neurosurgeons, plastic surgeons, and orthopedic surgeons [68, 69]. Despite their rarity, PNIs can result in devastating functional loss and represent an important neurologic emergency. Clinically, they typically present in the setting of trauma with neurologic deficit confined to a single extremity [70]. PNIs often occur in tandem with bony fractures and peripheral vascular injuries [70]. Traumatic PNIs can be loosely categorized into three broad groups based on mechanism: stretch/avulsion injuries, lacerating injuries, and compressive injuries [71].

Stretch and avulsion injuries are the most common types of PNI [70, 71]. They are usually the result of motor vehicle accidents in which the torsional force of impact results in the movement of an extremity in one direction and the patient's

trunk in another [70]. This results in a stretching of nerve roots, which, if severe enough, can cause complete nerve root avulsion from the spinal cord. Spinal imaging studies may reveal pseudomeningoceles indicative of dural nerve root sleeve disruption and adjacent soft tissue injury. Penetrating and lacerating PNIs typically occur as a result of gunshot and knife wounds. They are the second most common type of PNI and are often associated with injuries of adjacent vascular structures [70, 71]. These injuries are usually discovered on physical exam, as the external signs of trauma can be quite obvious. Compressive PNIs often occur as a result of local hematomas, soft tissue swelling, and bony hypertrophy. They cause indirect neural injury via external compression [71].

Operative interventions for PNIs vary widely based on the mechanism of injury, extent of neurologic deficit, presence of additional injuries, and surgeon preference [72, 73]. Surgical interventions may involve decompression, direct repair, removal of neuromas, and nerve grafting or transposition [72, 74]. Nearly all interventions employ the use of pre- and postoperative electromyography, and intraoperative nerve action potential and somatosensory evoked potential recordings [72]. Given the increased incidence of osteoporosis and bony fractures in the elderly, it is likely that they are at increased risk for PNIs in the setting of trauma. Therefore, since early identification of PNIs can maximize the potential for a functional recovery, it is imperative that elderly patients undergo complete neurologic examination as part of their trauma evaluation.

Tumors

Intracranial primary or metastatic tumors can cause medical emergencies via mass effect from tumor growth, edema in the surrounding brain, intratumoral hemorrhage, or seizures. Initial management should focus on the treatment of elevated ICP symptoms, blood pressure control, and seizure cessation. Further discussion of these lesions can be found in Chap. 87.

Conclusions

Geriatric neurosurgical emergencies encompass a broad range of pathologies. Elderly patients have unique treatment challenges that must be accounted for by healthcare providers. The loss of cardiovascular reserve and the fundamental changes within the aging CNS appear to play a significant role in morbidity and mortality and should be carefully considered when treating and counseling geriatric patients with neurosurgical illnesses.

CASE STUDY

History

An 82-year-old male, with multiple medical problems, seeks medical attention after the acute onset of worst headache of life. He also notes nausea, photophobia, and neck pain. He denies trauma, numbness, weakness, tingling, seizures, chest pain, and shortness of breath. A noncontrast head CT (Fig. 86.8a) is obtained and the patient is subsequently transferred to a tertiary care center. During transfer, the patient is noted to become progressively lethargic.

Past Medical History

1. Hypertension
2. Coronary artery disease
3. Chronic renal failure
4. Type II diabetes mellitus
5. Atrial fibrillation

Admission Neurologic Examination

Temp: 99.1 degrees Fahrenheit, HR: 70 beats per minute, BP: 160/70 mmHg, RR: 10 breaths per minute, O₂, Sat: 98% on 4 liters nasal cannula
Lethargic, nonverbal

Opens eyes to noxious stimuli

Pupils equally round and reactive to light, bilaterally
Moving all extremities symmetrically, not following commands

Localizes to noxious stimuli

Unable to assess sensory function

2+ deep tendon reflexes throughout

Toes downgoing, bilaterally

Relevant Admission Laboratory Values

Na: 138

Troponin-I: 0.40

WBC: 8.9 k

PLT: 228 k

INR: 2.8

Clinical Course

Upon arrival to the tertiary care center, the patient is intubated for airway protection. Subsequently, he is treated for hypertension and his systolic blood pressure is maintained below 140 mmHg. He is also given 1 g of IV phenytoin for seizure prophylaxis and 6 U of fresh frozen plasma to normalize coagulation. A cerebral CT angiogram is obtained (Fig. 86.8b), which demonstrates an anterior communicating artery aneurysm. The patient is

FIGURE 86.8 (a) Noncontrast head CT demonstrates diffuse subarachnoid hemorrhage involving the bilateral Sylvian fissures as well as intraventricular hemorrhage and hydrocephalus and

(b) contrast-enhanced cerebral CT angiogram reveals an anterior communicating artery aneurysm (*single arrow*)

(continued)

CASE STUDY (continued)

transferred to the intensive care unit. His head of bed is elevated to 30°, he is sedated and hyperventilated, and a ventriculostomy catheter is placed to decompress hydrocephalus and manage elevated intracranial pressures. The patient's examination improves over the next 24 h; specifically, he begins to follow commands. An echocardiogram is obtained because of the abnormally elevated cardiac enzymes. The patient is found to have an ejection fraction of 35%. A family discussion is held regarding the risks and benefits of treatment and the decision is made to pursue endovascular therapy. The following day, the patient is taken to the angiography suite where he undergoes successful coil embolization of his intracranial aneurysm. Over the next 2 weeks, he is monitored carefully in the intensive care unit for evidence of vasospasm. His hydrocephalus resolves during this time and the ventriculostomy catheter is discontinued. His neurologic exam slowly improves, although his cognitive function appears somewhat diminished to his family members. He is extubated successfully. His ejection fraction also improves to 45% over this time period. He is later transferred to the floor and subsequently to a rehabilitation facility.

Discussion Questions

1. What are the most important initial measures that should be taken when caring for a patient with a ruptured intracranial aneurysm?
2. What are the possible etiologies of the patient's change in mental status during transfer to the tertiary care facility?
3. What is the clinical and operative significance of the elevated cardiac enzymes on admission?
4. What is the current standard of care for treatment of ruptured intracranial aneurysms in the elderly?

Discussion Answers

1. The most important initial measures to be taken when caring for a patient with a ruptured intracra-

nial aneurysm include: strict blood pressure control, administration of prophylactic anticonvulsant medications, and management of elevated intracranial pressures, if present.

2. Possible etiologies of the patient's change in mental status during transfer include: aneurysm rebleeding, hydrocephalus, and seizure.
3. Elevated cardiac enzymes in the setting of subarachnoid hemorrhage are associated with an increased risk of cardiogenic shock, pulmonary edema, and cerebral vasospasm. Elevated cardiac enzymes are also associated with higher rates of death and severe disability following aneurysmal subarachnoid hemorrhage. Therefore, when caring for patients with elevated cardiac enzymes, careful attention should be paid to optimizing their cardiopulmonary status. Moreover, in the setting of acutely elevated cardiac enzymes, it is often more judicious to treat patients with less invasive procedures (i.e., endovascular treatments) as opposed to maximally invasive procedures (i.e., open surgery), in order to minimize the degree of cardiac stress.
4. The current standard of care for treatment of ruptured intracranial aneurysms in the elderly is definitive surgical or endovascular repair in order to secure the aneurysm and prevent rebleeding. Aneurysm location, size, and configuration will often determine whether open surgery or endovascular techniques are the optimal approach to aneurysm repair. However, the patient's overall systemic health should be evaluated, and if significant comorbidities exist, strong consideration should be given to less invasive endovascular procedures, even if open surgery might provide a more definitive repair. Previously, elderly patients were treated with conservative, medical management without aneurysm repair. However, long-term studies have demonstrated that elderly patients have significantly better outcomes with definitive management and thus, this has become the standard of care. Nonetheless, elderly patients still fare worse than their younger counterparts, and as such, providers should have an open discourse with the patient and their family to discuss the potential need for long-term hospitalization, rehabilitation, and home care, so that treatment plans are made in accordance with the patient's wishes.

Chapter 87

Benign and Malignant Tumors of the Brain

Andrew D. Norden and Elizabeth B. Claus

Introduction

Data from the Central Brain Tumor Registry of the United States (CBTRUS) indicate that approximately 23,000 Americans were expected to be diagnosed with a primary cancer of the central nervous system (CNS) in 2007 [1]. The incidence rate of all primary malignant CNS tumors in the USA is estimated at 7.3 cases per 100,000 people annually [1]. Brain tumors are increasingly common as people age; approximately 15% of primary malignant brain tumors are diagnosed in individuals aged 70 years or more [2]. Survival rates among patients diagnosed with primary malignant brain tumors vary inversely with age. For example, among patients between the ages of 45 and 54, the 5-year survival rate is 24%, while this rate is only 5% for patients who are at least 75 years old (Table 87.1) [1]. In addition to those with primary brain tumors, up to 150,000 Americans are diagnosed each year with metastatic brain lesions [3], and many of these are elderly patients. This chapter provides a review and discussion of epidemiology and treatment of elderly patients with brain tumors. The focus is on primary tumors, but metastatic lesions will be addressed briefly as well.

Epidemiology and Prognosis

Glioma

Most primary brain tumors among the elderly are thought to be derived from glial cells and are therefore known as gliomas. Glial cells make up the supporting cells of the brain and assist neurons with a variety of structural, protective, and metabolic functions. Subcategories of glioma include

astrocytoma, oligodendroglioma, and mixed glioma. According to the World Health Organization (WHO) classification, gliomas receive a histopathologic grade on the basis of microscopic features including cellularity, nuclear atypia, mitotic activity, vascular proliferation, and necrosis [4]. WHO grade I gliomas are typically localized, noninfiltrating lesions that occur predominantly in the pediatric population. Grade II tumors are diffuse, infiltrative neoplasms that usually occur in young adults with a mean age of 39 years [5]. Among elderly patients, the majority of gliomas are high-grade or malignant gliomas (Table 87.2). Subtypes include glioblastomas (GBM; WHO grade IV), anaplastic astrocytomas (WHO grade III), anaplastic oligodendrogliomas (WHO grade III), and anaplastic oligoastrocytomas (WHO grade III).

GBMs are the most common malignant brain tumors in elderly patients; they represent nearly 20% of all brain tumors in adults and have an incidence rate of 3.1 per 100,000 person years. The median age of diagnosis is 64 years, and these tumors are 1.7 times more common in males [1]. Despite a number of recent advances, median survival among newly diagnosed GBM patients *younger* than 70 years who receive optimal therapy is only 14.6 months [6]. Fewer than 4% of patients achieve 5-year survival [1]. Most data suggest that elderly patients with newly diagnosed GBM have a median survival of less than 9 months [7, 8]. Indeed, age is among the most important prognostic factors in GBM [9]. An emerging body of literature suggests that molecular differences in brain tumors may explain prognostic variability between patients of different ages [10]. In one study of 140 GBM specimens, the prognostic significance of *TP53* mutations, epidermal growth factor receptor amplification, *CDKN2A/p16* alterations, and loss of chromosome 1p depended upon patient age [11].

Meningioma

Meningiomas are the most common primary intracranial tumors diagnosed in adults of all ages [1]. The prevalence

TABLE 87.1 Five-year survival rates among patients with primary malignant brain tumors of the CNS

Age (years)	Five-year survival rate (%)
0–19	66.0
20–44	49.2
45–54	24.0
55–64	11.1
65–74	6.7
75 +	4.7

Source: CBTRUS (2008). Statistical Report: Primary Brain Tumors in the United States, 2000–2004. Published by the Central Brain Tumor Registry of the United States [1]

TABLE 87.2 Age-specific incidence rates per 100,000 people per year for selected brain tumor histologies

Histology	Age at diagnosis (years)					
	35–44	45–54	55–64	65–74	75–84	85+
Glioblastoma	1.20	3.70	8.09	12.47	14.13	7.63
Anaplastic astrocytoma	0.48	0.60	0.89	1.07	1.00	0.30
Anaplastic oligodendroglioma	0.22	0.30	0.32	0.34	0.27	Unknown

of meningioma is estimated to be approximately 97.5/100,000 in the USA with over 150,000 individuals currently diagnosed. Data from CBTRUS reveal an age-adjusted incidence rate (per 100,000 person years) of 5.04 and 2.46 for females and males, respectively [1]. The incidence of meningioma increases with age with a median age of diagnosis of approximately 64 years. Although generally considered benign (WHO grade I), approximately 8% of meningiomas display aggressive features such as increased cellularity, high nuclear to cytoplasmic ratio, increased mitotic activity, patternless growth, and foci of necrosis and are classified as atypical tumors (WHO grade II). Approximately 2–3% of meningiomas exhibit frank malignant histological signs and are classified as anaplastic meningiomas (WHO grade III). Atypical and anaplastic meningiomas account for significant morbidity and mortality. Histology is an important predictor of tumor recurrence rates. Although detailed population-based data are not available, recurrence rates are estimated at 3–20% for benign meningiomas, 30–40% for atypical meningiomas, and 50–80% for anaplastic meningiomas.

Primary Central Nervous System Lymphoma

Primary CNS lymphoma (PCNSL) is an unusual extranodal non-Hodgkin's lymphoma variant that exclusively involves the nervous system and eyes. Only rarely is there spread to

the systemic compartment. PCNSL represents 3.1% of CNS tumors, with approximately 2,000 new diagnoses per year in the USA [1]. The reported incidence of PCNSL has increased over the past few decades, primarily due to increases in both immunocompromised individuals and the elderly. Between 1973 and 1984 in the USA, the incidence rate of PCNSL was 0.15 cases per 100,000 person years; between 1985 and 1997, the incidence rate more than tripled to 0.48 cases per 100,000 person years [12]. Reasons for the increase in incidence rates are controversial. Potential explanations include increased use of neuroimaging, changes in disease classification, and delayed response to a putative environmental toxin. Immunodeficiency is the strongest known risk factor for all subtypes of lymphoma, including PCNSL. Most immunocompetent patients with PCNSL are older adults, and there is a slight male preponderance. Although localized extranodal systemic non-Hodgkin's lymphoma is compatible with long-term survival in 70% or more of patients, PCNSL is almost universally fatal. Factors that predict decreased survival among patients with PCNSL include age greater than 60 years, impaired performance status, elevated serum lactate dehydrogenase, increased cerebrospinal fluid protein, and involvement of deep brain structures. Depending upon the number of adverse prognostic factors, 2-year survival rates vary between 24 and 85% [13]. A recent analysis in preparation by our group indicates that survival rates among PCNSL patients are increasing over time, perhaps due in part to advances in the chemotherapeutic management of this disease.

Risk Factors

The only well-validated risk factor for development of a glioma is exposure to ionizing radiation, generally in the form of therapeutic irradiation for cancer [14]. Radiation-induced brain tumors typically develop in young patients. A wide variety of environmental risk factors for primary brain tumors have been proposed [15]. The list of factors includes electromagnetic fields, trauma, occupational and industrial chemicals, medications including anticonvulsants, and viral infections, among others. Recent data show an intriguing association with atopy [16]. In a meta-analysis of 3,450 glioma patients, a history of atopy was associated with a relative risk for glioma diagnosis of 0.61 [17]. A history of an allergic condition or asthma was also protective. The biological basis for this association has yet to be elucidated. At present, no single risk factor has been consistently identified as being associated with cancer risk, particularly within the elderly population.

For meningioma, the evidence for ionizing radiation is even more marked with relative risks as high as 10 [18]. Evidence of an association between hormones and meningioma

risk is suggested by a number of findings including the increased incidence of the disease in women versus men (2:1), the presence of estrogen and progesterone receptors on some meningiomas [19], a potential association between breast cancer and meningiomas [20], and an association in some studies between exogenous or endogenous hormones and meningioma risk [21]. These findings warrant consideration in the use of hormone replacement therapy in postmenopausal women.

Genetics

Glioma

With respect to inherited genetic syndromes for glioma, highly penetrant but relatively rare inherited genes may exist for glioma susceptibility [22]. Some hereditary syndromes such as tuberous sclerosis, neurofibromatosis types 1 and 2, nevoid basal cell carcinoma syndrome, Li-Fraumeni syndrome as well as syndromes involving adenomatous polyps may be associated with a genetic predisposition to glioma. In a population-based study of 500 adults with glioma in San Francisco, less than 1% of cases had a known hereditary syndrome (one had tuberous sclerosis and three had neurofibromatosis) [23]. With respect to familial aggregation, the reported relative risks of brain tumors among family members of brain tumor cases range from nearly one to ten, with a twofold rate seen in larger studies [24]. Not all studies of siblings, and no studies of twins, have supported a simple genetic etiology. Formal segregation analyses have provided evidence for a genetic component but no clear mode of inheritance with approximately 5% of cases estimated to be familial [24]. One linkage study has been reported with statistically significant linkage to 15q23–26.3 for 15 Finnish families with multiple cases of glioma [25]. These data suggest, as for most neoplasms, that glioma development and growth is likely a function of the effects of many genes that are relatively prevalent but not highly penetrant and that interact with environmental exposures to confer risk. An international effort to locate genes for glioma via the collection of families with two or more members affected with glioma is currently underway (GLIOGENE), and results from the first genome-wide association study of glioma are currently in press. Recently, the first examination of DNA repair gene variants and glioma was presented with evidence for such an association [26]. In the most recent and largest study to date of genetic polymorphisms and meningioma risk, Interphone study reported a statistically significant association with meningioma for 12 single nucleotide polymorphisms (SNPs) drawn from DNA repair genes.

These investigators examined 1,127 tagging SNPs selected to capture most of the common variation in 136 DNA repair genes as well as an additional 388 putative functional SNPs (including 69 nonsynonymous coding SNPs that may identify the function of expressed proteins) in 631 cases and 637 controls drawn from five case/control series from the Interphone study. The Interphone study is a case/control project initially designed to examine the relationship between cell phone use and the risk of brain tumors, including meningioma. The group reported a novel and biologically intriguing association between meningioma risk and three variants in the gene that encodes breast cancer susceptibility gene 1-interacting protein 1 (BRIP1) (17q22) [26].

In addition to the study of inherited genes, scientists have attempted to elucidate the somatic genetic changes and pathways associated with the development of a number of primary brain tumors, including most prominently, those associated with the development of GBMs. GBM is considered to be a clinical manifestation of at least two pathways with respect to genetics (Fig. 87.1). One form appears to result from malignant progression of a low-grade astrocytoma. The timing of this transition or progression to a higher grade is variable, and it remains controversial whether aggressive therapy for a low-grade astrocytoma can prevent or delay the subsequent evolution of a GBM. There is evidence to suggest that the progression of tumor grade is associated with a series of genetic changes, similar to those seen for the progression from polyp to carcinoma in colon cancers. The second form of GBM appears to be a tumor that arises *de novo* in patients with no prior evidence of a low-grade glioma. When survival is measured for the two groups, there does not appear to be an advantage for either type. The latter *de novo* form is more commonly seen in the elderly population.

Data indicate that the evolution of GBM from a low-grade glioma is genetically distinct from the *de novo* GBM. Tumors that progress from a low-grade glioma to GBM are associated with p53 mutation. In contrast, *de novo* glioblastoma does not appear to manifest evidence of a p53 mutation; instead, these tumors have been shown to have amplification and mutation of epidermal growth factor receptor (*EGFR*) and amplification of *MDM2*, as well as loss of heterozygosity of chromosome 10 [27, 28]. Of interest is the fact that epidemiologic data from these studies suggest that advanced age is associated with *EGFR* and *MDM2* amplifications, a condition not present in gliomas arising in younger patients.

Meningioma

Few studies have examined the relationship between a personal diagnosis of meningioma and a family history of meningioma although evidence that such a history is

FIGURE 87.1 Magnetic resonance imaging (MRI) scan of a glioblastoma. (a) T1-weighted axial image shows a hypointense lesion involving the right parieto-occipital lobe and corpus callosum, with (b) central

necrosis and peripheral enhancement following gadolinium administration. (c) T2-weighted image shows hyperintense signal and mass effect upon the ventricular system.

associated with risk does exist. Using data from the Swedish Family Cancer Database, Hemminki and Li reported a statistically significant association between meningioma diagnosis and a parental history of meningioma [standardized incidence ratio (SIR): 2.5, 95% CI: 1.3, 4.3] [29]. A recently published hospital-based study found that the risk of meningioma was increased among persons reporting a benign brain tumor (OR: 4.5, 95% CI: 1.2, 15.0) [30]. Population-based surveys suggest that highly penetrant but relatively rare inherited genes may exist for meningioma susceptibility, although it appears at present that these genes may be primarily seen in families with neurofibromatosis 2. Collections of families with multiple family members diagnosed with meningioma and who do not appear to carry inherited mutations in the *NF2* gene are relatively rarely identified despite the fact that up to 1% of the adult population may harbor such a diagnosis, indicating a wide spectrum of phenotypic expression with respect to clinical import. At present no family based linkage studies of meningioma have been reported. Recently, data from Israel provide evidence for genetic predisposition to radiation-associated meningioma [31], highlighting the role of inherited genetic factors in meningioma risk modification. In the most recent and largest study to date of genetic polymorphisms and meningioma risk, investigators from the Interphone study examined that 1,127 tagging SNPs selected to capture common variation in 136 DNA repair genes as well as an additional 388 putative functional SNPs in a combined case/control series of 631 cases and 637 controls drawn from five case/control series from the Interphone study [26]. The group reported a novel association between meningioma risk and the SNP rs496851, which maps to intron 4 of the gene that encodes breast cancer susceptibility gene 1-interacting protein 1 (BRIP1) (mapped at 17q22).

Lymphoma

There is virtually no published data about the potential heritability of PCNSL. Due to the rarity of the disease, there is a limited understanding of its molecular pathogenesis, particularly in comparison to malignant glioma. While p53 mutations are rare, inactivation of the cell cycle regulators p14^{ARF} and p16^{INK4A} is commonly observed [32]. Other abnormalities include translocations of the *BCL6* gene and 6q deletions; both of these appear to have prognostic significance [33].

Symptoms

The presenting symptoms for intracranial lesions vary by tumor location, rate of growth, type of tumor, and age. In elderly patients, the most common presentations are confusion or mental status change, personality change, headache, seizure (often with associated motor or sensory deficits), and aphasia. However, any combination of neurologic symptoms is possible. Symptoms frequently develop over a period of weeks or months. Papilledema and nausea or vomiting are less common features in elderly patients, likely because posterior fossa tumors are uncommon in this age group. In some cases, the symptoms may be confused with more common conditions such as dementia (when cognitive complaints predominate) or cerebrovascular disease (when neurologic deficits develop acutely). The presenting symptoms may be subtle, particularly if the tumor is located in a clinically “silent” area of the brain such as the anterior frontal lobe or if it grows slowly (as is often the case, for example, with meningiomas). Tumor symptoms may present acutely, as with a seizure or hydrocephalus, when the flow of cerebrospinal fluid is suddenly blocked by the tumor.

Diagnosis

Most brain tumors in the elderly are now identified by neuroimaging with computed tomography (CT) or magnetic resonance imaging (MRI) scans (Fig. 87.2). Although these modalities are critical for tumor detection and often suggest the correct histologic diagnosis, tissue sampling is generally required before treatment can be initiated. These noninvasive tests are usually well tolerated by the elderly patient, but renal function may be adversely affected by iodinated contrast agents used in CT scanning. Elderly patients with impaired renal function may also be at risk for nephrogenic systemic fibrosis when they receive gadolinium-based contrast agents for MRI scanning [34]. In addition to CT and MRI, angiography may play a role in defining the vascular supply of tumors such as meningiomas, although in the elderly patient, the procedural risks may outweigh the benefits of any information gained [35]. In many instances, noninvasive vascular imaging with CT or MR angiography may be sufficient.

The use of diagnostic imaging is of particular interest in the elderly, as its increased use in western countries has been proposed as one of the reasons for the reported increase in brain tumors among the elderly in the 1970s and 1980s. An intriguing population-based study recently reported incidental findings detected on brain MRI scans obtained in nearly 8,000 individuals [36]. Among the abnormalities observed were benign tumors (1.6%), pituitary macroadenomas

TABLE 87.3 Distribution of incidental findings on brain MRI according to age

Finding	Age (years)		
	45–59 (n=750)	60–74 (n=993)	75–97 (n=257)
Meningioma – n (%)	4 (0.5)	10 (1.0)	4 (1.6)
Infarct – n (%)	30 (4.0)	68 (6.8)	47 (18.3)

Source: Data from Vernooij et al. [36]

(0.3%), vestibular schwannomas (0.2%), and one possible low-grade glioma (<0.1%). The benign tumors were mostly composed of meningiomas, and these ranged in diameter from 5 to 60 mm. There was also one case of multiple brain metastases in a patient with a history of lung cancer. The largest proportion of incidental meningiomas was discovered in subjects aged 75–97 years (Table 87.3). A continued examination of the incidence of brain tumors in elderly patients in relation to the proportion diagnosed solely by means of radiology will be of interest in the coming years.

Surgery

Unlike for PCNSL, in which the surgeon’s role is limited to biopsy for tissue diagnosis, surgery is a critical component of treatment for gliomas. Surgical options that are frequently considered include gross total resection, partial resection, and stereotactic biopsy. Unfortunately, data to guide surgical

decision-making are limited. There are no published studies that examined survival rates and quality of life among elderly patients with brain tumors by type of surgical management. Furthermore, there are no prospective, randomized trials of surgery for this age group. Despite limited data, the standard of care for most patients with GBM involves maximal safe resection followed by radiation and chemotherapy [6]. Some meticulous retrospective data suggest a survival benefit for patients who undergo maximal surgical resection [37], but this result is somewhat controversial. Important issues to consider in deciding between biopsy and resection in all patients include tumor location (and especially proximity to eloquent brain), the patient's general health, and degree of mass effect or midline shift. Stereotactic brain biopsy with a frame or frameless image-guided technique is safe, well tolerated, and typically requires only an overnight hospital stay. An important caveat is that biopsy allows for pathologic evaluation of a small portion of the tumor; according to one study, pathologic diagnosis (more often pathologic grade than histologic type) may change nearly half of the time if surgical resection is performed subsequent to biopsy [38].

The current literature uniformly reports age as the most significant variable correlated with survival, with a less favorable prognosis associated with increased age [39]. For this chapter, we reviewed data from the Connecticut Tumor Registry (CTR), which indicated that the overall 1- and 5-year survival rates for individuals over the age of 70 diagnosed with GBM were 20 and 3%, respectively. This age group, therefore, shows 1- and 5-year death rates that are 1.3- and 1.8-fold higher, respectively, than those of individuals diagnosed prior to 70 years, respectively. Within these CTR data, survival rates for individuals diagnosed with astrocytoma over the age of 70 are somewhat more encouraging, with 59 and 36% of these individuals remaining alive 1 and 5 years, respectively, after diagnosis. These older patients are 1.3 and 2.7 times more likely to succumb to their disease at these time points than are individuals diagnosed prior to age 70, highlighting again the deleterious effect of age on outcome.

Despite the fact that elderly patients have less favorable survival rates, there is limited evidence that surgery benefits these patients if they are selected carefully [40]. For example, the general medical condition and neurologic status must be considered. As would be expected, patients with poor Karnofsky performance status (KPS) scores, a measure of functional status (Table 87.4), do less well with respect to survival [14]. In general, elderly patients who undergo craniotomy for primary brain tumor resection achieve longer survival than those who undergo biopsy [40], but this benefit is complicated by intraoperative and postoperative mortality and morbidity rates, which exceed those in younger individuals [41]. Additionally, most studies that report better outcomes for elderly patients who undergo craniotomy are

TABLE 87.4 Karnofsky performance status (KPS) score

Score	Interpretation
100	Normal
90	Normal activity; minor signs or symptoms
80	Normal activity with effort; some signs or symptoms
70	Cares for self; unable to do normal activity or active work
60	Requires occasional assistance, but cares for most personal needs
50	Requires considerable assistance and frequent medical care
40	Disabled; requires special care and assistance
30	Severely disabled; hospital admission is indicated but death not imminent
20	Very sick; hospitalization necessary; active supportive treatment necessary
10	Moribund; fatal processes progressing rapidly
0	Dead

susceptible to selection bias, as the patients in these studies often have multiple favorable prognostic factors, age being the sole exception.

The specifics of surgical treatment vary according to histologic subtype and location of the lesion within the CNS. Most primary brain tumors in the elderly are located supratentorially, particularly in the cerebral hemispheres, making a surgical approach feasible. In general, if a tumor is surgically accessible (i.e., not deeply placed in such regions as the brainstem or hypothalamus), surgical resection appears to offer the greatest overall benefit to most patients (both young and old) with respect to survival and quality of life, as measured by the ability to function independently. A study by Kelly and Hunt examined a retrospective, consecutive series of 128 patients diagnosed with GBMs at 65–83 years of age (mean age 71 years) [42]. The study compared survival rates for individuals undergoing stereotactic biopsy with those undergoing stereotactic gross resection. The two groups did not differ significantly with respect to age, KPS score, or presenting symptoms. Individuals with brainstem, callosal, or thalamic tumors were treated primarily by biopsy rather than gross resection. The authors reported that the mean survival times in the biopsy and resection groups were 15.4 and 27.0 weeks ($p=0.01$), respectively. Of note, approximately 20% of elderly patients undergoing resection survived beyond 1 year. As is noted by the authors, patients were not randomly assigned to treatment groups; hence the assignment to treatment group and baseline expected survival are likely to be correlated. In addition, because of the small sample size, more sophisticated multivariate analyses could not sort out the interplay between treatment, irradiation, tumor location, and other variables.

Surgery has long been considered the treatment of choice for most meningiomas, as surgery alone is curative in most cases. In order to achieve cure of a benign meningioma, the tumor must be completely resected in addition to its dural attachment and infiltrated bone [43]. In 1957, Simpson

proposed a widely used five-level grading system that is based on the extent of surgical resection; Simpson grade 1 and 2 tumors are synonymous with gross total resection, although classification as grade 2 allows the dura to be left behind with reliable coagulation of the dural attachment. Advanced surgical techniques including image guidance and intraoperative imaging have increased the proportion of gross total resections in recent years [44]. Experimental approaches to optimize surgical resections such as laser-induced fluorescence spectroscopy [45], radioimmunoguidance [46], or intraoperative photodynamic diagnosis with 5-aminolevulinic acid [47] may prove useful in the future.

In an older series of 657 patients with surgically resected benign meningiomas, the recurrence rate at 20 years was 19% [48]. Comparable data have not been published for patients treated with modern neurosurgical techniques. Gross total resection results in a 5-year overall survival of approximately 85% and 5-year progression-free survival of approximately 90% for benign meningiomas [49]. Approximate recurrence rates for benign tumors that are incompletely resected are 30, 60, and 90% at 5, 10, and 15 years, respectively [43]. High recurrence rates are observed when atypical and malignant meningiomas are treated with surgery alone.

Although surgery may be curative, management decisions for patients with meningiomas must account for a variety of factors including patient age, performance status, tumor size and location, history of tumor growth, peritumoral edema, and symptoms. Small retrospective studies have recently attempted to quantify the growth rate of meningiomas during serial radiographic observation, but no large studies are available to allow for the prediction of growth either overall or by age. Many benign meningiomas are slow growing, although there is substantial variability in growth rates that cannot be reliably predicted using clinical factors [50, 51].

Radiation Therapy

Data show that individuals who receive radiation therapy after surgical resection for gliomas have an increased survival time relative to those who undergo surgery alone (with or without chemotherapy). The extent to which radiation therapy is effective, however, is once again dependent on age, with elderly individuals (defined in most studies as more than 60 years) faring less well [7]. Data from the CTR indicate that 44% of individuals diagnosed with all types of primary brain tumors over the age of 69 received radiation therapy. For those over the age of 69 years diagnosed with GBM or astrocytoma, data from the CTR indicate that there is no benefit from radiation therapy with respect to survival time. This differs from what is reported for younger individuals within the registry. For example, among patients

diagnosed with astrocytoma, those under 70 years of age who received radiation therapy had a survival time that was 1.33 times that of individuals who did not receive radiation therapy. Among patients diagnosed with astrocytoma who were 70 years of age or more, those who received radiation were less likely to survive than were those who did not receive such therapy. Although these data are intriguing, the statistics obtained from them must be interpreted with caution because there are insufficient data to explain these results.

The negative influence of age on outcome and survival in GBM patients is so pervasive it has led many clinicians and researchers to adjust treatment protocols for elderly patients in an effort to minimize the time spent in treatment, particularly when survival is estimated to be less than 6 months. For example, standard radiation therapy for a glioma is delivered in 1.8–2.0 Gy fractions with five treatments each week for a period of 6–7 weeks, with a total radiation dose of 60 Gy. A variety of abbreviated radiation schedules have been tested. In an important recent study, 100 newly diagnosed GBM patients who were at least 60 years old were randomized to standard radiation (60 Gy over 6 weeks; $n=51$) or a shorter course (40 Gy over 3 weeks; $n=49$) [52]. The groups were similar with respect to age, KPS, extent of surgical resection, quality-of-life, and time to start of radiation therapy. Median survival from the time of diagnosis was 5.9 months for the standard radiation group and 6.1 months for the abbreviated radiation group ($p=0.61$). Survival at 6 months was also similar. The trial measured health-related quality-of-life and found no difference between the groups. On the basis of these results and similar results obtained from a number of retrospective analyses, we routinely treat elderly GBM patients with abbreviated radiation therapy at our institution.

Given uncertainty about the benefit of radiation therapy for malignant glioma patients 70 years of age or older, a French group recently reported results from a trial in which patients were randomized to supportive care with or without radiation therapy (50 Gy over approximately 6 weeks) [8]. Patients had KPS scores of 70 or higher. The trial was stopped at the first interim analysis after 85 patients were enrolled. Patients in the two treatment groups were similar with respect to age, KPS, type of surgery, and use of corticosteroids. At a median follow-up of 21 weeks, 90% of patients had succumbed to the disease. The hazard ratio for death in the radiation group was 0.47 ($p=0.002$), indicating a 53% relative reduction in the risk of death compared with patients who received supportive care alone. Median overall survival was 29.1 weeks in the radiation group as compared to 16.9 weeks with supportive care alone. Progression-free survival was also significantly prolonged by radiation therapy. After adjusting for other predictors of survival, the hazard ratio for death in the radiation group was 0.42. Another interesting observation

was that the extent of surgery (gross total vs. partial resection or biopsy) was associated with survival (hazard ratio for death among patients who underwent gross total resection, 0.49; $p=0.005$). There were no differences in health-related quality-of-life associated with the addition of radiation therapy. These data convincingly demonstrate that elderly patients with good performance can benefit from radiation therapy.

While surgery is often the only treatment modality required for readily accessible meningiomas of the cerebral or cerebellar convexity, meningiomas that occur in many other locations cannot be completely resected without significant morbidity. Parasagittal tumors often abut or invade the sagittal sinus, generally requiring the surgeon to leave behind a margin of tumor tissue [44]. Other technically difficult regions include the cavernous sinus and clivus. Additionally, atypical and malignant meningiomas may have high recurrence rates following even gross total resection. Radiation therapy has a role in meningioma management when gross total resection cannot be safely achieved or when tumors recur following surgery; radiation is routinely provided as adjuvant therapy following resection of atypical and malignant meningiomas [53].

Published data regarding the use of radiation for meningiomas comprise primarily single-institution retrospective series of variable quality. These studies often include heterogeneous patient populations and are susceptible to selection bias. However, there is nearly universal agreement that radiation improves local control. In most modern reports, radiation doses of 50–55 Gy are provided in 1.8–2.0 Gy fractions to the gross tumor volume and a margin of variable size. Five-year progression-free survival for benign meningiomas treated with radiation following incomplete resection is at least 80% and may be higher than 95% [54]. Fractionated radiation with three-dimensional conformal planning or intensity-modulated radiation therapy [55] has reduced radiation dose to normal tissues, and toxicity rates of less than 2% are generally reported [56].

Stereotactic radiosurgery (SRS) is a technique of external irradiation that utilizes multiple convergent beams to deliver a high single dose of radiation to a discrete treatment volume, usually less than 3–4 cm. Radiosurgery can be performed with high energy X-rays produced by a linear accelerator, with gamma radiation, and with charged particles such as protons. All of the stereotactic radiation techniques produce a rapid fall-off of dose at the edge of the target volume resulting in a clinically insignificant radiation dose to normal nontarget tissue. Because many meningiomas are small, well-circumscribed, and easily identified on neuroimaging, they often represent excellent SRS targets.

Using SRS doses of 12–20 Gy to treat meningiomas as primary or adjuvant therapy, 5-year progression-free survival rates of 87–98.5% are reported; treatment-related

complications depend, in part, on the treatment dose and occur in 2.5–13% of cases [57]. Typical toxicities include symptomatic edema following treatment or injury to adjacent cranial nerves. Vascular complications such as internal carotid artery occlusion following SRS for cavernous sinus meningiomas occur rarely. In an effort to reduce toxicity, fractionated stereotactic radiotherapy (FSR) has also been evaluated in meningioma therapy. Potential advantages of FSR include the ability to treat tumors larger than 3–4 cm and tumors that are in close contact with critical structures such as cranial nerves, blood vessels, or the brainstem. At this time, there is no published data to suggest that one stereotactic radiation approach is superior. In the only reported comparative evaluation of FSR and SRS, there was no clear difference with respect to local control, toxicity, and impact on neurologic function [58]. However, interpretation of the results must take into account the differing indications for FSR and SRS treatment. Fractionation should generally be considered for tumors larger than 3–4 cm or those that are in close proximity to critical structures [57].

Chemotherapy

The first randomized clinical trials of chemotherapy for malignant gliomas studied nitrosoureas (carmustine [BCNU] and lomustine [CCNU]), lipid-soluble agents that readily cross the blood–brain barrier (BBB). These studies suggested that chemotherapy prolongs survival to a limited extent [59, 60]. However, they were limited by important methodological issues such as small sample size, failure to stratify patients according to histologic subtypes, and variable response criteria. Subsequent meta-analyses in 1994 and 2002 confirmed that chemotherapy provides a modest survival benefit (a 6–10% increase in 1-year survival) for patients with malignant glioma [61, 62]. In light of these data, most newly diagnosed malignant glioma patients in the USA received adjuvant chemotherapy. Frequently prescribed regimens were BCNU monotherapy or PCV (procarbazine, CCNU, and vincristine).

A new standard of care emerged in 2005 with the publication of a large, randomized, phase III trial that included 573 newly diagnosed GBM patients from 85 centers in Europe and Canada [6]. All patients underwent maximal feasible resection and standard radiation therapy (60 Gy over 6 weeks); they were randomized to receive temozolomide chemotherapy or no chemotherapy. Temozolomide is an orally bioavailable alkylating agent that readily crosses the BBB and in the majority of patients produces only mild adverse effects. Fewer than 10% of patients experience significant myelosuppression. Patients randomized to the chemotherapy arm received radiotherapy with concurrent

temozolomide at a dose of 75 mg/m²/day. After a 4-week break, patients received six cycles of adjuvant temozolomide (150–200 mg/m²/day for 5 days during each 28-day cycle). Median survival improved with temozolomide therapy from 12.1 to 14.6 months, and the 2-year survival rate also improved markedly from 10.4 to 26.5% ($p=0.001$).

Patients included in this landmark study by Stupp et al. were between 18 and 70 years of age (median 56). Therefore, these data leave unanswered the question of whether adding chemotherapy to radiation therapy and surgery is beneficial among elderly patients. No randomized data have been published to date, but some reports are informative. In a recent analysis, patients treated in the study reported by Stupp et al. were classified according to a modified version of the Radiation Therapy Oncology Group recursive partitioning analysis (RPA) classification [63]. The RPA model was developed to help stratify patients into homogeneous groups with similar prognoses for the purposes of comparison between clinical trials [9]. The modified version developed for retrospective analysis of the Stupp et al. trial included age, World Health Organization (WHO) performance status, extent of surgery, and mental status (Table 87.5). Because all patients in the study had GBM as opposed to anaplastic glioma, they were classified into RPA classes III–V. For RPA classes III, IV, and V, survival times were 17, 15, and 10 months, respectively. The benefit of chemotherapy was statistically significant for patients in RPA classes III and IV. For patients in RPA class V, however, the survival difference between the treatment arms was marginal. Median survival was 10 months for patients who received chemotherapy as compared to 9 months for patients who received radiation therapy alone ($p=0.054$). Since all the patients in class V were 50 years of age or older, this suggests that the benefit of chemotherapy for older patients is uncertain [63].

In a retrospective series, 43 patients 65 years of age or older (median 67) were treated after surgery with radiation and concurrent low-dose temozolomide (50–75 mg/m²). A small subset of patients also received adjuvant temozolomide. Median survival was 11 months and depended on the extent of resection and RPA class. All but five patients (88%)

tolerated radiation and concurrent chemotherapy without significant toxicity. Given that most previous series of elderly GBM patients found median survival rates in the range of 4–9 months, the authors conclude that concurrent chemotherapy is a reasonable consideration in the elderly population. Results from other small retrospective series support this conclusion [64]. Some clinical trial data suggest that temozolomide chemotherapy alone following surgery may also have a role [65]. Because the published data regarding the use of chemotherapy in elderly patients involve small numbers of patients with variable age, performance status, extent of resection, timing and dose of radiotherapy, and dose and schedule of chemotherapy, it is challenging to correlate the results and draw definitive conclusions. At present, it seems clear that chemotherapy may be useful for at least a subset of elderly patients. Future work will better define the characteristics of the patients who should be considered for aggressive medical treatment.

Another method of chemotherapy administration is interstitial chemotherapy. This approach involves direct administration of drug into the tumor resection cavity. The primary advantage is the ability to achieve high concentrations of chemotherapeutic agent at the site of the tumor with minimal systemic toxicity. Additionally, interstitial administration eliminates the problem of BBB penetration. Techniques that have been used include catheter implantation and placement of biodegradable polymer wafers impregnated with BCNU. The wafers are designed to release BCNU over several weeks after they have been placed on the surface of the tumor resection cavity. In a double-blind, randomized, phase III trial of 240 newly diagnosed malignant glioma patients, patients received either conventional therapy (surgery followed by radiation therapy) with placement of a BCNU wafer or conventional therapy with placement of an identical placebo wafer [66]. The median survival was significantly increased for the active wafer group (13.9 months) compared with the placebo wafer group (11.6 months). Adverse event rates were similar. Patients in this study were between 18 and 65 years of age.

As is clear from the discussion, elderly patients are excluded from many clinical trials for malignant glioma. Similar exclusion of elderly patients is noted in data from the Connecticut Tumor Registry, which lists only 8% of patients over the age of 70 years as having received chemotherapy for treatment of a CNS tumor. This exclusion reflects an underlying belief that chemotherapy is not beneficial in elderly patients, a belief that may be correct but is not clearly supported by high-quality data.

As opposed to malignant glioma therapy, the role of chemotherapy in meningioma therapy has largely been limited to treatment of tumors that recur after surgery and RT options are exhausted. Data obtained from small clinical trials and

TABLE 87.5 Modified recursive partitioning analysis classes

RPA Class	Criteria
III	Less than 50 years of age and WHO PS 0
IV	Less than 50 years of age and WHO PS 1–2 or At least 50 years of age, at least partial resection, and MMSE score at least 27
V	At least 50 years of age, biopsy only, and MMSE score less than 27

Source: Data from Mirimanoff et al. [63]

case series suggest that most chemotherapeutics have only minimal activity against meningiomas, although promising investigational medical therapies include somatostatin receptor agonists [67] and inhibitors of angiogenesis. In the case of PCNSL, methotrexate-based chemotherapy regimens represent the mainstay of therapy. Blood–brain barrier penetration by methotrexate is limited, so high-dose systemic treatment (4–8 g/m²) is required to achieve cytotoxic levels in the nervous system. When methotrexate-based chemotherapy is combined with whole brain RT, 2-year survival is observed in 43–73% of patients, and median survival is reported in the range of 30–60 months [68]. Because of treatment-related neurotoxicity rates as high as 25%, there has been growing interest in methotrexate-based chemotherapy alone without radiation. Small studies reveal promising results with median overall survival of 4–5 years [69]. At present, most centers that care for patients with PCNSL provide methotrexate-based combination chemotherapy regimens with or without radiation. The use of additional chemotherapeutic agents and intrathecal chemotherapeutics varies from center to center.

Corticosteroids

Steroid therapy is a useful adjunctive therapy for treatment of CNS tumors in patients of all ages. It may be particularly beneficial in older patients when surgical or additional treatments are deemed unwise [70]. The most frequently used steroid, dexamethasone, may be given intravenously or orally. Typically, the initial dose is approximately 10 mg, with maintenance doses of 2–6 mg every 6–12 h thereafter. The medication works by reducing vasogenic edema; clinical response and neurologic improvement are generally seen within 24 h. Although complications do occur (hyperglycemia, impaired wound healing, and gastrointestinal ulcers), the benefits often outweigh the risks, particularly with respect to quality of life.

It is important to note that corticosteroids alone may provoke rapid, dramatic tumor responses in as many as 40% of PCNSL patients [71]. The responses are almost always short-lived, but they can be problematic when they occur prior to definitive diagnosis. Because steroids result in lymphocyte apoptosis, such treatment can dramatically reduce diagnostic yield, regardless of diagnostic modality employed. Even stereotactic biopsy may be nondiagnostic in a patient who has been treated with a single large dose of dexamethasone. Of course, steroid administration may be mandatory in a patient who presents with decreased level of consciousness due to mass effect. In this case, definitive diagnosis may be delayed by weeks or months.

Metastatic Brain Tumors

Secondary, or metastatic, brain tumors represent the majority of brain tumors in the elderly, with intracranial metastases occurring in approximately one-third of individuals initially diagnosed with a systemic malignancy. The prevalence of brain metastases is rising because of improved survival of cancer patients thanks to therapeutic advances, the aging of the population, and enhanced detection of clinically silent lesions. Among the elderly, the most common origins of brain metastasis include lung cancer (50%), breast cancer (15–20%), and melanoma (10%). The next most frequent sources include renal cancer, colorectal cancer, lymphoma, and tumors of unknown primary. Metastases from breast, colon, and renal cell carcinoma are often single, while melanoma and lung cancer have a greater tendency to produce multiple metastases. MRI studies suggest that single metastases account for one-third to one quarter of patients with brain metastases. This is important because SRS is effective only in patients with a limited number of metastases.

Brain metastases are associated with a poor prognosis. Depending on the patient's age, functional status, extent of systemic disease, and number of metastases, median survival ranges from 2 to 14 months. Therapeutic modalities that may be used singly or in combination include surgery, SRS, whole brain RT, and chemotherapy. The optimal combination of therapies for each patient depends on the consideration of various factors including the location, size, and number of brain metastases; patient age, general condition, and neurological status; extent of systemic cancer; and the tumor's response to past therapy and its potential response to future treatments. There are limited data to indicate whether survival differs by age group, although, in general, elderly patients do less well with respect to survival and quality of life.

Surgery

The goals of surgery are to provide immediate relief of neurological symptoms due to mass effect, to establish a histological diagnosis, to provide local control of the metastasis, and if possible, to prolong survival. In general, surgery should be considered for patients with good prognostic factors when there is a single metastasis in an accessible location, especially if the tumor is producing mass effect. This approach is based on the results of two prospective randomized trials [72, 73]. In both studies, reasonably functional patients with a single brain metastasis and well-controlled extracranial disease were randomized to receive stereotactic biopsy of the metastasis followed by whole brain RT versus

surgical resection followed by whole brain RT. Patients in the surgery plus radiation group had fewer local recurrences, improved survival (40 versus 15 weeks and 10 versus 6 months), and better performance status than patients who received radiation alone. In addition, patients who had their single metastases removed remained functionally independent longer (38 vs. 8 weeks) and had fewer recurrences at the site of the original metastasis (20 vs. 52%).

Radiation

Patients who are deemed poor surgical candidates because of multiple or inaccessible lesions or poor performance status are best treated with whole brain RT. Recent data indicate that SRS may have an important role in brain metastasis management and may be a viable alternative to surgery in some situations [74]. For example, SRS may be useful for small metastases not producing mass effect. It can also be used to treat lesions in the brainstem or eloquent areas with less risk than surgery. Additionally, because of the noninvasive, outpatient nature of SRS, it is associated with less morbidity and may be a rational consideration in elderly patients. As is the case for conventional surgery, careful selection of patients is critical; patients without good prognostic factors are unlikely to benefit. Although the precise role for SRS remains to be defined by a randomized, prospective trial, many retrospective studies suggest that SRS outcomes for appropriately selected patients are equivalent to those achieved with conventional surgery.

Conclusions

Much of the reason for the poor prognosis noted in elderly patients diagnosed with primary brain tumors is related to the negative impact that neurologic deficits have on survival and the reduced capacity for recovery and adaptation present in the aged patient. Addition of other comorbid conditions (i.e., cardiac, pulmonary, renal, or musculoskeletal disease) associated with advanced age increases the risk of surgical intervention and reduces the systemic tolerance to radiation therapy and chemotherapy. As a result, elderly patients as a group are more likely to be functionally impaired by their disease than are younger patients; and they may have less capacity to withstand the adverse effects of therapy, potentially limiting their treatment options. The negative influence of age on outcome and survival in GBM patients is so pervasive that some have suggested it is not possible to demonstrate any survival benefit from any treatment in patients over the age of 70 years.

Elderly Americans, however, are probably healthier and less disabled than they were perceived to be in the past. This is reflected in all aspects of society including the workplace where mandatory retirement restrictions are beginning to fall and more and more senior citizens enter or reenter the workforce. Although as a group elderly patients may do less well, there may be a significant subset of individuals who benefit from treatment of their CNS tumors. These issues indicate that clinical trials examining the effect of various treatments for primary and metastatic brain tumors in the elderly are needed, including whether survival can be improved with less toxicity and morbidity. This issue remains controversial with respect to the cost/benefit ratio to society. For primary brain tumors, the effort would require multicenter trials, as reports of outcome are relatively rare. For metastatic lesions, the pool of eligible patients is much greater, allowing one or two centers to organize studies. The ability to mount such studies depends greatly on society's willingness to accommodate the medical needs of its aging population within the framework of stressed medical resources.

Summary

- Older individuals are more likely to be diagnosed with primary brain tumors; among elderly patients with GBM, the most common primary malignant brain tumor in adults, median survival is reported to be in the range of 4–9 months.
- The diagnosis of a primary brain tumor in an elderly patient is often suggested by results from a CT or MRI scan, but definitive diagnosis requires tissue confirmation.
- Although outcome data are limited, elderly patients who are healthy enough for surgery and have good performance status may be good candidates for aggressive resection of primary brain tumors.
- Radiation therapy and chemotherapy are important adjuvant treatments for adults with gliomas, and recent data suggest that a subset of elderly patients may benefit from these interventions as well.
- Corticosteroids are useful in managing brain edema related to tumors in patients of any age.
- The molecular pathogenesis of gliomas may differ in young and old patients, suggesting that the optimal therapeutic approaches may also be different between the two populations.
- Metastatic brain tumors are common and are associated with a dismal prognosis in elderly patients.
- In order to improve outcomes for elderly patients with brain tumors, older individuals must be included in clinical trials of surgical, radiation, and medical treatments.

CASE STUDY

An otherwise healthy 81-year-old woman with controlled hypertension presents to her primary care physician at the request of her family because of gait instability and mild confusion over the past 3 weeks. On exam, she is slightly disoriented and has a mild left hemiparesis. Concerned about possible stroke, the physician orders a brain MRI scan (Fig. 87.2). This shows a large, enhancing mass in the right parietal lobe that is interpreted as suspicious for malignant glioma. Given the location of the lesion in the right parietal lobe and involving the corpus callosum, surgical resection is not felt to be the best option. The patient and her family agree to stereotactic biopsy for definitive diagnosis. The procedure is uncomplicated, and the patient is discharged from the hospital after 48 h. High-dose dexamethasone is started immediately after surgery, which results in improved mental status and resolution of hemiparesis.

As expected, the pathology results return as glioblastoma. The patient and her family meet with an oncologist to discuss treatment options. In light of her advanced age and preference to minimize adverse effects to the extent possible, she agrees to an abbreviated course of radiation therapy with concurrent temozolomide chemotherapy. Because she tolerates this treatment well, she goes on to receive four cycles of adjuvant temozolomide. Unfortunately, after this treatment, the patient develops worsening left hemiparesis. A brain MRI scan shows tumor growth. The patient considers palliative surgical debulking and a variety of chemotherapy options, but she ultimately declines further treatment. She enrolls in a home hospice program where she enjoys relatively good quality-of-life for 6 weeks before experiencing a rapid neurologic decline. She dies comfortably at home with multiple family members present.

Chapter 88

Spinal Disorders and Nerve Compression Syndromes

Arash Yaghoobian and John M. Olsewski

Introduction

Spinal disorders and nerve compression syndromes of the elderly are common presenting complaints to both internist and surgeons. In fact, approximately 70% of all patients seeking medical attention have the complaint of back pain at one time in their life. More than 13% have pain lasting more than 2 weeks [1]. A directed history and physical examination and working knowledge of the spinal bony and neural anatomy are key elements for appropriate diagnosis and management. This chapter defines the major disorders affecting the geriatric population and guides the surgeon in the diagnosis and treatment options for each disorder.

Anatomy

The spinal elements, cord and cauda equina are housed by the vertebral column consisting of 33 bony vertebrae. There are normally 7 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 4 coccygeal vertebrae. The sacral and coccygeal vertebrae are fused. When viewed from the front, the spine is straight unless a preexisting or degenerative scoliosis is present. A lateral projection reveals a concave appearance to the cervical and lumbosacral vertebrae from back to front and a convex appearance to the thoracic vertebrae. This arrangement is referred to as cervical and lumbosacral lordosis and thoracic kyphosis [2]. Any reversal of this arrangement (e.g., cervical kyphosis) can be a clue to underlying pathology.

The spinal cord rests within the vertebral canal, which is normally triangular. The canal is guarded in front by the vertebral body, from the side by pedicles, and posteriorly by the laminae and spinous processes (Fig. 88.1). The nerve roots

leave the cord to become peripheral nerves through the neural foramen bounded by the pedicles above and below and by facet joints posteriorly. There are four facet joints associated with each vertebral level. The inferior facets lie posterior and medial to their superior counterparts, with which they interlock to provide motion and stability to the spine. In addition, between each vertebral body is a vertebral disc (Fig. 88.2). This structure acts as a shock absorber of the spine [2]. It is made up of an outer fibrocartilaginous ring, called the annulus fibrosus, and an inner gelatinous core; the nucleus pulposus. The intervertebral disc in the adult is avascular. Nutrients are delivered to the cells within the disc by way of diffusion through the central portion of the vertebral endplate. Alterations in any aspect of these structures, be it disc, foramina, or facet joints, can be a cause of pain or nerve compression leading to arm or leg pain depending on where in the spine compression takes place.

Biomechanics

The healthy spine is responsible for protecting the spinal cord and absorbing the forces of axial loading. Tremendous compressive forces act on the spine during everyday activities such as lifting and carrying. The osteoporotic spine often fails under these stresses, leading to compression fractures. Normally, six degrees of freedom are present between each vertebral body and the one below. Flexion, extension, right and left lateral bending, and clockwise and counterclockwise rotations comprise these motions [3]. Processes such as pain, trauma, and previous surgery impede spinal mobility and function.

Pathophysiology

Cadaver studies have shown that more than 70% of spines show signs of degeneration between 60 and 70 years of age. These findings may be localized to the disc, vertebral bodies, or facets; or they may involve combinations of structures [4].

It is important to note that most patients with such anatomic changes, even when confirmed by radiography, are asymptomatic [5] (Fig. 88.3). The natural history of spinal aging is often related to a degenerative process separated into three distinct stages. The first stage involves degenerative changes to the intervertebral disc, characterized by radial and circumferential tears of the annulus fibrosus. The aging disc loses its ability to retain water and these tears begin to propagate, leading to protrusion of disc material toward the

FIGURE 88.3 Seventy-five-year-old female had symptoms of spinal stenosis and degenerative disc disease. This lateral radiograph of the lumbosacral spine shows severe degenerative changes at the L2/L3 disc space, including disc space narrowing, vertebral body endplate sclerosis, neuroforaminal narrowing and traction osteophytes (arrows).

spinal canal or neural foramina. Further disc injury can lead to frank extrusion of disc material. As the internal disruption of the disc continues, local instability places increasing stresses on the adjacent facets joints, which hypertrophy in an attempt to provide stability to the spine. When this occurs in the context of a disc herniation, there is an increasing chance of nerve root and/or cord impingement. Furthermore, excessive motion may occur between vertebral bodies, leading to a “slip,” or listhesis, of one body on the other. Depending on the extent of intervertebral disc pathology, listhesis, or facet joint hypertrophy, clinical presentation can range anywhere from localized pain and radiculopathy to neurogenic claudication [3, 6, 7]. The clinician must know how to distinguish among these various processes.

Mechanisms of Back Pain

As mentioned, back pain can be related to various pathologic elements of the aging architecture. It may also be related to systemic manifestations such as tumor, infection,

FIGURE 88.4 This 83-year-old female presented with right buttock, groin, and anterior thigh pain. Although an MRI of her lumbar spine showed radiographic evidence of stenosis, her clinical examination was consistent with osteoarthritis of her right hip, as seen on this AP pelvis radiograph, and her symptoms were relieved with total hip arthroplasty.

or ankylosing spondylitis. Patients over age 60 with loss of appetite, fatigue, and night pain must be carefully evaluated for tumor or infection. Although rare, herpes zoster can cause back pain along a unilateral distribution prior to eruption of skin lesions. Back pain may be referred from renal colic, vascular, or splenic pathology. Patients often confuse hip pain and back pain. Similarly, back pain may be a result of a limb length discrepancy or pelvic obliquity. Assessment of hip range of motion, crepitus, and the nature of the complaint can distinguish between the two. We believe that all geriatric patients who warrant radiographic evaluation of their back pain should also undergo anteroposterior (AP) pelvis radiography to detect concomitant hip disease (Fig. 88.4). Lastly, back pain is known to have a large emotional component. Compensation workers and those involved in litigation cases often present with a back complaint for secondary gain [8–10]. Care must be maintained when labeling back pain as psychogenic; however, factors such as depression, especially in the elderly patient, may contribute and must be considered in the differential. A full history and physical examination is warranted to rule out organic pathology.

Specific Pathologic Entities of the Elderly Spine

Cervical Spine Degeneration

Cervical spine degeneration usually begins at age 45–55 and affects men more often than women. Any level of the cervical spine can be involved, but pathologic changes are most often seen at levels C5, C6, and C7. The predominating symptoms depend on the anatomic site of the disease (disc,

facet, neural foramina). The three most common presenting complaints are neck pain (mechanical etiology), radicular pain (nerve root compression), and myelopathic symptoms (cord compromise). A combination of the three elements is often evident [11, 12].

Neck Pain/Mechanical Pain

Patients may present with a complaint of neck pain often exacerbated by motion. Fatigue exacerbates the condition and rest alleviates it. Pain and discomfort may be localized to the midline neck or radiate to the occiput causing headache. It may also radiate to the interscapular region. Patients may feel worse in cold weather, not unlike arthritis in other body areas. Chronic splinting may lead to overuse of surrounding muscles leading to pain in the sternocleidomastoid or deltoid region. Mechanical neck pain can easily be confused with shoulder pathology. A history and physical examination consistent with discomfort with overhead activities is more likely to be related to rotator cuff pathology than cervical degeneration. The patient with rest or night pain, nonmechanical in nature, must be evaluated for the possibility of neoplasm or infection [13].

Physical examination can reveal midline tenderness to palpation. Typically, the examiner notes pain with rotation to the right or left. Strength in the upper extremities is preserved, and reflexes are present in the biceps, triceps, and brachioradialis distributions. Appropriate studies for a patient with mechanical symptoms include AP, lateral, and oblique radiographs. We also order flexion and extension views to detect any dynamic instability (Fig. 88.5). Radiographs typically show loss of disc height and possibly some mild loss of cervical lordosis. Arthritic changes in the facet joints may also be evident. It must be emphasized that such changes may be apparent in the completely asymptomatic patient, and that correlation of clinical and radiographic findings is mandatory.

Treatment of mechanical-type neck pain without neurologic involvement is almost always nonsurgical. First-line therapy involves use of a soft or hard collar in conjunction with a trial of nonsteroidal antiinflammatory drugs (NSAIDs) or a COX-2 inhibitor in an attempt to decrease the inflammatory process. Most patients have considerable relief over a 6-week period. Refractory cases can begin a physical therapy regimen with isometric neck and shoulder exercises followed by active strengthening. If 6 months of therapy does not significantly alleviate symptoms, the patient can be considered for surgery. Any patient considered for surgery for mechanical symptoms should receive an additional study such as magnetic resonance imaging (MRI) or computed tomography (CT) of the neck to delineate the exact nature of the degenerative process. The mainstay of surgical management is fusion via an anterior or posterior approach. The patient

FIGURE 88.5 Eighty-five-year-old male with symptoms of cervical spondylosis and stenosis. Flexion and extension lateral radiographs show evidence of dynamic instability (subluxation) of 4 mm of C7 on T1.

should be cautioned that the results of such surgery for pain relief are variable. In general, surgical management is reserved for all but the most refractory cases [14].

Radicular Neck Pain

Signs and Symptoms

The typical presentation of a patient with cervical radiculopathy is one of neck pain with radiation in the distribution of the affected nerve root. This pain may be acute in nature or develop slowly over time. The geriatric population usually presents with the latter, as the neural compression is related to narrowing of the neural canal from osteophyte formation (hard disc) and generalized loss of disc height rather than an acute disc herniation (soft disc). The patient often describes the pain as a burning or tingling sensation and sensory, motor, or reflex disturbances may or may not be present.

The area of radiation corresponds to the level of the neural compression. C4 compression affects the back of the neck; C5 the lateral shoulder and arm; C6 the lateral forearm, thumb, and index finger; C7 the middle finger; C8 the ring and little finger; and T1 the medial arm and forearm. These distributions are not exact, and there is a considerable amount of dermatomal overlap between the nerve roots. Patients often complain of exacerbation with particular motions: neck rotation and flexion toward the side of the arm pain and hyperextension of the neck. Furthermore, they may present

with motor weakness in the upper extremity. This too, roughly corresponds to the level of neural compression. C5 compression affects deltoid and biceps strength; C6 compression, wrist extension, and biceps; C7 triceps and wrist flexion; C8 finger flexion; T1, grip strength.

Physical examination should assess neck motion, tenderness to palpation along the midline, and the neck muscles. The physician should document the area of burning or tingling down the arm and correlate it with dermatomal distributions. Muscle weakness should be noted in the upper extremity, and this too is correlated with the area of sensory abnormality. Pain in a particular muscle group must also be assessed. Reflex testing with a hammer can reveal diminished reflexes in the biceps, brachioradialis, and triceps. Spurling's test (rotation and lateral bend toward the side of arm pain evokes increased symptoms) may be positive. In addition, holding the head and neck in extension can exacerbate symptoms. Placing the affected extremity with the palm of the hand on top of the head relieves the pain by expanding room for the neural elements [15].

Pathophysiology

As mentioned, radicular pain is secondary to compression of the exiting nerve roots from the neural foramina of the cervical spine. Recent studies have shown that mechanical forces may not be the only factor contributing to the development of pain. Stimulation of nerve roots by proinflammatory cytokines released from the intervertebral disc may also play an

important role in this regard. Although not fully understood, these chemical mediators, such as substance P, interleukins 1 (IL-1), IL-6, bradykinin, and prostaglandins can evoke an inflammatory and painful response [16, 17].

Imaging

As with purely mechanical pain, plain radiographs are the first-line study. The oblique film should be studied carefully, as it often demonstrates narrowing of a particular neural foramina and significant osteophyte. MRI or electrodiagnostic studies are reserved for surgical candidates. Axial and sagittal cuts at the level of the neuroforamina can be particularly useful (Fig. 88.6).

Natural History

The natural history of this disease is not as favorable as for purely mechanical neck pain. Despite nonoperative measures it is estimated that 25% of patients with radicular complaints are left with severe symptomatology [18]. These patients may be considerably improved with surgical management [19].

Differential Diagnosis

Cervical radiculopathy can be mimicked by many other conditions affecting the elderly population. Compressive neuropathies (carpal tunnel syndrome or cubital tunnel syndrome) may

lead to radicular-like symptoms. In addition, thoracic outlet syndrome, which represents compression of the brachial plexus or subclavian vessels from a cervical rib or hypertrophic scalene muscles leading to symptoms in the medial arm and forearm may present similarly to cervical radiculopathy [15]. Rotator cuff pathology may mimic a C5–6 radiculopathy. Multiple sclerosis may present with upper extremity sensory symptoms, such as tingling and weakness not following an anatomic distribution. Amyotrophic lateral sclerosis may appear as an upper extremity weakness with preservation of sensation. Finally, spinal tumors occasionally present with radicular symptoms. A careful history concerning systemic signs and night pain or nonmechanical pain must be sought [20].

Nonoperative Management

Nonoperative management of cervical radiculopathy is similar to treatment of mechanical neck pain. Patients are begun on a regimen of antiinflammatory medications, which often decrease the inflammation of affected nerve roots and leads to significant pain relief. Selective Cyclooxygenase-2 (COX-2) inhibitors may decrease the incidence of gastrointestinal side effects, but in controlled studies for osteoarthritis, they do not appear to be any more efficacious than nonselective NSAID [21]. A soft collar can be provided for comfort, followed by a course of passive stretching exercises and active strengthening of the neck, shoulder, and arm when symptoms subside. Patients unresponsive to those measures can receive epidural steroid injections or selective nerve root injections at the level of neural compression. Surgery is reserved for patients who have unremitting pain for 3–6 months despite conservative measures or those with progressive neurologic deficit [22].

Surgical Management

Common indications for surgical management include unremitting pain that fails to respond to conservative therapy or progressive neurologic deficits, such as weakness or numbness. All patients considered for surgical management should undergo preoperative MRI. This study can confirm the anatomic level of compression based on the location of the patient's radicular symptoms. As mentioned, it is less likely in the geriatric population to have radicular symptoms due to an acute disc herniation than due to slowly evolving nerve root compression from the spondylitic process. Surgery must be aimed at decompression of the affected nerve roots. The most common operation for radiculopathy at a single nerve root level is a discectomy and fusion from an anterior approach. The affected level of disc degeneration is removed completely, as are any visible osteophytes. Next, a piece of bone graft slightly larger than the original disc height is

FIGURE 88.6 Eighty-one-year-old male with symptoms of cervical myeloradiculopathy. Axial cut MRI shows evidence of both central and foraminal stenosis (arrows).

FIGURE 88.7 Sixty-six-year-old female with symptoms of cervical myelopathy from large central disc herniation at C5/C6 on MRI (*arrow*), treated with anterior cervical discectomy and fusion with plate fixation.

inserted into the former. This provides further enlargement of the neural foramina via distraction. If the graft is well impacted, no instrumentation need be placed; otherwise, a cervical plate can be used. The patient is placed in a postoperative collar for about 6 weeks. The goal here is solid bony fusion, which halts further degeneration and eliminates nerve root compression (Fig. 88.7).

Advantages of anterior discectomy, decompression, and fusion (ACDF) include complete access to the pathologic disc and bony spurring often found at the uncovertebral joint. In addition, the anterior approach is associated with a very low complication rate, the wounds are cosmetically appealing, and there is little postoperative pain. Disadvantages include difficulty with speech and swallowing in the acute postoperative period and an increased pseudarthrosis rate with multilevel decompression and fusion.

Decompression of affected nerve roots can also be accomplished via posterior approaches. With this procedure, small amounts of cervical lamina and facet are removed at the affected level. The surgeon may remove the offending disc material as well. As this procedure is less destabilizing than full discectomy, no bony fusion is needed. It is important to avoid the posterior approach in a kyphotic cervical spine, as the spinal cord will continue to be tethered anteriorly leading to an inadequate decompression.

Results

The results of surgery for radicular symptoms are encouraging. More than 90% of people can be effectively improved from their pain and discomfort. The best results have been obtained with anterior procedures, making it the recommended choice. Posterior approaches are reserved for foraminal stenosis without a large disc herniation, failed anterior approaches, or for patients unable to undergo anterior procedures for other reasons such as poor skin condition [20, 23].

Cervical Myelopathy

Cervical myelopathy involves compression of the cervical spinal cord (not exiting nerve roots) leading to classic symptomatology in the geriatric population.

Signs and Symptoms

Although neck pain may be present, it is not as constant a feature as with mechanical or radicular compression. In fact, there is a wide spectrum of symptoms from paresthesia to

weakness and upper motor neuron signs. Patients can complain of an increasing loss of manual dexterity, typically described as difficulty with handwriting and fastening buttons on clothing. Often they may describe a vague weakness and numbness to the upper extremities. Lower extremity weakness is a frequent complaint; it leads to gait disturbance (wide based) with frequent falling and episodes of instability. When advanced, bowel or bladder function may be affected. Physical examination should begin by noting the patient's gait. A wide-based gait is typical. Patients may be unable to open and close a fist rapidly. Spasticity of the upper extremities is not uncommon. An objective weakness of the upper and lower extremities may be evident. Wasting of the upper extremity is possible in long-standing cases. Reflex changes are important in the myelopathic examination. Typically, the upper extremities are hyporeflexive and the lower extremities hyperreflexive. Bilateral Babinski reflexes are often noted. A positive Hoffman reflex (flexion of the thumb or index finger upon flicking the nail of the middle finger) is a classic test for cervical myelopathy. The "finger escape sign" may be evident. The patient holds his fingers in adduction and extension; if the ulnar two digits drift into abduction in 30–60 s, the test is considered positive [24]. An inverted radial reflex (hyporeflexive brachioradialis with involuntary contraction of the fingers) is another classic sign for C5 myelopathy. Lhermitte's sign (cervical compression with flexion leading to an electric-like sensation in the upper and or lower extremities) is another such sign [20].

Pathophysiology

The etiology of the myelopathy is most often spinal cord encroachment secondary to a single or multilevel degenerative process. The arthritic changes of the facets, bodies, uncovertebral joints, and ligamentum flavum impinge centrally, leading to a reduced space available for the spinal cord. This process is usually slow and evolving, occurring over many years. Patients with a congenitally small spinal canal may develop symptoms more rapidly. A midline disc herniation can lead to the development of acute myelopathy, but this is uncommon except in those with congenitally narrow canals [25]. Pathoanatomic studies show that the degree of compression correlates with ischemia of neural tissue. Chronic histological changes include axonal demyelination, cell necrosis, and gliosis or scarring [26].

Natural History

Cervical myelopathy is a slowly progressive entity. Although most patients' initial complaints do not warrant surgical intervention, once the onset of myelopathy has begun, episodic deterioration is the most common course, and

surgical recommendation should be made. As many as 5% of patients have acute deterioration and require urgent intervention [27].

Imaging

Radiographic changes to the cervical spine associated with myelopathy are degenerative and typically found in patients above the age of 50. Initial studies include AP and lateral plain films of the cervical spine, which may have findings such as sagittal imbalance (kyphosis), coronal imbalance (scoliosis), disc space narrowing, osteophyte formation, and endplate sclerosis. Flexion-extension views are used to rule out instability. The space available for the spinal cord can be estimated on the lateral radiograph. A 13 mm distance between the back of the vertebral body and the back of the lamina at any given level is considered the lower limit of normal. Smaller distances are considered congenitally narrowed and may predispose toward myelopathic symptoms. In some cases, OPLL (ossification of the posterior longitudinal ligament) (Fig. 88.8) can be visualized as a bar of bone posterior to the vertebral bodies. MRI and myelography/CT scans of the cervical spine are invaluable for confirming the myelopathy. Axial cuts demonstrate the available room for the spinal cord as well as evidence of disc or osteophytes leading to canal narrowing. Sagittal MRI cuts can help determine the total number of cervical levels involved, extent of disc herniation, as well as the severity of disease from cord compression; myelomalacia or morbid softening of the spinal cord (Fig. 88.9).

Differential Diagnosis

All of the conditions listed for the differential diagnosis for cervical radiculopathy can mimic myelopathy as well. In particular, intra- or extradural tumors of the spine can lead to myelopathic symptoms. They are easily detected on the MRI scan. Furthermore, cerebellar pathology can lead to gait disturbance, as in myelopathy. Neurologic consultation should be considered if cerebellar pathology is considered the etiology of the gait disturbance [28].

Nonoperative Treatment

Patients can be started on a course of pain medication, physical therapy, and exercise modalities similar to patients with radiculopathy or mechanical symptoms. However, with increasing weakness, gait disturbance, or extremity pain, surgery is indicated. Furthermore, patients with any evidence of bowel or bladder disturbance secondary to cord compression should be considered for emergent decompression [22].

FIGURE 88.8 Sixty-two-year-old female with cervical myelopathy and findings of OPPL on both sagittal and axial MRI cuts (arrows).

FIGURE 88.9 Seventy-year-old male with cervical myelopathy and findings of myelomalacia of the spinal cord on T-2 weighted sagittal MRI (arrow).

Operative Treatment

Operative treatment of myelopathy focuses on decompression of the spinal canal to expand the space for the spinal cord. The procedure or approach depends on the nature and extent of pathology. If myelopathy is secondary to disc herniation or bony encroachment at one or two levels, the recommendation is anterior discectomy or corpectomy, decompression, and fusion. If the constriction is secondary to a congenitally narrow canal or encroachment at three or more levels, the decompression should be performed posteriorly. This can be done via laminectomies, foraminotomies, or “open door” laminoplasty (Fig. 88.10), depending on the clinical indication. Posterior approaches that do not include stabilization are contraindicated in patients with preexisting cervical kyphosis. While operative indications are based on both radiographic findings and clinical symptoms, rarely a patient may have severe stenosis with minimal deficit. This is a relative indication for decompression as a single hyperextension injury can lead to paraplegia. Counseling is required at a minimum.

Results

Results of surgery for myelopathy are often related to the duration and severity of the disease. If it is secondary to single-level disease without major gait disturbance, about 90% of patients are improved surgically. If symptoms are long-standing, with profound weakness or gait abnormality, the degree of recovery is unpredictable. It is for this reason that myelopathic patients

FIGURE 88.10 Axial CT bone window cuts of 60-year-old female with cervical stenosis treated with open door laminoplasty.

should be monitored aggressively and counseled early about the need for surgery with worsening symptoms [29–31].

Thoracic Degenerative Disease

Symptomatic disease in the thoracic spine is relatively uncommon in comparison to disease in the cervical and lumbar levels. The attachment of the ribs to thoracic vertebrae convey an additional stability to the thoracic spine, leading to less bony and soft tissue changes to the thoracic spine with aging. When present, thoracic disc disease can be debilitating and on occasion requires emergent intervention. Additionally, diagnosis may be complicated as there is a high prevalence of incidental thoracic disc degeneration and herniation in the asymptomatic patient population [32–34].

Signs and Symptoms

Pain is the most frequent presenting complaint. The pain may be localized to the involved thoracic vertebrae (axial pain) or radiate in a dermatomal band-like fashion unilaterally or

bilaterally around the chest wall. The T10 dermatomal level is the most common reported distribution of pain regardless of the location of disease [33]. Occasionally, the pain radiates to the lower extremity or hip region. Complaints of sensory abnormalities are the second most likely presentation. These may follow chest wall dermatomal patterns or manifest as paresthesias extending to the lower extremities. More concerning is the occasional complaint of weakness, gait disturbance, and loss of bowel and bladder control. These patients must undergo an aggressive workup. The physical examination may be completely normal early in the course of disease. Later, diminished sensation testing to the affected chest wall dermatome may be apparent. Motor weakness, diminished rectal tone, clonus, hyperreflexia, and other upper motor neuron signs (superficial abdominal reflexes or cremasteric reflex) may be noted in long-standing cases or with acute large disc herniations [8].

Pathophysiology

Degeneration in the thoracic spine is secondary to the same processes as in the cervical spine. Water loss to the disc with aging leads to incompetence of bony elements, including

FIGURE 88.11 Sixty-year-old male with symptoms of thoracic level myelopathy from large central disc herniation obliterating space available for spinal cord at T10/T11.

the facets and bodies of affected vertebrae. Osteophytes may form, leading to impingement of nerve roots or if centrally located on the cord itself. With the loss of disc height, the ligamentum flavum may become buckled over time and contribute to central impingement. Acute disc herniations can also occur and often lead to sudden onset of symptomatology [3, 6, 32]. As in the case with cervical or lumbar disease, the location of the disc herniation will dictate clinical presentation. Midline or paramedian herniations have the highest likelihood to precipitate myelopathic symptoms; radicular pain is often the result of lateral herniations.

Natural History

The natural history of thoracic disc disease is variable [32]. In the geriatric population a slow, gradual onset of symptoms is the most likely course. When not accompanied by motor signs or bladder or rectal incompetence, most patients respond well to nonsurgical treatment [35].

Imaging

Diagnostic imaging should begin with AP and lateral projections of the thoracic spine. These are often difficult to interpret because of overlying structures but may show disc narrowing or calcification within an affected disc space. These radiographs may also show evidence of excessive kyphosis in the thoracic spine, a possible predisposition to symptomatic disease. These screening studies should also be used to rule out acute injury (fracture) or potential neoplastic

lesion. MRI of the thoracic spine is currently the premier modality for evaluating suspected thoracic disc disease. Sagittal and axial cuts can determine the site of pathology (disc level, central, or foraminal) and bony vs. disc impingement (Fig. 88.11). It must be stressed that all radiographic findings must be closely correlated to the physical examination and patient complaints because the presence of an asymptomatic radiographic abnormality is quite common [36].

Differential Diagnosis

A number of conditions can mimic thoracic disc disease, including neurologic conditions (amyotrophic lateral sclerosis, multiple sclerosis) and infectious causes of back pain (e.g., discitis, osteomyelitis). Spinal tumors or dural arteriovenous malformations can have similar presentations [32]. Herpes zoster often appears as a unilateral dermatomal chest wall pain band prior to the onset of the classic rash [8]. It is especially prevalent in the geriatric population. Cardiac or pulmonary disease refers to the posterior chest wall on occasion.

Nonoperative Treatment

Avoiding precipitating flexion or extension motions (activity modification) is the first-line therapy. Patients may be begun on NSAIDs for pain relief, which often relieves the occasional pain and discomfort. In the acute phase, the rehabilitation should consist of modalities such as heat, ice, and

massage. More aggressive therapy is initiated after this period to promote range-of-motion, flexibility, and strength. A trial of brace immobilization can be suggested in more refractory cases. Patients must be monitored for development of motor weakness or bladder/bowel symptoms. These patients should be seriously evaluated for surgical therapy.

Operative Treatment

Patients manifesting motor weakness, bladder symptoms, and other upper motor neuron signs are candidates for surgical therapy. Patients with pain unresponsive to nonoperative modalities are also appropriate for surgical management. A preoperative MRI scan or myelography followed by CT scan is mandatory in all surgical cases. Surgery involves removing the offending disc, ligament, or bony material. The approach and technique depend on the level of pathology and the surgeon's familiarity with the surgery. Approaches include transternal, transpedicular, costotransversectomy, transthoracic [37], or thoracoscopic [38]. Thoracic spine surgery is among the most challenging operations performed by the spine surgeon. Appropriate intraoperative neural monitoring and consultation with a thoracic or vascular surgeon can ensure a more predictable result.

Results

Results of surgery are often dependent on the severity and duration of the complaint. Acute-onset weakness secondary to thoracic herniation offers a good chance of restoring neurologic function if dealt with emergently. More than 75% of patients are significantly relieved of their pain and discomfort [39]. Surgery for long-standing weakness or bladder dysfunction may halt the progression of the disease but does not restore full, premonitory function.

Lumbar Degenerative Disease

Low back pain in the elderly ranks as one of the most frequent complaints of patients presenting to internists and family practitioners. Attention must be paid to the nature of the pain, its duration, and its aggravating and mitigating factors. Conditions with back pain only, such as degenerative disc disease, must be distinguished from conditions affecting the lower extremities such as sciatica and lumbar spinal stenosis. Referred pain to the back from abdominal, retroperitoneal, or vascular pathology is not infrequently found in the elderly population and must be discerned via an accurate history and physical examination [40].

Degenerative Disc Disease/Mechanical Back Pain

With aging, the lumbar spine alters its original architecture. The aging disc loses height as its water content decreases. Disc space height between adjacent vertebrae diminishes, most commonly at L4–5 [8]. This leads to incompetence of the bony elements of the lumbar spine and increased micro-motion between adjacent vertebrae. Osteophytes develop at the facets and along the vertebral body itself [41] (Fig. 88.12). Additionally, the paraspinal musculature becomes affected and may tend toward reflex spasm.

The typical patient with degenerative disc disease offers a history of chronic back pain with pain-free intervals. This point is important for distinguishing this condition from tumor, infection, or other systemic processes. The pain is localized to the lower back with some radiation across the midline or upper buttock, but it does not radiate to the lower extremities. Patients often relate morning stiffness with a decrease in symptoms as the day progresses. Rest or recumbency relieve the pain, and certain activities or motions tend to exacerbate it. Often, sitting in a firm chair that tends to stabilize the spine relieves pain, whereas sitting in a soft cushioned seat sags the lumbar spine and increases discomfort.

FIGURE 88.12 Seventy-year-old female with symptoms of lumbar spinal stenosis and evidence of traction osteophytes (*arrows*) present at both L3/L4 and L4/L5 on this lateral lumbosacral spine radiograph.

Pain may be present during exercise but often is more pronounced several hours after activity or the next morning.

The physical examination should note the presence of scoliosis, spinal range of motion in flexion and extension, bending, and lateral rotation. The abdomen should be inspected for muscle tone, which is often diminished, and the presence of any masses, suggestive of intra-abdominal pathology. Tenderness along the affected region of the spinal column is not uncommon. Asking the patient to maintain a semiflexed position often leads to exacerbation, as does asking the patient to drop down on his or her raised heels. Of note, reflexes are normal, full strength of the lower extremities is present, and no clonus or other upper motor neuron signs exist.

First-line imaging studies are AP and lateral radiographs of the lumbosacral spine and an AP view of the pelvis to help distinguish the presence of coexistent hip disease. If symptoms have been of short duration, less than 6 weeks, radiographs need not be obtained, as management will not differ based on their findings. Furthermore, the degree of symptomatology has limited correlation with the radiographic findings. As mentioned, narrowing at the L4–5 level is most common, but patients may also have extensive evidence of multilevel disease with severe arthrosis and little or no symptomatology [42].

Treatment for mechanical back pain is predominantly non-surgical. A short duration of bed rest, 2 days, may be prescribed in conjunction with administration of NSAIDs to decrease the inflammatory component. Exacerbating motions are to be avoided. Next, a physical therapy regimen should be instituted. Strengthening of the abdominal musculature can relieve stress on the paraspinal muscles and vertebral column.

Extension exercises of the lumbar spine are often helpful for pain relief. Flexion exercises in select patients are of benefit but may lead to increased pain. A holistic aerobic reconditioning program should be instituted to ensure a more adequate overall physical profile.

Many patients obtain significant relief from lumbosacral corset or brace wear during symptomatic periods. Other modalities include massage, trigger-point injections, and ultrasound therapy. Most patients obtain significant pain control and improved functional abilities through the use of such nonoperative modalities.

Surgery is only rarely indicated for this condition. Patients with unremitting pain unresponsive to other modalities can be considered. A secondary study, such as MRI or discography, should corroborate the patient's symptomatology. Secondary gain factors such as workmen's compensation or other litigation portends a poor surgical result. The clinician must be sure that a concomitant psychological disorder is not present. The surgical procedure is a solid arthrodesis of the spine most commonly from a posterior approach. Posterior fusion techniques, however, are numerous and can include anything from a posterolateral to interbody approach. The

benefits of interbody techniques include a midline fusion mass and a large bony surface area, which are associated with a decreased incidence of pseudoarthrosis. Interbody fusion can be further broken down to anterior, posterior, lateral, or transforaminal approaches; and which is selected depends on the pathology the surgeon is addressing. It can be accomplished with or without the use of instrumentation. The theory behind this procedure is to stop motion at the level of the degenerated disc. In the appropriately selected patient, pain relief can be expected 50–80% of the time [43–45].

Sciatica

Sciatica is a general term referring to irritation of lumbar or sacral nerve roots (or both) leading to back pain with radiation down the leg. The most common cause is from protrusion, extrusion, or sequestration of an intervertebral disc. The site of pain and numbness depend on the nerve root involved and the site of involvement. Patients are generally 30–50 years old upon presentation, but the elderly can also be affected with this entity.

Signs and Symptoms

If presenting acutely, patients often recall a straining or twisting event to the back, such as lifting a heavy object. Motor vehicle accidents can also lead to acute herniations. The injury leads to intense pain in the back, followed by pain and numbness in the lower extremities. Over the next several days the back pain becomes less intense, and the lower extremity symptoms predominate. Activities such as bending, walking, and exercise exacerbate the symptoms, whereas lying supine tend to relieve the pain. Coughing or sneezing worsens it.

Upon presentation the patient may exhibit “sciatic scoliosis” [45]. This refers to a standing posture where the back and trunk tilt away from the side where painful bending occurs. Examination of range of motion to the spine often reveals restriction, especially to forward flexion, which increases the pressure within the disc. Occasionally, no restriction in motion is present. Examination of the lower extremities is most important in the consideration of sciatica. Midline herniations (less common) may lead to bilateral leg involvement, whereas lateral herniations (more common) produce unilateral symptoms.

Signs and symptoms are dependent on the particular disc and nerve root involved, corresponding to particular sensory and motor dermatomal levels. The most common level for herniation is the L4–5 disc affecting the L5 nerve root. Herniation affecting the L2–3 roots leads to numbness and paresthesias to the anterior thigh and weakness in hip flex-

ion. L4 root involvement leads to medial calf symptoms and knee extension and ankle weakness. L5 root involvement affects sensation along the lateral calf and dorsal foot with weakness to ankle or great toe extension. If the S1 root is affected, the numbness predominates along the posterior calf and the lateral and plantar foot, with weakness to ankle plantar flexion. S2–4 nerve root disease manifests as perianal sensation loss and bowel and bladder dysfunction. It must be emphasized that most patients presenting with a history suggestive of sciatica do not have evidence of motor weakness upon presentation. In fact, the only findings may be subjective numbness and pain in a particular anatomic site of the leg with gross sensation still intact. Reflex testing may reveal abnormalities on examination. Knee jerk is diminished if L4 roots are impinged. Ankle jerk is diminished if S1 is affected. Finally, an absent cremasteric reflex may be present if sacral roots are involved. It must be remembered that symmetric reflex decrease is common in the elderly.

Special nerve root tension signs are helpful for detecting sciatica and nerve root irritation. The femoral stretch test is performed with the patient prone; the affected leg is raised off the table with the knee flexed and the hip extended. Pain or electricity down the anterior thigh or medial calf is suggestive of L2–4 nerve root irritation. The straight leg raise test is performed with the patient supine and the extended knee raised off the table. Pain along the ischial tuberosity radiating down the posterior thigh and lateral foot indicate stretch to the sciatic nerve with irritation to the L5–S1 nerve roots. If pain is present soon after attempting to raise the leg with a tendency toward knee flexion, it is indicative of tight hamstrings and not a positive straight leg raise test. If the pain is accentuated when the foot is quickly dorsiflexed, it is known as a positive Lasegue test. Perhaps the most specific test for sciatica is the contralateral straight leg raise in which the opposite extremity is raised and pain travels down the affected extremity. Digital examination can document rectal tone, and the lower extremity pulses should be noted [46].

Pathophysiology

The mechanism by which herniated disc material leads to pain is a topic of intense research. Mechanical compression of nerve roots by disc material can lead to vascular injury to the nerves and other forms of trauma. However, it does not appear to be enough to induce the syndrome of sciatica. Contents from the nucleus pulposus, such as interleukins and prostaglandins, may induce edema and fibrosis of adjacent nerve roots. In addition, direct channels may form over time between the disc and adherent nerve roots, leading to further inflammatory responses. Hence the most probable explanation for painful sciatica is a combined mechanical and neurotoxic effect of disc material on involved nerve roots [47, 48].

Natural History

The natural history of sciatica is favorable. More than 50% of patients are relieved of symptoms by 1 month, and in 90% of patients the symptoms resolve by the end of 3 months [8, 49]. Hence most patients can be effectively managed without the need for surgery.

Imaging

Standard AP and lateral lumbosacral radiographs are first-line studies. Most cases fail to reveal anything other than degeneration at various levels. L4–5 is most commonly affected. In fact, acute sciatica is more likely to appear in the setting of normal disc height without narrowing than in one with evidence of degeneration. Hence it is less prevalent in the elderly population. Occasionally, plain films demonstrate a transosseous herniation in which the disc carries with it a small part of the vertebral body into the spinal canal. Patients considered for surgical decompression should undergo MRI studies of the lumbosacral spine to confirm the clinical diagnosis (Fig. 88.13). Keep in mind that 35% of patients older than 40 years have MRI or CT evidence of disk herniation in the absence of symptoms [5, 50]. Electromyography (EMG) studies can also be helpful in difficult cases.

FIGURE 88.13 Seventy-nine-year-old female with onset of bilateral leg pain from large central disc herniation at L4/L5 (arrow) present on this T2-weighted sagittal MRI.

Differential Diagnosis

When an accurate history and physical examination are conducted, sciatica does not present a problem to diagnosis. On occasion, intraspinal tumors present as nerve compression with unremitting pain, which can be easily discerned by MRI. Other neurologic conditions such as multiple sclerosis (MS) or amyotrophic lateral sclerosis (ALS) can be mistaken for sciatica. Vascular claudication can also present with paresthesias to the lower extremities. A good history and neurovascular examination can help discern between the two. One entity that must be immediately recognized is cauda equina syndrome. It presents as a massive midline disc herniation leading to bilateral buttock and leg pain and loss of bladder (urinary retention most common) or bowel control (or both). The patients may also demonstrate diminished rectal tone and decreased perianal sensation. Saddle anesthesia of the buttocks is common. Such patients should undergo urgent MRI to define the site of obstruction and urgent surgery to decompress the neural elements [8, 46, 49].

Nonoperative Treatment

Therapy should begin with a trial of NSAIDs to decrease pain and the inflammatory component of the sciatica. A short course of bed rest, 2 days, can also be helpful. Patients should then be encouraged to ambulate and begin a therapy regimen similar to that for axial back pain. Precipitating activities should be avoided. In particular, flexion exercises may increase symptoms, as they tend to increase pressure within the disc. An aerobic conditioning program must be instituted in the overall therapy scheme. If no relief is achieved after 6 weeks, the patient may benefit from an epidural steroid injection (Fig. 88.14). As mentioned, 90% of patients with sciatica are significantly relieved of symptoms by 3 months [49].

Operative Treatment

Only 10% of patients with sciatica warrant surgical consideration. Patients with bowel/bladder symptoms should warrant consideration immediately upon onset of symptoms. Those with increasing neurologic deficit, particularly motor weakness, should be considered for early surgery. Lastly, patients without relief from nonsurgical therapy should undergo surgical decompression. The standard procedure for disc herniation leading to sciatica is midline decompression with laminotomy and disc excision. It is usually done without fusion. However, if back pain was a source of pain prior to the onset of leg symptoms, some surgeons opt toward fusion in the same surgical sitting. Also, if considerable bone was removed when decompressing the nerve root

FIGURE 88.14 Epidurogram of 65-year-old female treated for radicular pain with transforminal subpedicular selective nerve root injection of both L5 and S1 nerve roots (Case Courtesy of Sireen Gopal, MD).

and stability is in question, the spine should be fused at that level [51, 52].

Geriatric patients in particular are susceptible to “far lateral herniations.” These disc herniations occur outside the spinal canal itself at the level of the neural foramina. Preoperative MRI is helpful for detecting this condition. The surgeon must be careful to ensure that the decompression and disc excision extends laterally into the neural foramina and that the nerve root is free at the end of the procedure. Other surgical procedures available for disk excision include chemonucleolysis and percutaneous discectomy [49]. The indications for these procedures are few, and the results must be weighed against the gold standard of open excision. Recently, arthroscopic spinal procedures have been used in the treatment of disc herniation. More long-term data are needed to assess its usefulness for management of sciatica in the elderly.

Results

If appropriately selected, more than 90% of patients obtain relief from sciatica by surgical disc excision. Patients with long-standing motor weakness may not regain full strength postoperatively. In addition, up to 10% of patients are at risk of having a recurrence of their herniation [49].

Degenerative Lumbar Spinal Stenosis

Lumbar spinal stenosis, also known as spinal claudication, represents narrowing of the overall dimension of the lumbar spinal canal leading to a classic symptomatology. Stenosis may be central, in which the central canal has reduced dimension, or lateral, in which individual nerve roots are encroached by a hypertrophic facet joints, redundant ligamentum, or bulging annulus. Patients are generally elderly, most over age 65, so the geriatric clinician must be intimately familiar with the often subtle presentation of this disease entity.

Signs and Symptoms

Elderly patients with central stenosis usually present with a history of chronic back pain that may have recently improved or worsened. A dull ache across the lumbosacral region is often present, but lower extremity symptoms predominate. A vague or heavy feeling in both legs is described which is slowly progressive. Some patients also have a feeling of the legs giving way. Additionally, the patient states that he or she can only walk several blocks before the pain becomes severe. Pain is positional; sitting relieves the pain, while erect posture and prolonged standing worsens it. Patients often describe relief from leaning forward over a shopping cart, as this tends to widen the overall dimension of the spinal canal. Lying supine with the spine in extension may exacerbate the condition, and as a result night pain is often a feature of this condition. Lateral stenosis patients may present similarly but with unilateral complaints. Physical examination may demonstrate sensory or motor weakness as with sciatica but is most remarkable in most cases for its lack of specific findings. This constellation of symptoms, referred to as neurogenic claudication must be differentiated from vascular insufficiency where leg pain diminishes with cessation of activity rather than a change in position. If radicular pain is present, it is most common in the L5 distribution (91%), followed by S1 (63%), L1–L4 (28%), and S2–S5 (5%) [33]. Straight leg testing, strength, and reflex examination usually are normal [53].

Pathophysiology

The normal young lumbar spinal canal is triangular and has abundant room to house the neural elements. The spinal cord usually ends at approximately the midbody of L1. Below this level the cauda equina nerve roots exit through their respective neural foramina without impingement. The aging process leads to incompetence of the disc, inbuckling of posterior ligamentous structures (particularly the ligamentum flavum), and osteophytes of the facets. All these factors may lead to

FIGURE 88.15 Axial MRI cut showing facet joint hypertrophy (arrows) resulting in severe spinal stenosis.

medial encroachment into the canal leading to central spinal stenosis. When the absolute area of the lumbar canal is reduced to $<100 \text{ mm}^2$, absolute stenosis exists [54]. In dog-based experimentation, when the thecal sac is compressed acutely (45% of original size) there are measurable changes in both motor and sensory function [55]. When the cross-sectional size of the thecal sac is reduced to 65 mm [2], the pressure in the cauda equina can increase to 50 mm Hg, which correlates with decreased nerve conduction [56]. Furthermore, some patients have an abnormally narrow, or trefoil-shaped, canal, which makes them even more susceptible to the development of stenosis. An acute disc herniation may also contribute to stenosis of the canal, although it is less commonly seen. Lateral stenosis is similarly the result of osteophytes of the facets, particularly the superior articular facet, and chronic disc disease leading to stenosis at the level of the neural foramina (Fig. 88.15). A common scenario is spondylolisthesis causing spinal stenosis. Spondylolisthesis refers to the vertebra above slipping in front of the vertebra below. Various causes exist, but the most frequently encountered scenario in the elderly is that of a degenerative spondylolisthesis. Chronic disc degeneration with concomitant arthrosis and incompetence of the facet joints allows vertebral slippage and elongation of the vertebral elements of the upper vertebrae. The slippage most commonly occurs between the L4 and L5 vertebrae. It may lead to signs and symptoms of central stenosis or of L5 nerve root impingement. It may manifest with pain along the lateral calf and with ankle or great toe weakness [45, 49].

Natural History

Spinal stenosis is usually a chronic disease process. Symptoms are often present for many years prior to presentation to a clinician. With continued aging and spinal degeneration,

the stenotic spinal canal and neural foramina tend to reduce further in size. Although most patients do not require surgery, 15% have slowly worsening symptoms as the years progress [57].

Imaging

Standard AP and lateral radiographs are first-line studies. Pathology such as fracture, tumor, or infection must be ruled out. X-rays may reveal chronic disc degeneration, arthrosis, scoliosis, and possibly spondylolisthesis. If spondylolisthesis is present, additional flexion and extension views can demonstrate if the slippage increases with those maneuvers and represents a more dynamic and unstable situation. MRI is invaluable for confirming the diagnosis and confirming compression. Axial cuts can give a true measurement of the cross-sectional area of the canal and of stenosis at the foraminal level and lateral recess. CT scans are helpful for determining the contribution of the bony elements and osteophytes to the stenosis. Prior to the advent of MRI, myelographic CT scan had been the gold standard.

Differential Diagnosis

Vascular claudication is the most common entity entering in the differential diagnosis of lumbar spinal stenosis. An accurate history and physical examination can often discern between the two. First, vascular claudication has more severe distal lower extremity pain, whereas neurogenic claudication typically has a proximal to distal pain pattern. Also, with vascular claudication, pain is relieved by ceasing to walk and standing still, whereas neurogenic claudication patients need to sit down and lean forward to relieve the pain. Lastly, vascular patients have significant relief from lying supine, whereas stenosis in the canal may be increased in the supine position. The physical examination in the vascular claudicant is also noteworthy for the trophic skin changes secondary to arterial disease and the lack of peripheral pulses. Nonetheless, the two conditions can coexist in the elderly population, and consultation with a vascular surgeon should be sought in equivocal cases. Any of the previously mentioned neurologic conditions can also mimic lumbar stenosis. Unilateral or foraminal stenosis can present similar to atypical sciatica [8, 45, 53].

Nonoperative Treatment

Nonoperative treatment includes short courses of bed rest, if helpful, and antiinflammatory medications. Physical therapy with an emphasis on aerobic conditioning, and abdominal

strengthening should be employed. Weight loss alone can significantly diminish symptoms in the stenotic patients. Flexion exercises are also helpful. A corset or back brace may be worn for support. Epidural steroid injections can be utilized, especially with acute exacerbations. Narcotic analgesics should be avoided as they have addictive properties and fail to target the underlying etiology.

Operative Treatment

Patients unresponsive to nonsurgical measures and those with increasing pain, gait disturbance, or with bowel/bladder dysfunction should be considered for surgical therapy. The cornerstone to surgical management is adequate decompression of all stenotic segments. The preoperative MRI and CT scans must be carefully evaluated for all possible locations of stenosis. Not infrequently the entire length of the lumbar canal must be decompressed to ensure adequate room for the neural elements. The surgeon must be meticulous when addressing the bony, disc, and ligamentous contributions to the narrowed canal. To assure an adequate decompression, nerve roots should be carefully mobilized and the neural foramen probed with the appropriate instrumentation. If no more than 50% of any facet level must be removed and the spine is not unstable for other reasons, fusion is not needed to ensure a good postoperative result. If degenerative spondylolisthesis exists, fusing these segments should be strongly considered in light of the findings of numerous long-term studies [58–60]. Fusion attempts may be supplemented with instrumentation. Studies have shown that while there is a better chance of achieving arthrodesis with instrumentation following posterolateral fusion, clinical outcomes may not differ [33]. Further studies should be done to better understand this issue (Fig. 88.16).

Results

Among appropriately selected patients, more than 75% have significant relief postoperatively [61, 62]. Workmen's compensation patients, secondary gain, and smoking are among the predictors of a poor result [63].

Adult Scoliosis

The normal adult spine when viewed from the front is straight. Any deviation or curvature in the lateral plane is referred to as scoliosis. In actuality, the curvature represents a three-dimensional deformity with rotation of all the vertebral elements and the rib cage. Scoliosis generally affects

FIGURE 88.16 Seventy-five-year-old female with symptoms of spondylosis and spinal stenosis with multilevel spondylolistheses treated with posterior decompression and instrumented fusion from L3 to S1.

adolescent girls, but the elderly population may also present with scoliosis from various causes.

Pathophysiology

The two major categories of adult scoliosis are the idiopathic and degenerative varieties. Adult idiopathic scoliosis usually is an extension of its adolescent variant and results from a missed or untreated diagnosis. As mentioned, young girls present with this condition during adolescence. The curves are usually in the thoracic spine and are not painful during youth. Curves of less than 40–50° tend not to progress once growth has stopped [64]. Larger curves may progress into adult life. Most are thoracic curves in which the convexity of the curve is to the right. The pathophysiology is unknown, although a hereditary pattern seems to exist. By the same token, there has never been a causal relationship established between osteoporosis and degenerative scoliosis. The recommended treatment of curves of more than 40–50° is fusion during adolescence; bracing and observation are recommended for lesser curves (20–40°). Adult degenerative scoliosis primarily affects the lumbar spine. Disc degeneration, facet arthrosis, degenerative stenosis or listhesis, compression fractures, osteoporosis, and muscle imbalance may contribute to the three-dimensional deformity, yet none have been shown to be directly related [65]. Abnormal rotation of the lumbar vertebral elements is also evident. Why

certain patients with chronic disc degeneration develop a concomitant lumbar scoliosis and others do not is not known [66–68].

Natural History

Degenerative lumbar scoliosis is characterized by minimal structural vertebral deformity, advanced degenerative changes, and a predominance of lower lumbar curves [65]. Adult scoliosis arising from adolescent scoliosis generally does not present a problem with curves <40–50°. For larger curves, pain is often localized to the concavity of the curve (where the facet joints are excessively loaded) [41]. Nerve roots along the concavity may be compressed, and the patients may present with signs of nerve root irritation. Cosmetic concerns such as increasing rib prominence and shoulder asymmetry may be presenting complaints. For extremely large curves (>100°), shortness of breath secondary to diminished lung capacity can be a problem [69, 70] (Fig. 88.17). Degenerative scoliosis usually is less a cosmetic concern, as curves tend to be much smaller. Patients present with nonspecific back pain usually along the concavity of the curve, signs of nerve root irritation, or even spinal stenosis. Progression of deformity is expected in patients with an interest line passing through the disc space of L4–5 or below, as well as in cases where the index curve or vertebral rotation is extensive [65].

FIGURE 88.17 Eighty-year-old female with thoracolumbar adult scoliosis measuring 140°.

Nonoperative Treatment

Adult scoliosis should be approached with caution. Nonoperative treatment should be fully exhausted prior to surgical consideration. NSAIDs, bracing, medical management (i.e., bisphosphonates), weight reduction, exercise, and epidural steroids may be employed.

Operative Treatment

Patients with refractory pain, evidence of spinal imbalance, or signs of neural compression can be considered for operative treatment. All patients should undergo full-length radiography of the entire spine in the PA and lateral projection. Bending films can help assess the degree of rigidity to the curve. Additionally, patients with symptoms of nerve root compression or spinal stenosis should undergo MRI or myelography of the affected area.

The operative approach to treatment must be highly individualized. If the presenting problem is back pain without nerve root compression or stenosis, a posterior approach with curve correction, instrumentation, and fusion are recommended. If nerve root compression or stenosis is significant, careful decompression of the affected area must be

included. Lumbar degenerative curves can often be approached anteriorly. Combined anterior and posterior approaches may be needed for difficult rigid curves [68]. If the only symptom is that of a single nerve root compression, simple posterior decompression without curve correction or fusion is reasonable. For patients with pulmonary compromise due to thoracic curves, curve correction to allow increased pulmonary capacity is of paramount importance.

Results

Surgery for adult scoliosis is associated with a high incidence of complications, many of which are medical in nature, including blood loss, infection, pneumonia or atelectasis, inability to achieve fusion, and neurologic injury. Adult curves are stiffer than pediatric curves, and achieving curve correction is limited. Patients must be carefully selected and appraised of these potential complications. Residual back pain may remain despite the presence of a solid fusion [71, 72].

Trauma

Spinal trauma and spinal cord injury represent significant sources of morbidity and mortality. It is estimated that more than 50,000 spine fractures occur yearly, with neurologic injury occurring one-fifth of the time [73]. Most are secondary to significant energy mechanisms such as motor vehicle accidents, falls from heights, and gunshot wounds. The patients generally are young, 20–40 years old, but the elderly are not immune to these injuries. Patients presenting to emergency rooms or practitioners with a history and mechanism suggestive of spinal injury warrant a full evaluation. The elderly often sustain spinal injuries with lesser degrees of energy because of fragility, osteoporosis, or other predisposing conditions of the spine.

Cervical Spine Trauma

Patients sustaining cervical spine trauma present with the complaint of neck pain and or extremity weakness if spinal cord injury has taken place. The mechanism of injury must be carefully ascertained and preexisting medical conditions and any loss of consciousness delineated. The physical examination must be thorough. The cervical spine is examined for evidence of soft tissue contusion as well as tenderness to palpation. Flexion, extension, and rotation are documented. A careful overview of upper extremity motor power, sensation, and reflexes is undertaken.

FIGURE 88.18 Helical CT scan sagittal reconstruction of unilateral facet perch at C6/C7 in 60-year-old male who fell on his head (Case Courtesy of Nathaniel Tindell, MD).

Any abnormality on the examination should prompt the treating physician to obtain cervical spine radiographs. The standard trauma protocol for cervical spine injury includes an AP, lateral, and open-mouth odontoid view. The lateral view must demonstrate C1–T1 to be considered adequate. Recent studies show that helical computed tomography (CT) can be safely used in place of plain radiograph to evaluate the cervical spine for osseous abnormalities such as fracture and dislocations after high-energy trauma (Fig. 88.18). If a pure ligamentous injury is suspected, supervised bending cervical spine films or MRI is recommended [74]. If the mechanism of injury is significant, such as a motor vehicle accident, an AP pelvis and chest radiograph should also be obtained.

A variety of injuries can occur in the cervical spine including flexion-type compression injuries, dislocation of one vertebra on another, burst injuries of the vertebral bodies, spinous process fractures, and lamina fractures. Treatment is affected by the degree of instability present and whether a neurologic injury has occurred. In cases presenting with an acute progressive neurologic injury, urgent MRI, CT or myelogram CT, and surgical decompression with stabilization comprise the treatment of choice once the patient is medically stabilized. Urgent decompression offers the best chance of recovery of neurologic function. Injuries with a static neurologic injury can be addressed on a more elective basis. If an injury has occurred without neurologic injury, the

degree of instability rendered greatly influences further management. Attempts have been made to define criteria for cervical spine instability [3]. The amount of vertebral body destroyed, the angulation and translation at the injury site, and disc space narrowing contribute to the relative instability of the injury.

Certain injuries do not confer instability to the spine. They include isolated lamina fractures, spinous process avulsions or fractures, and simple compression injuries to isolated vertebral bodies. These injuries can be managed with a hard or soft collar depending on the level of patient discomfort. Other injuries are inherently unstable. All dislocations are unstable. They must be reduced regardless of whether neurologic injury has occurred [75] (Fig. 88.19). Difficulty with reduction warrants an MRI to ensure that an entrapped disc fragment is not present [76]. If present, an anterior disc excision should precede the reduction. Following reduction of dislocations, the spine should be stabilized via posterior fusion. When the posterior ligamentous complex is injured, it should be treated by elective posterior fusion [75].

Frequently, patients have negative radiographic and MRI findings despite persistent pain. The severity of these whip-lash injuries should not be underestimated. The patient should be placed in a hard collar for support and given adequate muscle relaxant and pain medication. A follow-up appointment with an orthopedic surgeon should take place within 2 weeks. If pain persists, the patient should obtain

FIGURE 88.19 Bilateral facet perch at C7/T1 in 62-year-old male hit by tree branch in the back of head with onset of paraplegia, successfully treated with open reduction and instrumented fusion.

flexion and extension views of the cervical spine to rule out a ligamentous injury [77].

Thoracolumbar/Lumbar Spinal Trauma

As with cervical spinal trauma, thoracolumbar and lumbar spinal trauma is usually the result of high-energy injuries. Timely and appropriate evaluation is crucial to successful management and outcome of these injuries.

Upon presentation to the emergency room, a thorough history and physical examination must take place. Preexisting medical conditions, mechanism of injury, and loss of consciousness at the scene should be ascertained. If secondary to a motor vehicle accident, questioning as to the use of a seat belt or lap belt is important. Assuming the patient maintains stable vital signs, a thorough examination is undertaken. In particular, the presence of bruising to the flank or back suggests a significant injury to the spinal column or retroperitoneum. A thorough examination of all four extremities for motor, sensation, and reflex responses is vital. A rectal

examination should be done to document tone. The presence of any neurologic deficit must be noted. Patients noted to have neurologic deficit should be given intravenous steroids. When administered within 8 h after injury, steroids have been shown to be helpful in recovering some neurologic function [78].

Once adequately stabilized, the patient should undergo appropriate radiography. AP and lateral films of the thoracolumbar spine for those with suspected injuries are first-line studies. An AP film of the pelvis, a chest radiograph, and films of the cervical spine complete the trauma series.

There are numerous mechanisms of injury to the thoracolumbar spine leading to various injury patterns, including axial compression, flexion, extension, rotation, and distraction mechanisms. Flexion-distraction injuries are associated with the use of a lap belt without a shoulder strap, which is associated with a high incidence of visceral injuries. They should be suspected in a patient after a motor vehicle accident, particularly with abrasions across the abdomen.

Treatment must be individualized to the patient and the injury pattern. Goals of treatment are rapid mobilization of the elderly patient with the avoidance of further neurologic deterioration. Emergency surgery is indicated only in cases of worsening neurologic deficit. Emergent CT or MRI should be performed in these cases to detect the site of neural compression. A canal or foraminal decompression should take place to remove impinging fragments, and the spine should be stabilized with instrumentation and fusion. The decision to approach the spine from an anterior or posterior approach depends on the injury pattern and the site of neural compression. Generally, more thorough decompression is possible from an anterior approach.

In cases of static neurologic deficit, elective surgery to decompress the canal may be beneficial for regaining neurologic function. Timing of surgical decompression is a topic of debate. We tend to intervene during the first week, although recovery of some neurologic function has been noted with late decompression [79–81].

If no neurologic deficit is present, treatment should be based on the relative stability of the injury and the propensity for satisfactory healing. Certain injuries are stable. Examples include isolated fracture of a spinous process or transverse process secondary to a direct blow. Patients can be managed with a short period of bed rest and pain medication. A brace may be worn for comfort. Compression fractures of the spine are usually secondary to flexion mechanisms (Fig. 88.20). When the height of the anterior vertebral body is compressed less than 50% of the posterior aspect of the body and when no reversal of lumbar lordosis is present, the injury is relatively stable. Treatment can be placement in a thoracolumbosacral orthotic molded in

FIGURE 88.20 Sixty-five-year-old female with sudden onset of pain while opening a window. Lateral lumbosacral spine radiographs shows compression fracture at L1 (Case Courtesy of Nathaniel Tindell, MD).

extension for several months and pain control. In cases of persistent or exaggerated pain that renders the patient incapable of prolonged mobilization, kyphoplasty or vertebroplasty has been shown to improve symptoms allowing for more rapid rehabilitation [82]. These procedures involve percutaneous dilation of the vertebral body with insertion of bone cement. Kyphoplasty utilizes an inflatable balloon tamp which limits the possibility of extravasation of cement to neighboring tissue (Fig. 88.21).

Injuries with anterior compression of more than 50% of the posterior body vertebral height or with reversal of lumbar lordosis are more unstable injuries because they connote injuries to the posterior ligamentous complex of the spine [3]. Surgical stabilization and fusion offer the most predictable healing results. Surgery also allows more predictable restoration of sagittal alignment.

Other injuries further destabilize the spine. They include all fracture-dislocations of the spine and most flexion-distraction injuries. To ensure healing, preservation of neurologic function, and avoidance of postinjury deformity, surgical stabilization and fusion should be undertaken. It is usually done from a posterior approach.

Systemic Disorders of the Spine

Osteoporosis refers to decreased bone mass and increased risk of fracture. The vertebrae are the bones most commonly affected. This condition affects up to 20 million people yearly and represents a significant source of morbidity and cost. This is a condition of the elderly, with postpartum women affected more than twice as frequently as men. An understanding of the pathophysiology and treatment of this entity is essential for the geriatric clinician [83].

FIGURE 88.21 Sixty-four-year-old female with low back pain after fall and radiographic evidence of compression fracture at L1 treated with kyphoplasty (Case Courtesy of Nathaniel Tindell, MD).

Pathophysiology

Bone is a living tissue constantly undergoing resorption and formation under the control of osteoblasts and osteoclasts. Peak bone mass is generally achieved during the third decade of life. Adequate daily calcium and vitamin D intake as well as exercise are essential for achieving the highest peak bone mass possible. Once peak mass is attained, resorption of bone exceeds formation, leading to a gradual diminution in bone mass. The rate of resorption is higher for women than it is for men. Rates of resorption further increase with the onset of menopause, probably secondary to the absence of estrogen, which acts to increase calcium absorption. Genetics also plays an important role in the development of osteoporosis. Fair-skinned individuals of northern European descent have the highest risk of disease progression. Other associated factors include early menopause, smoking, sedentary life style, phenytoin use, and excessive alcohol intake [83].

With advancing age, susceptible individuals may experience fragility fractures. The spine and the hip are most commonly affected. These fractures are often seen after minor trauma such as lifting or tripping.

Evaluation

Evaluation begins with a thorough history with attention to the aforementioned predisposing factors. The onset of pain and discomfort must be discerned. A history of long-standing pain, night pain, or other systemic signs such as fever or weight loss, should alert the physician to the possibility of tumor or infection rather than an osteoporotic fracture. The presentation is usually of local pain to the affected vertebrae without neurologic deficit or radiation to the lower extremities.

Examination reveals tenderness at the fracture site. Patients with previous vertebral compression fractures may demonstrate increased kyphosis to the thoracic spine. Radiographs of the affected area reveal osteopenia, decreased bone mass, and fracture of the affected vertebrae. In the thoracic spine this usually takes the form of an anterior compression or wedged appearance. In the lumbar spine more generalized flattening of the vertebrae occurs. It is not uncommon for asymptomatic or minimally symptomatic vertebral compression fractures to be discovered incidentally by radiography.

For first time presenters, laboratory tests should be done to rule out the reversible causes of osteoporosis, which include hyperthyroidism and increased cortisol levels. Otherwise, routine blood values are normal including calcium, hemoglobin, phosphorus, and alkaline phosphatase levels [84].

More sophisticated methods for evaluating osteoporosis include dual energy X-ray absorptiometry (DEXA). This test subjects patients to a low dose of radiation with high accuracy. Bone mass is quantified in terms of density within standard deviations of normal. Individuals with more than two SD of normal are considered osteoporotic and are at significantly increased risk of fracture [8].

Treatment

The cornerstone of management is prevention. As mentioned, ensuring adequate calcium and vitamin D intake as well as exercise during youth are the most reliable methods of increasing peak bone mass [85]. Patients older than 65 should maintain a daily intake of 1,500 mg of elemental calcium. This is especially important in susceptible individuals. Once fracture has occurred, the goals include pain relief, patient mobilization, and prevention of further bone loss and deformity. Pain relief can be managed with NSAIDs or a short

FIGURE 88.22 Seventy-six-year-old female with multiple compression fractures, kyphosis, and progressive neurologic deficit treated with posterior cement augmented instrumentation and fusion with restoration of sagittal profile and improvement in neurologic status.

course of a narcotic analgesic. Several days of bed rest may be prescribed, after which the patient is encouraged to mobilize. The latter can be aided with the use of a thoracolumbar orthosis molded in extension, which should be worn until pain is resolved and follow-up radiographs show no increase in the deformity. Usually 6–12 weeks suffices.

Pharmacologic treatment of osteoporosis includes administration of supplemental calcium and vitamin D, which can help avoid further bone loss. The use of estrogen in perimenopausal and postmenopausal women has been shown to reduce vertebral compression fractures. Other agents include bisphosphonates (Fosamax) [86], which also decrease osteoclastic activity, and fluoride, which stimulates osteoblastic proliferation. The appropriate pharmacologic protocol should be managed by a knowledgeable internist or rheumatologist.

Most of these injuries heal uneventfully. Surgery is rarely indicated for management of osteoporosis of the spine. One indication is an acute fracture with neurologic deficit, which is a rare occurrence. Loss of bowel/bladder control is another indication for surgical decompression. Other indications for surgery include progressive deformity with unremitting pain. The clinician must also be aware of insidious onset of neurologic deficit in the setting of multiple compression fractures with increasing kyphosis or scoliosis (Fig. 88.22). This situation may represent spinal stenosis due to anterior canal compromise. It can occur months to years after injury. Therefore it is recommended that osteoporotic fractures be followed on a regular basis until increasing deformity has definitively stopped. These patients are often risky surgical candidates because of their multiple medical problems. Additionally, poor bone quality makes fixation difficult. The surgical approach depends on the deformity and may be

anterior, posterior, or combined. Patients must be made aware of the significant risk of these surgeries [88].

Studies have shown an association with multilevel compression fractures and a higher risk of death from pulmonary complications in women 65 years and older [88]. Kyphoplasty may be used to stabilize a progressive kyphotic deformity from an osteoporotic compression fracture in the acute or subacute period. In some cases, actual height restoration can be achieved. Long-term complications associated with this procedure include an increased risk of vertebral body fracture from forces exerted by the adjacent cement-injected level [82].

Infections of the Spine

Infections of the spinal column are common in the elderly or the immune compromised population. Diabetes, rheumatoid disease, concurrent urine infection, skin ulceration, and abscesses predispose to spinal infection. Unfortunately, the diagnosis is often missed early in its course, leading to delay in treatment and increased patient morbidity [89].

Vertebral Osteomyelitis: Pyogenic and Mycobacterial

Presentation

The most common presentation of vertebral osteomyelitis is chronic vague back pain. Hematogenous spread is the most common mode of transmission. The lumbar region is most

commonly affected followed by the thoracic and cervical regions. Patients relate that the pain is not activity-related and is not relieved with standard measures. Furthermore, it often wakes the patient at night or prevents sleep. Patients may complain of systemic manifestations such as fever, chills, weight loss, and loss of appetite; but these findings are often absent. The physical examination may reveal local erythema and increased temperature over the affected region. The area may be tender to palpation with surrounding muscle spasm. Range of motion is often restricted owing to pain and spasm. Fewer than 10% of patients have neurologic findings upon presentation, although diabetes and a cephalad level of involvement put the patient at increased risk [90].

Laboratory results may indicate an elevated white blood cell (WBC) count but are often normal. The erythrocyte sedimentation rate (ESR) is an extremely sensitive but nonspecific test, with elevated values in more than 90% of cases. It is, however, an excellent method for serial monitoring of the response to treatment.

If fever is present, blood cultures should be obtained but are often negative outside of temperature spikes. Radiographs can be entirely normal early in the disease; later they reveal destruction of the anterior vertebral metaphysis, diminished disc space height, and reactive subchondral bone formation. With mycobacterial infections the disc spaces are remarkably well preserved until late in the disease process [91]. Paraspinal shadows may be prominent owing to soft tissue extension of infection. A technetium bone scan with gallium has a more than 90% accuracy record for infection of the spine, but MRI is currently the modality of choice for confirming the diagnosis of infection; it distinctly reveals decreased signal to the disc and vertebrae on T1-weighted scans and increased signal on T2-weighted scans [92].

Treatment

The key to management of osteomyelitis is identification of the offending agent. *Staphylococcus aureus* causes approximately half of all infections but *Escherichia coli*, *Staphylococcus epidermidis*, and *Pseudomonas* are other common organisms [89]. Recently, *Mycobacterium tuberculosis* has made a resurgence among the immune compromised and the elderly. Hence, suspected patients should undergo PPD testing and chest radiography in a search for pulmonary nodules. Thorough evaluation of the MRI scan to look for anterior and paravertebral masses and anterior bony destruction should be undertaken. These are classic findings associated with spinal tuberculosis. Other granulomatous diseases of the spine are also being seen with increasing frequency in this population.

Blood cultures, if positive, can direct antibiotic therapy. Unfortunately, they are positive only 25% of the time. In the absence of positive cultures, biopsy may be attempted via

closed technique, CT- or fluoroscopy guided. The yield for closed technique is approximately 75%. If the closed technique fails, open biopsy is mandatory to establish organism identification. Tumor and infection can have similar clinical and radiographic appearances, so all tissues should be sent for pathologic study. Gram staining, aerobic and anaerobic, Mycobacterium, and fungal testing should take place. Once an organism has been identified and its sensitivities established, antimicrobial therapy can be instituted. Six weeks of intravenous therapy followed by oral antibiotics is standard. Additionally, the spine should be immobilized in a brace. Multidrug therapy consisting of isoniazid, rifampin, ethambutol, and pyrazinamide are recommended for tuberculosis infections. Patients are usually treated for 6–12 months. The course of the disease should be monitored by clinical examination, repeat laboratory tests, and repeat MRI at appropriate intervals. When identified early, most infections can be resolved without the need for major surgical procedures [93].

Surgery

Drug therapy is the treatment of choice for spinal infections. Surgery is indicated in specific instances: inability to establish diagnosis; failure of medical management to relieve pain and sepsis; worsening neurologic deficit; or increasing deformity and bony destruction. Additionally, patients with spinal tuberculosis in the cervical region and a neurologic deficit should be treated with surgical débridement because of the high risk of paralysis without surgical intervention. An attempt should be made to delay surgery for 2 weeks to allow the antibiotics to decrease the inflammation and allow an easier surgical approach [94].

If surgery is indicated, the approach and procedure are dictated by the location of the infection. Most of the infections are located anteriorly in the vertebral bodies. The approach therefore is usually anterior via removal of infectious material including the involved vertebral bodies and any soft tissue abscess. Iliac crest bone graft or fibular strut graft should replace the removed bodies. Sometimes a vascularized rib may be utilized with thoracic level infections (Fig. 88.23). If the spine is rendered unstable, an additional posterior fusion can be utilized for further stabilization [90, 95].

Epidural Abscess

Epidural abscesses are foci of infection in the potential space of the spinal canal outside the covering of the cord itself. They occur most commonly in the elderly and are a true medical and surgical emergency. More than 10% of cases are misdiagnosed at the initial visit to a physician.

FIGURE 88.23 Seventy-two-year-old male with osteomyelitis, discitis, and psoas abscess at L2/L3 treated with anterior approach, debridement, vascularized rib strut graft fusion and instrumentation.

Predisposing factors are similar to those of osteomyelitis of the spine.

Epidural abscesses may arise via hematogenous spread from a distant site or via direct extension from a focus of vertebral osteomyelitis. Most abscesses are in the lumbar and thoracic region and are located dorsally within the canal. Cervical abscesses are less common but usually represent an extension of vertebral osteomyelitis and are located anteriorly [96].

The most frequent presentation is that of pain localized to the site of the abscess. Patients look and feel ill. More than 50% of patients have increased temperature upon presentation. The examination is otherwise nonspecific and may include spasm, tenderness, and restricted range of motion. Patients may have signs of nerve root irritation. Usually,

neurologic deficit is absent during the first 48 h followed by neurologic dysfunction over the next several days. Frank paresis may evolve if left untreated. Early diagnosis and treatment are essential.

Laboratory values often reveal an increased WBC count and ESR. Radiographs are not usually helpful but may show vertebral endplate erosions or increased soft tissue outlines, especially in the cervical spine. If the diagnosis is suspected, urgent MRI of the affected region is done. The addition of gadolinium further sensitizes the study. Findings are of decreased epidural signal on T1-weighted scans and hyperintensity of the abscess on T2-weighted images [97].

Once the diagnosis is established, broad-spectrum antibiotics to include coverage of *Staphylococcus*, *Streptococcus*, and *Mycobacterium* when indicated, should be administered

without delay, followed by urgent surgical decompression. If located in the lumbar or thoracic region simple drainage with laminectomy may suffice. Cervical abscesses necessitate an anterior approach and removal of vertebral bodies with fusion. If the diagnosis is established early, the prognosis is good; delay may lead to mortality rates in excess of 10% [96].

Tumors of the Spine

With the exception of multiple myeloma, primary neoplasms of the spine are rare, especially in the elderly. Metastatic lesions of the spine, however, are common in this population. Other than lung and liver, the spine represents the most frequent site of metastasis and is the most frequent site of skeletal metastasis [98].

Presentation

Patients present most frequently with the complaint of back pain localized to the site of metastases. The pain is slowly progressive and does not respond to standard analgesics, rest, or other modalities. Frequently, night pain is present resulting in an inability to fall asleep. Systemic symptoms such as fever, weight loss, and lethargy are often communicated. Neurologic signs and symptoms may be present, suggesting invasion of the spinal cord or nerve roots by the lesion. The patient may present with chronic progressive back pain, with an acute onset of severe pain, which is often the result of a fracture through a pathologic lesion.

Evaluation

As always, the history and physical examination are the keys to proper evaluation. Back pain in the setting of a current or prior malignancy should alert the physician to the possibility of spinal metastases. Standard laboratory test may reveal anemia, increased alkaline phosphatase, elevated ESR, or in the case of multiple myeloma elevated urine and serum electrophoresis measurements. Standard radiographs of the affected region should be obtained. Close attention should be paid to vertebral body changes and pedicle destruction, as they are the frequent sites of the metastatic deposits. Unfortunately, radiographs are frequently normal, as approximately 50% of marrow replacement must occur to cause findings on plain films [99]. If clinical suspicion exists, an MRI scan should be obtained. MRI is extremely sensitive for the marrow changes seen with malignancy. Metastases appear hyperintense on T2-weighted images.

MRI also enables study of the spinal cord, epidural space, and surrounding soft tissues. This is especially important when evaluating patients with neurologic deficit. Once MRI confirms a lesion, a bone scan is recommended to localize additional bony deposits. Of note, multiple myeloma is frequently cold on bone scans. A chest radiograph may reveal a module suggesting the lung as the site of the primary malignancy.

Management

Once a metastatic lesion to the spine has been established, its pathology must be ascertained. This should be done by correlating the remainder of the workup (laboratory results, radiographs, abdominal or pelvic CT, colonoscopy) or if necessary via biopsy of the lesion. This may be done via a closed technique using CT or fluoroscopic guidance. If this is unsuccessful, an open biopsy must be performed. Once a definitive diagnosis is established, further management must emphasize a team approach, including the help of an internist, oncologist, orthopedic surgeon, and neurosurgeon.

The most sensitive prognostic indicator for survival is not the extent of the spinal lesion but the primary diagnosis. Hence, any treatment must take into account the expected lifetime of the patient. Patients with breast cancer and multiple myeloma have a longer life expectancy, often more than 2 years from the diagnosis. Gastrointestinal and lung malignancies involving the spine have a much shorter life expectancy.

Available modalities include analgesics, bracing, radiotherapy, chemotherapy, and surgery. If no neurologic deficit is present or fracture has not occurred, there is no need for emergent surgery. The radiosensitivity of the lesion should be determined and the effectiveness of chemotherapy. For example, multiple myeloma and lymphoma are extremely radiosensitive. If the tumor is radiosensitive, irradiation can be done. If significant pain relief occurs, it may serve as definitive management. Emergent surgery is indicated for patients with progressive neurologic deficit or fracture of a vertebral element with a propensity for instability, further neurologic injury, or both. All additional lesions must be dealt with on an individual basis. Specifically, surgery may be indicated for unremitting pain unresponsive to other modalities and large lesions suspicious of impending fracture or instability. For highly vascular tumors, such as thyroid and renal cell carcinoma, where irradiation and surgery are planned, surgery should take place prior to initiation of radiotherapy. This is to prevent wound healing complications associated with radiation use. The surgery must be highly individualized. Anterior lesions should be approached anteriorly and posterior lesions posteriorly. Generally,

FIGURE 88.24 Sixty-eight-year-old female with metastatic lung carcinoma to posterior elements of T12 with neurologic deterioration treated with posterior decompression, instrumented fusion, and full neurologic recovery.

lesions causing neurologic compromise necessitate an anterior approach. All pathologic tissue should be removed and the spine stabilized with instrumentation. Careful study of the preoperative MRI is necessary. If possible, asymptomatic lesions are included in the stabilization. If life-span is limited, fusion is not mandatory, but if doubt exists as to life expectancy, fusion should be performed [100].

Results

The prognosis for spinal metastases is the same as for the primary lesion. Spinal surgery is never curative, only palliative. However, in patients with unremitting pain and neurologic compromise, surgery enables an improved life style and easier mobilization (Fig. 88.24).

CASE STUDY

Sixty-five-year-old male with history of chronic low back pain and intermittent bilateral lower extremity paresthesia. The patient described worsening lower extremity pain with prolonged standing and walking long distances. He reported a need to sit to relieve symptoms and no difficulty while climbing stairs (see Fig. 88.12).

Neurovascular examination was essentially normal, significant only for loss of lumbar lordosis and a forward

flexed gait. Radiographic evaluation was significant for a degenerative lumbar spondylolisthesis at L₃/L₄, degenerative disc disease, and disc desiccation. Spinal stenosis was confirmed by magnetic resonance imaging.

Patient was indicated for posterior lumbar laminectomy, instrumentation, and posterolateral fusion from L₃ to L₅. Postoperatively, the patient had resolution of his symptoms and clinical/radiographic fusion at 3 months time. Rehabilitation was required to restore basic functional capacity.

Section XII
Musculoskeletal System and Soft Tissue

Chapter 89

Invited Commentary

Roby C. Thompson Jr.

During the past 45 years, the ability to provide expanded care for geriatric patients with soft tissue and musculoskeletal disease and injury has expanded exponentially. As I reflect on the changes experienced in my practice as an orthopedic surgeon from 1963 to now, I am struck by a wide range of opportunities related to advances in either technology or our understanding of the biology of the connective tissues. These advances have fed off each other; in some circumstances, they have been largely dependent on their own merit, whereas in others, they are intimately linked. I have divided this introduction into advances dependent on one or the other – basic biology or technology – and interdependent fields.

Biologic Advances

During the early 1960s, the field of wound healing was just beginning to emerge from the histologic understanding of soft tissue repair and fracture healing to more quantitative understanding of the role of foreign bodies and the cellular response to injury. The advances that have occurred in our understanding of soft tissue healing of tendons and ligaments are responsible for much improved outcomes for patients of all ages with tendon lacerations or ligament tears. We have learned that the temporal relations of repair and reaction to injury dictate the appropriate rehabilitation of these injuries. As a result, rather than external immobilization in a cast for 3–6 weeks to protect a torn ligament or lacerated tendon, those injuries are now treated with early surgical intervention and early controlled motion to enhance the healing and the mobility of the injured part. Likewise, the role of surgical intervention in fracture healing during the 1960s was considered heretical by some because of the complications of

fixation failure and infection. Much of this was due to a lack of appreciation of the concomitant soft tissue injury associated with the fracture and the need for managing the fracture based on the magnitude of the soft tissue injury. This point is best exemplified by the expanded classification systems of “open fractures” to three or four strata depending on the author who has studied these injuries. This has been a great leap forward in managing what were previously described as “compound fractures.” It has allowed expanded opportunities for return to function by patients who were previously subjected to prolonged immobilization in casts or traction and for what the great fracture surgeons of the 1960s, such as Harrison L. McLaughlin, Preston Wade, and Reginald Watson-Jones, called “fracture disease.”

As a result of our better understanding of the relations between soft tissue injury and fractures, we have been able to modify our treatments to capitalize on early limb function using a variety of techniques. These have spanned “functional bracing,” early ambulation in casts for femoral and tibial fractures, and early hand motion for “Colle’s fractures,” among others. From our expanded understanding of open fractures based on the early classification of Gustilo and Anderson, we learned that a type 1 open fracture with minimal soft tissue injury (e.g., a low-velocity gunshot wound) could be managed with local irrigation and débridement, with conventional fracture management for that fracture. This is in contrast to proceeding to an operating room environment for a type 3 fracture with massive soft tissue damage with or without comminution that demanded meticulous, thorough débridement on an as-necessary basis to provide healthy tissue for wound healing and resistance to infection.

Concomitant with our understanding of fracture repair and bone formation was an expanded understanding of the use of bone grafts largely based on the work of Marshall Urist, C. Andrew Bassett, and others. They pointed out that bone grafts could be osteoproduative, osteoconductive, or even osteoinductive, depending on the characteristic of the graft and how it was applied. We now know that when osteo-production is required from a bone graft, it can occur only with autogenous cancellous bone that is carefully handled to

University of Minnesota, Minneapolis, MN, USA
e-mail: thomp004@umn.edu

protect the transplanted osteoblasts. Moreover, the graft must be in a viable, receptive environment with adequate well-oxygenated blood supply. In a similar manner, we can rationally expect cancellous allogeneic bone prepared in a way that removes primary cellular antigens and decreases the transplant antigenicity of the residual protein matrix to be comparable to autogenous bone for filling a cavity that requires primary conduction of bone, such as a benign cyst of bone. We have also learned that massive allogeneic bone grafts can be used for reconstructing major skeletal defects, including osteoarticular defects with expectations of 75–80% 10 year function in limbs that were potentially doomed to amputation during the 1960s.

The expanded understanding of tumor biology and the role of surgery of those primary tumors of the musculoskeletal system is a product of the past 35 years. We now know that as sarcomas spread in tissue planes associated with bone and muscle compartments, amputating the limb with a sarcoma is not necessarily the best or the only way to remove the tumor for the best outcome of local control. Thus, with a soft tissue sarcoma of the vastus lateralis muscle in the geriatric patient, it would be unusual today to recommend amputation. Rather, resection of the involved muscle with a fascial envelope surrounding the muscle and reconstruction with muscle transfers and rehabilitation are recommended, following the principles described above for soft tissue healing.

Much of what the surgeon caring for the musculoskeletal system can provide to the geriatric patients of the 2000s is based on generic advances in medicine and on our better understanding of pharmacotherapy. With the advances in antibiotics, chemotherapy, and hormone replacement, we are better able to control the aging process, which is pathologic in certain individuals. The classic example is osteoporosis, and the discoveries of the estrogen dependence of the osteoblast–osteoclast relation for maintenance of skeletal mass. Through the development of a class of drugs called bisphosphonates, we now have the ability to block bone resorption, which holds out major opportunities for better control of osteoporosis. Additional therapies in tumor-related bone resorption are available as well.

Similar advances in the use of blood products and anesthesia have allowed the orthopedic surgeon reasonably to consider surgical intervention in an aging population that would have been unthinkable 35 years ago. For example, it is common today for elective joint replacements to be recommended in octogenarians in reasonably good general health. We are confident that the ability of anesthesiologists to monitor vital signs, oxygenation, and visceral functions allows most unexpected conditions to be corrected quickly, just as we have become accustomed to correcting coagulopathies in our pre- and postoperative patients by defining the problem and replacing the deficit component of the coagulation system.

Technologic Advances

The advancing experience with biomaterials and giant leaps in our understanding of the fundamentals of the biomechanics of the skeletal system have been products of the past 45 years. This time frame has seen many technologic changes; they have not all been advances, and many have subsequently been abandoned. Even those advances that have proved successful have been subject to misapplication as we grope for the appropriate application. If there is one lesson for the future, it would be to enhance our scrutiny of new technology and demand accurate, well-done outcome studies before we embrace the new technology.

With that editorial comment out of the way, I offer the following technologic advances as the most important of the past 35 years for the orthopedic patient. First is our understanding of biomaterials and the biomaterial interface with the biologic and mechanical environment. Biocompatibility was a science well on its way during the 1960s, but it has become a virtual cookbook science during the past few years. Hence, we rarely concern ourselves with the new material and its relation to the biologic environment when it is accepted for market by the U.S. Food and Drug Administration (FDA). In the field of musculoskeletal diseases, we have seen silicone and Teflon arthroplasty wreak havoc at the local level owing to wear product debris in the absence of reaction to an inert material product. Today, the biggest challenge in the field of joint replacement is defining the interface between artificial articulations that have minimal and tolerable wear and yet do not transmit unacceptable forces to the implant–bone interface, which is the link for long-term fixation of the implant. During the past 40 years, we have moved from catastrophic failures with total hips of stainless steel and Teflon articulation, or acrylic replacements of femoral heads, to more successful stainless steel or cobalt-chrome alloy replacements that rely on a press-fit interface with bone, yet frequently, there were only one or two options in size for this interface with articular sizing based on 0.25-in. increments. Today, we have a more than 20-year record of successful experience with the use of polymethylmethacrylate as a bone cement for implant fixation. We have learned new implant skills over the past 30 years that promise a more than 85% 20-year survival of the implants currently in use. Implant manufacturers have responded to competition and demand, and as a result, our patients can expect a large inventory of sizes and shapes for accommodating the individual idiosyncrasies of their anatomy.

The field of internal fixation for fracture care has paralleled the implant development for joint disease. The linked technology of low-exposure intraoperative fluoroscopy and our better understanding of infection control and fracture healing has led to a change in the management of most displaced fractures, which allows early return to function,

diminished hospitalization, and lower complication rates with a superior functional outcome.

The midshaft femoral fracture is a good example. If one looks at the standard of care during the 1960s, it was skeletal traction for 6–8 weeks followed by a spica cast for a similar time period, frequently associated limb length discrepancy and, commonly, a stiff knee. This practice was measured against an open reduction and internal fixation with an intramedullary nail or plates and screws that even in skilled hands carried a 10% infection rate. Today, those fractures are most commonly treated with closed intramedullary fixation. Commonly, there is a 3- to 5-day hospital stay with return to full unrestricted weight-bearing in 4 months, with expectations of a normal knee joint in most cases. The common expectation for any intraarticular fracture in the current environment is anatomic restoration of the joint surface through open or semiopen techniques, with early joint motion providing maximum functional return.

Another major technologic advancement of the past 35 years has been the ability to perform semiopen surgery via endoscopic techniques. Arthroscopy was the forerunner of much of the endoscopic surgery that is now common in all fields. Introduction of the Watanabe arthroscope during the 1960s was a major opportunity for orthopedists to see

the pathology in the joint, but until the fiberoptic light and hand-held video camera made the arthroscope a practical tool for correcting pathology and removing loose bodies or torn meniscii, the potential went unrecognized. Once again, the 3- to 5-day hospital stay with an open arthrotomy for a meniscus injury has become same-day surgery, with patients returning to active performance in weeks rather than months.

The other technologic advance with dramatic effect in bone and soft tissue surgery has been the ability to perform free vascularized tissue transfers as a result of the introduction of intraoperative microscopy and magnification for microvascular anastomosis. The biologic understanding of the rheology of microvascular flow and reflow has been essential to the successful application of this technology.

The future for soft tissue and skeletal injury and disease management is exciting. Looking back over the past 45 years makes one realize how unpredictable that future may be. The emerging science of biologic manipulation of tissue growth and reconstitution seems real and potentially achievable over the next 30 years. One might eventually resurface a joint with genetically engineered tissue to replace injured or diseased tissue or use a series of linked cytokines or growth factors to reverse a fracture nonunion or reconstitute a skeletal defect.

Chapter 90

Age-Related Changes in Bone and Soft Tissue

David Rispler and Susan M. Day

Introduction

The population of the United States is aging – by 2030, the US Census Bureau estimates that 1 in 5 will be 65 or older. The rapid increase in the size of this population is expected to significantly impact orthopaedic practice especially. The aging process, a normal decline in cell, tissue, and organ function, ultimately leads to progressive changes in the physiology of all the components of the musculoskeletal system: bone, cartilage, muscle, ligament, and tendon. Such change can result in several clinical problems for patients and their treating physicians. Among the most common ailments affecting the geriatric patient are fragility fractures, joint degeneration, and injuries to the aging athlete. The risk of fragility fractures increases as patients suffer from diminished bone mass, osteoporosis, and diminished muscle bulk, which results in weakness that can magnify the effects of neurologic degeneration on gait and posture. Another progressive disabling condition is joint degeneration leading to pain, stiffness, and decreased mobility. As the baby boomer generation matures, but continues to participate in high-impact activities, patients present to physicians with more overuse injuries and traumatic injuries to the muscles, tendons, and ligaments, which function to protect our joints and skeleton.

Physicians, especially orthopaedic surgeons, are the first to document the culmination of these aging processes in elderly individuals, since they are the primary physicians seen when a significant injury, often in the form of a fracture, occurs. Fragility fractures are quite common in the elderly, and they are one of the most important predictors of significant osteoporosis, and risk for further fracture. Orthopaedic surgeons can play a positive role in the management of ongoing

aging processes, through diagnosis of underlying disease, treatment, and follow-up, to prevent future injury. The potential importance of this kind of intervention will increase as the US population ages.

In this chapter, we discuss the anatomy and physiology of aging on each part of the musculoskeletal system, as well as current trends in diagnosis, treatment, and management of musculoskeletal ailments related to aging. An overview of these effects is summarized in Table 90.1 for bone and in Table 90.2 for the rest of the musculoskeletal system.

Bone

Bone consists of several cell types, (osteoblasts, osteocytes, and osteoclasts) organic extracellular matrix (Type I collagen), and ground substance (glycosaminoglycans, or GAGs), produced by the cells. Inorganic materials in the form of mineral salts and hydroxyapatite crystals [$\text{Ca}_{10}(\text{PO}_4)_6 \text{OH}_2$] make the tissue hard and rigid. The organic component gives the bone its flexibility and resilience [1] (Fig. 90.1). A progressive loss of bone density has been observed as part of the normal aging process. The longitudinal trabeculae become thinner, and some of the transverse trabeculae are resorbed [2]. In some patients, this decreased volume of bone tissue and decrease in size is minimal. In others, the decrease becomes pathologic, causing osteopenia or osteoporosis, leading to fragility fractures, deformity, and loss of height (Fig. 90.2).

Bone provides support, movement, protection, and calcium homeostasis. It is a dynamic organ that is constantly remodeled. This remodeling is achieved by the coupling of bone formation, which is the function of osteoblasts, and bone resorption, which is the function of osteoclasts, orchestrated by hormones, growth factors, and cytokines. Early in life, the process of formation and resorption is closely coupled to maintain calcium homeostasis. It is a continuous process throughout life and one that is influenced by genetic and environmental factors including lifestyle choices, gender, pubertal status, physical activity, drugs, and diet [3]. As we

age, this process can become easily uncoupled with a reduction in osteoblast activity, increased osteoclast activity, and alterations in hormone stimulation.

Bone mass reaches its peak at around age 25 and is maintained for several years. By age 40, most adults begin losing bone at a rate of 0.5–1.0% per year. For women, menopause differs per individual, but it accelerates bone loss to 1–5% per year. This accelerated phase lasts for 5–10 years and eventually returns to 0.5–1.0% per year [4] (Fig. 90.3). Skeletal regions lose bone at different rates [5] (Fig. 90.4). Cortical bone, found in the diaphysis and the outer envelope of all bones, is composed of concentric lamellae of densely packed mineralized collagen fibers. Cortical bone represents

the greatest bone loss that occurs with age. The imbalance in bone remodeling leads to porosity, and long bone cortices become thinner over time [6].

Cancellous bone, in contrast, loses density. Trabeculae decrease in number, and the architecture of cancellous bone changes as a result. In spite of these differences, the loss of

both cortical and cancellous bone with increasing age contributes to bone fragility. Cancellous bone loss is rapid in early menopause, resulting in two clinical issues. First, wrist fractures increase in frequency, and as more cancellous bone deteriorates, the risk of vertebral fractures increase. Second, bone mineral density (BMD) (determined from DEXA scans,

FIGURE 90.4 Cancellous and cortical bone loss occur at different times and different rates (reprinted with permission from ([5], p 193)).

discussed below) is lost in the vertebral spine before decreases in the hip region are evident. In addition, the cancellous bone of the spine is the earliest measure to determine if interventions are helping to increase BMD.

The Cellular and Molecular Basis of Bone Remodeling

Bone remodeling in adults results in the complete turnover of the skeleton in approximately 10 years and is achieved by tight coupling of osteoblast and osteoclast cell activity [7]. Osteoclast activity removes old bone which is followed by osteoblast activity that deposits new bone. During each remodeling cycle, the amount of bone formed decreases with advancing age [7–9].

Our understanding of bone remodeling at the cellular and molecular level is constantly expanding. A complete review is beyond the scope of this discussion [7], but key players are briefly mentioned here. Bone morphogenetic proteins (BMPs, specifically BMP-2 and -4) maintain the supply of osteoblasts by stimulating differentiation of periosteal mesenchymal cells to osteoblasts. BMP2/BMP4 activates osteoblast specific factor 2/ core binding factor a1 (*osf2/cbfa1*), which activates osteoblast specific pathway proteins, including osteopontin, bone sialoprotein, type I collagen, and osteocalcin [7]. Recent research suggests that Wnt proteins also play a role in transcriptional activation of osteoblast differentiation [10].

In addition to their role in calcium homeostasis, parathyroid hormone and 1,25 dihydroxyvitamin D₃ (1,25 (OH)₂ D₃) stimulate osteoclast formation from hematopoietic precursors. Osteoclast formation also relies to an extent upon osteoblast cells, since mice lacking osteoblast cells also lack osteoclast cells [11]. The basis for this dependency stems from the receptor activator of nuclear factor κB (RANK), which is expressed on osteoclast progenitor cell membranes, and RANK-ligand located on committed osteoblastic progenitor cells and T-cells [7]. The binding of RANK-ligand to RANK is essential for

clastogenesis. 1,25 (OH)₂D₃ and PTH, among others, stimulate the production of RANK in osteoblast cells. Osteoprotegerin is a glycoprotein that can bind RANK and inhibit osteoclast development. Further, wnt-3a is implicated in downregulation of RANKL, inhibiting osteoclast formation [10]. Many cytokines either enhance or inhibit production of osteoclasts. Finally, calcitonin, secreted by the C cells of the thyroid, appears to promote osteoclast apoptosis.

The hormone estrogen is widely understood to be important in bone remodeling and considered one of the most important determinants of osteoporosis [12]. Estrogen deficiency leads to a bone remodeling imbalance and decreases bone formation and increases bone degradation. Estrogen appears to exert its effects by decreasing the lifespan or activity of osteoclasts, and increases the lifespan of osteoblasts. The effect of estrogen on osteoblasts is to increase cell proliferation, the synthesis of bone matrix proteins and growth factors such as IGF-1 and TGF-β [13]. Estrogen inhibits bone resorption [14] and production of the cytokines IL-1, IL-6, and TNF [15, 16].

Several growth factors, including transforming growth factor β (TGF-β), affect both bone formation and resorption. TGF-β stimulates osteoclast formation and osteoblast differentiation. The interleukin family (IL-1, IL6, IL-11), TNFs, M-CSF, peroxisome proliferator activated receptor γ2 (PPARγ2), and prostaglandins E₂ and F₂ also affect both processes.

Calcium Homeostasis

PTH and 1,25 dihydroxyvitamin D impact calcium homeostasis. Vitamin D increases absorption of calcium in the GI tract, acting in concert with PTH. Vitamin D deficiency causes lower serum calcium, which stimulates releases of PTH and mobilizes calcium stores from bone. PTH increases calcium reabsorption from the kidney, causes bone to release calcium, and plays a role in GI absorption of calcium. PTH levels increase with age, in part because of lower levels of vitamin D. Lower vitamin D levels in the elderly are well documented and due mainly to decreased synthesis and decreased dietary intake. Hyperparathyroidism, common in elderly women, contributes to bone resorption and bone loss.

Diagnosis: Measurement of Bone Mass

BMD is correlated with bone strength in biomechanical studies of cortical and cancellous bone specimens [17]. Also, BMD is predictive of future fractures in epidemiological studies [18–20]. Bone mass can be measured by several techniques, but the clinical standard is the areal measurement of BMD using dual energy X-ray absorptiometry (DEXA),

which is reliable, reproducible, and cost-effective. The T-score, which is a comparison of an individual's BMD via DEXA scan to widely available gender, race, and age standards, is the basis for diagnosis. A T-score greater than -1 is considered normal, while T-scores of -1 to -2.5 are diagnosed as osteopenia, and T-scores lower than -2.5 are consistent with osteoporosis. The presence of fragility fractures indicates greater severity.

The DEXA scan shown in Fig. 90.5 is that of a 44-year-old perimenopausal woman who presented with a third metatarsal stress fracture. She is an avid runner, and her relevant medical and social history included long-term use of birth control medication and a vegetarian lifestyle that she had maintained for more than 20 years. DEXA scan showed a

lumbar spine T-score of -2.5. The total hip T-score was -1.5, and her distal one third radius was -0.7.

This case illustrates important elements of DEXA scan interpretation and diagnosis. First, the pattern and variability of T-scores seen in this scan from different skeletal regions are typical. T-scores in the lumbar spine nearly always show the greatest bone loss since the spine consists mostly of cancellous bone, which is first to show decreases in BMD. Second, in terms of diagnosis, the lowest T-score is used - in this case, -2.5, consistent with a diagnosis of osteoporosis. Although the T-score from the spine is an average, it is not valid to average the T-scores from different skeletal areas (in this example, the average score would be -1.6, which is consistent with osteopenia, not osteoporosis). Third, DEXA

Stress Fx--Eval. for Osteopenia

Report
DEXA BONE MINERAL DENSITY STUDY

INDICATION: Stress fracture. Osteopenia.

The findings include the following T-score results, the patient's percentage of normal compared to young adults, and Z-score results:

Site	T-Score	% Peak Reference	Assessment	Z-Score	% Age Matched
Lumbar Spine	-2.5	74%	Osteoporotic	-2.1	77%
Total Hip	-1.5	81%	Osteopenic	-1.2	83%
Distal Radius	-0.7	94%	Normal	-0.2	98%

IMPRESSION: The patient has borderline osteoporosis.

RECOMMENDATIONS:

1. Continue regular weightbearing exercise (30 minutes per day, at least three times per week).
2. Maintain adequate calcium intake (1000 mg per day) and vitamin D (800 to 1000 IU per day).
3. Consider antiresorptives as a preventative measure.
4. A followup study in two years is suggested.

Images and graphical representations of bone mineral density progression are viewable on the Saint Mary's Healthcare PACS and are also available in color hard copy, which can be sent to the referring physician's office upon request (616-685-6209).

scan analysis and diagnosis should be performed by the attending physician. In the example above, the radiologist's interpretation was borderline osteoporosis, with recommendation to continue weight-bearing exercise (30 min per day, at least three times per week), maintain adequate calcium intake (1,000 mg per day) and vitamin D (800–1,000 IU per day), and consider antiresorptives as preventive measure, with follow-up scans in 2 years. Given the patient history, recent fracture, and lumbar T-score of -2.5 , a diagnosis of osteoporosis with high risk of recurrent fractures is the appropriate diagnosis. Further, in addition to maintaining calcium and vitamin D intake, 25-hydroxyvitamin D levels should be assessed in this patient to determine whether higher supplementation is required. Finally, while follow-up DEXA scans are helpful to monitor patient BMD, the use of antiresorptives is very controversial given the age of this patient, and the mechanism of action of antiresorptives. Because antiresorptives decrease osteoclast activity and bone turnover, they maintain bone, but do not add to bone mass. Recent studies have shown that such adynamic bone can lead to subtrochanteric fractures with long-term use of bisphosphonates [21]. Given this patient's age, an anabolic agent should be considered first if there are no contraindications.

DEXA scans have limitations in that they do not measure bone quality or bone volume. Currently, no single test measures quality of bone. However, the FRAX tool is a mathematical model that predicts the likelihood of fracture in the next 10 years by taking ten risk factors into account (such as smoking and family history of osteoporosis). Knowing the likelihood of fracture, in turn, helps to determine how aggressively to manage bone loss in patients. For instance, although the potential side effects from medications may be great, this may be outweighed by a high risk for fracture and associated morbidity.

Another method of bone assessment is quantitative computed tomography (QCT), which is expensive, but allows greater assessment of bone quality. The use of CT is preferable when differences in size (such as extreme obesity) distort the analysis of bone mineral content [22, 128]. The use of ultrasonography (US) is useful for screening, but this technique is not as reproducible as others. Calcaneal measurements using US are predictive of fracture risk in the hip but are less predictive of fracture risk in the lumbar spine [23].

Management and Prevention

In the elderly, the main result of ongoing changes in bone remodeling physiology is osteoporosis. One of the most important clinical outcomes of osteoporosis is fracture. Fractures heal more slowly and less effectively with advancing age. Over time, the periosteum thins and bone-reforming potential of the periosteal mesenchymal cells decrease

with age, although there is evidence that this is not due to a decrease in the size of the mesenchymal stem cell population [24]. This decline in the rate of fracture repair is probably related to general decrease in bone remodeling, decrease in the expression of cytokines, and a reduction in the inflammatory response to injury [25].

There are a number of treatments currently used to manage bone loss in the elderly. In addition, strategies to reduce the risk of injury are important, as none of the currently available agents can completely reverse bone loss, probably because osteoporosis is so often diagnosed long after significant loss to bone density has occurred. Here, we look at treatments that can reduce the risk of injury (falls) and slow or stop continued bone loss.

Nonpharmacologic

There are several nonpharmacologic methods to reduce the risk of injury resulting from bone loss, including calcium supplementation and vitamin D supplementation, as well as physician counseling on lifestyle choices (tobacco and alcohol use) and fall prevention (via hip protectors, exercise, and balance training). For instance, healthy bone remodeling and mineral density requires adequate calcium intake. Dietary intake of 1,200 mg calcium is the standard recommendation of the National Osteoporosis Foundation in patients 50 years of age and older [26]. While lifestyle choices and fall prevention techniques are beyond the scope of this discussion, we discuss vitamin D supplementation below.

The importance of vitamin D supplementation is clear. Vitamin D supplementation (specifically vitamin D₃, or cholecalciferol) of 400–800 IU is currently recommended in all older patients, although many experts now advise 2,000 IU or more in part because toxicity with overdose is rare [27]. Vitamin D deficiency is commonplace in the elderly, because of decreased absorption in the gut and decreased ability of the skin to produce vitamin D [25]. High doses (800 IU) of vitamin D appear to reduce the risk of vertebral and nonvertebral fractures [28]. Further, 800 IU doses of vitamin D were associated with a lower incidence rate of falls compared to placebo [29].

Pharmacologic Treatment

Currently available treatments for bone loss in the elderly are categorized as antiresorptive or anabolic. Antiresorptive agents decrease the resorption of bone and include bisphosphonates, calcitonin, hormone replacement therapy, and selective estrogen receptor modulators. Anabolic treatments increase bone

formation and include parathyroid hormone injection. These treatments are discussed below.

Antiresorptive Agents

Bisphosphonates: Bisphosphonates are nitrogen-containing compounds that bind bone and decrease the activity and lifespan of osteoclasts. They increase BMD by decreasing the rate of bone resorption. They are commonly prescribed, and there are four available in the US: alendronate, risedonate, ibandronate, and zoledronic acid. Each of these bisphosphonates has been shown to increase BMD and to reduce the risk of vertebral fractures [30–36]. Reductions in the rates of hip fractures have also been demonstrated for alendronate, risedonate, and zoledronic acid [31, 37–39]. Overall, bisphosphonate treatment reduces the incidence of vertebral fractures by 40% or more, depending on the study. Common side effects of bisphosphonate treatment are gastrointestinal irritation and ulceration, although the injectable forms of the drug are associated with fewer of these symptoms. These compounds lead in rare instances to osteonecrosis of the jaw, particularly in those undergoing dental procedures (risk is 1/10,000 to 1/100,000) [40].

Long-term treatment of osteoporosis with bisphosphonates has revealed that bone turnover may become oversuppressed, which results in spontaneous nonspinal fractures. These fractures result from the inability of the bone to withstand deformation before breaking and are likely the result of accumulation of microfractures that result from normal wear and tear on the bone that has not been remodeled [41, 42]. A recent study showed that discontinuation of alendronate after 5 years was not associated with a large increase in bone turnover, suggesting a prolonged persistence of the effects of alendronate [43].

Calcitonin

Calcitonin decreases bone resorption by inhibiting the function of osteoclasts [44, 45]. The result is an increase in BMD and decrease in fragility. A large, 5-year, randomized controlled trial showed a 33% reduction in vertebral fractures when 200 IU calcitonin were administered intranasally daily [44].

Selective Estrogen Receptor Modulators

Selective estrogen receptor modulators (SERMs) bind to estrogen receptors and selectively act as agonists or antagonists. Raloxifene is the only SERM that is approved

for the prevention and treatment of osteoporosis, and it has been shown to increase BMD, decrease vertebral fractures, and appears to have antiresorptive properties [46–49]. Raloxifene use is associated with an increased risk of stroke and thromboembolism, and thus, benefits and risks must be considered with its use in the treatment of osteoporosis [50]. Other SERMs are currently under development which may have antiresorptive effects without such side effects [51].

Estrogen

Estrogen replacement and estrogen plus progestin replacement therapy have been demonstrated to decrease the number of osteoporotic fractures [52, 53]. However, the associated health risks (increased stroke risk, deep vein thrombosis, and increased rates of breast cancer and uterine cancer) precludes the use of estrogen replacement for those with osteoporosis [52, 54].

Anabolic Agents

Teriparatide (parathyroid hormone), the only anabolic agent available in the treatment of postmenopausal osteoporosis, increases bone turnover rates. Long-term subcutaneous injections of teriparatide are associated with a 9–13% increase in BMD in the lumbar spine and decreased risk of vertebral and nonvertebral fractures [55]. In spite of this, teriparatide use is relatively uncommon because of high cost, inconvenience, and potential side effects. Side effects include swelling, pain, weakness, injection-site erythema, and potential for serum hypercalcemia, although the side effects are reduced with longer treatment [56]. Teriparatide use longer than 2 years is not recommended because evidence suggests that the incidence of osteosarcomas is possible, although only 1 human case history of sarcoma in 300,00 patients has been observed [57, 58].

Summary

The treatments for osteoporosis are not curative, and all have potential risks. However, most treatments can modify the disease and decrease the risk of future vertebral, hip, and distal radius fractures. In spite of this, many patients do not receive treatment. Numerous studies have shown that patients treated for their fragility fractures do not have the proper follow-up treatment of osteoporosis [59, 60]. It is imperative that health professionals involved in the acute

care of elderly patients with fractures initiate the process of proper evaluation of their underlying conditions with a DEXA scan and laboratory tests, followed by referral to a physician who is experienced in osteoporosis management. Several studies have shown an improvement in management of osteoporotic patients when using a clinical strategy for management of the disease [61, 62].

Muscle, Tendon, and Ligament

These three types of connective tissues are involved with the movement and protection of the skeleton and joints. Degeneration of these structures in the aging athlete is becoming an increasing problem. As the athlete becomes less flexible, they have an increased incidence of sprains, strains, and overuse injuries. As athletes decrease their BMD and lose the protective effect of these tissues, they become prone to stress fractures [63].

Muscle

Skeletal muscle has a unique skeletal unit, the fiber consisting of a long cylinder cell with hundreds of nuclei. Within each fiber rests a sarcomere composed of actin and myosin filaments that initiate a contraction when the fibers slide past each other. Fibers are encased by endomysium, a loose connective tissue. These fibers are aligned together as fascicles, which are held together by the perimysium. The complete named muscle is surrounded by the epimysium (Fig. 90.6). The ability of the muscle to provide a forceful contraction is related to the physiologic cross-sectional area of the muscle. With aging, both the number of cells and size of these muscle fibers decrease. This results in a decreased ability to generate maximum contraction [64].

Muscle is a contractile tissue, in which individual cells act in concert to produce and cause a movement. Skeletal muscle is anchored to the bone by tendons. These two structures are attached along the musculotendinous border. This area is

FIGURE 90.6 Skeletal muscle structure (reprinted with permission from [64], Fig. 1).

the most susceptible to injury [65]. Skeletal muscle makes up approximately 40% (females) to 50% (male) of the adult mass. There are two types of fibers, type I, or slow twitch, and type II, or fast twitch [64].

Similar to bone, peak muscle mass is reached by about 30 years of age. Muscle mass is progressively lost after that at a rate of about 4% per decade between the ages 20 and 30, and at 10% per decade after the early 50s [66]. Both the size and number of muscle cells decrease with age, resulting in sarcopenia and decreased muscle strength. Muscle atrophy results from the loss of both type I and type II fibers. Type II muscle fibers lose more size compared with size loss in type I fibers and hence much of the age-related decrease in muscle strength is attributable to loss of these fibers. Muscle loss is accelerated when levels of growth hormone, testosterone, or thyroxine decrease. Further, more muscle is lost in weight-bearing muscles compared to nonweight-bearing muscles. Evidence of these changes are shown in athletic performance as maximal running and swimming velocities for sprint and endurance events decline from the third to eighth decades [67].

These physiologic changes predispose the aging athlete to muscle strain, which results from forcible stretching of a muscle. Histological studies have shown that muscle strain injuries cause a disruption of muscle fibers a short distance from the myotendinous junction. The patient presents with acute pain experienced during intense activity. Muscles that are frequently involved cross two joints, act mainly in an eccentric fashion, and contain a high percentage of fast-twitch fibers. Diagnosis relies on history and exam. Rarely is an MRI indicated. Initial treatment consists of rest, ice, and compression. As pain subsides, physical therapy should be initiated to restore flexibility and strength [65].

Most muscle injuries heal, but some result in incomplete functional recovery. Because of this, the current research is evaluating the use of human recombinant growth factors to regenerate muscle, gene therapy to deliver growth factors to injured muscle, and antifibrotic therapy [64]. Until treatment is developed that restores function in these injuries, prevention is the key. Methods to decrease the risk of injury include decreasing fatigue [68], warming up the muscle [69], and preconditioning the muscle [70]. Also, to prevent injury and improve long-term function, aging patients can benefit from regular weight-bearing exercise to increase strength and muscle mass [71, 72].

Tendons

Tendon connects muscle to bone and functions to withstand tension. It is noncontractile and consists of a tough band of fibrous connective tissue composed mostly of parallel type I

FIGURE 90.7 Tendon structure (reprinted with permission from ([79], p 188, Fig. 1).

collagen that is cross-linked to fascicles and tertiary bundles [73–75]. Cellular elements of tendon consist of tenocytes and tenoblasts that lie between the collagen fibers along the long axis of the tendon [76], and other cells include chondrocytes at the bone attachment and insertion sites, synovial cells of the tendon sheath, and vascular cells (Fig. 90.7). Elastin, though limited to 2% of the dry mass of tendons, is very important to allow the tendon to adapt to function and to lengthen in response to stress.

After maturation, tendons undergo many changes that bring about a general decline in structure and function beginning in the third decade. There is a decreased vascularity and cellularity leading to reduced collagen turnover, decreased proteoglycan and water content, and an increase in insoluble collagen. Together, these cause the tendon to become stiffer and less compliant. This decline in the aging tendon is characterized by a reduced ability to adapt to environmental stress and loss of function [77]. Among the many changes, part of the tendon insertion becomes hypovascular [78, 79]. Because of this, metabolic pathways shift from aerobic to more anaerobic energy production [80]. Microscopically, older fibroblasts appear flatter and possess fewer protein-producing organelles, such as Golgi and endoplasmic reticuli [25]. Tensile strength reaches a plateau and declines with age [81]. This decline is related to decreases in total collagen content [82]. The loss of collagen and its cross-linking, as well as the changes in elastin, leads to an increase in tendon stiffness [83, 84].

These physiologic changes predispose the aging laborer and athlete to several pathologic conditions including tendinopathy and spontaneous, low-energy tendon rupture. When patients present with overuse conditions affecting tendons, clinicians frequently use tendonitis or tendinosis to define the entity. Histological exam of the tissue supports the use of tendinopathy as the proper clinical entity. This disorder shows haphazard healing with an absence of inflammatory cells,

FIGURE 90.8 Photomicrograph of severe tendinopathy (reprinted with permission from [78]).

noninflammatory collagen degeneration, fiber disorientation, hypercellularity, scattered vascular ingrowth, and increased interfibrillar glycosaminoglycans [85–87] (Fig. 90.8). In these patients, avoidance of aggravating activities, and conservative treatment is initiated which may include anti-inflammatories, local cortisone injections, and physical therapy. These common modalities can be helpful though no controlled studies have shown Level 1 evidence to support their use. Corticosteroid injections need to be judiciously used because they can inhibit protein synthesis, leading to collagen thinning and can predispose the tendon to rupture [88, 90] (Fig. 90.9). Operative treatment is reserved for patients who fail conservative treatment. Although there are several different techniques depending on the tendon involved, surgery is intended to revitalize, debride, and bypass the area of tendinopathy [78].

Treatment of these tendinopathy conditions is important to avoid tendon rupture. In fact, most laypeople think of tendon ruptures in young healthy athletes, but tendon ruptures generally affect patients as they age [90]. Spontaneous rupture of healthy tendons almost never occurs: preexisting degenerative histologic changes are present almost always. Clinically, tendon ruptures are important injuries to be diagnosed and treated urgently to maintain long-term function. Physical exam by an experienced musculoskeletal physician can detect these ruptures by palpation of structures, loss of active joint motion, and occasionally radiographic findings. If the diagnosis is uncertain or referral to a musculoskeletal physician cannot be arranged quickly, then an MRI can be helpful in confirming the diagnosis. Although the individual timing varies, surgical repair of tendon ruptures need to be performed within an early time frame to provide the best results. For example, rupture of the flexor digitorum profundus to the hand (“Jersey finger”) needs to be performed

FIGURE 90.9 Degeneration of tendon structure due to repeated corticosteroid injection (reprinted with permission from [78]).

within the first week. Ruptures of the achilles, patella, quadriceps, and distal biceps need to be performed within the first 3 weeks. Acute rotator cuff repairs can be delayed but still have the most reliable results if performed within the first 3 months.

Ligament

Ligaments are dense connective tissues composed mostly of type I collagen. Their ultrastructure is similar to that of tendons, but their fibers are more variable and have a higher elastin content [91]. Ligaments attach to the bone at both its origin and insertion. They function to provide stability to joints and proprioception. Mechanoreceptors and free nerve endings help ligaments provide feedback to the neuromuscular system to avoid injury.

As ligaments mature, they undergo an increased number and quality of collagen cross-links with a concomitant increase in fibril diameter [92]. After maturation, collagen content decreases which contributes to the gradual decline in the mechanical properties of ligaments. This loss of ultimate tensile strength, increase in stiffness, and inability to withstand deformation make the ligaments and the joint they protect at risk for deformity and injury (Fig. 90.10). Ligament insertions into bone also become weak and can lead to avulsion fractures. In addition, studies have suggested that the number of mechanoreceptors in ligaments decreases with age resulting in the inability to process where the joint is in space [93].

The physiologic changes in ligaments can lead to several different clinic problems. First, the ligament can attenuate, lengthen, and lose its ability to provide stability. For example,

FIGURE 90.10 Grading ligament sprains.

the loss of ligament integrity can allow the arthritic joint to become more deformed, accelerating degeneration and causing pain. For surgeons, joint replacement, paying attention to rebalance the ligament structures, especially in the knee, is very important to the success of the surgery [94].

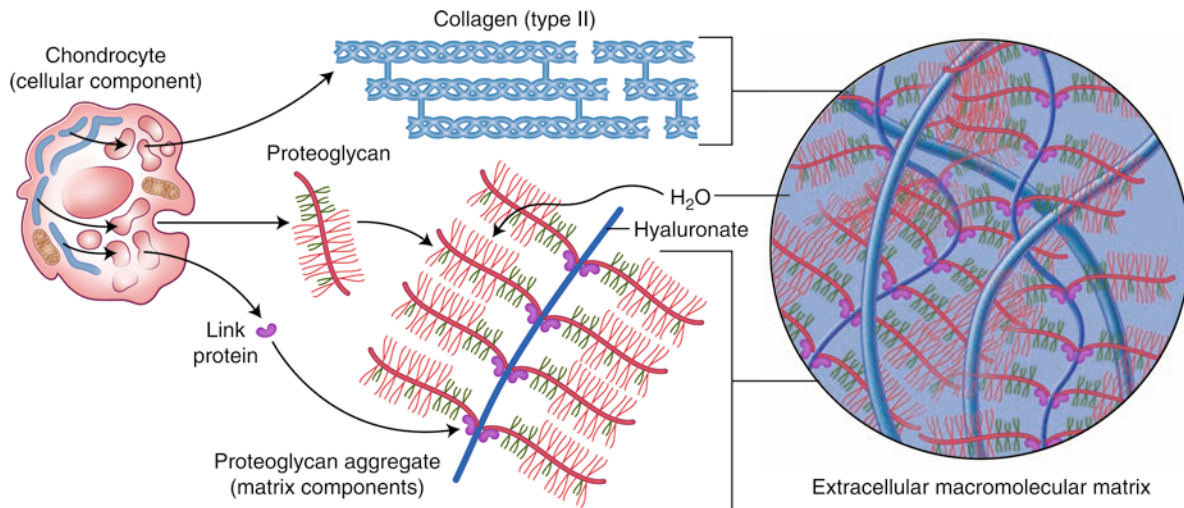

Another clinical entity involves acute trauma to the ligament at the ligament–bone interface, causing an avulsion fracture. Ligament tears are described as degrees of sprain. Grade I involves mild stretching of the ligament. Grade II causes the ligament to tear, but still maintains continuity, and Grade III results in tearing and separation of the fiber ends. Treatment and recovery depends on the individual patient and the joint involved.

One interesting example of a ligament tear is the anterior cruciate ligament (ACL) of the knee. If this ligament completely tears, it will not heal or reconstitute itself. This is becoming more common because many older patients are participating in high-impact sports that increase the risk of an ACL tear. Historically, middle-age patients who have sustained ACL tears have been offered conservative treatment with rehabilitation and avoidance of activities that require them to quickly change directions. But, as patients' expectations and lifestyles have changed, many opt for surgical reconstructions. A recent study has confirmed that in carefully selected patients of 50 years of age and older, surgical reconstruction of the ACL can achieve similar results to those in younger patients with no increased complications [95].

Articular Cartilage

Articular cartilage is an amazing structure. It provides pain-free and almost frictionless motion. In fact, the coefficient of friction (0.003–0.006) is significantly less than ice (0.1 at 0°C). Designers of joint replacements have tried to develop bearing surfaces such as metal on metal, ceramic on ceramic, and highly cross-linked polyethylene and metal, but none has been able to come close to the wear properties of healthy articular cartilage. The resiliency and durability of cartilage are due to their histological infrastructure and physical arrangement. However, cartilage is poorly regenerative.

Normal hyaline cartilage consists of a matrix of proteoglycan aggregates, type II collagen and chondrocytes [96]. Like other soft tissues, cartilage is composed mostly of water (80% of wet weight). Large proteoglycans consist of a core structure of hyaluronate (unsulfated glycosaminoglycan). Link proteins branch off of this structure and provide a surface for aggrecan molecules, composed of a core protein and radiating glycosaminoglycan chains. The chains are extremely important because, along with the collagen bundles, they provide compressive strength and load-absorbing properties. The main molecules are chondroitin-4-sulfate, chondroitin-6-sulfate, and keratan sulfate. The relative proportion of each of these glycosaminoglycan chains changes over time and is unique in each individual. The hydrophilic nature and high density of negative charges underlie articular cartilage resiliency (Fig. 90.11).

Cartilage is a very complex unique structure able to resist high compressive loads. Early in life, chondrocytes, the cells, produce collagen fibrils and the ground substance, proteoglycans that provide the backbone for cartilage. In aging, the body loses the ability to generate this matrix and repair damage.

The cartilage relies on a certain proportion of water to optimize its function. The interaction of the collagen fibrils and the negatively charged glycosaminoglycans produce a matrix that attracts water.

FIGURE 90.11 Composition of articular cartilage.

This matrix is woven into a complex anatomical structure that provides the unique mechanical properties. These different microscopic structures are orientated differently depending on the depth and layer of the cartilage which changes from the articular surface to the subchondral bone. The organization of these layers includes the superficial zone, the middle zone, the deep zone, the tidemark, and the calcified zone before anchoring to the subchondral bone (Fig. 90.12). The alignment of the chondrocytes differs depending on the layer. The superficial zone, the gliding zone, possesses chondrocytes that are flattened and parallel to the joint with low amounts of proteoglycans. The middle zone shows spherical chondrocytes and large amounts of proteoglycans. The deep

layer contains larger spherical chondrocytes and the highest concentration of proteoglycans but the lowest water content. The calcified zone contains collagen fibrils that help anchor the cartilage to the bone by passing from the radial deep zone through the tidemark to the subchondral bone [96].

Despite the resiliency of cartilage, it undergoes age-related changes because chondrocytes do not reproduce themselves. There is a debate concerning the relationship between age-related changes and the development of degenerative arthritis. The biochemical changes differ, and while aging does not always lead to arthritis, it is a risk factor, since more than 50% of those over the age of 65 have radiographic evidence and symptoms of osteoarthritis [97, 98].

FIGURE 90.12 Structure of articular cartilage.

In aging, the large proteoglycan structures, chondroitin sulfate and keratin sulfate, which form a compressive hydration gel by binding to hyaluronan via link protein, decrease in the amount present and change in ratio. The amount of chondroitin sulfate decreases, and the amount of keratin sulfate increases [99]. This leads to a decrease in water content and an increase in the stiffness of the tissue. Collagen remains relatively unchanged, but the number and size of chondrocytes decrease. In addition, the levels of advanced glycation end product pentosidine, which are low up to 20 years of age, increase linearly after that. Higher pentoside levels are associated with a stiffer collagen network. The resulting matrix articular cartilage that is lost or damaged is replaced slowly, leading to fraying of articular cartilage [100]. Damage is difficult to repair also, since chondrocytes are not migratory but are bound by lacunae within the tissue.

Arthritis, on the other hand, leads to distinct biochemical changes. The proteoglycans decrease, and their ratio changes. In contrast to aging, chondroitin sulfate increases and keratin sulfate decreases with osteoarthritis. This as well as the damage to the structural integrity of cartilage leads to an increased water content, causing increased permeability, decreased strength, and decreased modulus of elasticity. Collagen content decreases, and collagen becomes disorganized. Hyaluronan and its link proteins fragment and become smaller.

The outward appearance of cartilage changes as the joint deteriorates. The pristine white color darkens. The surface

may soften, fissure, and flake off. Eventually, full thickness loss of cartilage occurs, and the subchondral bone becomes eburnated. Radiographically, the joint space narrows, the subchondral bone appears sclerotic, osteophytes form, and the joint deforms (Fig. 90.13). There is some debate as to what to call this process. These kinds of changes have been called osteoarthritis. However, the suffix, “itis,” means “inflammation.” Most consider this to be wear and tear arthritis and suggest that the term osteoarthrosis might be more appropriate. A new theory based on recent studies is that chondrocytes are actively releasing catabolic enzymes such as interleukin-1, neutral proteases, and metalloproteinases, causing degeneration that *can lead to* inflammation and cause further degenerative changes [101, 102]. In general, aging is different than degenerative arthritis but aging results in the loss of tensile properties of cartilage, leading to a loss of stiffness, fatigue resistance, and strength [96]. Intuitively, these changes cause susceptibility to damage from the daily repetitive microtrauma of the joints and may be the precursor that allows the development of early degenerative changes.

Evaluation of osteoarthritis should begin with history, physical exam, and radiographs. Before obtaining radiographs, it is helpful to have an understanding of the best views for diagnosis. For most patients, weight-bearing views will fully visualize the amount of joint space loss and deformity present, which might not be evident in nonweight-bearing views. There are several grading systems all with some

FIGURE 90.13 Histopathology of osteoarthritis.

inherent difficulties in intra and interobserver reliability. One of the most common is the Kellgren and Lawrence system using levels I–IV [103, 104]. Grades I and II are considered mild. Grade III is considered moderate, and Grade IV is severe bone-on-bone arthritis. Currently, MRIs are frequently used for assessment of arthritis. However, these tests should be ordered infrequently in elderly patients with arthritis

symptoms. Studies have shown that after a certain age, almost every patient – even those that are asymptomatic – will have a surgical lesion on MRI. For instance, knee MRIs are frequently obtained to detect a degenerative meniscus tear even though the patient already has advanced degenerative changes. Such MRIs almost always are read as a meniscus tear, but they really just indicate that the knee is

undergoing degeneration. In several studies, asymptomatic patients over the age of 65 underwent an MRI of their knee, and despite a lack of symptoms, 75% had a meniscus tear read by the radiologist on their MRI [105, 106].

Clinical management of degenerative arthritis includes treatment of the symptoms and halting progression. Although a full discussion of the treatment of degenerative arthritis is beyond the scope of this chapter, it involves activity modification, weight reduction, use of non forceful stretching and strengthening, pharmacologic intervention with Tylenol, nonsteroidal anti-inflammatories, nonaddictive pain medications, use of external aids and injections with either cortisone or synovial fluid replacement. Recent attempts to reverse the process and regenerate cartilage have not been successful. Several different types of treatments have been touted to alter the natural history of the disease including glucosamine/chondroitin sulfate [107, 108], electrical stimulation [109, 110], and synovial fluid replacements [111–113]. These treatments have demonstrated efficacy in decreasing pain and improving function. However, none of these adjunctive modalities is supported by Level 1 evidence that they produce changes to aging or degenerative cartilage to produce structurally or biomechanically normal articular hyaline cartilage [111–113].

Surgery can be an option to treat degenerative arthritis, but there are still no surgical options to help the body regrow hyaline cartilage. For instance, the efficacy of arthroscopic procedures of the knee for debridement of arthritis and for degenerative meniscus tears is questionable. Two recent studies comparing arthroscopic and conservative treatment have shown no clinically significant differences at 2 years when treating either degenerative meniscus tears or degenerative arthritis [114, 115]. In addition, Mosely et al. NEJM randomized 180 patients with knee OA into sham surgery, arthroscopic lavage, and arthroscopic lavage and debridement and found no difference in pain and function [116]. Despite these findings, arthroscopy does seem to play a role in treatment of patients with mild degenerative arthritis who present with a degenerative meniscus tear. However, it is important to select only those patients with mild OA and clinical findings consistent with mechanical symptoms of catching and locking with pinpoint pain on the posterior joint line [117].

There have been two procedures claiming to replace cartilage by transplantation, namely, the osteoarticular transplantation system (OATS) and autologous chondrocyte implantation (ACI) (Figs. 90.14 and 90.15). These two procedures cannot reverse global degenerative arthritis and can only be used to treat focal defects in the weight-bearing articular cartilage of joints. The OATs procedure involves taking plugs of bone and cartilage from nonarticular parts of the joint to fill in the defects. In the ACI procedure, cartilage cells are harvested and then grown in vitro. They are then

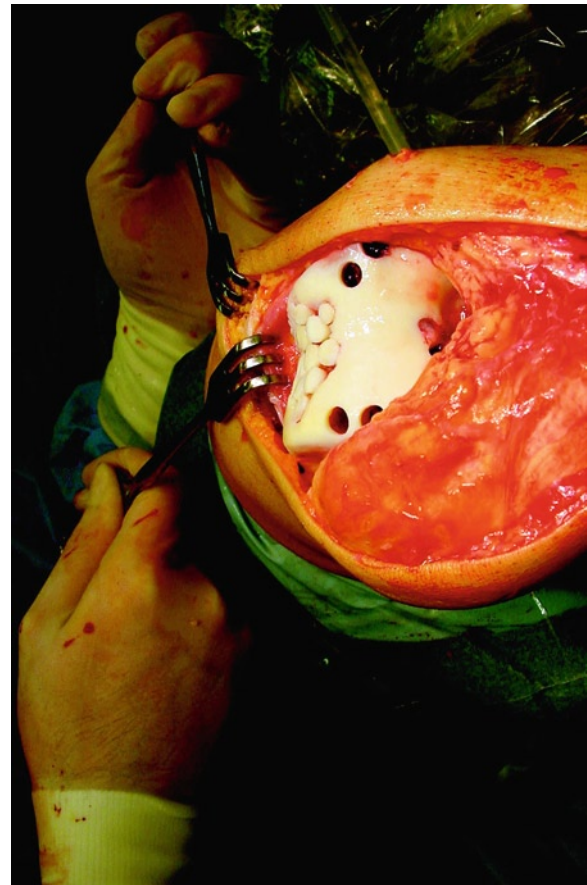

FIGURE 90.14 OATS procedure (osteoarticular transplant system) (reprinted with permission from Hangody L, Fules P (2003) Autologous osteochondral mosaicplasty for the treatment of full-thickness defects of weight-bearing joints: ten years of experimental and clinical experience. *J Bone Joint Surg* 84-A(Suppl 2):25–32).

placed in the defective area and held in place with a periosteal patch. Both procedures have shown positive results. On follow-up arthroscopy, the areas do seem to be filled with very similar-looking cartilage macroscopically. But, histopathologically, these specimens are not characteristic of hyaline cartilage and are more characteristic of fibrocartilage (scar cartilage) [118–121]. Definitive treatment for degenerative arthritis requires either joint fusion or total joint replacement [122, 123].

Intervertebral Disc

Intervertebral disc is a fibrocartilaginous soft tissue found between the vertebrae which functions to absorb the stress placed on the spine. One of the most common complaints of middle-aged and older patients is back pain, thought to result in part from the changes in intervertebral disc. Fissures and

FIGURE 90.15 Autologous chondrocyte implantation.

cracks appear in the intervertebral disc which begin in the periphery (annulus) and extend to the central region (nucleus). During the aging process, the collagen content of the annuli increases both outward in the disc and downward along the levels of the spinal. There is a concomitant decrease in proteoglycan and water content [124]. These changes in chemical composition apparently lead to stiffness and pain in the back [125]. Additionally, these age-related changes may result in disc herniation and nerve compression resulting from spinal stenosis [124].

Treatment options are limited. Degradation of intervertebral disc tissue with enzymatic injections has been a current focus of research and can stimulate regeneration. So far, experiments using such injections show regeneration of intervertebral disc in older animals, but results are not consistent [126]. Also, disc transplantation is an area that is currently under investigation [127].

Conclusion

As the population of elderly people increases, so too will age-related injuries and degenerative disease of the musculoskeletal system. Attempts at regenerative medicine using both traditional and alternative treatments have become popular. In fact, patients spend huge sums of health-care dollars on unproven alternative and complementary products claiming to reverse the aging process. For some treatments, there has been some promising preliminary research, but clinical application is a long way off. The best current advice for patients to decrease age-related degeneration and disease is to stay active, engage in weight-bearing, aerobic, and balance exercise, maintain proper nutrition, and use proven supplements including vitamins such as calcium and vitamin D.

When injury occurs, orthopaedic surgeons may need to adjust current standards of practice in elderly patients.

Traditionally, treatment has been conservative. However, patients are living much longer than previously, and more have active lives. Longitudinal studies on the benefits and risks of choosing conservative or aggressive treatment for injury are needed so that surgeons and patients can be better informed. For instance, the patients in their 70s with a chronic attritional tear of the rotator cuff are traditionally treated conservatively. However, if these patients live well into their 90s, and continue to be healthy and otherwise active, more than likely they will develop a difficult problem of rotator cuff arthropathy. This outcome may be far worse than the results from initially treating the injury aggressively. This kind of issue will play a prominent role in the near future, and surgeons must rethink standard treatment plans in this age group.

Chapter 91

Common Benign and Malignant Skin Lesions

Marcus A. McFerren and David J. Leffell

The elderly patient presents us with a variety of benign and malignant skin lesions. The ability to differentiate various cutaneous neoplasms is especially important in the geriatric population because of the higher incidence of malignant skin tumors that arise in aging skin. The aim of this chapter is to acquaint the surgeon with normal skin anatomy, with changes in skin anatomy during aging, and with the pathophysiology, diagnosis, and treatment of common benign and malignant skin tumors of the elderly.

In general, we recommend an annual total body skin examination for any elderly patient who has any of the following independent risk factors: fair skin color; history of blonde, red, or light-colored hair; green, gray, or blue eye color; a family or personal history of skin cancer; chronic occupational or recreational exposure to the sun; a history of sunburns; or anyone with numerous or atypical nevi. Many patients with a personal history of skin cancer should be seen every 6–12 months.

Basic Skin Anatomy

The skin is composed of two layers: a stratified squamous epithelial layer, or epidermis, and an underlying connective tissue layer, or dermis. The interface between these two layers is termed the dermal–epidermal junction and is characterized by downward folds of the epidermis into the dermis. These folds, called rete ridges, provide mechanical support against shearing forces. Embryologic downgrowths of epithelium into the dermis give rise to epidermal appendages such as hair follicles, sweat glands, and sebaceous glands. Beneath the dermis lies a fatty layer of subcutaneous tissue that serves to insulate and protect the underlying structures.

Epidermis

The ectoderm-derived epidermis is comprised of four cell types: keratinocytes, melanocytes, Langerhans' cells, and Merkel cells. Keratinocytes are specialized stratified squamous epithelial cells that make up most of the epidermis. As keratinocytes migrate upward from their origin at the dermal–epidermal junction, they differentiate, forming four morphologically distinct layers. The innermost layer, which contains the germinative keratinocytes, is called the stratum basale. Immediately above the stratum basale, keratinocytes enlarge to form the stratum spinosum, or prickle cell layer. Progressive maturation leads to the accumulation of intracellular keratohyalin granules, giving rise to the next cell layer called the stratum granulosum.

Keratinocytes at the outermost portion of the stratum granulosum lose their nuclei and fuse to form a cornified layer or stratum corneum. These dead keratinocytes function to protect the underlying cells and prevent dehydration. They are eventually exfoliated at a rate that matches the production of cells at the basal layer.

Neuroectoderm-derived melanocytes, which comprise 1% of epidermal cells, are located in the basal layer of the epidermis. They synthesize melanin, which is taken up by nearby keratinocytes and serves to protect the skin from penetration of ultraviolet light, which can damage underlying epidermal and dermal cells. Langerhans cells make up 3–5% of the epidermal cell population. They are derived from cells of the monocyte/macrophage lineage and act as antigen-presenting cells in the skin. Merkel cells are the least abundant cells of the epidermis, comprising less than 1% of all epidermal cells. Their origin is uncertain, either arising from the neural crest or as modified pluripotent amine precursor uptake and decarboxylation (APUD) lineage neuroendocrine keratinocytes. Like melanocytes, they are also located in the basal layer of the epidermis. They function as mechanoreceptors as well as in the induction of the perifollicular nerve plexus during development.

Dermis

The mesoderm-derived dermis sits just below the avascular epidermis, supplying it with a rich neurovascular system. Histologically, the dermis can be divided into two layers. Occupying the space around the rete ridges is the superficial papillary dermis, which is composed of a loosely woven arrangement of connective tissue bundles. Beneath it lies the reticular dermis, so named for its denser, interwoven pattern of connective tissue fibers. The resident cells of the dermis are mostly fibroblasts, which secrete collagen, elastin, and ground substance. Collagen and elastin give the skin its toughness, distensibility, and flexibility. Ground substance, which is comprised of polysaccharides and proteins, provides a supportive matrix for the connective tissue fibers. The overall structure accommodates the network of vascular, lymphatic, and nerve plexi that supply the skin. Other cellular constituents of the dermis include mast cells, macrophages, lymphocytes, and other leukocytes.

Epidermal Appendages

During embryologic development, epidermal cells invaginate and migrate into the dermis forming adnexal structures such as hair follicles, sebaceous glands, and eccrine and apocrine sweat glands collectively termed epidermal appendages. Hair follicles are composed of modified keratinocytes that form a tubular structure enclosed by a collagenous sheath. Each hair follicle is associated with one or more sebaceous glands, which secrete sebum, an oily viscous fluid composed of triglycerides, free fatty acids, wax monoesters, squalenes, and sterols. Sebum functions to help moisturize and waterproof skin and hair. Apocrine glands are modified sweat glands located in the axillae and groin. Like sebaceous glands, they secrete their product into the follicular lumen. In some mammals, they have a demonstrated pheromonal function in territory marking and sexual communication [1]. In humans, their role is uncertain. With the exception of the groin and axillae, the remainder of skin is covered by eccrine sweat glands. These glands are thermoregulatory in their capacity to secrete sweat and immunologic in their capacity to excrete active cytokines [2]. They are independent of the hair follicle having ducts that open directly onto the skin surface.

Skin Function

The basic functions of the epidermis, dermis, and epidermal appendages include that of a physical barrier as well as homeostasis, thermoregulation, immunologic defense,

communication, and sensation. As a physical barrier, the skin protects the body from ultraviolet radiation-associated DNA damage, microorganisms, and toxic chemicals. Far more than simply a sheet of protective wrap, the skin continually regenerates itself by sloughing off damaged cells, and providing a fresh interface for the ever-changing environment. Central to its barrier function is the maintenance of water balance and protection against dehydration. Not all water loss is damaging, however, and eccrine gland-mediated evaporative water loss is critical to thermoregulation. In the battle against microbial invaders, the skin provides the first line of defense. The skin hosts both adaptive and innate immune functions; in the skin itself, circulating lymphocytes and antibodies encounter foreign materials and activate antigen-presenting cells. Cathelicidins, neutrophil-derived polypeptides resident in the skin, also function in antimicrobial defense and cell–cell signaling [3]. Additionally, it is often a fundamental disruption in the immunologic function of the skin that facilitates the development of cutaneous malignancies. In social interaction, the communication and sensory functions of the skin are intertwined. Skin and hair are central to our mechanisms of physical attraction. Neural modulation of the cutaneous blood supply conveys information in interpersonal communication, and the skin is the organ through which touch, temperature, itch, pleasure, and pain are perceived.

Changes in the Skin Associated with Aging

The intrinsic changes that occur in aging skin are important for understanding the pathophysiology of benign and malignant lesions that affect senescent skin.

Epidermis

Between the third and seventh decades, the turnover rate of keratinocytes is reduced by 50% [4]. The slower epidermal turnover rate increases the duration of keratinocyte exposure to carcinogens such as ultraviolet radiation, making the epidermis more susceptible to the development of keratinocytic neoplasms. Decreased proliferative capacity of keratinocytes also prolongs wound healing.

The aging epidermis also undergoes structural alterations. The rete pegs at the dermal–epidermal junction retract, making elderly skin more susceptible to shearing forces. Keratinocytes in the basal layer become increasingly pleomorphic, displaying variations in size, shape, and staining pattern [5]. With age, the stratum corneum increases in thickness due to a slower rate of desquamation. This thicker

stratum corneum has reduced intercellular lipid content and reduced water-binding capacity, predisposing aging skin to xerosis, or drying, with cracking, compromised barrier function, and subsequent irritation and inflammation [6, 7].

Melanocytes also undergo age-related decrease in number over time. After age 30, the surviving population of melanocytes drops by 8–20% each decade [8]. As a result, less melanin is produced which allows greater penetration of ultraviolet radiation resulting in an increase in the risk of developing skin cancer. Like melanocytes, Langerhans cells also diminish in number with age. Langerhans cells are especially sensitive to UV radiation and are further functionally impaired by the age-related decrease in protective melanin. This UV-induced immune suppression compromises the cell-mediated immune response in elderly skin, thereby more readily permitting the development of tumors.

Dermis

As the skin ages, the dermis thins and becomes less vascular. Collagen fibers become thickened, less resilient, and the dermis becomes more susceptible to shearing injuries. Elastin fibers display structural degradative changes, resulting in skin laxity and wrinkle formation [5]. The amount of ground substance decreases, reducing the supportive dermal matrix, and so structures such as blood vessels become more susceptible to damage. This manifests clinically as easy bruising in the elderly. Thinning of vessel walls may also contribute to the increased susceptibility to ecchymoses. Other changes in cutaneous vasculature include a decrease in the density of vessels. Diminished cutaneous circulation can lead to impaired clearance of foreign material, delayed wound healing, and diminished thermoregulatory capacity. The aging skin also loses its ability to mount an inflammatory response, leading to muted clinical presentations of cutaneous disease.

Epidermal Appendages

Marked age-related changes also occur in the epidermal appendages. There is an overall reduction in the number and function of eccrine sweat glands, leading to a decrease in thermoregulatory capacity. Apocrine glands attenuate and accumulate lipofuscin with a resultant reduction in secretory function [6]. Sebaceous glands enlarge with age, but their sebum production is paradoxically reduced. These changes in sebaceous glands manifest clinically as sebaceous hyperplasia and xerosis.

Benign Lesions

Epidermal Lesions

Seborrheic Keratoses

Seborrheic keratoses are common, benign, flat-topped papules or plaques that are composed of hyperproliferating keratinocytes. They typically appear during the fifth decade, though early lesions can present in the fourth decade. Early lesions manifest as discrete 1- to 3-cm skin-colored to dark-brown patches that progress to form slightly elevated, warty, greasy plaques. Their exophytic growth pattern makes them appear “stuck on.” [9] Although seborrheic keratoses can be found on any part of the body, they are most prevalent on the face and upper trunk (Fig. 91.1). Males and females are equally affected; the lesions occur more frequently in whites.

A histologically identical variant of the seborrheic keratosis, dermatosis papulosa nigra, is commonly found in patients with darkly pigmented skin. Clinically, these lesions present as multiple 0.1–1.0 cm rough brown to black papules of the face. They are especially common on the malar cheeks, forehead, neck, back, and chest.

FIGURE 91.1 Seborrheic keratosis, the most common benign cutaneous tumor in the elderly. Its significance lies in its potential to mimic malignant melanoma. Although treatment is not normally indicated, the lesion, which may appear rough or greasy, may be irritated necessitating removal. Alternatively, if there is suspicion about melanoma, biopsy is indicated.

The number of lesions on any given individual can vary from one or two up to hundreds [9], often increasing in number as the patient ages. Once formed, seborrheic keratoses are permanent, remaining in place unchanged for the lifetime of the individual. Seborrheic keratoses are benign and have no malignant potential. However, the eruption of multiple lesions in a short duration of time, known as the sign of Leser–Trelat, has historically been thought to point to internal malignancy, particularly gastrointestinal adenocarcinoma, breast carcinoma, and lymphoma. Despite a large number of case reports and anecdotal evidence in support of an association between widespread eruptive seborrheic keratoses and internal malignancy, the data to support this phenomenon as a true paraneoplastic process is largely lacking [10]. Multiple seborrheic keratoses may, however, occur as a familial trait with autosomal dominant inheritance or may be precipitated by an inflammatory dermatosis.

Histologically, seborrheic keratoses show accumulation of immature keratinocytes with papillomatosis between the basal layer and stratum corneum. Focal keratinization may occur, leading to the formation of horn cysts within the lesion. Melanocytes usually proliferate in the lesion and transfer melanin to immature keratinocytes, accounting for the wide spectrum of color the lesions can acquire.

The diagnosis of seborrheic keratoses is made clinically. Some early lesions may be confused with solar lentigos or pigmented actinic keratoses. Differentiation may be made upon closer inspection with a hand lens, which can reveal a characteristic verrucous appearance and at times the presence of horn cysts. Late lesions may resemble a pigmented basal cell carcinoma (BCC) or malignant melanoma. If a lesion is thought to be a BCC, a shave biopsy is recommended. For lesions suspicious for malignant melanoma, an excisional biopsy should be performed.

Although seborrheic keratoses require no therapy, some patients prefer to have them removed for cosmetic reasons. Treatment should be rapid and nonscarring. This can be accomplished with light curettage, which destroys the superficial layer of the epidermis and minimizes the risk of scarring. The potential for regrowth exists. Should this occur, retreatment may be performed as necessary. Electrodesiccation should be avoided, as it may cause excessive scarring [11]. If the clinical diagnosis is unclear, a shave biopsy should be performed.

Solar Lentigo (Senile Lentigo, Actinic Lentigo)

Chronic sun exposure can induce melanocytes to proliferate locally forming multiple 0.5–2.0 cm brown macules known as solar lentigos, “liver spots” or “age spots.” Their presence in more than 90% of individuals over the age of 70 has led to the unflattering descriptive term “senile lentigo,” but they are often found on light-skinned persons of any age. These lesions are

FIGURE 91.2 Solar lentigo, seen mostly on the face and dorsa of the hands, has tan to brown pigmentation and is flat. They may be of cosmetic concern and occasionally must be biopsied to rule out lentigo maligna.

localized to sun-exposed areas, such as the cheek, forehead, nose, dorsa of hands and forearms, upper back, and chest (Fig. 91.2). They affect males and females equally and are more commonly seen in Caucasians than in Asians.

Solar lentigos can be confused with other benign lesions, such as early seborrheic keratoses, and premalignant lesions such as pigmented actinic keratoses and lentigo maligna. To differentiate solar lentigos from seborrheic keratoses and pigmented actinic keratoses, the lesion must be examined with a hand lens in oblique light. Seborrheic keratoses and pigmented actinic keratoses generally display features of epidermal change, whereas solar lentigos are completely flat. Lentigo maligna, like solar lentigo, may not show epidermal changes. However, it has distinct variations in color from light brown to dark brown with flecks of black. If any lentigo has an irregular border, change in pigment, or focal thickening, a biopsy should be performed to exclude lentigo maligna.

Histologically, solar lentigos display elongated, club-shaped rete ridges containing numerous melanocytes and increased melanin production without cellular atypia or nest formation. Most solar lentigos have virtually no malignant potential. Rarely, a small proportion of lesions occurring on the face slowly develop into lentigo maligna [9]. The incidence of malignant transformation is so rare, however, that most lesions require no treatment. If the patient finds these “age spots” cosmetically unacceptable, treatment can be accomplished in several ways. Topical and physical therapies including cryotherapy, laser, and dermabrasion have been investigated. Cryotherapy and topical retinoids, particularly 0.05% retinoic acid, have demonstrated good effect in randomized controlled trials. Among laser treatments, Q-switched ruby and 532 nm Nd:Yag have been shown effective in controlled trials without randomization [12]. Application of bleaching agents may decrease the pigment, but ongoing treatment is necessary. For those seeking treatment, the use of sunscreen to prevent new lesions should be emphasized.

Melanocytic Nevocellular Nevi (Moles)

Benign nevocellular nevi, or moles, are small, well-circumscribed macules and papules that vary in color from skin-colored to tan and brown (Fig. 91.3). They are composed of nests of melanocytes located in the epidermis, dermis, and rarely subcutaneous tissue. If the cluster of melanocytes is localized to the dermal–epidermal junction, the nevus is classified as a junctional nevus; if the cells are in the dermis, it is called a dermal nevus; and if there are features of both, the lesion is referred to as a compound nevus. Dermal nevi may be pigmented, nonpigmented, smooth, or have a verrucous surface.

Nevocellular lesions are acquired during childhood and early adulthood. They typically increase in number up to the age of 40, following which they begin to involute. With the exception of dermal nevi, most nevocellular nevi disappear by the age of 60. As some junctional and compound nevi age, their melanocytes migrate into the dermis and assume features of dermal nevi. If new nevocellular lesions are acquired after mid-adulthood, they should be regarded with a high degree of suspicion and closely followed to rule out the development of malignancy [13].

Benign Dermal Lesions

Acrochordons (Skin Tags)

Skin tags are soft, pliable, skin-colored to tan-brown pedunculated polyps that occur in intertriginous areas such as the neck and axillae. They are common in middle-aged and elderly individuals, with at least 50% of individuals above the age of 50 having at least one [14]. Over time, they can become larger and more numerous. Skin tags are especially

FIGURE 91.3 Nevi of medical significance are uncommon in the elderly, but new pigmented lesions that are not seborrheic keratoses should be evaluated.

prevalent in postmenopausal women, pregnant women [15], and obese individuals, suggesting a hormonal influence on their development. The exact etiology of skin tags is unknown, though some familial groupings have been noted. Early studies suggested that skin tags could potentially serve as cutaneous markers for colonic polyps [16], but more recently, that association has been largely disproved [17]. The association between diabetes mellitus and multiple skin tags is less clear [18, 19].

Histologically, skin tags consist of protruding loose fibrous tissue covered by a thin epidermis attached to the skin by a narrow stalk. Upon visual inspection they are easily recognized, though they are rarely misdiagnosed as pedunculated seborrheic keratoses, pedunculated melanocytic nevi, neurofibromas, or molluscum contagiosum. Their size offers a clue to their diagnosis: Skin tags tend to be smaller than the average pedunculated melanocytic nevus or neurofibroma.

Skin tags have no malignant potential but tend to be a cosmetic nuisance, especially if they occur in areas exposed to friction such as the belt line. When infarcted, they can cause considerable discomfort. Treatment consists of simple excision requiring no local anesthetic. Lesions can be severed at their base by grasping them with forceps and cutting them with scissors, razors, or scalpels. Skin tags may also be electrodesiccated.

Xanthelasma Palpebrarum (Eyelid Xanthomas)

Xanthelasma palpebrarum is seen mostly in adults in their fourth to fifth decade. They present as yellow velvety plaques confined to the eyelids. The lesions often begin as small yellow spots that initially may be confused with milia or senile closed comedones. They grow over a span of months to form coalescing plaques on the upper eyelids and around the inner canthus (Fig. 91.4). Once their growth stabilizes, these plaques remain permanently.

Histologically, xanthelasma palpebrarum is characterized by lipid-laden macrophages in the superficial dermis.

FIGURE 91.4 Xanthelasma. These cholesterol deposits occur on the upper and lower lids and can best be removed surgically. They are yellowish with a smooth surface.

Approximately 50% of patients who present with these lesions have an underlying disorder of lipid metabolism, such as familial hypercholesterolemia or familial dysproteinaemia. Patients with these disorders typically have elevated low-density lipoprotein (LDL) and apoprotein E levels and are prone to atherosclerotic cardiovascular disease. Patients who present for the first time with xanthelasma palpebrarum should have their serum lipoproteins and apolipoproteins checked. If the levels are within normal limits, no further testing need be pursued, as nearly half of the patients who present with the lesion have no lipid disturbances. The etiology of xanthelasma palpebrarum in patients with no lipid disorder is unknown.

Systemic therapy with lipid-lowering agents rarely affects the appearance of these lesions. Prior to the advent of laser therapy, excision, cryotherapy, and topical application of 30% trichloroacetic acid were the preferred methods of treatment. With most of these treatments, however, recurrences are common. Excision with primary closure is effective in only 60% of patients and is limited by the location of the lesions [20]. Some authors have advocated excision with secondary intention healing, thereby minimizing the risk of ectropion and complications with skin grafting [21]. Although healing by secondary intention may allow greater margins of resection and therefore minimize the rate of recurrence to as low as 7% [21]. The risk of scarring and infection may make this procedure risky in the hands of the untrained. Recently, various laser modalities including erbium:YAG [22], Argon [23], and 1064 Q-switched Nd:YAG [24] have been utilized in the treatment of xanthelasma with good cosmetic outcomes. Ultrapulse CO₂ laser in only one treatment session has shown excellent results without complications or recurrences at follow-up of up to 1 year [25]. Though promising, the efficacy of these new modalities must be further studied in controlled clinical trials to establish their proper role in therapy.

Sebaceous Hyperplasia

Sebaceous hyperplasia is a benign lesion that is often found on the face of older patients. It typically presents as a cream to yellow umbilicated papule on the forehead, cheeks, eyelids, and nose of individuals over the age of 30 (Fig. 91.5). The incidence of sebaceous hyperplasia increases with age such that about 25% of patients over the age of 65 carry these lesions. Its etiology is unknown, but genetic factors most likely play a role in its pathogenesis as most lesions occur independent of sun exposure and arise in patients of northern European heritage.

Sebaceous hyperplasia often begins as a small, 2- to 3-mm papule with a central depression. This depression represents the opening of a wide sebaceous duct that is surrounded by several enlarged sebaceous gland lobules, lending the lesion its characteristic lobular configuration.

FIGURE 91.5 Sebaceous hyperplasia. These lesions represent benign hypertrophy of the sebaceous glands. With their central umbilication and rounded edge, they are occasionally confused with basal cell carcinoma.

Some lesions of sebaceous hyperplasia contain central telangiectasias. This feature, combined with the papule's translucent appearance, often leads clinicians to confuse sebaceous hyperplasia with BCC. A clue to the correct diagnosis can be obtained with diascopy (applying pressure on the lesion with a glass slide), which reveals the yellow-white color of sebaceous hyperplasia. Relying on diascopy for diagnosis is not perfect: the yellow-white color sometimes leads to the incorrect diagnosis of xanthomas. Xanthomas can usually be differentiated by their larger size and absence of umbilication [26].

When the clinical diagnosis is uncertain, a biopsy should be performed. In general, no treatment is necessary unless cosmetically desirable. Cryotherapy, in a single freeze-thaw cycle or shave excisions of the elevated portion of the lesion, has been variably successful. Electrodesiccation and curettage should be avoided, as it may result in scarring.

Chondrodermatitis Nodularis Helicis

Chondrodermatitis nodularis helicis (CNH) typically presents as a painful, erythematous nodule on the helices of men over the age of 40. Approximately 30% of cases of CNH occur in young individuals and in women, but the location varies to include the antihelix, tragus, antitragus, and concha [27]. The tender nodule, which often displays central crusting and ulceration, is typically surrounded by hyperemic skin. It enlarges to reach its maximum size of 0.5–2.0 cm within a few months and then remains unchanged indefinitely without evolution to malignancy (Fig. 91.6).

This disorder is thought to be due to compromised local blood supply as a result of pressure or cold temperatures. It often arises in individuals who habitually sleep on one side. Aggravating factors include cold temperatures, pressure from head gear, and trauma. Despite the characteristic

FIGURE 91.6 Chondrodermatitis nodularis helices. This benign condition of the ear is painful and may present with eroded epidermis. It can be confused with squamous cell cancer of the ear, which usually is not painful.

exquisite tenderness of these lesions, CNH is often mistaken for squamous cell carcinoma (SCC). Biopsy, which is indicated only if there is a degree of suspicion for SCC, characteristically reveals degenerated homogeneous collagen surrounded by vascular granulation tissue with acanthotic overlying epidermis containing a central ulcer. The perichondrium is thickened and shows a lymphocytic infiltrate.

Treatment of CNH may be medical or surgical. Medical therapies include intralesional injection of steroids and collagen [27] and cryotherapy. Conservative management has been advocated in the first instance [28]. Intralesional steroids, such as triamcinolone acetonide administered at a 5–10 mg/ml dose, are generally reserved for first-line treatment of early lesions, as it is successful in only 25% of cases [29]. Higher cure rates, approaching 85% [30], are achieved with surgical approaches, including excision. Electrodesiccation and curettage can be easily performed with adequate margins by allowing the curette to be the guide. Necrotic cartilage, which tends to be soft, is removed easily. Curettage is stopped when healthy, firm cartilage is reached [31]. Techniques for excision vary widely: some advocate removal of abnormal auricular cartilage only [29, 30, 32], whereas others recommend removal of involved cartilage as well as overlying skin [4, 33]. Leaving the overlying skin intact has the advantage of decreasing the deformity of the ear, resulting in a better cosmetic result [34, 35]. A cure rate approaching 100% over a

FIGURE 91.7 Hemangioma. This deep-seated hemangioma on the upper lip is benign, but in the absence of the ability to blanch on compression, it should be biopsied to rule out other tumors.

2-year follow-up period has been reported using CO₂ laser surgery [36, 37], but recent data from large-scale comparative trials are not yet available. To prevent recurrences, the patient should be instructed to minimize pressure and trauma to the ear.

Cherry Hemangioma (Campbell de Morgan Spots)

Cherry angiomas are small, benign, bright red to violaceous, dome-shaped papules that are commonly found in middle-age and older adults. They become more numerous with age. They are distributed over the trunk and proximal extremities and can vary from 2 to 8 mm in diameter (Fig. 91.7). Their etiology is unknown.

Histologically, cherry angiomas are characterized by the presence of numerous dilated capillaries lined by flattened endothelial cells with edematous surrounding stroma and collagen homogenization. The overlying epidermis is frequently thinned with fenestrations.

Cherry angiomas are diagnosed clinically and require no treatment. Occasionally, they are mimicked by angiokeratomas, venous lakes, nodular melanomas, or metastatic carcinomas. If nodular melanoma or metastatic carcinoma is suspected, an excisional biopsy should be performed. If a cherry angioma is at a site of recurrent trauma and therefore prone to ulceration or if it is at a site that is cosmetically unacceptable to the patient, it can be treated by shave excision, cryotherapy, electrodesiccation, or laser ablation.

Venous Lakes

Venous lakes are angiomatous dilations of venules occurring on the face, lips, and ears of patients who are usually above the age of 50. They manifest clinically as dark-blue to

violaceous papules with an irregular, cobblestone appearance. After an initial growth phase these lesions stabilize and do not regress. The cause of venous lake formation is unknown. It occurs with equal incidence in both sexes. Microscopically, the lesion reveals small, single-layered interconnected vessels (or one large dilated space) in the upper dermis surrounded by a thin wall of fibrous tissue. A venous lake can resemble a pyogenic granuloma, which should be removed or biopsied, or a nodular melanoma, which requires an excisional biopsy. In most instances, however, venous lakes can be easily distinguished clinically by applying prolonged pressure to the lesion, which causes it to lose its violaceous hue as the venous bed empties.

Treatment of venous lakes is cosmetic. They can be obliterated with electrocoagulation or laser; the long pulse Nd:YAG has recently shown promise [38]. Alternatively, they can be surgically excised, but there is a risk of a cosmetically unacceptable scar.

Premalignant Lesions

Actinic Keratoses (Solar Keratoses)

Actinic keratoses (AKs) are discrete, scaly, pink to red papules that are found on chronically sun-exposed skin of the face, ears, neck, forearms, and dorsal hands. They have a rough quality, allowing them to be more easily felt than seen. Typically, they arise in middle-age individuals, though they may occur at earlier ages in people living in latitudes closer to the equator. Actinic keratoses are generally considered premalignant lesions with a conversion rate to invasive SCC ranging between 0.075 and 0.096% per lesion per year [39]. For the average person with multiple actinic keratoses, the chance of developing invasive SCC has been estimated at 10–20% over a 10 year period if those AKs are left untreated [40]. An alternate viewpoint characterizes actinic keratoses not as premalignant lesions, but rather as malignant lesions akin to SCC in situ [41].

The SCCs that arise from AKs have been considered to be less aggressive than those arising *de novo*, with a metastatic rate of only 1.6% [39], although there is some doubt about this association.

There are three clinical subtypes of AKs: hypertrophic, pigmented, and lichenoid (Fig. 91.8). The hypertrophic variety develops as a thickened papule that may border on early squamous cell cancer. Pigmented AKs can resemble solar lentigo, seborrheic keratoses, nevi, or in situ melanoma. Lichenoid AK may mimic lichen planus. In general, AKs are relatively easy to recognize clinically and do not require a biopsy unless there is suspicion of malignant transformation.

FIGURE 91.8 Actinic keratoses. This is one of the most common sun-related lesions in the elderly. It is biologically and clinically premalignant and should be treated because of the risk of malignant transformation. The lesions can vary in size from 1 to 2 mm up to more than 1 cm and have a rough surface overlying a reddened background.

Biopsy typically reveals large, bright-staining keratinocytes with mild to moderate basal layer pleomorphism that spares follicular units. The abnormal keratinocytes do not invade the dermis.

Because AKs are considered premalignant [41], treatment is ablative and the method determined by the number and location of lesions. If a patient presents with fewer than 10 AKs, cryotherapy is the method of choice. Flat to slightly raised lesions are treated with liquid nitrogen until frosted. For lesions that are thick and hyperkeratotic, 3–5 s of freezing may be necessary. With this technique, cure rates as high as 98% have been reported [41, 42]. Light electrodesiccation and curettage and CO₂ lasers are other effective methods for scattered lesions, but they have the disadvantages of requiring local anesthesia and may increase the risk of scarring.

For numerous lesions, topical fluorouracil (5-FU), which selectively targets abnormal keratinocytes, is one treatment option. It is applied as a 1%, 2%, or 5% cream or solution once or twice daily until the AKs become inflamed and ulcerate. The treatment period can last 2–6 weeks and can cause significant discomfort, which may hamper patient compliance. Inflammation can be minimized with mid-potency topical steroids during the healing phase without affecting the efficacy of the treatment. The recurrence rate with 5-FU is high.

Additional topical methods of treating actinic keratoses include immunologic manipulation with the toll-like receptor-7 agonist imiquimod and the use of the cyclooxygenase inhibitor diclofenac. Clinical investigation of daily topical imiquimod has revealed clinical clearance rates ranging from 45 to 84% [43–45]. Notable side effects include edema, inflammation, and erythema. Three-percent diclofenac in 2.5% hyaluronic acid gel has been investigated and revealed clearance of up to 50% of target lesions with xerosis and rash at the application site cited as adverse events [46, 47].

Exfoliative methods of treatment and lesion reduction include chemical peels with trichloroacetic acid and dermabrasion (by laser or with diamond fraize). Chemexfoliation with 35% trichloroacetic acid, on a repeated basis, can decrease the number of AKs. The advantage of these methods is that their efficacy is not dependent on patient compliance, and they can have the added benefit of improving cosmetic appearance.

Photodynamic therapy, PDT, has been used increasingly to treat actinic keratoses and a variety of other superficial neoplastic lesions. In the process of PDT, a photosensitizing compound, typically the hemoporphyrin derived 5-aminolevulinic acid (5-ALA) or its methyl ester (mALA), is applied directly to diseased skin and incubated for 4–16 h. In the skin cells, ALA is converted to protoporphyrin IX. It is believed that upon illumination with red, blue, noncoherent, or laser light, the photosensitizing compound releases cytotoxic reactive oxygen species leading to overwhelming oxidative stress and cell death.

Growing data support the use of PDT in the treatment of actinic keratoses with response rates comparable to cryotherapy and 5-FU. A number of prospective vehicle-controlled trials have been performed, revealing clearance rates ranging from 77 to 99% with recurrence rates as high as 30% after 1 year [48]. Depending on the duration of incubation and the nature of light activation, transient pain may be a consideration. It is usually manageable with local measures, but post-treatment edema and scaling can be expected depending on the extent of the treatment area.

Patients presenting with AKs usually have a history of chronic sun exposure, which places them at increased risk for developing other skin cancers. Therefore, it is important to follow these patients at regular intervals and to emphasize preventive care by recommending sun protection strategies.

Actinic Cheilitis

Actinic cheilitis is a premalignant disorder of the lip. It usually localizes to the mucosal surface of the lower lip where sunlight exposure is greatest but occasionally occurs on the upper lip (Fig. 91.9). The lesion initially presents as an edematous erythematous patch that progresses to an indurated,

scaly plaque with a whitish-gray to brown discoloration. Vertical fissuring and crusting can occur and become painful. Vesicles may arise and burst, giving rise to superficial ulcerations, which may then become secondarily infected. Eventually, warty nodules may form that can undergo malignant transformation to SCC.

The main risk factor for developing actinic cheilitis is chronic sun exposure, as evidenced by a higher incidence of the lesions in people living in sunny regions, outdoor workers, and light-skinned individuals. Its decreased incidence in women may be due to the protective effects of lipstick [4].

Histologically, actinic cheilitis displays regions of flattened, atrophic epithelium adjacent to acanthotic areas. The epidermis may also show disordered maturation without evidence of nuclear atypia. Lymphocytes and plasma cells infiltrate the dermis, which frequently shows signs of solar elastosis such as basophilic degeneration of collagen and elastic fibers.

Actinic cheilitis is often confused with other forms of cheilitis, including lupus erythematosus, lichen planus, and eczematous cheilitis secondary to contact allergies. The occasional blistering may lead to the diagnosis of sunlight-induced herpes simplex virus infection. The propensity for these lesions to develop into SCCs should alert the clinician to look for features associated with malignancy such as ulceration, persistent flaking or crusting, generalized atrophy with focal areas of leukoplakia, and a red and white blotchy appearance with an ill-defined vermilion border. Any lesion with suspicious features should be biopsied.

If the lesion is not indurated, a trial of conservative therapy with opaque zinc oxide or titanium dioxide containing sunscreens and topical steroids may be initiated. Because of the sensitivity of the lip area, ablative treatments can be painful and problematic. Topical agents can be used but can also

FIGURE 91.9 Actinic cheilitis. This confluent, hyperkeratotic tumor of the lip is sun-induced. It can be asymptomatic or develop painful fissures. It is premalignant and biologically analogous to actinic keratoses on nonmucosal skin.

cause a painful reaction. In one approach, topical 5% fluorouracil can be applied three times daily for 9–15 days resulting in brisk ulceration followed by a 2- to 3-week period of healing. Even with good compliance, recurrence rates range from 17% at 22 months to 60% at 50 months [49, 50]. Alternative, less aggressive modes of application may be tried. Photodynamic therapy with mALA and red light [51] or ALA and long-pulse pulsed dye laser have been advocated with the latter achieving complete clearance rates of 68% [52]. Imiquimod has been advocated in the treatment of actinic cheilitis [53], but high rates of aphthous ulcers have been noted to limit its utility [54]. Diclofenac 3% gel has been used, but there have been no blinded controlled trials to support its efficacy [55]. The most aggressive form of therapy is vermilionectomy which involves excision of the vermilion border down to orbicularis oris muscle with subsequent advancement of a labial mucosal flap [30]. This procedure should be reserved for cases of actinic cheilitis that do not respond to laser, photodynamic, or other therapy.

Cutaneous Horn

Cutaneous horn is a clinical term used to describe a hard, yellowish-brown, conical outgrowth of skin, resembling an animal's horn. Cutaneous horns develop on sun-exposed areas such as the scalp, upper part of the face, tips of the ears, and dorsum of hands; they may grow as long as 20 cm [56]. They can arise from benign, premalignant, or malignant epidermis. A clue to malignancy can be obtained from close examination of the surrounding epidermis: If the skin surrounding the lesion is normal looking or slightly acanthotic, the lesion is more likely to be benign, whereas inflammation or induration of the surrounding skin suggests malignancy. More than 60% of cutaneous horns are derived from benign lesions of epithelial hyperplasia, such as warts, skin tags, seborrheic keratoses, and nevi; 23% arise from premalignant lesions including actinic keratoses, and the remaining 16% arise from mostly squamous cell cancer. Horns arising from basal cell cancer and metastatic and sebaceous carcinomas have been reported [56, 57]. Therefore, all horns should be biopsied with care to preserve their base by performing a deep tangential biopsy.

Bowen's Disease (Squamous Cell Carcinoma In Situ)

Squamous cell carcinoma in situ that localizes to the epidermis is referred to as Bowen's disease. It typically arises in individuals over the age of 60 and has a slow, indolent course.

FIGURE 91.10 Bowen's disease. This large plaque is an extreme example of squamous cell carcinoma in situ, or Bowen's disease. This noninvasive cancer does not extend down the hair follicles, so failure to eradicate cells at this level, surgically or otherwise, may result in recurrence of the tumor.

Although not invasive into the dermis, it must be considered a variant of squamous cell cancer. Approximately 5% of the lesions progress to invasive SCCs [58]. Bowen's disease initially presents as a slowly enlarging, solitary, erythematous macule with a sharp border that can evolve into a scaling, crusting plaque usually 2–6 cm in diameter (Fig. 91.10). When this lesion develops on the penis, it is known as erythroplasia of Queyrat. Its etiology has been associated with chronic exposure to solar radiation, psoralens ultraviolet A (PUVA) therapy, radiation, and environmental toxins such as arsenic, mustard gas, pesticides, and herbicides.

The clinical differential diagnosis for Bowen's disease includes other papulosquamous diseases such as psoriasis and lichen simplex, superficial BCC, actinic keratoses, and dermatitis. If a lesion looks suspicious for Bowen's disease, a biopsy should be performed.

Microscopically, the keratinocytes in Bowen's disease demonstrate full-thickness atypia with hyperchromatic nuclei, loss of polarity, and decreased intracellular adhesions. Giant cells and mitotic figures may be frequent. By definition, tumor cells do not invade the dermis, although the upper dermis may be infiltrated by mononuclear inflammatory cells.

Bowen's disease can be treated with excision, Mohs microscopically controlled surgery, or with destructive therapies such as cryotherapy, electrodesiccation and curettage, topical 5-FU, imiquimod, and photodynamic therapy. Histologic confirmation should be obtained before using one of the destructive modalities. Cryotherapy has had reported cure rates of 90–97% [42, 59]. Retrospective studies support the use of topical imiquimod [60]. Photodynamic therapy with ALA and MAL has increasingly been used in the treatment. On the basis of the evidence of four randomized

single- and multicenter-controlled trials [59, 61–63] initial cure rates have been shown to range from 88 to 100% and 1 year recurrence rates range from 0 to 12%. The significant disadvantage of topically applied treatments including photodynamic therapy, however, is that the vehicle often cannot penetrate the epidermal appendages. If the tumor involves the appendages, it may not be fully eradicated. Excision, where feasible, remains the therapeutic method of choice for Bowen's disease. Because of indistinct borders, Mohs surgery is often the treatment of choice.

Lentigo Maligna (Hutchinson's Freckle)

Melanoma In Situ

Lentigo maligna is a noninvasive disorder of atypical melanocytes that is limited to the epidermis. This flat, pigmented lesion, which occurs on sun-exposed skin of elderly fair-skinned individuals, develops into invasive melanoma in about 1 of 750 cases per year [64]. As a result of its malignant potential, most authors view lentigo maligna as a melanoma in situ [65]. The major risk factors for developing lentigo maligna are chronic cumulative sun exposure and light skin color. Additional risk factors include a history of severe sunburn, radiation exposure, estrogen and progesterone therapy, and use of nonpermanent hair dyes [66]. The incidence of lentigo maligna, which is slightly higher in women, peaks during the seventh and eighth decades, with the average age of onset around 65 years.

Clinically, lentigo maligna presents as a uniformly flat macule ranging in size from 3 to 20 cm with intralesional variations in color (Fig. 91.11). The color often appears as a

FIGURE 91.11 Lentigo maligna. It is melanoma in situ on sun-exposed skin. Although this lesion is small and easy to excise, these lesions are often long-standing in the elderly and can reach sizes that make excision unfeasible.

disorganized array of dark browns and black on a background of light browns, pinks, and white. The borders of the lesion tend to be irregular with a notched, “geographic” shape.

Biopsy of lentigo maligna reveals cytologically atypical melanocytes proliferating in distinct units throughout the basal layer. These atypical melanocytes can extend far beyond the clinical margin, leading to a high recurrence rate. The black areas of the lesion often display the most advanced histologic changes, whereas the white areas show signs of regression. Regions with surface irregularity may signify invasion.

Several lesions can simulate lentigo maligna, including seborrheic keratoses, solar lentigos, pigmented actinic keratoses, pigmented Bowen's disease, and pigmented BCC. However, these lesions tend to be more uniform in color and rarely contain black pigment. Seborrheic keratoses can usually be distinguished based on their characteristic verrucous surface. Solar lentigos do not exhibit variations in color as seen with lentigo maligna. Pigmented carcinomas tend to be raised. To confirm the diagnosis, an incisional punch or shave biopsy that includes the most darkly pigmented area is recommended.

Complete excision is the treatment of choice for lentigo maligna. Conventional surgery, which provides a 91% cure rate [67], should be performed with 0.5-cm margins if feasible [68]. Depending on the clinical circumstance, mapped serial excision may be required to ensure removal of what can often be very large lesions. This approach is especially helpful for periocular and other cosmetically sensitive areas of the face [69–71]. Mohs surgery has been suggested as a treatment [72], and cure rates as high as 97% have been reported [73]. However, the technical issues related to frozen section interpretation of melanocytic lesions make use of conventional margin analysis preferable at this time, either in a staged fashion or single excision where feasible.

Some lesions of lentigo maligna do not lend themselves to excision because of their size, location, or the patient's comorbid conditions. In such cases, destructive therapies such as CO₂, ruby laser, electrodesiccation and curettage, X-ray therapy, cryotherapy, topical azelaic acid, and topical imiquimod have been used. The major disadvantage of these methods is that they do not provide a specimen to confirm that the cancer has been properly and completely eliminated. These methods may also fail to treat the adnexal melanocytes, which can lead to recurrence. This is suggested by the high recurrence rate of lentigo maligna that occurs with these modalities: 20–25% for electrodesiccation and curettage, 6–36% for cryotherapy, up to 100% for azelaic acid, and up to 38% for irradiation [66]. Small case series utilizing irradiation have, however, demonstrated recurrence rates as low as 0–7% [74, 75]. Topical imiquimod has been advocated [76], but no controlled trials have been performed. A variety of single wavelength and combination laser treatments have

been attempted in the treatment of lentigo maligna including argon [77], Q-switched Nd:YAG [78], and Q-Switched ruby [79], but no large controlled trials exist. Laser and imiquimod may be viable therapeutic options in the patient who cannot undergo more aggressive approaches or whose lesion technically precludes excision. Cryosurgery may leave scar tissue that can mask recurrence, especially the development of an invasive desmoplastic melanoma. This is the greatest risk of incomplete treatment of melanoma in situ, and the patient must be aware of this potential problem.

Malignant Lesions

Epidermis

Squamous Cell Carcinoma

Squamous cell carcinoma (SCC) is a malignant tumor of keratinocytes that arises on sun-damaged skin and on mucous membranes. The incidence is higher in men but occurs more frequently on the extremities in women. Individuals over the age of 55 are most frequently affected, with the mean age of onset at 60 years.

The biggest risk factor for SCC is chronic sun exposure. This is evidenced by the fact that SCC occurs most frequently in geographic areas that have sunny climate, such as California and Florida. Also, the incidence of SCC is higher in people who work outdoors. Other predisposing factors include prior trauma, frostbite, ionizing radiation, PUVA therapy, exposure to chemical carcinogens (arsenic, topical hydrocarbons, nitrogen mustards), viruses (human papilloma virus strains 16,18,31,33, and 35), and chronic immune suppression. These tumors may also arise from preexisting pathology, such as the chronic inflammatory lesions of discoid lupus, burn scars (Marjolin's ulcer), osteomyelitis sinuses, lichen planus, and chronic stasis dermatitis. SCC of the lip may additionally be provoked by tobacco use.

SCCs may arise from a premalignant lesion such as actinic keratosis or Bowen's disease. A clue to malignant transformation in these lesions is increased induration and inflammation. Patients often notice that the lesion is growing or changing. Well-differentiated SCC typically presents as an indurated papule, plaque, or nodule with overlying adherent hyperkeratosis. It may become ulcerated or bleed with formation of a central crust and surrounding firm, scaly margin. If the carcinoma is undifferentiated, it may appear as a fleshy, granulating nodule with central ulceration and a necrotic base.

Clinically, SCCs may resemble actinic keratoses, amelanotic melanoma, granulomatous disease, or adnexal tumors.

FIGURE 91.12 Squamous cell cancer. This large lesion was present for many months. Occasionally, when the lesion arises over a 6-week period, keratoacanthoma, a variant of squamous cell cancer, must be considered.

If a lesion appears suspicious for malignancy, it must be biopsied (Fig. 91.12).

Dermatopathologic examination typically reveals masses, strands, or buds of atypical keratinocytes that proliferate downward into the dermis. In well-differentiated tumors, keratin pearls may be present within or on the surface of the tumor. Undifferentiated types display multiple mitoses and little evidence of keratinization.

SCC has the capacity to metastasize. The metastatic potential depends on the location and size. For SCCs arising from actinic keratoses, the metastatic propensity reportedly is low (approximately 0.5%) [80], whereas for those developing de novo, the risk is 7.7–13.7%. Tumors arising from preexisting pathology, such as a burn scar, have a much higher rate of metastasis, estimated to be 20–40%. Patients presenting with an SCC should have regional lymph nodes examined clinically, as regional lymphadenopathy is often the first sign of metastasis. The prognosis for tumors that have spread is poor, with an estimated 5-year survival rate of 26% if the metastasis is localized to regional lymph nodes and 23% if it has spread systemically [81].

The most widely used method for treating SCC is excision. Simple excision with clinically normal-appearing margins is often satisfactory for most lesions up to 0.5 cm. For tumors that are large, deep, recurrent, and have aggressive

histology, or are located in areas with high metastatic potential (e.g., lips or ears), the Mohs microscopically controlled technique should be performed. This is a tissue-sparing, office-based method that involves the sequential excision and mapping of the cancer. The final defect can be repaired immediately or allowed to heal by second intention. The Mohs technique has a 3% recurrence rate compared to an 8% recurrence rate with simple excision. As an alternative to excision, small, superficial tumors (<0.5 cm) can be destroyed by electrodesiccation and curettage, which yields a 5-year cure rate of approximately 90% [82]. Radiotherapy can also be effective but is typically reserved for patients who cannot undergo surgery or as adjunctive therapy in high-risk areas with perineural invasion. It is extremely expensive. The treatment regimen can take as much as 4–6 weeks. This method relies on patient compliance; but if used properly, it has a 5-year cure rate similar to that of electrodesiccation and curettage [82]. Topical retinoids have also been shown to be effective for some inoperable lesions [83]. Lymph node dissection is not indicated unless nodes are clinically involved.

Keratoacanthoma

Keratoacanthomas (KAs) are well-differentiated SCCs. Interestingly, in some cases, they have a tendency to resolve spontaneously. KAs most often appear as isolated lesions on sun-exposed areas of middle-age or older individuals. The lesion begins as a small papule that rapidly enlarges over 4–8 weeks to form a painless nodule often containing a central keratin-filled crater. KAs occur twice as often in men as in women and are most commonly found in Caucasians.

The cause of this lesion is unknown. Human papilloma virus has been extracted from some lesions. Others have been associated with carcinogens including UV light, pitch and tar, and other factors such as trauma and immune suppression [84]. Keratoacanthomas are usually solitary, but multiple lesions may arise as part of a syndrome such as Muir–Torre, Ferguson Smith, or generalized eruptive KAs of Grzybowski [85].

Clinically, KAs appear as well-differentiated SCCs. Unlike most other SCCs, KAs have a history of rapid onset and are not usually associated with regional adenopathy. The history of rapid onset (4–6 weeks) is key to making the diagnosis and distinguishing the KA from other types of SCC. Biopsy of a suspicious lesion is required because KAs can behave like aggressive SCCs, especially when located in the central face. Biopsy can be incisional or excisional so long as it is inclusive of the full depth of the tumor down to the subcutaneous fat. Typically, a biopsy shows a large central crater filled with keratin surrounded by buttressing epidermis. The keratinocytes often display nuclear atypia, mitotic figures, and dyskeratoses. KA-type SCCs can be differentiated from

other SCCs histologically based on the presence of epithelial “lips,” which surround a central crater, and intradermal abscesses with an accompanying inflammatory infiltrate – both of which are rare features of SCCs.

There remains legitimate controversy regarding the true nature of KAs. Some authorities classify the lesion as a benign epithelial neoplasm [86], whereas others view it as an aborted malignancy [85] or a well-differentiated subtype of SCC [9, 87]. We consider KAs as a form of SCC. Unlike other malignancies, KAs can spontaneously regress, but they have also been shown to metastasize and ultimately be fatal [87]. Therefore, the question of identity becomes more than an academic exercise. KAs should be definitively treated.

Currently, most experts favor early intervention to minimize local tissue destruction because localized scarring can occur with spontaneous healing. Those who favor excision recommend Mohs micrographic surgery because it allows resection with tumor-free margins while maximizing the preservation of normal skin. In a study examining 42 KAs treated by Mohs surgery, the rate of recurrence after 2 years was less than 3% [88]. Other treatment modalities include: curettage and desiccation, which has a recurrence rate of 8% [85]; cryosurgery, which is beneficial for small early KAs; radiation therapy; topical and intralesional 5% 5-FU; interferon- α 2a; podophyllin; intralesional steroids; systemic retinoids; and bleomycin [84]. Intralesional methotrexate has been advocated in cases where surgery is not an option and has a reported 92% rate of clearance based on retrospective analysis [89]. Any lesion that does not respond promptly to the above nonsurgical treatments by involuting at least 60% should be excised [30].

Basal Cell Carcinoma

Basal cell carcinoma (BCC) is the most common type of malignant cutaneous neoplasm, constituting 75% of all nonmelanoma skin cancers. BCCs are not thought to be associated with a premalignant lesion. Though they are slow-growing tumors that rarely metastasize, they can be locally invasive and destructive. BCCs most commonly present on habitually sun-exposed skin of the head and neck in fair-skinned individuals over the age of 40. Aside from chronic sun exposure, race, and age, other predisposing factors include genetic defects (basal cell nevus syndrome, xeroderma pigmentosa, Bazex syndrome, Rombo syndrome), radiation exposure, immune suppression, and prolonged contact with chemical carcinogens such as arsenic. The incidence of BCC in the United States has been estimated at approximately 150 cases per 100,000 per year, with men more frequently affected. One exception to this trend is in the lower extremities where the lesion arises three times more commonly in women.

The exact cell of origin of the BCC is unclear. It is thought to be derived from either the pluripotent stem cells of the epidermis or the matrix cells of epidermal appendages. The tumor cells histologically resemble cells in the stratum basale with compact, basophilic nuclei and scant cytoplasm. However, in support of the epidermal appendage derivation, tumor development occurs only in areas of the skin that have the capacity to develop hair follicles. The tumor cells grow in strands or nests into the dermis, displaying little anaplasia and infrequent mitosis. In the more aggressive variants, finger-like strands can extend far into dermal stroma, inducing significant fibrosis. A lymphocytic dermal infiltrate is usually present.

Morphologically, BCCs can be classified into at least five subtypes: noduloulcerative, cystic, pigmented, superficial, and morpheaform. The most common is the noduloulcerative variant, which usually starts as a small papule that slowly enlarges, appearing translucent and pearly with a rolled border and overlying telangiectasias (Fig. 91.13). As the tumor continues to grow, it eventually exceeds its own blood supply and becomes necrotic and centrally ulcerated (“rodent ulcer”). Most lesions are asymptomatic, though some are pruritic. Noduloulcerative BCC may resemble melanocytic nevi, sebaceous hyperplasia, molluscum contagiosum, SCC, verruca vulgaris, keratoacanthoma, amelanotic melanoma, atypical fibroxanthoma, or an adnexal tumor.

Cystic BCC presents as a smooth, pearly, erythematous nodule that rarely ulcerates. The cystic cavity may contain necrotic debris or mucin. This BCC variant can mimic other cystic lesions, such as epidermal inclusion cysts and hidrocystomas.

Excess melanin from epidermal melanocytes can cause BCCs to become pigmented. Pigmented BCCs often occur in dark-skin individuals and can be clinically confused with melanoma. Unlike melanoma, the border of this BCC variant

FIGURE 91.13 Basal cell cancer. The large nodule on the chest is a neglected basal cell cancer. Actinic keratoses and severe solar damage are noted on the rest of the chest.

is often rolled, and the color is browner in contrast to the black–brown hue of malignant melanomas.

The superficial variety of BCC appears as erythematous, scaling, raised plaques with irregular borders. This tumor does not invade beyond the superficial dermis. It is often confused clinically with benign processes (e.g., localized eczema or psoriasis). Superficial BCCs can be differentiated by biopsy.

The most aggressive BCC subtype is the morpheaform, or infiltrative, variety. This locally destructive lesion typically appears as a whitish, sclerotic patch with ill-defined borders. It is firm upon palpation due to the extensive fibrous stroma associated with the tumor. The strands of tumor cells can travel well beyond the clinical margin, making these tumors notoriously difficult to treat without the Mohs technique. Their differential includes morphea and scar.

Rarely, BCC will metastasize with a reported incidence of 0.0028 to 0.5% [91]. Metastatic BCC tends to occur more frequently in Caucasian men, occurs on the head and neck, and has no increased risk with a particular histologic subtype although many so-called metastatic basal cell cancers have had squamous features. In contrast to the relatively benign course of primary BCC, metastatic BCC has a 5-year survival of 10% [91] and commonly affects the lymphatics, lungs, bone, and skin.

Knowledge of the pathology of these five primary BCC subtypes is important when choosing the appropriate method of treatment. In addition to taking the morphologic type into account, the proper treatment modality also depends on the size and location of the tumor, the age and comorbid conditions of the patient, and patient preference. For patients who can undergo surgical procedures, electrodesiccation and curettage, simple excision, and Mohs surgery are the methods of choice. With the exception of the morpheaform subtype, most small, nonrecurrent varieties of BCC can be treated with simple excision, achieving a cure rate exceeding 95% [92]. For large tumors (>1–2 cm), recurrent cancer, infiltrative subtypes, or cancer in the central face, which may invade deeply, Mohs surgery is recommended. It has the added benefit of being tissue-sparing and offers a cure rate approaching 99% for nonrecurrent lesions [93].

Nonsurgical treatment methods include radiotherapy, photodynamic therapy, and topical chemotherapy with agents such as 5-FU and imiquimod. Both topical agents are reserved for the superficial type of BCC because they cannot readily penetrate beyond the dermis. The treatment course can last from 2 to 6 weeks or more, thus requiring high patient compliance. For 5-FU, clinical clearance rates up to 90% have been reported with extended treatment courses of up to 12 weeks [94]. For imiquimod, five times weekly use for 6 weeks has produced 1 year clearance rates as high as 85% and 5-year clearance rates approaching 80% [95]. Photodynamic therapy with ALA and MAL has been used in

the treatment of superficial and nodular BCC. Prospective trials comparing standard surgery to MAL in the treatment of nodular lesions have revealed inferior complete responses for MAL-PDT (76–96%) at 5-year follow-up [96]. Amino-levulinic acid PDT has shown response rates of 87% for superficial lesions and 53% for nodular lesions [97]. Increased response rates of nodular BCC to ALA-PDT with adjunctive curetting are controversial. Radiotherapy can also be used to eradicate BCCs but is best reserved for patients who cannot undergo therapy with other destructive modalities. Cutaneous atrophy at the treatment site is a common side effect. The overall cure rate approaches 90%.

Treatment of metastatic BCC relies on aggressive surgery, irradiation, and/or palliative chemotherapy with cisplatin, cyclophosphamide, 5-fluorouracil, bleomycin, and vincristine. A regimen with oral retinoids, imiquimod, and celecoxib has been disappointing [98].

For patients presenting with a BCC, regular follow-up is essential because a patient with one BCC has a 36% chance of developing a second lesion within 5 years [93]. The protective use of sunscreen should be emphasized.

Melanoma

Melanoma is a malignant tumor of epidermal melanocytes. It is the fifth most prevalent cancer among men and the sixth most prevalent cancer among women in the United States. Its incidence is rising faster than any other cancer [99]. The current lifetime risk of developing melanoma is estimated at 1 in 55. In 2008, it is estimated that 62,480 people will be diagnosed with and 8,420 will die of melanoma. Age-specific incidence rates are highest in elderly patients. Approximately 40% of melanomas are diagnosed in individuals over the age of 65, and these elderly patients seem to have a worse prognosis than their younger counterparts. Specifically, although no comprehensive stage for stage studies have been performed, Austin (1994) notes that among a cohort of 442 patients with stage I and II melanomas, those over age 65 demonstrated a significantly lower 5-year disease-free survival [100].

Nearly 60% of melanoma deaths occur in patients over 65 years of age. Elderly patients have different incidences of melanoma subtypes than younger patients. Men and women are disproportionately affected, and men have a worse prognosis. Male and female incidence rates are 24.6 and 15.6 per 100,000 respectively, and the melanoma death rate in men is more than double that of women (3.9 vs. 1.7 per 100,000) [101].

The main risk factor for melanoma is high exposure to UV radiation, as demonstrated by an increased incidence of the tumor with decreasing latitude. Other predisposing factors include fair skin, blond or red hair, a family history of melanoma, congenital or atypical nevi, an inability to tan,

and an antecedent blistering sunburn. Pigment is a protective factor, as demonstrated by the relative rarity of this tumor in dark-skinned individuals.

Melanoma is traditionally classified into four clinico-pathologic variants: superficial spreading melanoma, nodular melanoma, lentigo maligna melanoma, and acral lentiginous melanoma. Superficial spreading melanoma (Fig. 91.14) is the most common subtype, comprising 40–50% of all cases in patients over age 65 [102]. It typically presents on the trunk in men and on the legs in women in their fourth to fifth decade. The tumor often begins as a small pigmented lesion that develops irregular features such as marked variations in color involving reds, whites, blues, and blacks, as well as notched borders. The tumor is characterized by a radial growth phase, where malignant cells are localized to epidermis, followed by a vertical growth phase, which signifies dermal invasion. The vertical phase is often heralded by elevation, bleeding, and ulceration of the lesion.

The second most common type of melanoma in the elderly is the nodular melanoma. These lesions present as elevated, dome-shaped, reddish-brown nodules most commonly localized on the legs or trunk; they arise more frequently in men. They have a short radial growth phase and therefore rarely grow to more than 2 cm in diameter. As they quickly enter their vertical growth phase, nodular melanomas can easily bleed and ulcerate and develop satellite lesions with surrounding inflammation. The tumors begin to develop during the fifth to sixth decade and peak in incidence during the eighth decade, with men more frequently affected than women. Nodular melanomas must be differentiated from seborrheic keratoses, pyogenic granulomas, and pigmented BCCs. Amelanotic melanoma, considered a subtype of nodular melanoma, displays a similar rapid vertical growth phase. These lesions may lack pigment and prove difficult to diagnose.

FIGURE 91.14 Melanoma. This example of superficial spreading melanoma has irregular edges and variable coloration. The elderly have an increased incidence of melanoma relative to other age groups, and early diagnosis is the key to cure.

Lentigo maligna melanoma develops in preexisting lentigo maligna lesions. Although lentigo maligna melanoma represents only 5% of all malignant melanoma cases, it accounts for 10% of melanoma cases in the elderly. Lentigo maligna is, in essence, an in situ melanoma that is in a horizontal growth phase that can last for decades before proceeding to a vertical growth phase. Transformation to lentigo maligna melanoma is defined as invasion of malignant melanocytes into the dermis and is heralded by the formation of an elevated nodule.

Like lentigo maligna melanoma, acral lentiginous melanoma also occurs with a disproportionately greater frequency in the geriatric population. Unlike all other subtypes, these melanomas most commonly affect Blacks, Asians, and Hispanics. Acral lentiginous melanoma appears as a macular, hyperpigmented area with irregular borders and a blue to black color; it arises on the plantar or palmar surfaces of the hands and feet, on mucous membranes, and in the subungual areas of nails. Its location often leads to the mistaken diagnosis of traumatic hematoma. These tumors are therefore often diagnosed at an advance stage. When the tumor becomes invasive, it may appear nodular and ulcerate and may bleed.

Any pigmented lesion that has undergone changes in size, shape, or color or is inflamed, oozing, bleeding, or itching, or is larger than 5 mm in diameter should be considered malignant until proven otherwise by biopsy. The most frequently occurring colors in melanomas are shades of brown, red, white, or blue and black. Pinks and reds signify inflammation. A blue color arises from light scattering from pigment deep within the dermis (Tyndal effect) and is a poor prognostic indicator.

Lesions suspicious for malignant melanoma should undergo elliptical or tangential excisional biopsy. For large tumors or those that cannot be completely excised because of their anatomic location, an incisional biopsy, such as a punch or elliptical biopsy, is recommended.

Although prognosis depends on the type of lesion and the presence or absence of lymphatic invasion, the single strongest prognostic factor is the depth of the melanoma measured in millimeters (Breslow depth) (Table 91.1). Clark's level is sometimes reported but is no longer used as reliably as the Breslow depth. Clinical subtypes of melanoma vary in aggressiveness. For example, lentigo maligna melanoma has a long horizontal growth phase and is usually recognized prior to the development of metastases.

The American Joint Committee on Cancer has devised a classification system for melanomas that not only takes depth into account but also the extent of regional or distant metastasis. The seventh edition was published in 2010 and is currently the system in use [103]. This clinical staging system is designated the TNM classification. The T component is based on Breslow thickness and histologic evidence of ulceration. Newly added was mitotic index for small, T1 lesions,

TABLE 91.1 Clark and Breslow classification of malignant melanoma

Clark level		
I	Tumor does not invade dermis	
II	Tumor invades only papillary dermis	
III	Tumor expands into papillary dermis but spares reticular dermis	
IV	Tumor invades reticular dermis	
V	Tumor invades subcutaneous tissue	
Breslow level (mm)	Excision margin	Sentinel node studies
1	1 cm	No
1.0–1.5	1–2 cm	+/-
1.5–4.0	2–3 cm	+
4	3 cm	No

Breslow depth does not correspond precisely to Clark level. It is used for prognostic purposes and to direct therapy.

less than one millimeter in thickness. The N component is based on the extent of regional lymph node involvement and the tumor burden of the nodes. While the sixth addition allowed use of microscopic staging of lymph nodes, newly added in the seventh edition is the immunohistochemical designation of positive lymph nodes using melanoma-associated markers such as HMB-45, Melan-A/MART-1. The M component is based on anatomic site of distant metastases and the serum lactate dehydrogenase level. The TNM classification defines five stages based on prognosis: stage 0 (in situ melanoma), stage II (local disease), stage III (regional nodes, in transit and satellite metastases), stage IV (distant metastases). The stage groupings and clinical/pathologic criteria are described in Table 91.2.

Elderly patients tend to present with poor prognostic features and therefore have increased mortality rates. Malignant melanoma in the elderly tends to present later, be thicker, have histologic ulceration, and be of nodular type. Additionally, elderly patients present more frequently with satellite and in transit metastases and have anatomic localization to areas other than the head and neck [104]. The reasons for this are complex but likely include some combination of decreased vision, increased tolerance for skin lesions, decreased social support, and increased comorbidity.

Patients presenting with malignant melanoma should be thoroughly evaluated. This includes a complete physical examination with special attention to a total body skin examination and lymph node palpation, laboratory studies including a complete blood count with differential, liver function tests, and chest radiography. Treatment of malignant melanoma depends on the depth and stage of the tumor. Though most authorities agree that excision of the primary lesion is the mainstay of treatment for all stages of malignant melanoma, there is controversy surrounding the size of the excisional margin and the method with which the margins are obtained.

TABLE 91.2 American Joint Committee on cancer classification for malignant melanomas

Stage	Classification			Clinical and pathologic criteria
O	Tis	NO	MO	In situ melanoma
IA	T1a	NO	MO	1.0 mm ² or less in thickness, no ulceration, mitoses less than 1/mm ² +
IB	T1b	NO	MO	With ulceration or mitotic rate more than 1/mm ²
	T2a	NO	MO	1.01–2.0 mm ² in thickness
IIA	T2b	NO	MO	1.01–2.0 mm ² with ulceration
	T3a	NO	MO	2.01–4.0 mm without ulceration
IIB	T3b	NO	MO	2.01–4.0 mm ² in thickness with ulceration
	T4a	NO	MO	>4.0 mm ² in thickness without ulceration
IIIA	T1-4a	N1a	MO	Any invasive T excluding >4 mm ² in thickness with ulceration, 1 regional node with micrometastases ^a
	T1-4a	N2a	MO	Any invasive T excluding >4 mm ² in thickness with ulceration, 2–3 regional nodes with micrometastases
IIIB	T1-4b	N1a	MO	Any invasive T, 1 regional node with micrometastases
	T1-4b	N2a	MO	Any invasive T, 2–3 regional nodes with micrometastases
	T1-4a	N1b	MO	Any invasive T excluding >4 mm ² in thickness with ulceration, 1 regional node with macrometastases
	T1-4a	N2b	MO	Any invasive T excluding >4 mm ² in thickness with ulceration, 2–3 regional macrometastases
IIIC	T1-a/b	N2c	MO	In transit or satellite metastases without nodal metastases
	T1-4b	N1b	MO	Any invasive T, 1 regional node with macrometastases
	T1-4b	N2b	MO	Any invasive T, 2–3 regional macrometastases
	Any T	N3	MO	Any T, ≥ 4 regional nodes including in-transit or satellite metastasis with positive metastatic nodes
IV	Any T	Any N	M1	Any lesion with distant skin, subcutaneous, lymph node, or organ metastases

^aMicrometastases now includes those seen on standard H&E staining or with melanoma-specific immunohistochemical markers

In situ lesions (Clark's level I, TNM stage 0) are by definition noninvasive. The goal for treatment of these lesions is to remove all tumor cells locally. If standard excision is the method of choice, usually 0.5-cm margins are adequate for in situ lesions. However, if the tumor is clinically ill-defined, wider margins may be advisable. The tumor margins should be assessed with a Wood's lamp and marked prior to administration of anesthesia. Lesions that have invaded the dermis and that are up to 1 mm in depth require excisional margins of 1 cm. Margins of 2 cm are recommended for lesions with a Breslow depth of 1.0–4.0 mm. Any lesion more than 4 mm thick should undergo wide excision with margins up to 3- to 5-cm.

The role of lymphadenectomy in malignant melanoma is controversial. Prophylactic lymphadenectomy is not indicated for in situ lesions, as they do not show evidence of metastasis. Sentinel lymph node biopsy, a procedure that permits biopsy of the first node that drains a regional lymphatic plexus and is thought to be representative of all nodes in that region, is advocated for all patients with primary melanomas >1 mm thick and for patients with high-risk thin (<1 mm) or stage IB (ulcerated) melanomas. The role of sentinel node biopsy versus clinical observation has recently been addressed by the Multicenter Selective

Lymphadenectomy trial-1 [105]. This prospective randomized multicenter trial demonstrated that the result of the sentinel node biopsy is the most powerful independent predictor of survival, but it did not demonstrate that the sentinel lymph node biopsy itself leads to a survival advantage. Contrary to previous speculation, the performance of the sentinel lymph node biopsy was not associated with the development of in-transit metastases. Despite the absence of a clear survival benefit, the sentinel node biopsy does provide valuable staging information and can lead to better management of regional disease. Patients with nodal metastases as demonstrated by the sentinel node biopsy should undergo complete lymph node dissection [106]. Lymph node involvement carries a poorer prognosis, with the 5-year survival dropping to 40%. Because malignant melanoma is considered a radioresistant tumor, the role of irradiation in metastatic disease is mostly palliative.

In the treatment of advanced metastatic disease, immunotherapeutic strategies are a focus of great interest. Specifically, an increasing number of clinical trials with interleukin-2, interferon, allogeneic whole-cell vaccines, recombinant viral vectors, adoptive immunotherapy combined with lymphodepletion, CTLA-4 blockade, allogeneic cell lysates, and dendritic cell manipulation are advancing our understanding of

tumor immunology and maybe extending life [107, 108]. The prognosis of patients with widely metastatic disease remains poor, but the full development and refinement of these strategies are progressing.

The perception that aggressive systemic therapy may have unacceptable toxicity in the elderly has limited our understanding of the effect of patient age on chemotherapy efficacy and toxicity. In the treatment of melanoma with isolated limb perfusion, patients of increased age demonstrated similar response rates with no increase in local or systemic toxicity [109]. Similarly, in a small group of elderly patients treated with high-dose IL-2 for melanoma and other tumor types, there was no demonstrated increase in adverse events to warrant their exclusion in future studies [110]. Therefore, while chronological age itself may not affect the efficacy or toxicity of any particular therapy, practical considerations necessitate the careful evaluation of comorbid disease, functional and mental status, support network, and patient willingness to tolerate the difficult side effects of treatment.

Patients who have been diagnosed with melanoma need close follow-up because they may be prone to developing a second primary tumor. Most recurrences arise within the first 18 months but can be delayed for many years. Follow-up should occur four times a year for the first year and at least twice a year thereafter [111]. Early recognition of local or regional disease or new primary melanoma lesions in this population can significantly alter the mortality rate from malignant melanoma.

Atypical Fibroxanthoma

Atypical fibroxanthoma is a spindle-cell neoplasm of mesenchymal origin that develops on the head and neck of elderly, light-skinned individuals. The tumor clinically presents as an asymptotic, solitary, firm nodule less than 2 cm in diameter which may go on to ulcerate or hemorrhage. Grossly, the lesion can resemble a SCC, BCC, epidermoid cyst, or pyogenic granuloma. Risk factors for tumor development include chronic sun exposure, radiation, local trauma, and male gender.

One of the unique features of this tumor is its malignant-appearing histology. Aside from the well-defined tumor margins and absence of deep tissue invasion, the tumor appears histologically indistinguishable from malignant fibrous histiocytoma [112]. It is composed of sheets of polymorphous cells, including spindle cells, large polyhedral cells, and giant multinucleated cells with marked nuclear atypia and numerous mitoses.

Despite its malignant histology, atypical fibroxanthoma has a relatively benign course. Metastases, however, have

been reported [113]. This has led some to classify the tumor as a superficial form of malignant fibrous histiocytoma [112], therefore requiring treatment.

Mohs surgery is the treatment for atypical fibroxanthoma. Recurrence rates range from 0 to 6.9% [114, 115]. Electrodesiccation and curettage is not considered adequate treatment because it does not remove the deep tissue, which may be invaded by tumor cells. The recurrence rate with tumors treated by wide excision is estimated to be approximately 10% [114]. Mohs surgery, which has the added advantage of conserving more normal tissue than wide excision, is currently the preferred method of treatment.

Merkel Cell Carcinoma

Merkel cell carcinoma is a rare malignant tumor of the neuroendocrine-derived Merkel cell. This tumor of unknown etiology typically affects persons over the age of 65, though cases of Merkel cell carcinoma developing in individuals as young as 7 years of age have been reported [116]. There have been no documented differences in incidence between men and women.

Merkel cell carcinoma manifests as rapidly growing, solitary, pink to violet nodules on sun-exposed skin. These firm, dome-shaped nodules are most commonly distributed on the head and neck (50% of cases), extremities (40% of cases), and trunk (10% of cases) of elderly Caucasians. Most tumors are less than 2 cm in diameter but can grow to become as large as 15 cm. The overlying epidermis may be shiny and intact with fine telangiectasias, or it may be ulcerated. Because of its nonspecific presentation, Merkel cell carcinoma is often not recognized prior to biopsy. It may be misdiagnosed as an SCC or BCC, a desmoplastic or amelanotic melanoma, a pyogenic granuloma, or a cutaneous metastasis of an oat cell carcinoma. Light microscopy may not be diagnostic because the tumor mimics other poorly differentiated small-cell tumors. The tumor is typically comprised of clusters of small, undifferentiated cells possessing scant cytoplasm that form trabeculae separated by strands of connective tissue. The trabeculae may extend down to the subcutaneous fat but do not invade the epidermis. Frequent mitoses and necrotic cells may be present. Confirmation of the diagnosis may require electron microscopy, which shows the characteristic secretory granules and paranuclear fibrous bodies.

Once the diagnosis of Merkel cell carcinoma is confirmed, a complete physical examination with attention to regional lymphadenopathy and organomegaly and a thorough workup including chest radiography and baseline laboratory tests, with liver function tests, should be performed. Merkel cell carcinoma is an aggressive tumor with

a high rate of local recurrence and early lymphatic spread. The treatment protocol for Merkel cell carcinoma is stage-dependent. Stage I or localized disease that has no evidence of lymph node metastases is treated by wide local excision. For localized tumors, adjuvant therapy with irradiation of the primary site is frequently employed, especially if there is angiolymphatic invasion. The role of prophylactic or elective complete lymph node dissection is controversial, but it has been utilized because of the high incidence of lymph node metastases in early disease [117, 118]. Limited studies have advocated a role for lower morbidity sentinel lymph node biopsy in the early detection of regional lymph node metastases, but the overall data to demonstrate its role in predicting survival end points is weak. Sentinel node biopsy may, however, be useful as a tool in determining the appropriate nodal basin for elective radiation therapy [119].

About 55–65% of stage I lesions progress to stage II or locally recurrent disease [120]. Stage II disease is defined by metastases to regional lymph nodes. Treatment involves wide excision of the primary tumor in combination with irradiation and lymph node dissection. Despite aggressive therapy, which may also involve chemotherapy, the mortality rate of stage II disease approaches 66%.

One-third of all patients with Merkel cell carcinoma progress to stage III, or systemic disease involving distant metastases. Stage III disease is managed primarily with chemotherapy. Chemotherapeutic agents similar to those used for treating oat cell carcinoma have been shown to be the most efficacious. The prognosis for stage III disease is grim, with an expected survival of less than 12 months. The average length of survival may increase with the use of *in vitro* assays that test a tumor's specific drug sensitivities, allowing optimization of the chemotherapeutic regimen [120]. Targeted chemotherapy has recently shown preliminary experimental success with intratumor natural human tumor necrosis factor, systemic imatinib, isolated limb perfusion, and autologous peripheral blood stem cell transplantation receiving attention [119]. Owing to the high recurrence rate of this tumor, patients who initially present should be followed monthly for the first 2 months, every 2–3 months for the next 2 years, and every 6 months thereafter.

Dermis

Angiosarcoma

Angiosarcoma is a rare malignant tumor arising from vascular or lymphatic endothelium. The lesion often starts as a

dusky erythematous, painless, “bruise-like” macule with poorly differentiated margins that proceed to ulcerate and hemorrhage as the cancer progresses to involve subcutaneous tissue. This aggressive vascular tumor, which affects men more commonly than women, has a predilection for the scalp and face of patients over the age of 60. Its etiology is unknown, although human herpes virus 8 [121] and environmental toxins such as Thorotrast, vinyl chloride, and insecticides have been implicated [122]. Chronic lymphedema and chronic radiodermatitis are predisposing factors.

Histologically, the early stages of the tumor show endothelial cell-lined intercommunicating vascular channels that appear to dissect through collagen bundles [123]. During the later stages, the tumor loses its organized vascular pattern and develops into large cell aggregates. There is subsequent formation of solid nodules of tumor followed by invasion of vascular channels.

The clinical appearance of this purple, flat, indistinctly bordered tumor often leads to its misdiagnosis as a bruise, hemangioma, or infections such as chronic cellulitis, localized lymphedema, or scarring alopecia [123]. The persistence of a bruise-like lesion, especially in an elderly individual, should warrant a biopsy. Angiosarcomas are frequently recognized late in their course, which partially accounts for their poor prognosis, with an estimated 5-year survival 12–27% [122]. They tend to recur locally and metastasize early in their course. Important prognostic factors include size, grade, and location of the tumor. High-grade tumors >5 cm located on the face tend to carry the worst prognosis [122, 123]. The mainstay of treatment is local excision combined with radiotherapy. Other forms of treatment, such as chemotherapy, have not been shown to alter survival significantly [121] but may be useful for short-term palliation [124].

Conclusions

Common cutaneous neoplasms that afflict the elderly arise from the epidermis or dermis and can be benign, premalignant, or malignant. Recognizing these lesions is important for providing care to a growing geriatric population. A regular, thorough skin examination enables physicians to monitor the elderly patient closely for the development of precancerous and cancerous lesions, which can ultimately be life-threatening. Minimizing the risk of malignant tumor development by avoiding precipitating factors such as UV radiation should be emphasized in this population.

CASE STUDY

Recurrent Basal Cell Carcinoma On The Nose Of A 75-Year-Old Woman

A 75-year-old woman presented with a slowly growing scar-like lesion at the junction of the right nasal ala and cheek. It was present for approximately 3 years. She noted a one-month history of a nonhealing lesion at the same site. Dermatologic history was significant for a BCC of the right nasal ala that was treated by electrode-siccation and curettage 5 years earlier. There was no history of radiation therapy. Her medical history was significant for insulin-dependent diabetes and hypertension. Social history was significant for loss of her husband 2 years ago. She lives alone.

Examination of the right cheek and right nasal ala demonstrated a 1.5 × 1.5 cm irregular, indurated, smooth-surfaced, shiny plaque with an indistinct border. Within this lesion, on the right ala, was a 3-mm crusted telangiectatic papule with hemorrhagic crust.

Laboratory data, including CBC, LFTs, and renal function tests were normal. A biopsy from the edge of the plaque demonstrated irregular, narrow, strand-like proliferations of palisading, basaloid tumor islands in a dense fibrous stroma that extended to the base of the biopsy. These histologic features were consistent with BCC, sclerosing or morpheaform subtype. Mohs surgery was selected as the treatment of choice

The first stage of Mohs surgery revealed a BCC with distinct nodular and morpheaform features. There was a focal area of epidermal ulceration and a nodule of palisading basaloid tumor islands extending from the deep epidermis into the superficial and mid-dermis. In the deeper and lateral sections, there were morpheaform strands of basaloid cells extending to the margins of the specimen. The tumor was cleared after the second stage of Mohs surgery. The postoperative defect extended to the cartilage of the ala and measured 2.5 × 2.3 cm. The wound was repaired under local anesthesia only in the office setting with an auricular cartilage graft and subcutaneous hinge flap. The secondary defect was closed in a linear fashion, and the area over the graft was left to epithelialize by second intention.

Discussion

Morpheaform BCCs and BCCs of mixed type that have morpheaform features are slow-growing, asymptomatic, and resemble scars, making them easily neglected by elderly patients. The clinical borders are indistinct, and the histologic tumor often extends far beyond what the clinical appearance would suggest. These cancers have a propensity for invasion and destruction of adjacent tissues, and they have a higher risk of recurrence than other subtypes of BCC.

Superficially destructive procedures such as cryotherapy, electrodesiccation and curettage, topical imiquimod, or elliptical excision have an increased risk of recurrence as demonstrated in this case. Mohs micrographic surgery is the treatment of choice as it offers the most complete margin evaluation and provides for immediate reconstruction if indicated. Mohs surgery is an office procedure performed using local anesthesia and is generally well tolerated. To facilitate the procedure, there should be proper preoperative consultation that addresses mental status issues, medication use, anticoagulants, the need for prophylactic antibiotics, and comorbid conditions. In the perioperative period, elderly patients often require additional support including attention to positional and emotional comfort as well as monitoring for orthostatic hypotension, hypoglycemia, and cardiovascular events. Anxiety can often be allayed with casual conversation.

Because of the large defects that may result from excision of morpheaform lesions, comorbidities such as diabetes, vascular disease, and the generalized slower wound healing in the elderly must be considered. It must be remembered that complex multistage repairs, while technically possible, may not be advisable in the elderly considering longer operative times and prolonged recovery.

In the postoperative period, pain is most often managed with acetaminophen alone. When more potent analgesics are required, slower drug metabolism, decreased glomerular filtration rates, and potential drug interactions from polypharmacy must be considered. Additionally, the postoperative need for complex or prolonged dressing changes with uncommon materials should be avoided. In general, wound care instructions are discussed with the patient as well as any caregiver present. Before discharge, adequate time is provided for patients to ask questions including concerns for cosmesis and recurrence. As follow-up, we advocate same evening and 24-h phone calls with lesion checks at 1 week.

Chapter 92

Surgical Management of Soft Tissue Sarcoma in the Geriatric Population

Charlotte E. Ariyan and Murray F. Brennan

Introduction

The management of soft tissue sarcomas in the elderly population requires a multidisciplinary approach. These rare tumors have a wide range of growth patterns and metastatic potential, much of which can be discerned by the pathologic subtype. Increasing age alone has repeatedly been demonstrated to have a negative impact on death from this disease. While surgery continues to be the primary treatment for sarcomas, radiation and chemotherapy have selective utility. The benefits of an aggressive approach must be weighed against the morbidity of treatment, particularly in the geriatric population.

Risk Factors

The majority of soft tissue sarcomas have no defined cause and are secondary to sporadic multiple mutations. However, hereditary forms do exist and are important to recognize (Table 92.1), as the mutation confers a lifelong risk of disease that may be augmented by prior treatments such as chemotherapy or radiation. The retinoblastoma population is an example of this phenomenon. These patients present at a young age for treatment, which often involves radiation. Forty-year follow-up of patients with hereditary retinoblastoma has found secondary malignancy in 36% of the patients, many of which are sarcomas [1, 2].

Additional risk factors for sarcoma include environmental toxins. Radiation predisposes to the development of sarcomas, and can be seen after radiation for any cancer, but particularly breast cancer, Hodgkin's disease, prostate cancer, and cervical cancer [3]. The majority of these radiation-induced sarcomas are high grade, and the ability to com-

pletely remove the new tumor predicts survival [4]. Chronic lymphedema predisposes to lymphangiosarcoma, or Stewart Treves syndrome [5]. Although there has been a suggestion that veterans exposed to Agent Orange have an elevated risk of sarcoma, this has never been shown to be a significant factor in case-controlled studies [6]. Vinyl chloride and polyvinyl chloride exposure are associated with an increased risk of hepatic angiosarcomas [7].

Staging

Soft tissue sarcomas are classically defined by size, depth, grade, and presence of lymph node or distant metastasis [8]. The presence of lymph node metastasis is rare. There are over 50 different subtypes of sarcoma, with different potential for recurrence and metastasis. More recently, Memorial Sloan-Kettering Cancer Center (MSKCC) has developed a nomogram to predict survival from sarcoma [9]. The factors demonstrated to most accurately predict survival are sarcoma subtype, grade, size, anatomic site, depth, and patient age. This nomogram has been validated with patients at other institutions [9, 10].

Evaluation and Biopsy

Most patients with soft tissue sarcomas present with an asymptomatic mass [11]. The differential diagnosis of a mass includes a hematoma, benign lipoma, lymphoma, germ cell tumor, and sarcoma. A history of an enlarging or changing lesion should raise the suspicion for a malignancy. Physical exam should focus differentiation between a soft, mobile lesion and one that is fixed or invading local structures.

Imaging will assist in determining the features of the mass and its relation to neurovascular structures. An MRI will clearly demonstrate fat and muscle planes and may be more useful in the elderly population that tends to have an increased fat composition. A CT Scan will often clarify intra-abdominal

TABLE 92.1 Risk factors for development of soft tissue sarcoma

Risk factor	Sarcoma
Gene mutation	Desmoid
Gardner's syndrome/ APC mutation	
Li-Fraumeni syndrome/ p53 mutation	Soft tissue, osteogenic
Neurofibromatosis type 1/ NF-1 mutation	Malignant peripheral nerve sheath tumor
Retinoblastoma/Rb mutation	Soft tissue, osteogenic
Radiation	Primarily high grade, multiple subtypes
Lymphedema	Lymphangiosarcoma
Postsurgical or parasitic	

lesions with improved clarity. PET scans are rarely used as sarcomas tend not to be FDG avid. Some lesions will be homogeneous and small and can be observed. Any lesion that is changing, heterogeneous on imaging, or large should be considered for biopsy or removal.

Biopsy can be performed by fine-needle aspiration (FNA), core-needle biopsy, incisional biopsy, or excisional biopsy. An FNA rarely provides enough tissue for utility. A core biopsy can be performed easily in the clinic with 95% accuracy [12]. An incisional biopsy provides an abundance of tissue; however, it requires a surgical procedure for the patient and risks the formation of hematoma postoperatively. This procedure must be carefully planned with a longitudinally oriented incision that can be incorporated in a future resection. Small tumors that are less than 5 cm and easily resectable can be removed by an excisional biopsy.

The biopsy grade and histologic subtype will be the most important data gained from the biopsy. Integration of this information with the site, size, and depth will provide important prognostic information. This can be used to derive an optimal treatment plan for the patient.

Surgery for Sarcoma in the Geriatric Population

Of over 7,000 adult sarcomas removed at MSKCC and maintained in our database, there is a difference in the histopathological subtype of soft tissue sarcomas based upon age. As shown in Fig. 92.1, the common subtypes such as malignant fibrous histiocytoma (MFH), liposarcoma, and leiomyosarcoma prevail in both groups; however, there are a few notable differences. Synovial cell sarcoma is classically a tumor of young patients. Desmoids are slow-growing tumors that tend not to metastasize; therefore, the low incidence of these patients seen in our database may reflect a referral bias of older patients. As the designation of MFH is being more

FIGURE 92.1 Incidence of sarcoma subtypes over a 25-year period at Memorial Sloan-Kettering Cancer Center (MSKCC). The data is shown for the geriatric population, and for those patients under 70. The data is expressed as the total number of sarcomas ($n = 7,531$).

accurately defined in recent years, it is possible that the higher prevalence in the geriatric population reflects the imprecision of earlier diagnoses.

The decision to operate on an extremity sarcoma in an elderly patient is based upon multiple factors. First, there must be an adequate understanding of the natural history of the disease in the absence of treatment. Second, there must be awareness of the additional therapies, namely radiation or chemotherapy. The morbidity of treatments, surgical or medical, must then be balanced with the risk associated with the tumor and the underlying condition of the patient. The major advancement in understanding the natural history of sarcomas comes from the ability to subtype sarcomas based on histopathology and molecular features. With this understanding, a physician can tailor the treatment to the individual patient. This review will focus on treatment of the most common types of sarcomas in the geriatric population.

Extremity/Truncal Sarcomas

The primary treatment of an extremity or truncal sarcoma is surgical excision. The type of surgery is guided by subtype and anatomic location. In the geriatric population, the most common subtypes in the extremity are malignant fibrous histiocytoma (MFH), liposarcoma, and leiomyosarcoma as shown in Fig. 92.2. In the trunk, the most common subtypes are MFH, angiosarcoma, and liposarcoma. This is in contrast to the younger population, where synovial cell is observed

more often in the extremity, and desmoids are observed more often in the trunk. Additional therapy includes radiation and chemotherapy, which can be administered in an adjuvant or neoadjuvant fashion.

FIGURE 92.2 Incidence of common extremity subtypes by age for patients. Data shown is percentage of total extremity lesions in the database at Memorial Sloan-Kettering Cancer Center (MSKCC) ($n=3,073$).

Surgical Management

The grade of the tumor and the size are the first items that will guide the treatment algorithm. Both can be obtained from the clinical exam, radiology studies, and possible biopsy. As shown in Fig. 92.3, any lesion less than 5 cm can be primarily removed, if it is in a location where the postoperative field of radiation would not cross a joint or damage a major neurovascular structure. Lesions greater than 10 cm should be biopsied, as some high-grade lesions can be offered neoadjuvant chemotherapy.

Role of Amputation

A prospective, randomized trial published in 1982 did not demonstrate a survival advantage for amputation in patients with extremity sarcoma. Forty-three patients, all undergoing chemotherapy, consented to either amputation or wide excision (WE) with postoperative radiation. Analysis at 5 years demonstrated an increased local recurrence rate in patients with WE; however, there was no difference in disease-specific survival (DSS) at 5 years (71% vs. 78%, $p=0.75$) [13]. The efficacy of

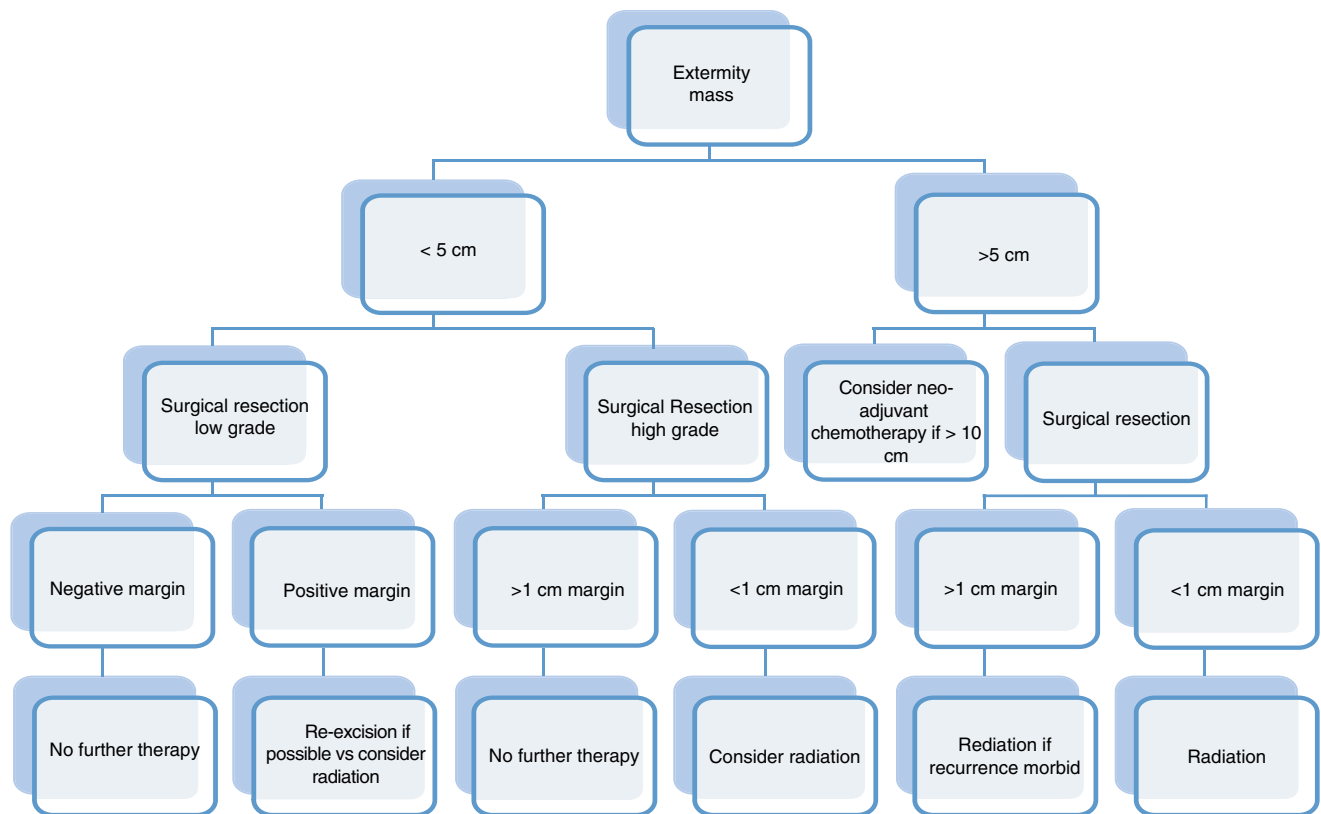

FIGURE 92.3 Treatment algorithm for extremity sarcoma in the geriatric patient.

FIGURE 92.4 Incidence of amputations in patients at Memorial Sloan-Kettering Cancer Center (MSKCC) from 1968 to 2006. Note the increase in the number of limb-sparing surgeries performed since the 1980s. While the number of amputations remains relatively stable, the number of amputations per procedure performed has markedly decreased.

limb-sparing surgery (LSS) in managing sarcomas has been confirmed in follow-up studies from later time periods [14]. The indications for amputation currently are limited to large tumors, where limb-sparing resection would not remove the majority of the disease or would result in a limb with poor function. Over the years, the incidence of amputation has diminished for extremity sarcoma, as shown in Fig. 92.4, and many complicated lesions can be managed with surgery alone or in combination with radiation and chemotherapy.

Low-Grade Extremity Lesions

Atypical lipomatous tumors (ALT) and well-differentiated liposarcomas are similar and should be treated with a wide local excision that preserves function and obtains a negative margin. For those patients with a complete, R0 resection, the risk of recurrence is extremely low. In a study of 91 patients with ALT or well-differentiated liposarcoma, there were no recurrences in 10 years of follow-up for those patients with a negative margin and the absence of a sclerosing component. Distant metastatic disease developed in only one patient who had dedifferentiated sarcoma in the recurrence [15]. Geriatric patients with a microscopic positive margin can either be reexcised or observed, as a recurrence may not happen, or it may take many years to develop. There is no role for adjuvant radiation or chemotherapy in these lesions.

Dermatofibrosarcoma protuberans is a low-grade tumor. Only the fibrosarcomatous variant carries a small risk of metastatic disease [16]. These lesions should also be treated with primary surgical resection. Because DFSP tend to grow along tissue planes that extend beyond the palpable tumor, whenever possible the operation should include a margin of normal subcutaneous tissue around the palpable mass, and the underlying fascia. With surgery obtaining negative margins, the rate of local recurrence is <5% at 5 years; therefore, there is a limited role for adjuvant chemotherapy or radiation [16].

Desmoids are composed of myofibroblasts. The management is complicated, as they do not have metastatic potential yet they can be locally invasive. Extremity desmoids should be treated with a wide excision to obtain negative margins yet preserve functional outcome. In a series of 189 extremity desmoids, the local recurrence rate at 5 years for patients with a negative margin was 22%; in patients with a positive margin the recurrence rate was 24%, yet some of those patients had adjuvant radiation [17]. This provides evidence that debilitating operations should not be performed in an effort to obtain negative margins. The role of radiation therapy for extremity desmoids remains controversial but radiation should be used sparingly. Desmoids are low-grade tumors that never metastasize, and even when they do recur locally they can remain stable for many years even without treatment, as demonstrated in the case at the end of this chapter.

High-Grade Lesions

The common high-grade sarcomas of the extremity and trunk in geriatric patients include leiomyosarcomas, malignant fibrous histiocytoma (MFH), liposarcomas (dedifferentiated, pleomorphic, myxoid round cell), and angiosarcoma. The primary treatment of these lesions is surgery, alone or in combination with radiation or chemotherapy.

Malignant fibrous histiocytoma (MFH) is a term that has been used to characterize high-grade lesions with a fibrohistiocytic pathology over the years. Today, with improved histologic subtyping, many of the lesions originally characterized as MFH can be assigned other high-grade nomenclature, or are referred to as high-grade undifferentiated pleomorphic sarcoma. Therefore, today this term encompasses lesions that are high grade and can not otherwise be placed into another grouping. However, myxofibrosarcomas are one type of MFHs which have a more discernable pattern and characteristic growth pattern.

Myxofibrosarcomas tend to occur in the extremity of elderly patients. These tumors can have satellite nodules or extensions well beyond the primary location of the tumor, which may in part explain the greater than 50% recurrence observed in some series [18–20]. One strategy to minimize recurrence is to carefully review the preoperative CT Scan or MRI for evidence of multifocal lesions as well as sites of distant spread such as lung, bone, soft tissue, and mesentery [21]. These tumors are often relatively resistant to radiation and chemotherapy, making surgery essential to local control.

Angiosarcoma is an aggressive tumor of the blood or lymphatic vessels. Risk factors include a limb with chronic lymphedema (Stewart–Treves Syndrome) [22], as well as radiation. It has been noted in the breast and pelvis after radiation for malignancy [4, 23], and therefore it unfortunately is a near lethal consequence of treatment aimed to reduce local recurrence. This tumor is aggressive and often multifocal at presentation, which challenges the ability to obtain negative margins. The overall survival is poor, with ranges reported between 21% at 2 years [24] and 40% at 5 years [4], so the utility of radiation, a potential causative factor, in reducing a local recurrence needs to be balanced with the risk of development of an aggressive secondary malignancy. In patients with extensive and multifocal angiosarcoma at presentation paclitaxel-based neoadjuvant chemotherapy may be used.

Malignant peripheral nerve sheath tumors (MPNST) can arise sporadically or when associated with NF-1 from neurofibromas. Most MPNST are high grade, and they commonly occur in the trunk or extremity in the geriatric population; however, they can arise from the nerve sheath anywhere in the body. MPNST has an infiltrative, poorly discernable growth pattern that extends beyond the palpable tumor along the fascicles of the nerve root. Surgery should include a 2 cm margin with an additional 2–3 cm of the nerve whenever possible. Preoperatively, the patient needs to be educated and prepared for possible loss of motor function. Patients with acceptable comorbidities and a large (>10 cm) MPNST should be considered for neoadjuvant chemotherapy, while smaller tumors should receive surgical resection and radiation. Survival for MPNST tumors treated aggressively parallels that of other high-grade sarcomas [25].

Role of Radiation

Radiation reduces the risk of local recurrence when used as an adjuvant to surgery, and it can be used in a preoperative fashion to shrink tumor away from vital structures. These benefits of radiation must be balanced with the long-term complications: limb edema, fibrosis, bone fracture, wound complications, and formation of a radiation-associated sarcoma in the future. Fortunately, randomized controlled trials

have helped to clarify which patients are most likely to benefit from radiation.

Extremity/truncal radiation is delivered by brachytherapy catheters (BRT) or external beam radiation therapy (EBRT) as a means to improve local control. A prospective randomized trial compared the use of brachytherapy (BRT) catheters, placed at the time of surgical resection, to surgical resection alone. While BRT increased the rate of local control at 5 years in the patients with high-grade tumors (89% vs. 66%, respectively, $p=0.0025$), it had no effect in patients with low-grade tumors [26]. Trials with external beam radiation therapy (EBRT), in contrast, demonstrated improved local control in high-grade and low-grade lesions [27]. Disease-specific survival was not altered by radiation with either brachytherapy or EBRT [28, 29]. Therefore, adjuvant radiotherapy should be considered for patients with large, high-grade sarcomas. Patients with low-grade sarcomas, or high-grade tumors <5 cm, can be treated with primary surgery alone if wide margins (1–2 cm) are obtained, as the recurrence rate is low [29].

An additional randomized trial demonstrated that radiation can be delivered preoperatively or postoperatively, with equal efficacy in decreasing local recurrence but with different complications based on the timing of delivery [27]. Preoperative radiation targets primarily the tumor mass, yet it can make pathological analysis of the specimen more difficult and result in a higher rate of wound complications after surgery. Postoperative radiation encompasses an area around the incision, and therefore it is a larger radiation field. There is increased limb edema and fibrosis over the long term. In an elderly patient, these risks need to be balanced with the comorbidities expected in long-term survival of the patient.

Intensity modulated radiation therapy (IMRT) is a method of delivering radiation to the tumor while minimizing damage to adjacent vital structures such as nerves, arteries, and bone. Therefore, the negative effects of radiation on neighboring nerves, arteries, and bone can be decreased. For example, a large sarcoma resection with periosteal stripping and requiring circumferential radiation is associated with a high risk of bone fractures that reaches 29% at 5 years [30]. This fracture rate can be reduced to 6.4% with the use of IMRT [31].

Chemotherapy in Extremity/ Truncal Sarcomas

Multiple attempts have been made to define the role of adjuvant chemotherapy in sarcoma, and unfortunately no one combination has substantially improved survival. The enthusiasm for chemotherapy, in part, began with the use of the anthracycline doxorubicin. In a randomized trial of patients with extremity sarcoma, adjuvant doxorubicin improved overall and disease-specific survival at 3 years [32], but with further follow-up,

this survival benefit did not persist [33]. Many additional trials followed attempting to demonstrate a survival advantage with chemotherapy. A meta-analysis of the most vigorous trials failed to reveal an improvement in overall survival with chemotherapy. ($p=0.12$). However, when the analysis was limited to the subgroup of patients with extremity sarcoma, a 7% absolute benefit in overall survival was demonstrated at 10 years ($p=0.029$) [34]. Since 1990, anthracyclines have been combined with alkylating agents such as ifosfamide in an attempt to improve efficacy. However, anthracyclines are cardiotoxic, and therefore the geriatric patient must be carefully assessed prior to administration of anthracyclines.

Ifosfamide is an alkylating agent that delays time to disease progression in patients with advanced, unresectable, or metastatic sarcoma [35].

A recent study utilized ifosfamide in an adjuvant fashion in 104 patients with high-grade extremity sarcoma after surgery. One arm of the study underwent observation, while the other arm underwent treatment with adjuvant epidoxorubicin and ifosfamide. After 2 years, the trial was stopped because, at interim analysis, there was a significant increase in disease-free survival (48 months with chemotherapy vs. 16 months with observation, $p=0.04$) and overall survival (75 vs. 46 months, respectively, $p=0.03$) [36]. However, on longer follow-up the difference in survival no longer persisted [37].

While the role of ifosfamide in an adjuvant manner remains unclear, there has been data to support its role in a neoadjuvant approach. The utilization of neoadjuvant ifosfamide in combination with doxorubicin and mesna resulted in a 21% improvement in disease-specific survival at 3 years in all patients with extremity subtypes of high grade, deep tumors >10 cm. In this study, the most commonly represented subtypes were MFH, liposarcoma, synovial cell, and leiomyosarcoma [38].

Further studies have also supported the role of neoadjuvant chemotherapy in the treatment of liposarcomas. There are three biological groups of liposarcoma, which includes five subtypes: (1) well-differentiated/dedifferentiated, (2) myxoid/round cell, and (3) pleomorphic. The high-grade subtypes with a high risk of systemic recurrence are myxoid/round cell (>5% round cell component) and pleomorphic [39–43]. A retrospective analysis of patients with extremity liposarcoma from MSKCC and UCLA compared patients who received chemotherapy to a similar cohort of patients who did not receive chemotherapy. There was no improvement in survival demonstrated with doxorubicin therapy; however, ifosfamide combined with doxorubicin therapy demonstrated an improved DSS at 5 years compared with no chemotherapy (92% vs. 65%, respectively, $p=0.0003$) [44]. This translates into a 31% survival benefit for lesions >10 cm. Based on the results of this retrospective study, and in the absence of any prospective randomized data, neoadjuvant doxorubicin and ifosfamide chemotherapy can be offered only to elderly patients with large (>10 cm), extremity

round cell or pleomorphic liposarcoma, with an excellent performance status. Dedifferentiated liposarcoma of the extremity is not sensitive to chemotherapy and has a lower risk of metastatic disease; therefore, chemotherapy is not used in this subtype.

Synovial cell sarcoma is very uncommon in the geriatric population. This is a disease of young adults that is associated with a high risk of metastasis and death [45], and therefore, larger lesions are treated with systemic chemotherapy based on retrospective data [46].

Retroperitoneal Sarcoma

Subtypes and Goals of Surgery

The most common subtypes of retroperitoneal sarcomas, regardless of age, are liposarcomas and leiomyosarcomas as shown in Fig. 92.5. Retroperitoneal sarcomas can grow large without specific symptoms; therefore, they are often detected late, at which time they are often large (>10 cm) and encroach on major abdominal structures [47].

Upon presentation, a biopsy is performed when there is concern for a benign process or other malignancy that would not mandate surgical intervention. Additional tumors to consider are lymphomas, angiomyolipomas, pancreatic tail tumors, benign schwannomas, adrenal tumors, and metastatic germ cell tumors. While primary surgical resection obtaining negative margins is associated with improved survival, removal of adjacent organs is not always necessary [47]. If the mass does not encase the renal vessels or invade the renal hilum, a parenchymal-sparing capsular stripping can be performed without compromising disease-specific survival [48].

Surgical management of retroperitoneal liposarcomas must take into account the subtypes, which have been shown to be one of the most important factors in DSS. In a study of 177 patients, the well-differentiated subtype had a very good survival and much lower recurrence rate than the dedifferentiated liposarcoma. The local recurrence rate for patients with well-differentiated liposarcoma was 31% at 3 years compared with 83% at 3 years for dedifferentiated liposarcoma. The dedifferentiated subtype had a 30% risk of distant disease at 3 years. In contrast, well-differentiated liposarcoma rarely developed distant metastasis (1% risk of distant disease at 3 years) [48].

Leiomyosarcomas of the abdomen commonly involve vessels and can involve major structures such as the inferior vena cava. Surgical resection can safely be performed with IVC ligation as long as drainage of the kidneys is preserved [49]. Many abdominal leiomyosarcomas have now been classified as gastrointestinal stromal tumors (GIST) as discussed below.

FIGURE 92.5 Subtypes of sarcoma in the retroperitoneum seen over a 25-year period at Memorial Sloan-Kettering Cancer Center (MSKCC). The majority of retroperitoneal tumors are either liposarcoma or leiomyosarcoma, which do not differ by age.

Radiation in Retroperitoneal Sarcomas

Retroperitoneal sarcomas have a high local recurrence rate, with prevalence of 20–50% depending on the length of follow-up [47, 50, 51]. Median survival after local recurrence is only 28 months [47]; therefore, consideration has been given to both chemotherapy and radiation in retroperitoneal sarcomas. While there is little data to support the use of chemotherapy, radiation, which addresses the local treatment failure, has been considered.

Radiation of the retroperitoneum is a difficult task as radiation cannot be delivered without risk to the surrounding vessels and intestine. However, small studies suggested that high-dose radiation improves local control [52, 53]. A prospective trial of preoperative radiation in patients undergoing a R0 or R1 resection demonstrated an improvement to 60% local recurrence-free survival in intermediate- or high-grade lesions, at a median follow-up of 40 months, with an associated increased morbidity [54]. Further multi-institutional randomized trials are needed to define the role of preoperative radiation therapy for the treatment of retroperitoneal sarcoma; however, these trials have closed secondary to poor accrual. Newer techniques of external beam radiotherapy such as IMRT may enable administration of radiotherapy with less toxicity to surrounding organs and vital structures.

Locally Recurrent Retroperitoneal Sarcoma

Recurrence in retroperitoneal sarcomas is more difficult to treat, in part secondary to prior contamination and scarring of tissue planes, as well as the aggressive nature of the tumor. Surgical removal must not only remove the mass, but also any tissue plane violated in a previous resection such as drain

tracks or skin flaps. In difficult cases, the surgeon may have to remove the recurrent tumor with an adjacent neurovascular structure, and this should be carefully planned ahead of the operation. An alternative is to give a trial of neoadjuvant radiotherapy or chemotherapy before the tumor is excised to spare a major resection.

Abdominal Desmoid

Abdominal desmoids can arise spontaneously or in association with familial adenomatous polyposis (FAP). Desmoid tumors arising in patients with FAP, commonly present in patients at a younger age, and they are related to the mutation in the adenomatous polyposis (APC) gene, effecting β -catenin levels [55–58]. Sporadic desmoids have been linked to mutations in the β -catenin gene itself [59–63]. Regardless of the mutation, desmoids do not metastasize and have an unclear natural history. There have been multiple case reports of spontaneous regression of even multifocal tumors [64–67]. Patients on medical therapy fail to have progression of the tumor at least 50% of the time. Whether this is due to the inherent nature of the tumor itself or as a result of the medical therapy has not been clarified by a randomized trial. Most recently, a small clinical trial of abdominal desmoids with the anti-inflammatory sulindac and tamoxifen resulted in a 77% PR/CR [68]. At St. Mark's hospital, all patients with intra-abdominal desmoids first receive medical therapy with sulindac. If there is tumor progression, tamoxifen or other chemotherapies are added. Only patients who fail these conservative measures are then considered for surgical intervention [69]. In the geriatric population, a trial of this more conservative treatment algorithm is warranted.

GIST

Treatment of Primary Disease

Gastrointestinal stromal tumors (GIST) commonly present as asymptomatic pedunculated or submucosal masses arising in the gastrointestinal tract. On imaging, GIST tumors are well-circumscribed, low-density lesions, with possible areas of enhancement or necrosis. A suspected GIST should be removed for diagnosis and treatment if localized and the patient can tolerate the operation. Biopsy risks rupturing the mass and only complete resection offers the best chance of cure.

The important factors of the primary tumor that predict risk of recurrence are the anatomic location of the GIST, size, and mitotic index. For example, a distal small bowel GIST greater than 5 cm with a mitotic index >5 per 50 high-power field (HPF) has an 85% chance of recurrence, while a tumor <2 cm with ≤5 mitoses per HPF has a negligible chance of recurrence regardless of site [70, 71].

A majority (80%) of GIST tumors have an activating mutation of the KIT receptor tyrosine kinase and have therefore been successfully treated with the kinase inhibitor imatinib [72]. Expression of cKit is not enough to predict a response to imatinib, however, and mutation analysis should be performed before considering therapy. For example, exon 11 mutations respond well to imatinib, while exon 9 mutations do not [73, 74]. A small percent (5–10%) of GISTs harbor a mutation in platelet-derived growth factor alpha (PDGFRA) [75], some of which may be resistant to imatinib, but the new multikinase inhibitors such as sunitinib may have efficacy.

The role of imatinib as an adjuvant to surgical resection was evaluated by the ACOSOG intergroup trial. Patients were randomized after complete resection of a tumor >3 cm to 1 year of imatinib at 400 mg daily or placebo. There was a significant improvement in recurrence-free survival with imatinib treatment, although no difference was seen in disease-specific survival [76]. Longer follow-up will help clarify if imatinib prevents, or merely delays, the onset of disease recurrence. It may be that therapy initiated at the time of disease recurrence will be equally effective.

Metastatic GIST

Prior to imatinib, patients with metastatic GIST had a poor survival measured in months. However, recent trials have demonstrated that high-dose imatinib in metastatic disease can result in actual 2-year survival, with 50% of patients alive without disease progression [77]. This raises the question whether surgery should be utilized in conjunction with imatinib therapy to reduce tumor burden, or whether these patients should just be maintained on imatinib therapy. The major downside to imatinib is the development of resistant disease. Studies have demonstrated that resistance develops as soon as 6 months, with a median time to drug resistance of 20 months [77]. A recent study of 40 patients with metastatic GIST supports surgical intervention for those patients with disease that responded to imatinib. Patients with multifocal resistance, however, have a poor 1-year survival (36% alive at 1 year) and should not proceed to surgical debulking but should be considered for a clinical trial with a second line tyrosine kinase inhibitor [78].

CASE STUDY 1

A 73-year-old male with a history of retinoblastoma at age three for which he had eye enucleation and radiation. Past medical history also significant for coronary artery disease, resection of multiple lipomas, a partial nephrectomy for renal cell cancer, as well as an appendectomy. The patient's mother and daughter also had retinoblastoma. The patient presented with a small mass on his face in the field of radiation. Biopsy was consistent with a high grade, <5 cm leiomyosarcoma, and he underwent a wide local excision with negative margins.

Discussion

This patient had childhood retinoblastoma, which is related to a mutation in the retinoblastoma (RB1) gene. In hereditary forms of retinoblastoma, the cumulative risk of developing a secondary malignancy such as sarcoma is 36% [1]. Long-term follow-up of patients such as this with hereditary retinoblastomas has demonstrated that the most common subtype observed is leiomyosarcomas, almost all of which have been observed in patients with prior radiation [2]. Surgical resection is the treatment of this high-grade tumor. There is no role for further radiation. The patient needs continued follow-up for development of recurrence or another sarcoma. This emphasizes the importance of life-long surveillance for such patients with the loss of the Rb tumor suppressor gene.

CASE STUDY 2

A 38-year-old male with an extremity mass. Imaging revealed the mass to extend from the pelvic sidewall to the lower extremity. Biopsy was consistent with a desmoid tumor. The patient had no other comorbidities. He was started on tamoxifen and has had stable disease, with a partial response for 13 years as shown in Fig. 92.6.

Discussion

This case, although not in an elderly patient, demonstrates the importance of cautious observation in patients with desmoid tumors. A surgical option for this patient would be a hemipelvectomy, which would have decreased the quality of life. Stable disease such as this, for more than a decade, is further evidence that many desmoids can be treated without surgery in the geriatric population.

FIGURE 92.6 Thirteen-year follow-up of large extremity desmoids managed with nonoperative therapy.

CASE STUDY 3

85-year-old male with a history of coronary artery disease who underwent a coronary angioplasty and had moderate dementia requiring assistance in a nursing home. The patient presented with a large fungating mass of the thigh that was interfering with ambulation. Biopsy was consistent with a high-grade MFH. After a careful consult with the family and the medical team, a surgical excision was performed. At operation, the mass involved the entire anterior compartment of the thigh down to, but not including, the femoral vessels. Pathology confirmed the high-grade MFH, but margins were microscopically

positive. The patient's wound was slow to heal and he underwent careful observation and continued with his functional life. Three years later he had a local recurrence, which was excised without incident. One year later, the patient died of other causes at his nursing home.

Discussion

This case highlights the need to balance the use of medical therapies to maintain the quality of life. The large MFH tumor in this patient could be treated with

(continued)

CASE STUDY 3 (continued)

neoadjuvant chemotherapy, but clearly the morbidity of this treatment with only a marginal potential benefit would not be warranted in this patient. A more aggressive surgical procedure could have been performed, but this would have risked leaving the patient with a functionally compromised or absent limb, and removing all

measurable tumor provided good functional relief for the patient. Postoperative radiation therapy is generally well tolerated, and it could have been utilized in the patient. The decision not to was based on his poor ability to heal his primary wound, and the concern of the patient and family regarding the ability to tolerate weeks of radiation therapy. The expected local recurrence was easily managed with a minor surgical intervention.

Summary

Soft tissue sarcomas represent a heterogeneous group of tumors with varying malignant potential. The decision to operate on a geriatric patient with a sarcoma must be undertaken carefully, with the underlying knowledge that older patients tend to have a decreased disease-specific survival from sarcoma. Surgery remains the mainstay of treatment in patients who can tolerate it. Radiation is generally well tolerated and can be used as an adjuvant to surgery in patients with high-grade tumors. Chemotherapy has yet to show a dramatic improvement in survival and should be used judiciously.

The ability to obtain a complete surgical resection is the primary governor of outcome in patients with retroperitoneal and visceral sarcomas. Many patients will recur locally and this can lead to death from progressive loco-regional disease. The majority of retroperitoneal and visceral sarcomas are poorly responsive to conventional chemotherapy, so chemotherapy is generally only used for palliation of disease in a patient who can tolerate it.

The management of GIST tumors hopefully represents the future of treatment in sarcoma. As characteristic mutations are identified in subtypes, new targeted therapies can be developed. As the population ages, treatment of sarcomas in the geriatric population will continue to involve a multidisciplinary approach to maximize treatment and maintain quality of life.

Chapter 93

Pressure Sores in the Elderly

Alexander Y. Lin and Mary H. McGrath

Introduction

Capillary perfusion pressure is the source of life for all the cells in our body, and yet, it averages a modest 22 mmHg throughout most systems in the body. Venous capillary closing pressure is about 12 mmHg, and arterial capillary pressure about 32 mmHg [1]. This delicate homeostasis can be upset by something as simple as excessive external pressure on tissue. This situation requires two unyielding surfaces: one an underlying bony prominence and the other an external plane such as a bed, chair, or even a transport gurney. The most common bony surfaces involved, in order of occurrence, are the sacrum, calcaneus, ischium, and greater trochanter [2]. In fact, these areas are subject to pressure exceeding 30 mmHg when lying supine, sitting, or lying on the side, respectively [3]. This situation is usually benign as our autonomic nervous system prompts us to shift our weight frequently to avoid chronic pressure.

Prolonged pressure, as in an elderly patient who is obtunded or with limited mobility, leads to chronic pressures exceeding the capillary perfusion pressure, resulting in compromised oxygenation, ischemia, and eventually tissue necrosis. Studies in models of ischemia have demonstrated that external pressure greater than 60 mmHg for 2 h leads to irreversible tissue damage [4]; clinical studies confirm this range [5, 6]. The sequelae of this damage are pressure sores with ulceration, infection, and exposure of bone. The estimated annual cost of hospital-acquired pressure sores alone is in the \$3 billion range [7].

Pressure ulcers are a disease of the elderly: about two-thirds of pressure sores occur in patients over 70 years of age [8]. Most of the remaining are in spinal-cord injury patients. Fourteen percent to 17% of patients in a U.S. acute-care

hospital have pressure sores, and the incidence of new hospital-acquired pressure sores is 7–9% [2]. The majority of pressure ulcers occurring in the acute-care hospital setting develop within the first 2 weeks of admission [9], probably because patients are more bed-bound until their acute issues are diagnosed and stabilized. In this elderly population, the presence of multiple comorbidities contributes to the etiopathogenesis of pressure ulcers. Although pressure sores are associated with a twofold increase in mortality [10], they are not usually the immediate cause of death. More commonly, comorbidities that lead to pressure sores such as cardiovascular, neurological, or orthopedic diseases have their own high mortality rates.

The goals in the management of pressure sores are: identification of the etiological factors, elimination of these factors, wound care and debridement to prevent chronic infection from progressing to an acute infection, and consideration for surgical coverage if benefits of repair outweigh risks of anesthesia and recurrence.

Pathophysiology

Both extrinsic and intrinsic factors contribute to the pathogenesis of pressure ulcers. Extrinsic factors include unrelieved pressure as seen in debilitated or spinal-cord injury patients, and also factors that worsen the local wound environment, such as moisture in the perineal area [11], incontinence [12], and shearing forces from patient repositioning. Intrinsic factors include underlying conditions that lead to poor wound healing, such as advanced age [13, 14], diabetes, malnutrition, and edema. Edema may occur in the elderly due to other systemic illnesses and sets up a downward spiral where dependent edema is worsened by pressure exceeding the capillary venous outflow pressure, leading to even worse edema in the dependent regions, compensatory increased arterial pressure, extravasation and worsening edema (Table 93.1).

Extrinsic pressures can also be augmented by positioning, and clinical studies show that some commonplace positions are particularly problematic. In a semirecumbent position with the head of the bed elevated, only friction keeps the

TABLE 93.1 Extrinsic and intrinsic factors contributing to pressure sore formation

Extrinsic	Intrinsic
Limited mobility	Advanced age
Loss of protective sensation	Skin fragility
Abnormal positioning due to spasticity or contracture	Poor nutritional status
Friction and shearing forces	Dependent edema
Chronic moisture	Immunoincompetence
Other mechanical factors that increase pressure	Infection
	Medical conditions

**FIGURE 93.1** Topographic pressure maps of the human body in millimeters of mercury. (a) Supine (*left*) and prone (*right*) positions. Note that in the prone position, the highest pressures are centered on the sacrum and heels, exceeding 30 mmHg. (b) Seated position reveals pressures much greater than 30 mmHg for the ischii (reprinted from Lindan O (1961) Etiology of decubitus ulcers: An experimental study. Arch Phys Med Rehabil 42:774, with permission from Elsevier).

patient from sliding down. This situation leads to shearing forces on the skin and soft tissue overlying the sacrum which mechanically creates ischemia that predisposes to ulceration [15]. Topographic pressure maps show why certain areas, such as the sacrum, heels, and ischii are prone to ischemic damage (Fig. 93.1) [3].

Malnutrition is prevalent among older patients, with the 2002 Nutritional Screening Initiative estimating the rate of malnutrition among hospitalized elderly as 40–60%, nursing home residents as 40–85%, and home-care elderly patients as 20–60% [16]. Malnutrition increases the likelihood of developing pressure ulcers at least twofold [17].

The Braden Scale for Predicting Pressure Sore Risk is a widely used nursing assessment tool to help predict patients' risk of developing pressure sores. Although there is no clear evidence that risk-assessment scales decrease incidence of pressure ulcers, the Braden scale has reasonable predictive capacity with high interrater reliability [18]. This scale accounts for several extrinsic and intrinsic etiologic factors by scoring six subscales: sensory perception, moisture, activity, mobility, nutrition, and friction/shear. The lower the subscale score, the worse the risk, so the lower the combined Braden score (ranges from 6 to 23), the higher the risk of pressure sore development.

Intrinsically, different tissues can tolerate ischemia at varying levels. Muscle, with its high metabolic requirements, is more sensitive to hypoxia than is skin or subcutaneous fat. Although most pressure sore severity indexes recognize early skin changes as “low-grade,” some degree of muscle damage is inevitable by the time the skin shows changes.

Pressure ulcers are some of the most difficult wounds to heal given their dependent positions, relative lack of blood supply, and patient comorbidities that may compromise wound healing in the elderly population. Identifying these causative factors is the first step in the evaluation and management of these wounds.

Evaluation

The evaluation of a pressure sore begins with a careful history and physical exam. The history is essential to establish which of the extrinsic and intrinsic factors contribute to the etiology and chronicity of the wound. Without addressing these factors, therapeutic efforts will fail, whether surgical or nonsurgical. For instance, a sacral pressure sore is bound to recur after surgical coverage if an air mattress and turning schedule are not implemented for an elderly stroke patient with limited mobility.

The most common classification system is the National Pressure Sore Advisory Panel Consensus Development

Conference scale developed in 1989. It is based on which tissue level is exposed in the wound. It is a purely visual scale that does not account for deeper destruction and simply stages according to the four main layers of tissue:

- Does not pass skin
- Does not pass subcutaneous fat
- Does not pass muscle
- Involves bone

Stage I: Skin intact but reddened for more than 1 h after relief of pressure. This stage represents intact skin with various degrees of erythema that does not blanch when compressed. This wound is potentially reversible if extrinsic forces and intrinsic wound healing factors are optimized.

Stage II: Blister or other break in the dermis with or without infection. Here, the skin breaks down which can expose subcutaneous fat. By maintaining coverage over the wound, these wounds often can generate granulation tissue and undergo wound contraction to heal by secondary intention. Because there is violation of skin, the local environment must be monitored even more carefully for moisture and soiling to allow this stage to heal. Stage I and II pressure ulcers are the most prevalent [2].

Stage III: Subcutaneous destruction into muscle with or without infection. Here, bone is not exposed, so theoretically, this can heal and contract over the bony prominence. However, this is usually a short-lived stage as muscle is the most oxygen-sensitive tissue and thus most sensitive to ischemic necrosis, quickly reaching the final stage of exposed bone.

Stage IV: Involvement of bone or joint with or without infection. This is the most common stage that prompts a surgical consultation, as the ulcer is down to the etiologic bony

prominence. With bone exposure, there is desiccation and contamination of the surface of the bone, and by definition, there is at least superficial osteitis.

In 2007, the staging system was updated with two new stages [19].

Suspected deep tissue injury. Purple or maroon localized area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. This new stage allows clinically suspicious deep tissue injury to be identified.

Unstageable. Full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed. This new stage points out that eschar or necrosis makes it difficult to determine depth of destruction. These eschars are frequently the superficial aspect of a deep wound, as seen in the example in Fig. 93.2.

In Stage IV pressure ulcers, the most superficial aspect of the exposed bone is desiccated and is therefore necrotic and colonized with the flora of the skin and surrounding areas. This is an osteitis, or inflammation of bone, rather than a hematogenous osteomyelitis that requires long-term systemic antibiotics. If the deep bone has good blood supply, and the patient is not immunocompromised, a patient can tolerate this osteitis for protracted periods as long as good wound care prevents extension of the zone of injury.

Osteomyelitis is infection of the bone. Definitive diagnosis of the extent of osteomyelitis is made during surgical debridement when bone is excised for biopsy and bacterial culture. Imaging modalities to diagnose osteomyelitis have been used, including radiography, tagged white blood cell scans, and magnetic resonance imaging (MRI) [20]. However,

FIGURE 93.2 Elderly homeless man found sitting on the corner of a street, confused. (a) Right ischial pressure sore completely covered with eschar, making it unstageable. (b) After bedside debridement of necrotic tissue, the wound extends to the ischial tuberosity.

FIGURE 93.3 The patient presented with a chronic left ischial pressure sore with drainage. (a) Patient in prone position with open wound on his left ischium. (b) Computed tomography scan of patient (the left ischium

is on the *right side* of the scan) revealing a perianal fistula tracking to an ischial abscess. This underlying etiologic factor needs to be addressed before treating the ischial sore.

by the time clinical suspicion, raised by findings such as deep pus not accessible with bedside debridement or systemic infectious symptoms, is high enough to consider imaging, surgical exploration is more appropriate than imaging. Thus, imaging to diagnose osteomyelitis often is not needed. However, appropriate imaging may be useful to evaluate the extent of necrosis in high-risk surgical patients or to help determine the source of infection in atypical pressure sores, such as perianal fistula, or spinal hardware abscesses (Fig. 93.3).

Infections of soft tissue can be polymicrobial due to urine or stool in the area. Thus, *Proteus*, *Bacteroides*, *Pseudomonas*, and *Escherichia coli* can accompany the more common staphylococcal and streptococcal species. More than half of long-term care patients harbor methicillin-resistant *Staphylococcus aureus* (MRSA) organisms [21]. Cultures can be sent to determine sensitivities, but swab cultures are invariably positive due to local contamination. Intraoperative cultures are taken from bone deep to the surface of the wound, and deep soft tissue biopsies sometimes provide sensitivity information. In the presence of active infection, the mainstay of initial management is aggressive local and systemic treatment to restore equilibrium between the open wound and the local flora, and then the correction of etiologic factors so that the wound can heal.

Pressure sores always have localized inflammation or infection but uncommonly cause systemic symptoms unless high-stage or neglected. Patients with pressure sores who present for a fever or infection workup almost certainly have comorbidities, such as a urinary tract infection or pneumonia, that must be ruled out as a source of the systemic infection.

Management

The key to management of pressure sores comes down to three principles:

1. *Reduction of pressure* (and other deleterious extrinsic factors)
2. *Restoration of nutrition* (and other intrinsic factors promoting wound healing)
3. *Wound care* (to assess the current wound for active and chronic infection and debride as necessary, and to maintain a clean wound with frequent monitoring for new active infections)

This tripod addresses all of the factors in the etiopathogenesis of pressure sores. Only when these issues are addressed can the benefits of surgical flap coverage be weighed against the probability of either failure to heal or recurrence. High surgical risk or high recurrence risk patients should be offered nonsurgical treatment and maintenance. Notably, this maintenance can have a high nursing care cost with multiple social issues.

Reduction of Pressure and Deleterious Extrinsic Factors

Increased tissue pressure is expected over bony prominences, but prolonged pressure leading to irreversible ischemia is not. In bed-bound patients, as little as 2 h of pressure is

sufficient to develop a pressure sore [6]. Elderly patients may be chronically debilitated or acutely obtunded as outpatients or inpatients, and these conditions must be evaluated and optimized to the extent possible. However, even the spinal-cord injury patient, with lack of movement compounded by spasticity and contractures, can have pressure reduced. This requires turning the patient faithfully every 1–2 h to break the cycle of constant pressure and use of a lower pressure air mattress or an air-fluidized chronic pressure-shifting bed. Meta-analysis suggests that higher-specification foam mattresses and other technologic mattresses are better at reducing pressure ulcers than standard hospital foam mattresses [22]. Patients who use wheelchairs must learn to shift their weight constantly and to utilize a lower-pressure seat cushion. Many elderly patients sit in regular household chairs all day long, and even with intact skin sensation, are at risk of pressure ulcer development. In bedridden patients or those who keep their legs elevated on a footstool, heels must be unweighted or padded to reduce pressure. There are commercial products marketed to prevent heel ulcers, but there is insufficient data to determine whether these are better than simple elevation with pillows under the lower legs. Some device-specific clinical trials have suggested that these products, such as waffled foam [23] or cushioned doughnuts [24], can even increase the incidence of heel ulcers. Another way to redistribute pressure on abraded skin or early pressure sores is with thick adhesive dressings and foams marketed for this purpose. Consultation with a physiatrist can be helpful for finding adaptive devices for a patient's individual situation.

Muscle spasms and contractures are more common in patients with spinal cord injury and upper motor neuron defects. Contractures can both contribute to the etiology of the pressure sore by making bony areas more prominent, and they can make positioning and therapeutic efforts to relieve pressure more difficult. Physical therapy and splinting can alleviate the contracture, but sometimes, surgical release by orthopedic and plastic surgeons may be necessary.

Spasticity of large muscles, such as the hip flexors, can impede wound healing and compromise surgical treatment with a flap by placing repeated tension on the incisions and accentuating bony prominences. Spasticity can be addressed pharmacologically with muscle relaxants and antispasmodics, such as benzodiazepenes, baclofen, and cyclobenzaprine. Refractory spasticity may respond to infusion pumps, nerve blocks, rhizotomies, or epidurals [25]. Again, consultation with physiatry for medication, splinting, and physical therapy is useful.

Nursing care plays a major role in achieving reduction of extrinsic factors by regulating the air mattress, frequent turning, physical therapy assistance, reduction of shearing forces during patient transport, and keeping the area clean and dry. The most common pressure sores are in a dependent position

where moisture and debris accumulate. Both the elderly population and spinal-cord injury patients can have varying degrees of incontinence of urine and stool, which contribute to the contaminated environment surrounding these wounds. Urinary incontinence may need to be managed with a sheath or indwelling catheter until the pressure sore or surgical flap has healed. For fecal incontinence, a temporary or permanent colostomy may be indicated to increase the likelihood of healing or successful surgical repair.

Restoration of Nutrition and Other Wound-Promoting Intrinsic Factors

The population of patients with pressure sores generally has inadequate nutritional intake. Dietary intake of nutrients and protein is predictive of pressure ulcer development in elderly patients [14, 26]. Serum metabolic panels can help with diagnosis and treatment of malnutrition by monitoring markers such as albumin, prealbumin, C-reactive protein, retinol binding protein, and transferrin. Analysis of nitrogen exchange and food choices helps determine caloric and protein intake, as well as estimate requirements. Other supplements to consider include the vitamins A and C which are implicated in wound healing, zinc, protein shakes, pharmacologic enhancement of appetite (megestrol), tube feeding, and parenteral nutrition [16, 27]. Consultation with a nutritionist can help with the assessment of the above.

Other medical conditions need to be addressed, including anemia and diabetes, HIV, and conditions that lead to edema such as congestive heart failure, kidney disease, liver disease, and other causes of hypoalbuminemia. Patients may require antibiotic treatment as an adjunct to wound care. The duration of antibiotics may be up to 2 weeks for complex soft-tissue infection or 6 weeks for biopsy-proven osteomyelitis, and consultation with an infectious disease specialist is useful.

Wound Care (Active Debridement and Regular Maintenance)

The initial approach to wound care is similar to that for all open wounds: recognizing nonviable tissue and debriding all devascularized tissue. Nonviable tissue can appear as dry gangrene or eschar that is not actively infected and may be amenable to mechanical or chemical debridement. Mechanical debridement relies on irrigation, lavage, whirlpool, and sharp excision. Sharp debridement can be done at the bedside or in the operating room, and often the extent of necrosis is surprisingly extensive due to the greater sensitivity

of muscle to ischemia. For this reason, undermining of the wound beyond the skin edges characterizes pressure sores, and the wound may be substantially larger than the opening in the skin. Debriding agents such as proteolytics, fibrinolytics, collagenases, and sterile maggots have been described. Wet gangrene is necrotic tissue that is already superinfected and requires prompt sharp debridement.

In certain areas, such as the heel, pressure sores often are stable and dry. In these wounds, like frostbite injury, local wound care permitting gradual separation of the eschar may be preferable to sharp debridement to maintain as much viable tissue as possible. For these heel sores, dry dressings or topical antibacterials such as silver sulfadiazine are useful.

After debridement, several options are available. The wound can be allowed to heal by secondary intention using a variety of packing materials on a regular basis to allow the wound to heal from the base and prevent premature skin closure and abscess formation. Negative pressure therapy with a vacuum-assisted device can be used to facilitate the secondary wound healing process. These devices stimulate the formation of granulation tissue and encourage wound contraction, but the wound should be free of infection before sealing it under the occlusive vacuum dressing. As with other selected wounds, negative pressure therapy may help to downsize the surface area of a wound so that more complex reconstruction options of local or free flap can be replaced with simpler ones such as skin graft or primary closure.

In a patient with a spinal-cord injury, pressure ulcers in the denervated areas generally are not painful. In nonparaplegic elderly patients, the majority of patients experience pain with pressure ulcers and are particularly uncomfortable during wound care and dressing changes [28, 29]. Pain can be reduced with agents such as topical lidocaine or morphine, or systemic analgesics prior to dressing changes or continuously if necessary.

Surgical Treatment

Once nonsurgical management of a pressure sore addresses the etiology, and the factors that predispose to recurrence are corrected, the risk–benefit ratio of surgery versus the perioperative risks for an individual patient can be weighed. Well-recognized flaps have been developed for the most common pressure sores of the sacrum, ischium, and greater trochanter, but management must begin with adequate debridement of nonviable tissue, sinus tracts, and the bursa-like capsule that lines a chronic wound. Pressure sores that come to surgery almost always track to bone, and ostectomy is done to debride the exposed bone and obtain biopsies for bacterial culture. Ostectomy also serves to reduce the prominence of bone responsible for the sore so that the likelihood of recur-

rence is reduced. It may be helpful to enlist the participation of the primary medical team or infectious disease specialists to obtain special cultures in the setting of immunosuppression or other chronic illnesses. Finally, the cavity is filled with vascularized tissue with enough bulk to cover the bone and close the open wound.

Intraoperative Resection of Soft Tissue

The soft tissue lining a pressure sore cavity is contaminated and generally is poorly vascularized or fibrotic, depending on the duration of the ulcer. At surgery, this tissue is debrided back to normal-appearing, well-vascularized, pliant soft tissue. To accomplish this, a dye such as methylene blue can be used to coat the lining of the wound to identify any pockets or tracts; resection is complete when all the colored surfaces have been removed. It may take more than one operation to complete debridement before definitive flap coverage.

Intraoperative Resection of Bone

If the bone at the base of the wound is exposed, it is colonized with local flora and at least superficially desiccated with a nonviable surface layer. This is superficial osteitis with healthy bone with good blood supply just deep to the desiccated layer. Deeper infection with frank osteomyelitis would have been diagnosed preoperatively, and intraoperative planning for extensive bone resection, sometimes including the participation of an orthopedic surgeon, would have been scheduled.

Intraoperative debridement of the superficial bone is done using visual assessment of avascular bone versus bleeding bone. Using rongeurs and rasps to smooth jutting prominences or to excise heterotopic bone accomplishes the second purpose of bone resection: reducing the physical prominence of bone that causes pressure and predisposes to recurrence of the sore. After adequate bone debridement has been done, a biopsy of the deeper healthy-appearing bone is sent for bone culture. If this were positive, the remaining bone still is infected and the patient will need a long-term course of intravenous antibiotics to treat the osteomyelitis.

Bone resection needs to be approached with the awareness that it is not a benign process. When one of a paired set of pressure points, such as the ischii, is resected, the patient's weight is shifted to the contralateral side, increasing risk of a new pressure sore on the second side. Similarly, resection of both ischii can shift the weight-bearing surface to the perineum, resulting in later perineal or scrotal pressure sores.

Wound Coverage and Closure

For full-thickness ulcers, the basic principle is provision of vascularized tissue to cover bony prominences, lend adequate padding, fill the wound completely, and close the surface with durable soft tissue and skin that is under no tension. The “reconstructive ladder” principle in plastic surgery proposes that the basic, or “lowest rung,” options should be considered first, with complex reconstructive options held in reserve in case the wound recurs. However, it is important to recognize when simpler options will be insufficient, and one should choose a more complex option from the outset. In this population of patients, it is also important to consider that using complex muscle flaps at the outset means that they will not be available in the future.

Given the above criteria, where there is a robust vascularized bed over the bone, a select group of ulcers can be repaired by operations on the basic rungs of the reconstructive ladder: delayed primary closure or a skin graft. In general, these options have limited application. Primary closure places the surgical suture line directly over the area of pressure, whereas a flap moves the closure and scar away from the pressure point. A skin graft is a thin and fragile coverage option subject to the shearing forces that created the ulcer in the first place. In addition, a skin graft requires a clean, healthy recipient site with good blood supply and no exposed bone. Only the most superficial of pressure sores meets these requirements for a healthy, well-vascularized base and can be covered successfully with a skin graft.

More often, flap coverage is the surgical choice for pressure sore repair. A flap is different from a graft in that a skin graft has no blood supply and survives by acquiring it from the tissue onto which it is grafted. A flap carries its own blood supply that is preserved while the flap is transferred to a new area. Flaps are often described by their anatomic makeup. Cutaneous flaps are supplied by direct cutaneous vessels and axially oriented perforating vessels ending in a subdermal plexus. Fasciocutaneous flaps include skin, subcutaneous fat, and deep fascia. The blood supply originates from septocutaneous vessels that pass up along fascial septae and fan out at the level of the deep fascia to form a plexus from which smaller perforator vessels supply the subcutaneous fat and skin. Musculocutaneous flaps include muscle, fascia, subcutaneous fat, and skin combined as one unit, based on one or more vascular pedicles, which are musculocutaneous vessels that travel perpendicularly through the muscle into the overlying tissue. Muscle-only flaps have the same blood supply but will require a concurrent skin graft to cover the surface of the muscle.

Previous incisions, whether from trauma or prior surgery, can preclude certain flaps since these incisions and scars are areas where previous blood supply was likely transected. A complete surgical history is mandatory to understand the

surgical anatomy when previous flaps were used. Flaps can be designed so that they can be reelevated and readvanced in the future. Since pressure ulcers have a high rate of recurrence [30], another factor in flap selection is choosing one that preserves blood supply for potential future flaps. Finally, the size of the flap usually needs to be much larger than the ulcer, as the wound area enlarges after debridement. A generous flap provides bulk, minimizes tension on the closure, and moves the suture lines to the periphery away from the original ulcer’s central pressure point.

Free microvascular flaps are the most complex reconstructive options. They require harvesting a distant flap with its accompanying arteries and veins and transferring it to the recipient bed with microvascular anastomoses to recipient vessels. Elderly patients have comorbidities such as cardiovascular disease and poor general health that can make these lengthy microsurgical tissue transfers problematic.

The elimination of “dead space” is necessary to heal pressure ulcers where there is a soft tissue cavity. After introducing the vascularized flap, this is furthered with surgical drains exerting negative pressure and layered wound closure. Closed surgical drainage systems are used in the recipient bed during the initial phase of healing, and the donor site of a flap with significant dissection also needs a surgical drain to reduce the incidence of postoperative seroma and infection. Drainage should be maintained until the patient is achieving some degree of mobility and the output has tapered to a small volume per day for several days. Layered wound closure is a technique for further elimination of dead space by closing each level of tissue separately, using absorbable sutures to approximate the deep layers and evert the more superficial layers. The surgical wound is dressed carefully with multiple layers of antibiotic ointment and semipermeable dressings to create a barrier against soilage.

Sacral Pressure Sores

Sacral pressure sores develop in supine or semireclining patients with sufficient pressure and shearing over the sacral prominence. This is the most common pressure sore since debilitated, obtunded, or severely ill patients are bedridden and supine much of the time [2]. Given the broad, pointed shape of the sacrum and the thinness of the overlying soft tissues, most ulcers come to the surgeon with bone exposure. This precludes a skin graft in the sacral area, except in the shallowest of ulcers, and even then is useful only in a patient with good sensation and mobility. Chronically ill patients who will remain immobilized have too high a risk of recurrence through a skin graft. In general, flap coverage is a better option in patients who are surgical candidates.

FIGURE 93.4 The blood supply to the gluteus maximus muscle supplies perforators to the overlying soft tissue surrounding the sacrum. The piriformis muscle marks the midportion of the gluteus maximus muscle, with the superior and inferior gluteal arteries arising above and below the piriformis. The superior gluteal artery can be found one third

of the distance from the posterior superior iliac spine to the greater trochanter. The inferior gluteal artery appears halfway between the posterior superior iliac spine and the ischial tuberosity (reprinted from McCarthy J. *Current therapy in plastic surgery*. WB Saunders. © Elsevier (2005)).

The soft tissues surrounding the sacrum receive their blood supply from perforators from the superior and inferior gluteal arteries, which are also the arteries supplying the gluteus maximus muscles (see Fig. 93.4). Cutaneous, fasciocutaneous, musculocutaneous, and muscle flaps can be developed based on these vessels. The gluteus maximus can survive on either vascular pedicle alone [31]. However, utilizing both pedicles can increase flap reliability and the volume of overlying muscle and soft tissue and also make it easier to readvance the flap in the future if the sacral wound recurs. However, because this muscle extends and rotates the thigh laterally and is required for ambulation, the gluteus maximus is not considered expendable except in the spinal cord injury patient. If the patient has a chance of recovering ambulation, then only the superior or the inferior half of the muscle should be used. For sacral coverage, the superior half of the gluteal muscle is usually used as it is closer to the wound. Alternatively, a cutaneous or fasciocutaneous flap can be used to spare the muscle entirely.

Each half of the gluteus maximus muscle is shaped like a rectangle, originating from the ilium and inserting into the greater tuberosity of the femur. Muscle or musculocutaneous flaps of the superior half of the muscle are constructed and moved in two primary ways: a rotational flap or a V-Y advancement flap. A rotational flap can be as an advancement or with a musculocutaneous skin island. Either way, one end of the muscle is kept in contact with its blood supply,

and the other end is detached to advance the entire flap, or to transfer a skin island in a rotational arc to fill the defect.

The V-Y advancement technique involves creating a triangular-shaped skin island over the muscle, with one side being the defect and the other two sides forming a “V.” The central “V” is shifted into the open wound and the defect is closed in a “Y” configuration. A V-Y advancement flap can be designed in different ways. If not much bulk is needed, it can be a fasciocutaneous flap based on the gluteal perforators, and it can be advanced over the defect without needing to mobilize the muscle. For greater coverage with a V-Y flap, elevating the gluteus maximus as a musculocutaneous flap provides more bulk and permits more advancement of the overlying soft tissue because the blood supply travels with the muscle. This comes at the expense of a more extensive dissection to mobilize the muscle. Another way to get extended coverage of the sacrum is the use of bilateral V-Y advancement flaps, one based on the right gluteal area and one on the left gluteal area (see Fig. 93.5).

Ischial Pressure Sores

The ischial tuberosities are under high pressure in a seated patient. Unilateral or bilateral ischial sores develop in individuals who are seated for protracted periods of time without

FIGURE 93.5 This male nursing-home patient had a Stage IV sacral pressure sore with exposed sacrum. (a) Preoperative view in the prone position. (b) Postoperative view after bilateral gluteus maximus

musculocutaneous V-Y advancement flaps. Note the use of surgical drains under the flap donor sites.

adjusting their position and weight distribution. Ischial ulcers are challenging for several reasons. The pressure points are bilateral, which means that unweighting one side for pressure-reducing purposes shifts increased pressure onto the contralateral ischium. Resecting bone on both sides runs the risk of shifting weight-bearing onto the perineal soft tissues, which can cause later scrotal or urethral sores. There can be fistulae involving the rectum or urethra, and these may require diversion and control of the fistulae before addressing the ischial ulcers. Finally, because of the strong hip flexors, there can be flexion contractures with varying degrees of deformity which reduce mobility and the capacity for normal weight distribution in either the sitting or the lying position.

Because the ischium has a number of surrounding muscles, a variety of suitable flaps for coverage have been described. These include the inferior gluteus maximus rotational flap, inferior gluteal fasciocutaneous thigh flap, V-Y hamstring advancement flap, gracilis muscle flap, tensor fascia lata rotational flap, and rectus abdominis rotational flap. The first two are considered the most useful flaps and are described in more detail below.

The inferior gluteal fasciocutaneous thigh flap, also called the posterior thigh flap, is a good first choice. This flap is robust, reliable and leaves the gluteus maximus intact to preserve this option for use in case of future recurrence. The posterior thigh region is supplied by perforators from the descending branch of the inferior gluteal artery. This artery descends deep to the gluteal muscles in a midline axis between the ischium and the greater trochanter and courses toward the popliteal fossa. Thus, the flap design is an inverted triangle with its base at the inferior gluteal cleft and its distal point toward the popliteal fossa. The distal limit is about 8 cm proximal to the popliteal fossa [32]. The base of the flap should be about 10–12 cm wide, and the point of rotation is

5 cm superior to the ischial tuberosity (see Fig. 93.6a, b). The dissection is initiated inferiorly by identifying the posterior femoral cutaneous nerve and adjacent descending branch of the inferior gluteal artery. The artery is transected distally and preserved proximally as the flap is raised from inferior to superior up to the gluteus maximus muscle. Now, the flap can be rotated medially to fill an ischial defect (see Fig. 93.6c, d). If there is excess of the length of the flap, the distal end can be the denuded skin and the subcutaneous tissue tucked into the ischial crater to further eliminate dead space (see Fig. 93.7).

The other useful flap is the inferior gluteus maximus rotational flap. Like using the superior half of the gluteus maximus muscle for a sacral wound, the inferior half of the gluteus maximus flap can be rotated into the ischial wound as a rotation advancement (see Fig. 93.8) or a rotational island flap. In the latter case, a skin island over the inferior half of the muscle, lateral to the ischial defect, can be elevated with the muscle and rotated medially (see Fig. 93.9). Rotational flaps have an effective shortening of their pedicles as they rotate, and this must be taken into account when designing the flap. The gluteal muscle will need to be detached from its insertion on the femur as much as necessary to allow complete rotation. An attempt should be made to preserve the descending branch of inferior gluteal artery to allow a future posterior thigh flap.

Greater Trochanter Pressure Sores

Given the mobility of the hip, pressure sores over the greater trochanter characteristically have extensive bursa formation with less skin involvement. After resection of the

FIGURE 93.6 The inferior gluteal thigh flap. (a) The descending branch of the inferior gluteal artery comes off at the midline of the posterior thigh. (b) This descending branch supplies the posterior thigh soft tissues, so a flap is designed to allow rotation into the ischial defect and primary closure of the donor site. (c) Rotation of the posterior thigh flap medially, inset of the flap into the wound, and primary closure of the donor site. (d) Immediate postoperative view after inset of the flap (reprinted from McCarthy J. Current therapy in plastic surgery. WB Saunders. © Elsevier (2005)).

FIGURE 93.8 This woman had a recurrent right ischial pressure sore. (a) On her preoperative view, note the two vertical scars on her posterior thigh, evidence of a previous hamstring advancement flap. These scars preclude the use of a posterior thigh flap. (b) After debridement of the wound and rotational advancement flap of the inferior half of the

gluteus maximus muscle with its overlying soft tissues, the flap is *inset*, closing the ischial defect. Note the two surgical drains: one superiorly for the donor site, and one inferiorly for the ischial wound recipient site. (c) Postoperatively with good healing and intact closure at 3 months.

FIGURE 93.9 This man had a new-onset right ischial pressure ulcer. (a) Preoperative view in the prone position shows Stage IV wound that tracks to bone. (b) After debridement, the wound is larger, and a musculocutaneous island flap is designed lateral to the wound, overlying the inferior half of the gluteus maximus muscle. (c) Elevation of the

inferior half of the gluteus maximus muscle maintaining the perforators to the overlying soft tissue island. (d) Island flap is rotated medially into the defect and the donor site primarily closed. Note the two surgical drains: one in the donor site and one in the ischial wound recipient site.

FIGURE 93.7 This man had a chronic left ischial pressure sore that would not heal. (a) Preoperative view of ischial pressure with markings for a posterior thigh flap. (b) Elevation of the posterior thigh flap, showing it is a fasciocutaneous flap. (c) *Inset* of posterior thigh flap to fill the

entire defect, obliterate the dead space, and close the ischial pressure sore. Note the two surgical drains: one for the posterior thigh donor site, and one for the ischial recipient site.

trochanter, flaps available for repair of trochanteric pressure sores include local fasciocutaneous rotational flaps, tensor fascia lata (TFL) musculocutaneous flaps, inferior gluteal thigh fasciocutaneous flaps, and muscle flaps incorporating the vastus lateralis, rectus femoris, or rectus abdominis muscles.

The flap often selected for this defect is the tensor fascia lata (TFL) flap. The TFL lies adjacent to the trochanter and originates from the crest of the anterior superior iliac spine and descends to insert into the iliotibial tract of the fascia lata. It is a flap with a single dominant pedicle, the ascending branch of the lateral circumflex femoral artery. The flap can be designed as an inverted triangle with a maximum length of about 20 cm, with the base near the greater trochanter and the distal end towards the knee. The vascular source is about 10 cm below the anterior superior iliac spine along the anterior border of the TFL and must be preserved. The plane of dissection is between the TFL and the vastus lateralis. The pedicle can be identified on the deep medial surface of the TFL. Distally, the flap is detached from its insertion, but the origin proximally is not taken down unless more rotation is needed [33]. Once the TFL flap is elevated, it can be used as a rotational flap, a V-Y advancement, or a V-Y retroposition flap [34]. A V-Y flap places the most reliable portion of the flap over the greater trochanter, which is preferable to the rotational flap, which brings in the distal portion with the most tenuous blood supply (see Fig. 93.10).

Foot Pressure Sores

Pressure sores commonly occur over the heels, malleoli, and the plantar surfaces of the feet. Like other pressure sores, they are initiated by pressure, and most respond favorably to conservative treatment. Since a thick subcutaneous layer is not customary on the feet, most of these ulcers, unlike those in the pelvic girdle, are modest in size and depth. In non-weight-bearing areas where a somewhat less durable surface is necessary, these may be treated conservatively. A scar left by wound contraction and epithelialization may suffice. In larger wounds, debridement and split-thickness skin grafting may be helpful if the bed of the ulcer will support a skin graft. If the ulceration is large, osteomyelitis of the calcaneus may occur, in which event, debridement of any devitalized bone is required. Where flap coverage is mandatory, muscle flaps of the abductor digiti minimi, abductor hallucis, flexor digitorum brevis are described. Fasciocutaneous flaps based on the dorsalis pedis, medial plantar, and lateral plantar arteries can also provide coverage.

Postoperative Care

The postoperative care of surgical flaps includes selected intravenous antibiotics when needed for culture-positive osteomyelitis, protecting the surgical area from body fluids

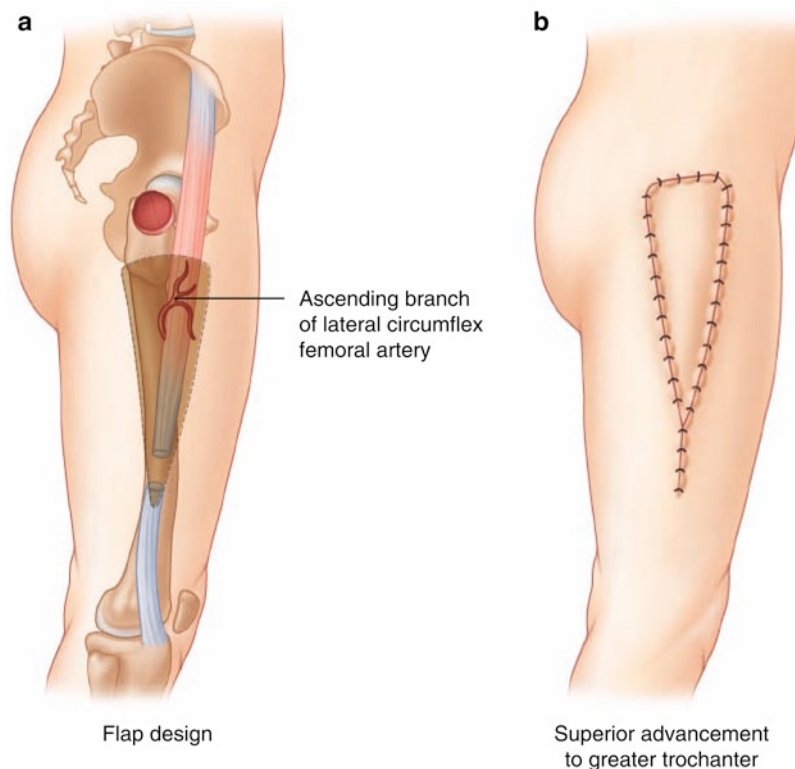

FIGURE 93.10 The tensor fascia lata V-Y advancement flap. (a) Design of the flap based on the ascending branch of the lateral circumflex femoral artery. Quality Medical Publishing, St. Louis).

and soilage, and pressure precautions. The latter is most critical, since a newly transferred flap is susceptible to pressure necrosis in the early postoperative period.

The postoperative protocol is customized depending on the patient, the pressure ulcer, and the flap chosen. It is customary to have 3–6 weeks with strict pressure precautions to allow soft tissue healing. For example, with a sacral or ischial pressure sore, the patient should be positioned prone or on either side with frequent turning, but never supine or sitting.

This may be difficult for the patient, so most often, the alternative is a specialized bed with an air-fluidized mattress. When it is time to begin ambulation, or resume sitting in a chair, the transition is carefully planned and executed with progressive increases in time each day with wound checks in between.

Regardless of the operative and postoperative steps, pressure ulcer flap coverage has a high rate of recurrence of about 40% over the long term [35]. This attests to the difficulty of controlling the etiologic factors of this disease.

CASE STUDY

A 72-year-old man with Alzheimer's dementia is having significant difficulty taking care of himself and performing the activities of daily living (ADLs). He has a history of two myocardial infarctions, congestive heart failure, chronic obstructive pulmonary disease, insulin-depen-

dent diabetes mellitus and is recovering from a colectomy for Stage III cancer, complicated by acute respiratory decompensation requiring ventilatory support. During his convalescence from the colectomy, he developed a 4-cm sacral pressure sore that is fibrinous, foul-smelling, and tracks to bone. Discuss the evaluation and management of this pressure sore.

Elderly patients with dementia and those with severe, acute conditions may be deconditioned and debilitated; being bedridden results in chronic pressure over the sacrum and a resultant pressure sore. Evaluation and treatment of the wound, and correction of the intrinsic and extrinsic factors contributing to the pressure sore are the first steps in taking care of this problem.

Since the wound is foul-smelling, it is assumed to contain necrotic tissue and harbor infection. After evaluation, initial treatment would be debridement. This could involve bedside debridement or operative debridement with cultures of the deep tissue. Wound care with local measures and additional debridement as needed should be ongoing while other evaluations are being done.

Intrinsic factors in his case include stabilizing his cardiopulmonary disease, managing his diabetes, and addressing his nutritional status. Baseline albumin, prealbumin, transferrin, and calorie and protein counts can be used to determine if wound-healing vitamins and protein supplements to maintain caloric intake are needed. Cardiac and pulmonary evaluation for candidacy for further surgery would be obtained.

Extrinsic factors to correct include elimination of pressure over the sacrum with a low-pressure or air-fluidized mattress and frequent turning. These protocols generally are available in the acute care setting and may be available in an extended care facility. His colon cancer should be discussed with his oncologist or colorectal surgeon, and if appropriate,

a diverting colostomy might be considered to eliminate incontinence and soiling of the sacral pressure wound.

If his general condition is deemed unsuitable for pressure sore surgery, a plan for chronic wound care with dressings, possibly negative pressure vacuum dressings, should be initiated. A schedule for intravenous antibiotics could be developed with infectious disease specialists if there were positive bone cultures. The patient's eligibility for placement would be determined with the help of social services. If ineligible for a long-term care facility, arrangements for home care with nursing support and the provision of a low-pressure bed for the home would be necessary.

If he is a good surgical candidate, debridement of the wound followed by a surgical flap would be planned. After the debridement, the wound is 8 cm in diameter. The soft tissues surrounding the sacrum receive their blood supply from the superior and inferior gluteal arteries. Either a rotational or a V-Y advancement flap can be considered, since he has no previous scars. He will be ambulatory, so sparing the gluteus maximus muscle is desirable. Given the size of the wound, bilateral V-Y fasciocutaneous advancement flaps would be a good choice.

His postoperative care would include the use of surgical drains, protective dressings with regular evaluation of the flap, bed rest on an air-fluidized mattress, deep vein thrombosis prophylaxis, antibiotic adjustments as dictated by intraoperative cultures, and management of his medical conditions. Provided the wound is healing satisfactorily, graduated mobilization could begin at about 4 weeks.

Conclusions

Pressure sores are a common problem, with a majority of them affecting the elderly population. The etiopathogenesis is complex, and a multidisciplinary approach is needed to properly evaluate and treat the patient. Extrinsic and intrinsic factors must be addressed before consideration of surgical flap coverage, since the pressure sore will recur postoperatively if they are not. Patients who are at high risk for surgery or recurrence can be treated nonsurgically since an open wound that is clean, even with exposed bone and osteitis, can be maintained with consistent nursing care.

A three-pronged approach summarizes the evaluation and treatment:

1. Reducing deleterious extrinsic factors: reduction of pressure with low-pressure mattress or wheelchair cushion, frequent turning, consultation with physiatry, physical therapy.
2. Improving beneficial intrinsic factors: addressing nutrition and comorbid conditions.
3. Wound care: mechanical or chemical debridement (bedside or operative) and pharmacologic dressings.

For the patient in whom all extrinsic and intrinsic factors are optimized, surgical repair of the pressure sore is undertaken with the understanding that there is typically a long-healing process and a high recurrence rate. The risks related to the operative and postoperative course need to be weighed carefully against potential benefits. Choices for coverage of these wounds can be cutaneous, fasciocutaneous, or musculocutaneous flaps with varying flap designs. These are customized to the patient depending on the location and size of the wound, and the availability of local tissues.

These wounds are some of the most difficult to heal, but with application of these medical and surgical principles, they can be managed, potentially alleviating the physical, emotional, and societal burdens that pressure sores impose.

Acknowledgment The authors wish to thank David S. Chang, MD, for contributing clinical case photographs for the posterior thigh flap.

Chapter 94

Orthopaedic Trauma in the Elderly

William Min, Kenneth A. Egol, and Joseph D. Zuckerman

Introduction

Injuries to the musculoskeletal system in the elderly can be devastating. Many medical and social factors specific to older patients require special consideration when dealing with these injuries both acutely and throughout their rehabilitation. The geriatric segment of the population is rapidly growing and sustains a disproportionate number of fractures compared to others [1–3]. The specific goal of all orthopaedic care is to restore patient function to a preinjury level. Decreased bone stock, muscular weakness, systemic disease, and poor mentation are some challenges that make a return to independent living status difficult following such injuries. Immobilization and the use of devices to assist in ambulation (crutches, walkers, and wheelchairs) may require an elderly patient to be subjected to institutional care for an extended period of time. The following is an overview of the etiology, pathophysiology, and treatment considerations in treating geriatric patients with fractures and associated injuries.

Preinjury Status, Perioperative Risks, and Treatment Considerations

In elderly patients with musculoskeletal injuries, orthopaedic intervention attempts to restore their preinjury level of functioning. Their past medical, functional, and cognitive histories have significant impact on how and if these goals can be reached. Before treatment is initiated for these patients, it remains prudent for the physician to become familiar with the patient's preinjury status.

Systemic diseases and complications can impact injury management. Chronic conditions such as cardiac and pulmonary compromise may diminish a patient's ability to tolerate

recumbency, surgery, and rehabilitation. The elderly typically have a higher number of medical comorbidities, and they are also on medications that can affect their health status, injury risks, and response to injuries and treatments [4].

Frequently, elderly patients may have inadequate cardiac and pulmonary reserves, which may not be evident until their physiology is significantly stressed during trauma. In patients over 60 years of age, there is typically a lower cardiac index as well as a lower amount of oxygen delivery and consumption [5]. Furthermore, the elderly also have been found to have a higher risk of developing ARDS following trauma [6]. These findings suggest that, in situations where their physiology is significantly stressed, the elderly may have a higher risk of mortality.

Anesthetic considerations must be taken into account when surgical treatment is selected. The American Society of Anesthesiologists (ASA) has developed a rating system for determining preoperative risks. This rating is considered to be a snapshot of the patient's "acute" medical condition as opposed to the absolute number of medical comorbidities, which portray the patient's "chronic" medical condition. These factors should be considered when planning treatment strategies for patient care. A patient's medical status can affect their intraoperative tolerance and response to surgical intervention and other orthopaedic treatments. For example, patients may develop hypotension during the cementing portion of hip arthroplasty. An elderly patient with little physiologic reserve may not tolerate such stresses, resulting in further cardiac and potential cerebrovascular insults.

Many orthopaedic procedures can be performed with either general or spinal anesthesia. Reports have shown no difference in mortality with either one [7–9]. However, some literature has demonstrated some differences in other outcome measures. Regional anesthesia has been shown to reduce acute postoperative confusion [9]. Covert found that the use of regional anesthesia increases the magnitude and frequency of hypotensive episodes when compared with general anesthesia. Following hip fracture surgery under spinal anesthesia, their patients exhibit better oxygenation in the early postoperative period than that after general anesthesia. These authors also

e-mail: william.min@nyumc.edu

found that the incidence of deep venous thrombosis is reduced following spinal anesthesia as compared with general anesthesia, and that they had less intraoperative blood loss (but, general anesthesia with controlled hypotension also reduced their amount of blood loss). However, they found that their 1-month mortality rate, approximately 8%, was unrelated to anesthetic technique [10].

The presence of diabetes mellitus has been shown to increase the risk of wound complications (dehiscence, infection) and cause delayed fracture union [11]. Additional complications, such as malunion and Charcot arthropathy, are prevalent in this patient population [12]. Peripheral vascular disease can also contribute to wound complications. These medical comorbidities, combined with skin conditions (changes in skin turgor and friability), frequently found in the elderly can result in soft-tissue complications, especially if the patient becomes sedentary or is immobilized in a cast for prolonged periods.

Thromboembolic disease is a significant threat, especially with lower extremity injury and surgery. Coupled with additional cardiopulmonary comorbidities, complications associated with a thromboembolic event can be devastating. Elderly patients may have associated risk factors that may heighten their chance of sustaining a thromboembolic event. It is imperative that either chemoprophylaxis or mechano-prophylaxis (or both) be implemented during the course of patient management. The current recommendations set forth by the American College of Chest Physicians (ACCP) are listed in Table 94.1 [13, 14].

In the elderly, the incidence of deep-vein thrombosis and pulmonary embolism is higher due to the greater frequency of risk factors. With the armamentarium of treatments available, including heparin, low-molecular-weight heparin, oral anticoagulants, consideration for treatment must be guided based on the clinical presentation, risk factors, and social conditions. Older patients may be at increased risk for

TABLE 94.1 Current DVT risk factors and prophylaxis from the ACCP

Risk factor points	Risk factors
1 Point	Minor surgery. Age 41–60, history of major surgery within 1 month. Pregnancy or postpartum within 1 month. Varicose veins. Inflammatory bowel disease. Leg swelling. BMI >25. Oral contraceptive use. Hormone replacement therapy
2 Points	Age >60 years. Malignancy or current chemotherapy or radiation therapy. Major or laparoscopic surgery (>45 min). Confined to bed >72 h. Immobilizing cast <1 month. Central venous access <1 month. Tourniquet time >45 min
3 Points	History of DVT or PE, Family history of thrombosis. Age >75 years. Factor V Leiden/activated protein C resistance. Risk factors of myocardial infarction, congestive heart failure, or chronic obstructive pulmonary disease. Congenital or acquired thrombophilia
5 Points	Major, elective lower extremity arthroplasty TKR, THR, Hip, pelvis or leg fracture within 1 month. Stroke within 1 month. Multiple trauma within 1 month. Acute spinal cord injury with paralysis within 1 month
Risk factor points total	Recommendations
1 or less (low-risk)	Early and aggressive mobilization
2 or less (moderate-risk)	LDUH q12h, LMWH <3,400 U daily, and GCS or IPC
3 or 4 (high-risk)	LDUH q8, LMWH >3,400 U daily, with or without IPC
5 or greater (highest risk)	LMWH >3,400 U daily, fondaparinux, and coumadins (INR 2–3). Dose-adjusted LDUH or LMWH may be used with or without IPC
Additional recommendations	
For elective THA	LMWH 12 h pre-operatively and/or 12–24 h after surgery, or 4–6 h after surgery at one half the dose initially followed by a full dose on the next day. Alternatively, fondaparinux (2.5 mg) started 6–8 h postoperative or coumadin started preoperatively or after surgery (INR target 2.5, range 2–3). Aspirin, dextran or IPC alone not recommended
For elective TKA	LMWH 12–24 h postoperative, fondaparinux 2.5 mg started 6–8 h post-operatively, or adjusted-dose warfarin administered preoperative and/or postoperatively and with INR range of 2–3 (target INR of 2.5). Optional use of IPC devices intraoperatively or immediately postoperatively. LDUH not recommended for sole use as prophylaxis
For hip fractures	LMWH or fondaparinux or adjusted-dose warfarin immediately administered postoperatively, with a target INR of 2.5 (range of 2–3) if bleeding is controlled; LDUH may be alternative (limited data). Aspirin alone is not recommended
For knee arthroscopy	No routine prophylaxis. Early mobilization. LMWH for patients with additional preexisting risk factors for DVT or prolonged tourniquet time
For elective spine surgery	No routine prophylaxis. High-risk patients should be treated with LDUH, LMWH, or perioperative IPC

BMI body mass index; *DVT* deep venous thrombosis; *IPC* intermittent pneumatic compression; *LDUH* low-dose unfractionated heparin; *LMWH* low molecular weight heparin; *PE* pulmonary embolism; *THA* total hip arthroplasty; *TKA* total knee arthroplasty. Source: Data from Ennis [123]

anticoagulant-related bleeding for several reasons: increased anticoagulant effect of warfarin, increased prevalence of comorbidity, and incidence of adverse drug reactions. The indications for use of an inferior vena cava filter are wider in the older age group, not only for those in whom heparin is contraindicated, or has failed, but also for those who require treatment indefinitely with contraindications to oral anticoagulant [15].

The patient's cognitive status pre- and postinjury is of significant importance when caring for the elderly. Since orthopaedic injuries and treatments usually require protracted physical therapy and rehabilitation, it is necessary for patients to comprehend instructions, clearly communicate, and perform multiple tasks. These requirements are further complicated by the effect of medications on elderly cognition. Individuals with Alzheimer's disease, cognitive deficits from cerebrovascular insults, Parkinson's disease, and other forms of dementia will have difficulty participating in the therapy required to attain preinjury functional status and may lead to a negative outcome in some instances. Their inability to meet rehabilitation goals may result in diminished functional and medical gains. These factors are important considerations when determining the feasibility and appropriateness of operative intervention. A radiographically perfect result does not always translate into a good functional outcome. For example, a comminuted distal radius fracture treated nonoperatively may result in suboptimal radiographic reduction, but their inability to cope with a lengthy rehabilitation course and associated operative complications makes the risks inherent with operative treatment more significant than the functional limitations potentially afforded by nonoperative modalities. In contrast, a patient with preinjury hemiplegia who sustains a humeral shaft fracture may not tolerate long-term immobilization of the functional upper extremity (the standard treatment) and may benefit from surgical intervention to allow earlier weight bearing, with use of the affected extremity for transfers and assisted ambulation.

Decreased bone mass, or osteopenia, is often seen in older patients and is often the result of osteoporosis or osteomalacia. Osteoporosis is a decrease in bone density that does not affect mineralization, while osteomalacia results from decreased bone mineralization with or without changes in bone density. In either situation, less loading and stress are required to cause fractures as compared to normal bone. Factors affecting bone density, such as sedentary life, excessive consumption of alcohol, smoking, certain medications (antiseizure medications such as phenytoin, primidone, and phenobarbital, and certain selective serotonin reuptake inhibitors) and comorbid conditions (i.e., renal disease, malnutrition), also contribute to the patient's overall medical condition [16, 17]. Not only should elderly patients with osteoporotic fractures be treated for those injuries but also with chemoprophylaxis and preventative measures to decrease the risk for

future fractures [18]. However, the cornerstone of adequately treating and minimizing the effects of osteoporosis and related conditions is adequate intake of calcium and vitamin D.

Osteopenia presents a problem with fracture stabilization and healing. It is difficult to attain stable fixation in fracture fragments that have decreased bone mass. Stable internal fixation is imperative to allow for early joint range of motion, weight bearing, and therapy without risking fracture displacement. Additionally, osteopenia increases the risk for nonunion since fracture callus in these patients is less dense and poorly organized. Fractures that have tenuous fixation, especially in the lower extremity, may preclude early ambulation, by protracting immobilization; further, "disuse" osteopenia may result.

Bone remodels according to Wolff's law, and the removal of external stresses can lead to significant bone loss. This situation can be reversed to varying degrees upon remobilization and reloading. Additionally, the use of hormone replacement therapy (HRT) is another option in treating bone loss. HRT's effects were investigated by the Women's Health Initiative Study Group. Their investigators found that women taking HRT had 34% fewer hip fractures and 24% fewer fractures than women not receiving hormones. However, the short-term use of HRT to relieve symptoms at the time of menopause does little to prevent fractures in women when they reach 75–80 years of age. Women who take estrogen to maintain bone density must continue taking estrogen because the beneficial effects on bones disappear when it is discontinued. Estrogens are still used to prevent osteoporosis but are not approved to treat a woman who has already been diagnosed with the condition [19].

When presented with osteoporotic patients, orthopaedic surgeons now have certain tools available to aid in the treatment of their injuries. Some of these include: the use of methylmethacrylate (cement) to augment screw fixation and the use of allograft and synthetic bone graft that act in an osteoconductive manner in situations of excessive bone loss [20, 21]. Calcium phosphate implants and cements have also been shown to be another adjuvant to treat these challenging fractures [22]. However, the recent introduction of locked plating technology and its theoretical enhanced fixation in osteoporotic bone has allowed for more secured fracture fixation, which may promote earlier mobilization and ambulation [23, 24].

Minimizing the complications of osteoporosis begins with medical treatment; the mainstay of which is calcium and vitamin D supplementation. In postmenopausal women, calcium supplementation alone can reduce the rate of loss or even increase bone mass. Women with osteoporosis who are older or have low calcium intake show the most benefit from calcium supplementation. The National Institutes of Health Consensus Conference recommends 1,000 mg of calcium a day for women of 65 years of age and younger on estrogen

HRT, and 1,500 mg a day for women younger than 65 and not on estrogen HRT and for women older than 65 years of age. The most commonly used form of calcium supplementation is calcium carbonate, such as OsCal 500 or TUMS. Additionally, vitamin D deficiency is common in the elderly, often from a poor diet, low exposure to sunlight, or aging skin's inability to synthesize vitamin D3. Vitamin D, 400 IU per day, should be added in these cases [25].

Estrogen replacement therapy stimulates bone formation, prevents bone loss, and has been shown to reduce the risk of fractures in various groups of women. For women who have retained their uterus, estrogen must be supplemented with progestin therapy to prevent potential changes in uterine tissue. Estrogen HRT may also alleviate menopausal symptoms and prevent heart disease. However, it may also increase the risk of breast cancer [25].

Bisphosphonates are a class of medications currently utilized to treat osteoporosis. Their mechanism of action is through the inhibition of osteoclasts, which are cells responsible for the resorption of bone. Examples of bisphosphonates include etidronate, pamidronate, and alendronate. Alendronate (Fosamax) has been shown to decrease the rate of bone mineral density loss at all skeletal sites and decrease the rate of fractures. However, the medication must be taken on an empty stomach and may cause gastrointestinal discomfort. It should not be taken by patients with a history of swallowing difficulties or abnormal narrowing of the esophagus [25].

Other pharmacologic treatment options include selective estrogen receptor modulators (SERM), which are used for breast cancer, those seeking alternatives for HRT, and osteoporosis. One type of SERM currently used to treat osteoporosis is raloxifene (Evista). This medication has demonstrated a beneficial effect on bone mineral density and is well tolerated. It is contraindicated in women who are pregnant or have a history of deep venous thromboses. Raloxifene has been found to cause an increase in BMD of the total body and hip similar to estrogen HRT, but has less of an effect on BMD of the lumbar spine. Raloxifene has also been shown to lower LDL cholesterol and is being studied as a way to prevent breast cancer [25].

Alternative medications to treat osteoporosis include calcitonin and parathyroid hormone (PTH) agonists. Approved for the treatment, but not prevention, of osteoporosis, calcitonin has been shown to prevent loss of spinal BMD, decrease the rate of vertebral fractures in women with osteoporosis, and possibly provide pain relief in some patients with fractures [25]. Calcitonin is a potent inhibitor of osteoclastic bone resorption; however, osteoclasts are able to escape from the inhibitory effects of calcitonin following continued exposure. Conversely, PTH agonists function as an anabolic agent to increase bone mass. A recent study has demonstrated that while PTH does decrease vertebral fractures and increase spinal bone density in postmenopausal osteoporosis

and glucocorticoid-induced osteoporosis, this occurs at the expense of a decrease in radius bone density [26]. The long-term safety and nonvertebral fracture efficacy are still unknown [26, 27].

The patient's preinjury ambulatory and function status can determine the type or the need for operative intervention. Studies have demonstrated that the ability of a patient to return to their preinjury level of ambulation and function is dependent upon their preexisting functional level, timing and type of operative treatment, and postoperative rehabilitation [28–31]. In Hagino's study, they determined the following factors that significantly affected walking ability at the time of discharge for elderly hip-fracture patients: (1) age, (2) dementia, (3) residence before injury, (4) anemia, (5) electrolyte abnormality, (6) abnormal chest X-ray, and (7) chronic systemic disease. A scoring system based on these factors was able to predict the ambulation prognosis for these patients [32].

While elderly patients may have fractures that appear to be similar to those of younger patients, the comorbidities, physiologic reserves, and functional status make the musculoskeletal injury more than just "a simple fracture." The elderly patient's ability to cope with the metabolic and physiologic demands placed from these injuries is often poorer than their younger counterparts, and as such, treatment must incorporate a multidisciplinary approach. Understanding the preinjury level of function and comorbid status is imperative to work toward the goal of reestablishing the patient's functionality. A multidisciplinary approach must be taken with input from the orthopaedic surgeon, geriatrician, anesthesiologist, physiatrist, therapist, and the caregiver.

Considerations in Elderly Trauma

The treatment of the geriatric trauma patient assumes a more complex role due to the associated comorbidities and functional status impairments seen in the aged. The incidence of geriatric trauma is expected to increase, partly due to the increases in the elderly population and also the increased levels of activity seen in this patient group. Therefore, in treating the elderly traumatic patient, it is important to factor in the following considerations.

While only comprising approximately 12% of the population, elderly patients account for approximately 28% of traumatic deaths. Elderly patients had twice the higher rate of mortality (after adjusting for Injury Severity Score and the Revised Trauma Score), and they were also more likely to succumb later [33].

While earlier literature had stated that the Injury Severity Score did not correlate to mortality in older patients, these studies were from series that included lower energy trauma

(such as slips and falls) into their overall study groups. However, if these injuries are excluded and then the actual traumatic mechanisms are examined, it has been conclusively demonstrated that the Injury Severity Scores correlate to mortality [34]. Additionally, Gallagher found that for patients older than sixty with Injury Severity Scores greater than fifteen, there was a 28% morbidity rate, a 36% 2-year mortality rate, and a 60% 2-year complication rate, with mortality rates increasing with patient age [35].

The timing of operative management of the elderly traumatic patient has been the subject of continued controversy. While medical optimization is necessary to minimize perioperative risks for the elderly, delays in operative management have been found to lead to significant increases in morbidity and mortality [28–31, 36]. However, the key to minimizing morbidity and mortality is to perform surgical intervention as soon as the patient is medically stabilized and adequately resuscitated. In the event that patients cannot obtain definitive treatment for their orthopaedic injuries due to underresuscitation, damage-control orthopaedics (by use of temporizing external fixation) may play a significant role.

In the past 30 years, the role of the “trauma center” has played a vital part in the care and treatment of multiply injured patients. Recent studies have also shown that they, along with centers capable of aggressive intensive-care monitoring, have played a significant role in the care of the elderly traumatic patient. Meldon examined the Glasgow Coma Scale, the Injury Severity Score, and the role of acute care in octogenarians in different admission settings. He found that patients with an Injury Severity Score of 21–45 had a 56% survival rate if directly admitted to trauma centers as compared to an 8% survival rate if admitted directly to a community institution [37]. Other studies have also stressed the importance of referring traumatic elderly patients who require adequate resuscitation and monitoring to the appropriate facility initially, as delays in treatment and transfer resulted negatively in mortality rates [38].

Hip Fractures

General Principles

Hip fractures in the elderly can be devastating or fatal, and their effects on the patient’s functional and psychological status are significant. Currently, 250,000 hip fractures, at a total medical expenditure of approximately 9 billion dollars, occur annually in the United States. By 2040, 20% of the population will be older than 65 years of age, and the incidence of hip fractures is expected to double by the year 2050 due to aging trends [39–41].

As individuals age, their chance of sustaining a hip fracture greatly increases, doubling every decade after 50 years. Hip fractures occur twice as often in females and are most frequently seen in Caucasian women (followed by Caucasian men, Afro-American women, and Afro-American men). This may be due to differences in bone density between different ethnic groups [42–44]. Institutionalized patients are also more likely to sustain hip fractures [45–47].

Typically, hip fractures in the elderly occur from low-energy trauma (i.e., fall while walking on a flat surface). They can be intracapsular (femoral neck) or extracapsular (intertrochanteric or subtrochanteric). The location of the hip fracture has a significant impact on the healing potential of the fracture, and this has led to different methods of operative fixation. Vascularity is more significantly compromised with intracapsular fractures, and as such, the role of arthroplasty remains an integral treatment option as compared to extracapsular fractures. More than 90% of hip fractures in patients over 65 are femoral neck or intertrochanteric in origin with a slight predominance for intertrochanteric fractures in the octogenarians [48].

Presentation and Management

Patients usually complain of hip and groin pain with an inability to bear weight on the affected extremity after sustaining a relatively low-energy fall. The supine patient will hold the affected extremity externally rotated with slight flexion at the hip; this position will present with a noticeable leg-length discrepancy. This position is one that yields the maximal capsular volume when there is a fracture hematoma, thus providing the most comfort [49].

During the evaluation of the patient, it is imperative that the physician ascertain the length of time from the onset of injury to presentation. Elderly patients who have been in positions of recumbency for prolonged periods will present with significant dehydration and electrolyte imbalance. These factors must be corrected before operative intervention. Additionally, the presence of pressure ulcers, rhabdomyolysis, and deep vein thromboses are likely following prolonged periods of immobilization. Evaluation of bony prominences, creatine phosphokinase, and Doppler ultrasonography, respectively, are warranted in any patient who presents after being “down” for an extended period of time.

A throughout physical evaluation should include a neurovascular exam of the affected extremity, examination of each extremity and the spine for other injuries, documentation of any loss of consciousness, mental status exam, and assessment of skin integrity in appropriate areas. Medical consultation should be obtained to prepare the patient for possible surgery. Injury films, baseline labs, chest radiograph,

FIGURE 94.1 Intertrochanteric hip fracture visualized on an AP view (a) and cross-table lateral view (b) of the right hip.

and electrocardiogram (EKG) should be attained at the time of presentation. Care should be taken when acquiring injury films, which must include an AP pelvis, a true AP of the affected hip, and a cross-table lateral of the hip (Fig. 94.1). Obtaining a frog-leg lateral in the case of a suspected hip fracture is detrimental by potentially causing pain, further displacing fracture fragments, and damaging vascular channels. Furthermore, a traction/internal rotation radiograph of the affected hip may aid in the diagnosis and surgical planning of the hip fracture [50].

Many centers have made a policy to acquire a baseline arterial blood gas (ABG) preoperatively, since hip fractures carry an inherent risk of deep venous thrombosis and pulmonary embolus (PE). However, a recent study has demonstrated that ABGs have poor positive predictive value for pulmonary embolism and add little to the positive predictive value or negative predictive value of a careful clinical examination. The study, therefore, concluded that acquisition of baseline ABGs as a routine part of the preoperative evaluation is not warranted [51].

The role of traction in hip fractures is debatable and subject to physician preference. While it may provide significant patient comfort in those with femoral shaft and subtrochanteric fractures, traction forces the hip into a less comfortable position (from its more comfortable flexed and externally rotated position). Therefore, it is not recommended that patients with hip fractures be placed into skeletal traction. To aid in patient comfort, however, a pillow under the affected limb may reduce pain. Furthermore, the

placement of a Foley catheter will eliminate the need for patient transfers to a bedpan, thereby reducing potential discomfort and further fracture displacement.

When the diagnosis of hip fracture is suspected clinically, but not clear with routine radiography, other studies are indicated. As stated before, a traction/internal rotation view will help visualize the entire length of the femoral neck. This view is conducted by shooting an AP hip radiograph as the physician pulls traction at the ankle while internally rotating the hip 15° (the average amount of anteversion seen in the adult femoral neck). Care must be taken to avoid shearing the skin of the lower extremity while performing the maneuver. If question remains, CT scans, technetium bone scans, or MRI may detect presence of an occult hip fracture. However, CT scans have been found to be an inferior modality in detecting these fractures [52]. Both MRIs and bone scans are more sensitive than plain radiography in detecting occult hip fractures, but the bone scan can only detect fractures 2–3 days after injury. On the other hand, the MRI can detect occult fractures that are less than 24 h old [53].

Nonoperative care is reserved for selected patients who are nonambulatory and too ill to undergo anesthesia. Ultimately, the preferred treatment of a hip fracture is surgery. Operative stabilization or arthroplasty will decrease the period of non-weight bearing, risk of malunion/nonunion, cardiopulmonary complications, and mortality. Additionally, operative treatment has been shown to be the most economically advantageous as compared to nonoperative treatment [54].

The risk of deep venous thrombosis (DVT) or pulmonary embolism (PE) is a concern requiring preventive measures. Historically, warfarin has been considered the standard for prophylaxis. Currently, low-molecular-weight heparin (LMWH) has been used subcutaneously with good results, without the need for constant laboratory monitoring (as is required for warfarin). LMWH can be administered within 12–24 h postsurgically. In situations that will not permit the use of pharmacologic prophylaxis, an inferior vena cava filter may be used. Studies evaluating the use of subcutaneous unfractionated heparin for DVT prophylaxis in orthopaedic patients have demonstrated less efficacy as compared to warfarin and LMWH. However, continuous intravenous infusion of unfractionated heparin has been shown to be adequate prophylaxis in patients that are started on warfarin and awaiting therapeutic INR levels [55–58]. Preoperatively, patients should be given pharmacologic and mechanical prophylaxis (i.e., venodyne boots, pneumatic compression stockings, etc.). Twelve hours prior to surgery, pharmacologic prophylaxis should be withheld (to decrease intraoperative and immediate postoperative bleeding complications) while mechanical prophylaxis should be continued.

The duration of DVT prophylaxis is still being debated. Prophylaxis is indicated while in the hospital after major surgery. There is evidence that the prevalence of asymptomatic deep vein thrombosis, detected by routine venography after major orthopedic surgery, is lower at hospital discharge in patients who have received 10 days rather than 5 days of prophylaxis. This observation supports the current ACCP recommendation for a minimum of 7–10 days of prophylaxis after hip and knee replacement, even if patients are discharged from the hospital within 7 days of surgery. As risk of DVT persists for up to 3 months after surgery, patients at high risk for postoperative DVT may benefit from extended prophylaxis (i.e., an additional 3 weeks after the first 7–10 days). Extended prophylaxis with low-molecular-weight heparin (LMWH) reduces the frequency of postdischarge DVT by approximately two-thirds after hip replacement; however, the resultant absolute reduction in the frequency of fatal pulmonary embolism is small (i.e., estimated at 1 per 2,500 patients). Indirect evidence suggests that compared with LMWH, efficacy of extended prophylaxis after hip replacement is greater with fondaparinux, similar with warfarin, and less with aspirin. Extended prophylaxis is expected to be of less benefit after knee than after hip replacement. In keeping with current ACCP recommendations, at a minimum, extended prophylaxis should be used after major orthopedic surgery in patients who have additional risk factors for DVT (i.e., previous DVT, cancer). If anticoagulant drug therapy is stopped after 7–10 days, an additional month of prophylaxis with aspirin should be considered [59].

Outcomes

As previously mentioned, the goal of hip fracture surgery is to restore the patient's functional outcome. One study showed that at 1-year follow-up, 41% of patients regained their preinjury level of ambulatory function, 40% remained community or household ambulators but required assistive devices, 12% became solely household ambulators, and 8% became nonambulatory. The factors shown to improve the possibility of attaining the preinjury ambulatory status are outlined in Table 94.2 [28].

Initial mortality rates are increased in elderly patients with hip fracture compared to age-matched controls. One-year mortality can be as high as 25% [60, 61]. The highest rate is seen in the first 6 months, and these rates progressively decline to the same as those of age-matched controls by 1 year. Factors shown to negatively affect 1-year mortality rates are outlined in Table 94.1 [29].

Timing from injury to surgical stabilization has been a subject of debate. Multiple studies have cited conflicting recommendations, with some recommending immediate operative stabilization as the key to minimizing mortality [62]. However, other studies have also found no correlation between the delay of surgical intervention and patient mortality [63]. However, the majority of these studies have been based on retrospective reviews of patient records or heterogeneous population databases and were poorly controlled [60, 61, 64]. A prospective study from our institution, controlling for age, sex, and comorbidities, was comprised of 367 hip fracture patients who were not suffering from dementia, were capable of activities of daily living, and had ambulatory abilities prior to injury. The study demonstrated that a delay to surgical stabilization of more than two calendar days doubled mortality [30]. Similar findings were reported in a recent study by Moran that found that delays of greater than 4 days in patients medically fit for surgery led to higher mortality rates at 3 months and 1 year after injury [36]. Furthermore, another study also demonstrated that delays of operative management of hip fractures

TABLE 94.2 Hip fractures: factors influencing outcome

Factors favorable to regaining preinjury ambulatory status	Factors contributing to 1 year mortality
Age below 85 years	Age over 85 years
Preoperative ASA rating of I or II	Preoperative ASA rating of III or IV
Intertrochanteric fracture	Preinjury dependency in activities of daily living
Male sex	History of malignancy (excluding skin cancer)
Absence of dementia	Development of one or more complications during hospitalization

significantly worsened the ability to return to independent living, increased the risk of pressure ulcers, and increased the length of stay [31].

Postoperatively, disparities exist in the rehabilitation protocols outlined for these patients. Protocols range from non-weight bearing to immediate weight bearing as tolerated. Biomechanically, it has been shown that joint reactive forces are greater across the hip when comparing nonweight bearing to toe-touch weight bearing [65].

Additionally, balance and upper extremity strength are important issues to consider when asking the older adult to be limited in their weight bearing. When patients are allowed to weight bear as tolerated immediately postoperatively, they self-regulate the amount of weight on the injured extremity and gradually increase the amount of weight bearing over time [66, 67].

Femoral Neck Fractures

Femoral neck fractures occur between the base of the femoral head and the intertrochanteric line. These fractures are considered intracapsular and, due to the location of the fracture relative to the femoral vascular anatomy, have significant effects on the blood supply to the femoral head. These implications weigh heavily on treatment options and their relative success rates.

The main blood supply to the femoral head comes from branches off the medial and lateral femoral circumflex arteries (medial with much greater contribution). These arteries form an extracapsular ring at the base of the neck with ascending branches that are intracapsular, forming a network ending in bony perforators to the femoral head. The intracapsular extensions represent terminal vessels of the extracapsular ring; the ascending vessels are at significant risk during femoral neck fracture, especially when displaced. Minimal vascular contribution to the femoral head also comes from the ligamentum teres (Fig. 94.2).

Many classifications have been used to describe femoral neck fractures. The most common classification is one derived by Garden in which Types I and II are nondisplaced while types III and IV represent displaced femoral neck fractures [68] (Fig. 94.3). Rates for future osteonecrosis of the femoral head or nonunion of the femoral neck fracture have ranged between 5 and 35%, with significantly higher rates in displaced fractures (5–10% for minimally displaced versus 20–35% for displaced) [68–72]. Nonunion requires reoperation in 75% of cases, while osteonecrosis requires revision surgery in only 30% of cases.

Surgery is the treatment of choice for this injury. In situ pinning should be performed for only minimally displaced/impacted fractures. Although these are inherently stable, they do have an 8–40% chance of displacement without

FIGURE 94.2 Contributing vessels to the major sources of blood supply to the proximal femur. Reprinted with permission from Browner, Jupiter, Levine, Trafton (2003) *Skeletal trauma: basic science, management and reconstruction*, 3rd ed. WB Saunders, Philadelphia. Copyright Elsevier (2003).

operative stabilization [73, 74]. Postoperatively, all patients should be allowed to weight-bear as tolerated with assistive devices, especially due to the difficulty the elderly have in following weight-bearing, gait, and balance guidelines. Furthermore, these patients will regulate their weight bearing based on pain [67].

In displaced fractures, obtaining and maintaining an adequate reduction with pinning is not always possible or advisable. In a physiologically younger patient, all efforts should be made for closed reduction and pinning, but in a physiologically older patient, there is a lower threshold for arthroplasty. This lower threshold is partly due to the lower demands that physiologically older patients would place on the implant, increasing its longevity. In a recent meta-analysis comparing internal fixation and arthroplasty for displaced femoral neck fractures, the authors found that arthroplasty significantly reduces the risk of revision surgery, but at the cost of greater infection rates, blood loss, and operative time [75].

Early reports raised concern for increased operative times and higher dislocation rates for primary total hip arthroplasty when performed for fractures as opposed to degenerative joint disease [56, 76]. However, Blomfeldt determined that a

FIGURE 94.3 Modification of Garden Classification of femoral neck fractures into Displaced (III and IV) and Nondisplaced (I and II) categories. total hip replacement provides better function than a bipolar hemiarthroplasty at 1 year postoperatively without increase the complication rate in the elderly [77]. Before entertaining the option of hip arthroplasty, one must ascertain if the patient can follow postoperative arthroplasty precautions to avoid dislocation. Neurologically impaired or cognitively impaired patients are suboptimal candidates. Currently, total hip arthroplasty is now the treatment of choice in the active elderly and, with improved implants and surgical technique, provides results that exceed those produced by hemiarthroplasty.

In the rare case of nonoperative care for femoral neck fracture, early mobilization to a wheelchair, adequate anesthesia, decubitus precautions, and physical therapy as tolerated are begun as soon as the patient is able to tolerate such activity. However, this option results in poor outcomes and should be avoided in those that can tolerate the surgery and the rehabilitation protocol.

Intertrochanteric Fractures

The intertrochanteric region is extracapsular, distal to the femoral neck between the greater and lesser trochanters. Since this region consists of metaphyseal bone with an abundant

blood supply, there is less danger of healing complications as compared to what is noted for femoral neck fractures. An important area of the intertrochanteric region is the calcar femorale. Located posteromedially, this area is an area of dense cortical bone that acts as an internal strut for the significant forces transmitted through the hip. The disruption of this region creates an unstable fracture pattern, and therefore, the implant of choice for treatment is dependent on the integrity of the calcar femorale. The greater trochanter lies superolaterally and is the insertion site of the hip abductors and short external rotators. The lesser trochanter lies posteromedially and is the insertion site of the iliopsoas (Fig. 94.4).

It is important to determine radiographically if these fractures are stable. The ability to obtain stability is based on cortical continuity of the calcar femorale. On plain radiographs, this stability is gauged by the lesser trochanter's position. If the lesser trochanter is nondisplaced without comminution, then the fracture is termed stable while displacement and comminution represents an unstable fracture. Other markers of instability include fractures that propagate from a superomedial to inferolateral direction (also known as "reverse obliquity" fractures), fractures with excessive posterior sag, and intertrochanteric fractures that extend into the subtrochanteric region. Reduction attempts to establish stability are performed with axial traction, and progression from abduction to adduction. Internal rotation will lock the fracture fragments while axial traction is maintained in adduction [78] (Fig. 94.5).

Surgery is the treatment of choice for almost all intertrochanteric fractures. Indications and goals for nonoperative treatment are similar to those mentioned for femoral neck fractures, but it should be noted that these fractures are often more difficult to manage nonoperatively because of pain and deformity associated with excessive muscle pull and fracture displacement. Closed reduction is attempted after spinal or general anesthesia has been initiated, usually on a fracture table. If reduction is unobtainable by closed means, an open reduction is performed. Commonly, a device incorporating a sliding screw and barrel inserted into the femoral neck with an accompanying side plate (also known as the "sliding hip screw") or intramedullary component is used. The telescoping nature of the implant supplies stability and facilitates compression across the fracture site to stimulate bony healing. The intramedullary devices are currently recommended for more unstable intertrochanteric fracture patterns, while the sliding hip screw design is more appropriate for stable fractures. Currently, lesser trochanteric fractures are not reduced and stabilized with hardware [79].

Rarely, primary prosthetic replacement is indicated in cases of severe comminution. This implant differs from traditional arthroplasty components due to the disruption of the calcar femorale (a necessary structure for traditional arthroplasty components). Implanting these prostheses is associated

with prolonged operative time, increased blood loss, and higher rates of dislocation as compared to elective total hip arthroplasties [79].

Subtrochanteric Fractures

The subtrochanteric region of the femur lies in the first 5 cm of the femur distal to the lesser trochanter. Fractures in this area are less frequent in the elderly than femoral neck or intertrochanteric fractures. Although these occur with high-energy situations in the young, they may follow a simple fall in aged individuals [43, 80].

Stability in these fractures is also based on the integrity of the posteromedial cortex [81]. Usually, these injuries are treated with an intramedullary nail or fixed angle sliding plate and screw implant. Osteonecrosis is rarely a concern with these extracapsular fractures [82, 83]. The challenge with operative fixation for subtrochanteric fracture lies in obtaining an anatomic reduction prior to implant insertion. The significant amount of displacement is due to the numerous deforming muscle forces in this region of the femur [84] (Fig. 94.6).

FIGURE 94.6 Subtrochanteric region of femur. Contributing muscle forces to displacement of fracture fragments. Reprinted with permission from Browner, Jupiter, Levine, Trafton (2003) *Skeletal trauma: basic science, management and reconstruction*, 3rd ed. WB Saunders, Philadelphia. Copyright Elsevier (2003).

The operative treatment for subtrochanteric fractures requires adequate reduction prior to fixation. Fixation devices include intramedullary nail devices, fixed angle devices (such as blade plates or dynamic condylar screws), and locked plate devices. The use of a sliding hip screw has been found to yield unacceptable failure rates [85, 86].

Ankle Fractures

Ankle fractures are very common fractures and on the rise in the geriatric population. The ankle joint consists of the distal aspects of the tibia and fibula (medial and lateral malleoli) and their articulation with the talar dome. The medial malleolus is connected to the navicular, calcaneus, and talus by the superficial and deep layers of the deltoid ligament. The lateral malleolus is connected to the talus and calcaneus by a three-ligament complex. The tibia and fibula maintain their relationship via a ligamentous complex known as the syndesmosis (which comprises of the anterior-inferior tibiofibular ligament, the interosseous ligament, the posterior tibiofibular ligament, and the transverse ligament) located distally (Fig. 94.7). These ligaments stabilize the ankle joint, or the mortise, by opposing the fibula in the fibular notch (also known as the incisura fibularis tibiae).

Injuries to the ankle can occur by many mechanisms, with the majority being low-energy rotational injuries [87, 88]. Frequently, ligamentous and bony injury can result from a twisting mechanism. Injuries can be bony, ligamentous, or a combination of both. Because bony and/or ligamentous injuries may both produce an unstable ankle joint, negative radiographs do not clearly rule out the presence of an unstable joint. If ligamentous injury is suspected due to signs and symptoms medially in the presence of an isolated fibular fracture, an external rotation stress radiograph should be considered [89].

Patients with ankle injuries often complain of an inability to stand or ambulate along with tenderness around the ankle joint following trauma. The patient may present with swelling and ecchymosis around the ankle. The circumstances of the injury must be elicited to establish the mechanism of injury. Many injuries that may be overlooked during the evaluation of ankle fractures should be excluded through a screening exam. These include fractures of the proximal fibula, lateral process of the talus, anterior process of the calcaneus, and proximal fifth metatarsal [90]. A standard radiographic series includes three views of the ankle joint (AP, lateral, and mortise (15° internal rotation view)) and full-length tibia/fibula films to exclude syndesmotic injury (also known as a Maisonneuve fracture, noticed by a fracture along the proximal fibula). Foot films may also be considered if the physical examination of the foot reveals suspected pathologies.

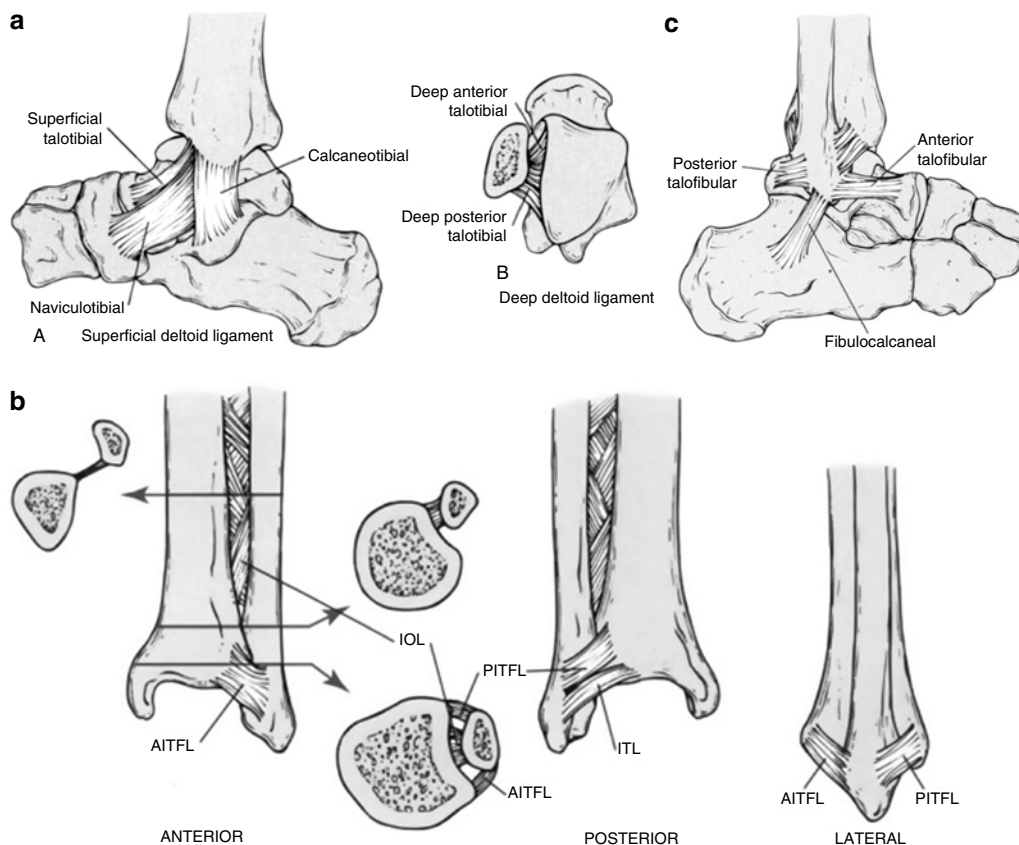

FIGURE 94.7 Ankle joint with ligamentous restraints: medial (a), syndesmosis (b), and lateral (c). Reprinted with permission from Browner, Jupiter, Levine, Trafton (2003) *Skeletal trauma: basic science, man-*

agement and reconstruction, 3rd ed. WB Saunders, Philadelphia. Copyright Elsevier (2003).

Treatment of ankle fractures depends on the mechanism of injury and stability of the fracture. An isolated fibula fracture occurring at or below the level of the tibia–talus articulation without medial-sided injury is considered stable and may be treated in a short leg cast or brace with early weight bearing. Fractures that are considered unstable are bimalleolar, bimalleolar equivalents, or those with a disruption of the syndesmosis (i.e., high fibula fracture with medial joint line tenderness, widening of the medial clear space of the tibia–talus articulation, or dissociation of the tibia–talus or tibia–fibula articulations). Slight malreduction may result in degenerative arthritis [89]. Surgery provides a stable reduction and allows the patient to begin early joint range of motion to help avoid later stiffness and risk of malreduction. In contrast with nonoperatively treated patients, surgically treated patients do not require long-leg immobilization and can be more easily mobilized with assistive devices.

Operative intervention has been shown to achieve better fracture position and better patient satisfaction, although complications with hardware loosening have been seen in women with osteoporosis [91, 92]. The presence of diabetes,

vasculopathy, or history of smoking increases the risk for soft-tissue complications (i.e., infection, wound dehiscence, etc.) with surgery.

Proximal Humerus Fractures

Proximal humerus fractures are frequently encountered in the geriatric population and occur four times more commonly in women [94]. Typically resulting from low-energy falls, the initial treatment of these fractures frequently requires immobilization, which interferes with activities of daily living. The majority of these fractures are stable and are best treated nonoperatively.

The shoulder joint has a complex bony and soft tissue relationship. The round humeral head articulates with the relatively flatter and shallower glenoid to form a joint that, while able to enjoy a relatively larger and more unrestricted range of motion, relies heavily on its soft-tissue connections for its stability. The shoulder capsule envelops this joint to provide static stability. Superficial to the capsule, the rotator

FIGURE 94.8 Shoulder joint with representation of rotator cuff restraints. Anterior and posterior views (from <http://www.nlm.nih.gov/medlineplus/ency/imagepages/19622.htm>).

ADAM

cuff, composed of the supraspinatus, infraspinatus, teres minor, and subscapularis (Fig. 94.8), with the help of the deltoid and scapular rotators, provide dynamic stability to the shoulder throughout its active range of motion. Each of these rotator cuff muscles insert into specific points on the humeral head, and each provide a direct of motion and stabilization integral for proper shoulder function.

Proximal humeral fractures result in relatively predictable fragments or parts based upon anatomic regions. Typically, they result in fragments that can be separated out as the humeral head, the greater tuberosity, the lesser tuberosity, and the shaft. Because of the typical insertion of the rotator cuff on some of these fragments, the pull of these muscles causes predictable directional displacement of these fracture fragments. As it is obvious to see that these fractures will affect the tension and function of these rotator cuff muscles, poorly treated proximal humerus fractures can significantly affect shoulder function and, therefore, patient outcome.

Patients with proximal humerus fractures complain of an inability to move the arm secondary to pain. During assessment of these fractures, it is imperative that a thorough neurovascular examination documents the presence of intact vascularity (distal pulses may be intact despite vascular injury about the shoulder due to the rich collateral flow) and sensation about the lateral aspect of the deltoid (to rule out damage to the axillary nerve or musculocutaneous nerve). While it will be difficult to assess deltoid strength to document axillary nerve integrity, the patient may be capable of slightly tensing their deltoid to demonstrate the nerve's function.

To adequately assess proximal humerus fractures radiographically, the physician should obtain at minimum three views of the shoulder. The shoulder "trauma series" includes the anteroposterior (AP), scapular "Y," and axillary views. Of particular importance is the axillary view, which is imperative to adequately document the presence of associated dislocations of the humeral head. However, the axillary view, unlike the AP and scapular "Y" views, is not the view used to measure the amount of fracture displacement or angulation [94].

Minimally displaced fractures represent 80–85% of what is seen in the elderly for injuries to the proximal humerus [95]. Provided that the fracture fragments move as "a unit" on clinical examination, it can be assumed that the surrounding soft tissues and periosteum provide stability. As such, these injuries can be treated with a brief period of sling immobilization (for approximately 1 week), followed by range-of-motion exercises (progressing from passive to active-assisted over 4–6 weeks). Minimally displaced proximal humerus fractures usually result in pain-free union [96, 97]. It is important to initiate early mobilization (as early as 72 h to less than 2 weeks) for impacted fracture that are treated nonoperatively, as it has been shown to help with quicker restoration of the physical capability and performance of the injured arm as compared to longer periods of immobilization (prior to commencement of therapy) [98, 99].

The role of surgical intervention has recently changed due to rising patient expectations and the innovation of fixation technologies. In the past, multifragment displaced fractures

that do not “move as a unit” on exam were occasionally treated nonoperatively. However, with more emphasis and importance placed on restoring the anatomy of the bony fragments with the appropriate rotator cuff tension and orientation, more of these fractures are undergoing operative treatment. Currently, the role and timing of surgery has been the subject of debate; however, if the patient is medically capable of undergoing operative treatment and will benefit from a function shoulder, then operative intervention is considered. Acute fracture/dislocations of the proximal humerus, however, should be addressed with operative intervention. Past studies had demonstrated that acute hemiarthroplasty is superior to attempting surgical stabilization and conducting delayed hemiarthroplasty [100, 101]. However, a recent study has shown no differences in outcomes associated with pain and patient satisfaction comparing acute versus delayed hemiarthroplasty. All patients had variability in outcomes related to function, and the only difference seen in delayed hemiarthroplasty was increased amounts of scar tissue during the surgical exposure [102]. Overall, low-energy, minimally displaced fractures exhibit better functional outcome compared to high-energy three and four part fractures with associated rotator cuff injuries [103]. Prosthetic replacement results in predictable pain relief, but its ability to result in predictable functional outcomes is more variable [104, 105].

Distal Radius Fractures

Fractures of the distal radius are frequently seen in elderly patients, particularly women, who fall on an outstretched hand. Predisposing factors are osteoporosis, increased incidence of falls in the elderly, dementia, poor eyesight, decreased coordination, medications, and history of strokes or transient ischemic attacks [106].

The wrist is composed of eight carpal bones and the distal radius and distal ulna. The articulations are maintained via a complex ligamentous network on both the dorsal and volar aspects of the wrist. Important factors in predicting a patient's need for surgery and ultimate outcome include the amount of displacement of the fracture fragments (assessed by its amount of angulation, comminution, and shortening), articular surface involvement, and preinjury level of function [107]. While dorsally angulated distal radius fractures that heal in this position can lead to abnormal carpal bone kinematics that may cause significant functional limitations [108], the possibility and clinical significance for the elderly wrist to undergo such changes is questionable.

The presentation of distal radius fractures is pain, swelling, and wrist deformity. The force responsible for a distal

radius injury can be transmitted proximally and can result in elbow injury. Radiographic examination should consist of PA, lateral, and oblique views of both wrists. Views of the contralateral wrist help in evaluating the adequacy of reduction.

The ability to determine the stability of a distal radius fracture was initially evaluated by the Lafontaine criteria [109]. Lafontaine suggested five factors to indicate instability: (1) initial dorsal angulation greater than 20°, (2) dorsal comminution, (3) radiocarpal intraarticular involvement, (4) associated ulna fractures, and (5) age greater than 60 years. However, recent studies have demonstrated that age was the only statistically significant risk factor in predicting secondary displacement and instability [110].

If the patient is physiologically active, has higher demands, and has an injury that involves the dominant extremity, treatment should be guided toward an anatomic reduction. Recent studies with the volar fixed-angle plate device for unstable distal radius fractures have shown it to provide stable internal fixation and allow early function [111]. However, in sedentary patients with low demands, functional outcomes are good despite the presence of deformity [112].

Common fracture patterns include: Colles (dorsally displaced articular surface with apex-volar angulation), Smith's (volarly displaced articular surface with apex-dorsal angulation), Barton's (volar or dorsal shear), nondisplaced, and concomitant fracture of the distal ulna [113] (Fig. 94.9). The goal of treatment is to restore function, enable painless range of motion, and maintain grip strength. Whether cast immobilization or surgery is conducted, finger range of motion is encouraged from the onset of injury since finger stiffness can adversely affect outcome.

Acute, distal radius fractures should be treated with a reduction and splint immobilization to grossly maintain alignment, protect neurovascular structures, and allow for swelling. Nondisplaced or stable, reduced fractures can ultimately be treated with a short-arm cast for 4–6 weeks. When anatomic reduction cannot be obtained or maintained, surgery, with external fixation or open reduction and internal fixation, is required. Implants and devices available to maintain anatomic reduction include plates, external fixators, pins, bone grafting, and calcium phosphate cement. Some of these implants and devices are used concurrently with the other implants or in isolation, depending on the fracture personality, patient factors, and surgeon familiarity.

If an adequate reduction is not obtained and if range of motion exercises are not encouraged, the incidence of pain, stiffness, and decreased grip strength greatly increases. Anatomic reduction (stable fixation) combined with early therapy results in excellent outcomes for up to 90% of patients [114].

FIGURE 94.9 Common patterns of distal radius fractures: Colles' (a) and Bartons (b). Reprinted with permission from Browner, Jupiter, Levine, Trafton (2003) *Skeletal trauma: basic science, management and reconstruction*, 3rd ed. WB Saunders, Philadelphia. Copyright Elsevier (2003).

Metastatic Pathologic Fractures

As neoplasms are prevalent in the elderly, pathologic or impending fractures are relatively common. With higher rates of survival for patients with cancer, the physician should

encounter more skeletal neoplasms than what was initially seen in the past. The most common form of cancer found in bone is a result of metastases [115].

Metastases usually arise from primary neoplasms in the prostate, breast, lung, kidney, and thyroid [116].

Prostate, adenocarcinoma, Hodgkin's lymphoma, and some breast cancers can be osteoblastic ("bone-forming" lesions that are radio-opaque on X-ray). Lung, kidney, thyroid, and some breast cancers are osteolytic ("bone-destroying" lesions that are radio-lucent on X-ray). Both osteoblastic and osteolytic tumors disrupt normal bony architecture and promote fractures. Most metastases affect the axial skeleton and the appendicular skeleton proximal to the knee and elbow. An exception is lung cancer, which is seen to metastasize distally. Multiple myeloma and lymphoma are common primary malignancies in older adults [117].

Nonoperative intervention includes casting and immobilization of the affected bone. Risks of immobilization include pneumonia, decubiti, and thromboembolic phenomena. Thromboembolism is especially a concern in this patient population, as their associated malignancies predispose these patients to a hypercoagulable state. Nonoperative treatment of patients with metastases is associated with higher rates of nonunion.

Operative treatment is preferable in patients with impending and completed pathologic fractures. Internal stabilization with intramedullary rods is frequently used in instances of long-bone involvement. The literature suggests a minimum life expectancy (between 1 and 3 months) for operative intervention [117, 118]. Most importantly, the goal of operative stabilization is to improve the quality of remaining life. This decision should be made following discussion between the surgeon, oncologist, patient, and caregiver. Upper extremity surgery can potentially improve independence with activities of daily living by relieving pain and providing stability. Lower extremity surgery can promote ambulation or transfers in the remainder of life. Most importantly, surgical stabilization, with or without adjunctive chemotherapy and radiotherapy, can alleviate pain.

Prior to undergoing surgery, a full-body bone scan and selected radiographs help determine sites of other metastases. Many authors advocate prophylactic internal fixation of impending pathologic fractures based on size and location of lesions [117]. The decision to proceed with prophylactic stabilization should be made based on the patient's level of function, pain, and life expectancy.

The Role of Rehabilitation

The role of rehabilitation is another important consideration in the treatment of geriatric trauma. Traumatic injuries may limit the patient's ability to ambulate and perform activities of daily living, and these limitations may lead to progressive loss of functionality, associated morbidity and mortality from prolonged recumbency, and increased length of hospital

stay [31]. In addition, treatments rendered to these patients have various weight-bearing and functional restrictions, and patients must be instructed and trained within these parameters to optimize their outcomes. As such, specific rehabilitation regimens, degrees of weight-bearing tolerances, and the length of rehabilitation have been extensively discussed in the literature.

These rehabilitation services come in the form of physical and occupational therapists, social workers, case managers, and inpatient versus outpatient rehabilitation centers. The decision to use one or a combination of these services is dependent upon the patient's injury, cognitive, functional, and social support status, the presence of polytrauma, the rendered treatment(s), and the type of rehabilitation desired by the treating physician.

The role and effectiveness of an inpatient rehabilitation program in the geriatric trauma population have been examined in the literature. Kauh et al. performed a retrospective observational pilot study examining the discharge outcomes, postdischarge health care use, and death rates among patients treated in a postacute geriatric rehabilitation unit (GRU) housed within a skilled nursing facility (SNF) with those treated in a traditional SNF [119]. At discharge from the nursing facility, GRU patients showed greater improvement in activities of daily living and mobility, had a significantly shorter length of stay, and were discharged to home more often. At 1 year, GRU patients had significantly fewer hospital readmissions. While GRU patients also had fewer emergency department visits and days in the hospital at 1 year, these results were not significant. The authors concluded that GRU may be an effective means to improve patient outcomes and reduce undesirable health care use after an acute illness.

Logters et al. examined strategies for postoperative care of patients with hip fractures, which included early discharge from the acute-care hospital and inpatient interdisciplinary rehabilitation facilities [120]. This prospective study examined the patient's activities of daily living before, at the end of rehabilitation, and 1 year after trauma. In addition, patient-related variables were correlated with these results. Ninety percent of patients improved their activities of daily living during rehabilitation. However, within 1 year, 40% of patients had deteriorations in their activities of daily living. Fifty-one percent of patients were reintegrated back to their homes, and patients who lived at home before trauma and were reintegrated back to their homes had significantly better activities of daily living at 1 year after trauma than patients who were living in a nursing-care facility before the trauma. The variables of age, level of cognition, and type of fracture had no influence on the long-term outcome. However, the study also noted that an extension of rehabilitation above the mean time period did not improve the sustainable clinical outcome

and that their policy for early discharge to geriatric rehabilitation is associated with extension of overall hospital stay. Therefore, the authors concluded that the benefits noted in this study should be weighed against the related increased health care costs.

However, there are other studies that do not demonstrate the benefits of inpatient rehabilitation. Koval et al. assessed the impact of an instituted intensive inpatient rehabilitation

on outcomes after femoral neck or intertrochanteric fractures [121]. Comparing patients managed with an instituted inpatient rehabilitation program to those who were not, the authors noted no differences in the hospital discharge status or in the walking ability, place of residence, need for home assistance, or independence in basic and instrumental activities of daily living at the 6 and 12-month follow-up examinations.

CASE STUDY

The patient is an 85-year-old woman with a history of hypertension and coronary artery disease. She is a limited community ambulatory requiring the occasional use of a cane as an assistive device. The patient sustained a closed right distal femoral spiral fracture after a mechanical fall (Fig. 94.10). In the emergency room, the patient was placed into skeletal traction and admitted for treatment.

After the patient was medically cleared for surgical intervention, she was taken to the operating room and treated with a periarticular locked plate. The decision to use this construct was based on the osteoporotic quality of her distal femur. There were no complications intraoperatively, and the patient was kept on antibiotic prophylaxis and initiated on DVT prophylaxis with enoxaparin. A continuous passive motion (CPM) machine was instituted on the first postoperative day to initiate passive range of motion to her right knee (from 0 to 90°). The CPM machine was continued for three days after surgery to maintain knee motion. The patient was kept nonweight bearing on her affected extremity for 6 weeks. Starting on the first postoperative day, the physical therapist assisted the patient with ambulation under these weight-bearing parameters.

The patient was subsequently transferred to an inpatient rehabilitation facility four days after surgery, and progressed well with the therapy program. The patient was discharged from the facility 3 weeks after admission. Radiographic examination of her affected extremity 6 weeks after surgery revealed callus formation along the fracture site (Fig. 94.11). At this point, the patient was permitted to perform partial weight-bearing activities with assistive devices. Three months after the surgery, the patient was nontender at the fracture site, and radiographs demonstrated adequate bony healing. The patient was then allowed to bear weight as tolerated.

Conclusion

Orthopaedic injuries are responsible for significant morbidity and mortality in the geriatric population. With increasing life-expectancy trends, orthopaedic problems are likely to increase. Ideally, treatment should focus on prevention of falls and management of osteoporosis. The primary goals of treatment are to decrease pain, allow mobilization, and return the patient to their prior level of functioning. Treatment must include patient education and rehabilitation. The improvement in functional outcomes borne from these interventions has been shown to result in decreased long-term cost to the health care system [122].

Acknowledgements The authors wish to acknowledge Drs. Frank A. Liporace and Kenneth J. Koval for their work in this chapter.

Chapter 95

Treatment of Degenerative Joint Diseases

Philip J. Glassner, James Slover, and Joseph D. Zuckerman

If 60 is the new 40, then 80 is the new 60. Nowhere is this more evident than in an adult orthopedic surgery practice. As the population ages, the number of patients developing knee and hip pain is increasing. Patients are living longer and desire, and expect, to maintain high levels of activity and function throughout their lives. There are many causes of knee and hip pain in the elderly, the most common being osteoarthritis. The purpose of this chapter is to review the treatment options for this highly prevalent disease and to briefly discuss the other causes of knee and hip pain that may be encountered in elderly patients.

Osteoarthritis can be treated with nonoperative or operative modalities. Once nonoperative therapies such as nonsteroidal anti-inflammatory medications (NSAIDs), physical therapy, assistive devices, activity modification, weight loss, and injections have been exhausted, operative management should be considered. Total knee arthroplasty (TKA) and total hip arthroplasty (THA) are the most common procedures performed to maintain the quality of a patient's life. In 2004, the number of total knee and total hip arthroplasties being performed annually in the United States was approximately 478,000 and 234,000 [1], respectively. Those numbers are expected to increase dramatically to 3.48 million TKAs and 572,000 THAs by the year 2030 [2].

Excellent outcomes, as defined by pain relief and improvement in quality of life, can be obtained in well over 90% of patients with a multidisciplinary team approach to this elderly population, including internal medicine and its subspecialties, rehabilitation medicine, and the orthopedic surgeon [3–5]. Throughout the course of this chapter, we discuss the underlying pathology of knee and hip pain, the preoperative evaluation, the operation, and the postoperative protocols, along with risks, complications, and outcomes of knee and hip arthroplasty.

Causes of Knee and Hip Pain

The most common cause of joint pain in the elderly is osteoarthritis, a disease primarily affecting articular cartilage. Articular cartilage is composed primarily of water (65–80%), collagen (the majority being type II collagen), proteoglycans, and chondrocytes. The function of cartilage is to decrease friction in the joint and to aid in an even distribution of forces to the subchondral bone. Synovial fluid lubricates the articular cartilage and nourishes it via diffusion, as articular cartilage is avascular [6].

Osteoarthritis is characterized by changes in articular cartilage, including an increase in the water content of collagen, alterations in the proteoglycans, and a failure of the chondrocytes ability to repair the cartilage. This degenerative process increases pressure on the subchondral bone, leading to remodeling and sclerosis of the bone, the formation of osteophytes and subchondral cysts, and asymmetric joint space narrowing. These are the most common findings on radiographic evaluation. It is important to note in the evaluation process that there may be little correlation between the amount of joint degeneration seen on radiographs and the symptoms of the patient. That is to say, a patient with advanced degeneration on a radiograph may have very little pain, and vice versa. This pathologic process ultimately leads to complete destruction of the articular cartilage, with bone-on-bone contact, and a stiff, painful joint.

Another important component of the knee joint is the meniscus, which also aids in load distribution. It is a C-shaped fibrocartilaginous structure located between the femur and the tibia. Originally, the meniscus was thought to be an embryological remnant, and if torn a total menisectomy was performed. However, in 1948, a study by Fairbank demonstrated late radiographic development of osteoarthritis following total menisectomy [7]. More recent studies have shown a strong correlation between complete menisectomy and poor outcomes [8,9].

Osteoarthritis is usually idiopathic, but it may be secondary to trauma, infection, ligamentous instability, osteonecrosis, or

underlying metabolic and neurologic disorders. The underlying cause of joint pain may also be from a hemorrhagic arthritis, such as from hemophilia or sickle cell disease, or it may be an inflammatory process.

The inflammatory diseases that cause knee and hip arthritis include rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), psoriatic arthritis, spondyloarthropathies, and crystalline arthropathies. There are laboratory findings that commonly aid in the diagnosis of these conditions, such as positive rheumatoid factor (RF) in rheumatoid arthritis and SLE, and positive HLA-B27 in ankylosing spondylitis (AS). Further, there are specific physical exam findings, such as morning stiffness in RA, as well as the altered radiographic findings of symmetric joint space narrowing, osteoporosis, and protrusio acetabuli that may suggest an inflammatory arthritis. If, during the evaluation of a patient, there is concern for an inflammatory process, appropriate lab work should be obtained, and referral to a rheumatologist as indicated.

Nonoperative Management

The typical presentation of a patient with degenerative joint disease is that of an insidious onset of pain and stiffness, leading to limitations in function and a decrease in quality of life. The management of a patient depends on the clinical symptoms and findings, as well as on the radiographic stage. Patients with early disease will often have pain after prolonged activity, commonly medial-sided or anterior patellofemoral complaints in the knee, and groin and thigh pain with hip disease. As the process progresses, patients may develop pain at rest, pain that interferes with sleep, or pain that limits activities of daily living, such as the ability to use public transportation or even put on shoes and socks. Pain can be referred from elsewhere, and therefore, it is always important to examine adjacent joints. For example, one should examine a patient's hips when they complain of knee pain, as pain may be referred to the knee from the hip via the obturator nerve. In addition, when evaluating knee or hip pain, one must always examine the spine, as pain may be referred to either location from a lumbosacral spine disorder.

Standard radiographs should be obtained based on the patient's history and physical exam. When imaging the knee, one should obtain a weight-bearing AP view, a lateral view, and a sunrise view to visualize the patellofemoral joint. For the hip, one should obtain an AP pelvis and cross-table lateral radiographs. Spine films can also be ordered as indicated. Review of the images will assist in the management of the patient by assessing the severity of the arthritic changes,

aiding the ability to evaluate other possible causes of pain, including fracture or tumor. Once a diagnosis of degenerative joint disease has been made, a treatment plan can be reached based on the underlying pathology and the severity of patient symptoms.

When a patient presents with joint pain, an attempt is made to relieve the symptoms. Often, the first line of treatment is a nonsteroidal anti-inflammatory medication (NSAID). It is imperative to take a careful medical history to identify contraindications to the use of NSAIDs, such as gastritis, ulcers, or renal disease, before prescribing any medication.

Newer medications, such as the COX-2 inhibitors (coxibs), were initially expected to cause a dramatic decrease in gastrointestinal side effects due to their mechanism of action. There are numerous studies comparing traditional NSAIDs with the coxibs, with some evidence of decreased upper GI complications with coxibs. However, there are other studies that show no statistically significant difference [10–12]. If a patient has a history of ulcers or gastritis, it is often prudent to prescribe a proton pump inhibitor (PPI) in conjunction with the NSAIDs to protect against gastric bleeding [13].

There has also been concern over increased risk of cardiac complications with the use of the COX-2 inhibitors. This began following the results of the VIGOR and APPROVE studies, where rofecoxib (*Vioxx*) was shown to cause a significant increase in the rate of myocardial infarction or stroke, which led to the removal of rofecoxib from the market. Studies have been performed since that time, on other COX-2 inhibitors, because of concern of a class effect of the drugs. A meta-analysis by Zhang in 2006 showed that a statistically significant increased risk of hypertension, renal dysfunction, ventricular fibrillation, and cardiac arrest were only associated with rofecoxib. There was no significant increase in the events with the use of celecoxib (*Celebrex*) or ibuprofen (*Advil*, *Motrin*) versus placebo [14]. If concerns remain after thorough evaluation, it may be prudent to have the patient consult with their medical physician prior to starting an NSAID.

Acetaminophen can also be prescribed, and it is not associated with GI or kidney problems, but high doses can lead to hepatic dysfunction. Tramadol is another option, as it acts uniquely on the *mu*-opioid receptor, providing pain relief without the side-effect profile of opioid medications (i.e., dizziness, constipation, respiratory suppression) and without GI or cardiac side effects. However, tramadol use must be monitored closely in patients with impaired renal or hepatic function [12].

If medications do not provide sufficient pain relief, an intra-articular injection may be offered. Options include either a lidocaine and corticosteroid combination or a series of viscosupplementation injections. Viscosupplementation

consists of a series of 3–5 weekly injections of hyaluronic acid (HA) products. Knee injections are performed by the physician in the office, but hip injections are typically performed by a radiologist, as they utilize fluoroscopic, ultrasound, or CT scan guidance. In addition to providing pain relief, intra-articular injections can be used as diagnostic tools, to confirm the location of a patient's symptoms. The lidocaine should provide almost immediate relief, and if it does not, one must consider other sources of the pain, such as referred pain from another joint. The corticosteroid may take 7–10 days to take effect and has variable results. A recent meta-analysis of knee injections by Aroll et al. showed consistently significant improvement at 2 weeks, and several studies showed improvement at 16–24 weeks [15]. A Cochrane review of intra-articular knee injections demonstrated no significant difference between corticosteroid and HA at 1–4 weeks but showed improved efficacy of HA at 5–13 weeks [16]. That same review showed triamcinolone hexacetonide to be superior to betamethasone with regard to pain relief at 4 weeks after injection [16]. Subsequent injections of corticosteroids generally provide a shorter period of pain relief (i.e., “diminishing returns”), such that it is uncommon to consider more than three injections in a specific joint.

Physical therapy and the use of assistive ambulatory aids can be used in conjunction with medications. Although patients are often reluctant to use a cane or a walker, as they do not like the stigma of appearing disabled, they should be counseled that assistive devices provide significant relief by decreasing contact forces at the joint and providing greater stability during ambulation [17]. If a patient is willing to use a cane, it should be placed in the hand on the painless side for hips and on the painful side for knees.

The role of formal physical therapy is to strengthen the muscles around the joint, improve or maintain range of motion, and attempt to decrease pain. A recent systematic review of physical therapy for patients with OA of the knee showed that weight loss and exercise are effective at reducing pain and improving function [18]. The same review demonstrated that modalities such as transcutaneous electrical nerve stimulation (TENS) and acupuncture can provide pain relief, but further research is needed in these areas as the quality of evidence is not as high [18]. A recent randomized controlled trial looking at the use of physical agents (i.e., heat packs, TENS, short-wave diathermy) prior to exercise demonstrated improved function and decreased pain as compared to a group who received exercise alone [19].

Physical therapy has also been shown to be beneficial for OA of the hip, although manual therapy may be more beneficial than exercise therapy as demonstrated in a study by Hoeksma. In this randomized trial, the manual therapy group had significantly better outcomes in pain, stiffness,

hip function, and range of motion at 5 weeks, with some benefit lasting as long as 6 months [20]. Furthermore, in both OA of the knee and hip, patients have had significant improvements in pain, range of motion, and quality of life following aquatic physical therapy regimens [21]. This most likely reflects the decreased impact this regimen places on the joints.

If these nonoperative options fail to provide sufficient relief, and a patient's quality of life is declining due to the joint pain and limited function, a discussion of surgical options can be undertaken with the patient.

The role of arthroscopy for degenerative joint disease is controversial. Several studies of arthroscopic debridement of osteoarthritic knees have shown significant improvements in pain relief, with high rates of patient satisfaction at up to 4 years [22–24]. However, a recent randomized controlled trial in *The New England Journal of Medicine*, as well as a Cochrane review, showed no added benefit of arthroscopic lavage and debridement over optimized physical and medical therapy in elderly patients with osteoarthritis [25,26]. There are far fewer studies evaluating the role of arthroscopy for degenerative joint disease in the hip, and most studies are small series of a younger population with early osteoarthritis. These studies did demonstrate good short-term results with debridement or microfracture, and arthroscopy may have a place in delaying the need for THA in young patients [27–29]. At this time, there is no data to support hip arthroscopy in the elderly patient.

If a patient has unicompartamental disease of the knee, one surgical option is a high tibial osteotomy (HTO). This procedure is generally performed on young, active patients without inflammatory disease. Another option for unicompartamental disease is a unicompartamental knee arthroplasty (UKA), in which only the diseased medial or lateral compartment is replaced. This surgery maintains bonestock in the unresurfaced compartments, as well as maintaining the cruciate ligaments. This is also performed in patients without inflammatory disease, those with a mechanical axis of no greater than 10° varus or 5° valgus, and with flexion contractures less than 15°. This surgical option is typically used in younger patients as their first knee surgery with the expectation of needing a later conversion to a TKA, or in elderly patients as their last knee surgery as they may not outlive the prosthesis.

A long-term follow-up study showed a 90 and 76% survival of UKAs versus HTOs respectively at 10 years, which dropped to 88 and 65% at 15 years [30]. Second decade survivorship of UKAs has been shown to be less than 90% in several studies and is often due to degeneration of the opposite compartment [30–32]. If HTO or UKA are not indicated or have been performed and failed, it is time for the patient to consider a total joint arthroplasty.

Once a patient is indicated for surgery, it is essential that they undergo a complete medical evaluation, so that their health is optimized prior to surgery. The patient will require routine labs including CBC, BMP, coagulation panel, and type and screen. An EKG and chest radiograph is also obtained. If there is any abnormality noted on EKG, or the patient has a history of cardiac disease, they should receive a cardiology evaluation, with consideration for a stress test and/or echocardiogram for further evaluation. The patient should also meet with the anesthesia team prior to the day of surgery so that they can address any concerns from their viewpoint.

Patients often donate 1 or 2 units of their own blood prior to surgery, or as an alternative, receive erythropoietin (EPO) preoperatively. The decision on which, if either, method is chosen is currently controversial. The initial impetus for donating autologous blood was a concern over disease transmission in the 1980s and 1990s. This risk has decreased with current testing techniques, but it is still estimated to be 1 in 493,000 for HIV; 2 in 63,000 for hepatitis B; and 1 in 103,000 for hepatitis C [33]. Guidelines regarding blood donation or premedication are based on preoperative hemoglobin. Generally, for a Hgb of 14–15 g/dl no intervention is needed; for a Hgb of 10–13 g/dl, preoperative EPO should be considered, as pre donating would decrease their Hgb further, thus increasing the need for allogeneic transfusion; and for those with a Hgb < 10 g/dl, a hematologic evaluation should be obtained to elicit the underlying cause of anemia. Patients with a Hgb > 13 g/dl are often given the option of donating blood preoperatively, although studies have shown that approximately 44% of these units are discarded. These guidelines are for patients undergoing primary joint arthroplasties [34]. When a patient is expected to have an increased blood loss, such as with a revision procedure, those with Hgb > 13 g/dl are often encouraged to pre donate blood.

Several studies have demonstrated the effectiveness of EPO. The first orthopedic studies were in the mid 1990s and showed a decrease in the risk of postoperative allogeneic blood transfusion from 53% in the controls to 16% in the patients who received EPO, which was statistically significant. When these groups were further stratified to the patients with preoperative Hgb between 10 and 13 g/dl, the results were even more impressive, with controls having a 78% risk of transfusion versus 14% in the EPO group [35–37].

A study in 2007, attempted to elicit postoperative differences in vigor and strength in patients who donated autologous blood compared with those who used EPO (600 IU/kg once weekly for 3 weeks preoperatively and a fourth dose within 24 h postoperatively). The study did not show significant differences in vigor or hand strength, but showed a significant difference in the need for allogeneic transfusion, with only 3% of patients in the EPO group

receiving allogeneic blood versus 14% in the autologous donor group [38].

This debate has led to the development of patient-specific strategies (PSS) in which algorithms are used to determine the appropriate management of a specific patient. These algorithms are procedure-specific, and even hospital- or individual surgeon-specific, so that operative blood losses may be accurately predicted. These estimates, combined with an evaluation of a patient's hemoglobin, weight, and medical comorbidities have led to preoperative management strategies that have caused decreased transfusion rates of 20–56%, reduced wasted autologous blood by 50%, and increased use of EPO by 11% [39,40]. All patients donating autologous blood or receiving EPO should receive iron supplementation. There are contraindications to the use of EPO, including severe heart disease, vascular disease, or recent myocardial infarction or stroke. Further, the prescribing physician should inquire whether a patient's insurance policy provides coverage of the injections, as this varies by company and by state.

Screening for methicillin-resistant *Staphylococcus aureus* (MRSA) is sometimes performed prior to elective surgery to try to decrease the risk of postoperative infection. This is performed using nasal swab cultures and at times perineal or groin swabs. Studies have shown that up to 5.3% of patients admitted electively to general or orthopedic surgical wards are colonized with MRSA [41]. Risk factors for MRSA infection include male gender, age > 70, prior hospital admission, prior antibiotic treatment, and living in a long-term care facility [42]. If a patient has a positive MRSA nasal swab, they can receive mupirocin nasal ointment in an attempt to decrease their postoperative risk of surgical site infection (SSI). For positive skin cultures, triclosan bathing is often used. A study by Sankar compared postoperative infections in patients undergoing elective total joint arthroplasties before and after the implementation of a MRSA screening and treatment protocol. One patient developed a postoperative SSI with MRSA, and this patient was in the preprotocol group. However, there was a significant difference in the overall infection rate between the two groups, with more MRSA lower respiratory infections developing in the preprotocol group. The increased infection rate in the preprotocol group resulted in an increased length of stay and increased cost of care. They concluded that screening elective orthopedic patients for MRSA decreased morbidity and was cost-effective [42]. A similar study was performed by Wilcox, in which pre- and postprotocol MRSA SSI infection rates in orthopedic patients were compared after introducing an MRSA screening and treatment program. Their results were more impressive with a decrease in MRSA SSI from 23/1000 to 3.3/1000 ($p < 0.001$) with prescreening and treatment [43]. A prospective, randomized, double-blinded study in the *New England Journal of Medicine* comparing a mupirocin

treatment group with a placebo group showed no significant difference in the overall *S. aureus* SSI rate, but did show a significant decrease in SSI among the patients who were *S. aureus* nasal carriers. They also concluded that screening and treatment with mupirocin was beneficial and cost-effective [44]. However, this study did not include orthopedic patients. A prospective, randomized, and double-blinded study from the Netherlands did find a significant decrease in the nasal carriage of *S. aureus* after mupirocin treatment, and a trend toward a decrease in SSI, but the difference was not statistically significant. Treatment also did not decrease the length of hospital stay [45]. Another point of controversy is whether MRSA carriers should receive vancomycin rather than cefazolin for prophylaxis. Many feel this should be done only after infectious disease consultation to avoid increased antibiotic resistance. Hospitals must make individualized decisions at this time, as there is no clear-cut support for screening and treating for nasal MRSA carriers. Assessing local MRSA rates, and individual patient risk factors may contribute to the decision making process. Further, large, multicenter randomized trials will likely be necessary to gain sufficient power to determine the effectiveness of screening and treatment protocols.

A risk assessment for venous thromboembolism, one of the most common complications after knee and hip replacement, is also performed for all patients undergoing surgery at our institution. The decision on which type of medication to be used (i.e., low-molecular-weight heparin, fondaparinux, aspirin, or Coumadin), along with a sequential compressive device for the lower extremities, is based on patient risk factors and type of surgery being performed (Fig. 95.1). This standardization of prophylaxis is important for decreasing postoperative thromboembolism, by ensuring that all patients receive appropriate prophylaxis. However, the best regimen to be used is not known, especially in patients who are at low risk. The American College of Chest Physicians recommends that patients undergoing THA, TKA, or hip fracture surgery receive thromboprophylaxis with LMWH, fondaparinux, or warfarin for at least 10 days postoperatively and that THA and hip fracture patients be considered for prolonged prophylaxis (28–35 days). A prospective cohort study of low-risk patients undergoing THA or TKA who received a 10-day LMWH regimen, by Burnett et al., found a 3.8% rate of symptomatic DVT and 1.3% rate of nonfatal symptomatic PE, which were higher than reported previously. The researchers found a 4.7% rate of wound complications, with 3.4% returning to the OR for drainage of a wound hematoma. This leads to a conclusion that LMWH may not be as effective as prior studies have shown and that wound complications need to be considered when recommending appropriate DVT prophylaxis [46]. A study by Dorr et al. compared the results of low-risk THA and TKA patients receiving aspirin and intermittent pneumatic

compression devices (IPCs) to a high-risk group receiving LMWH and/or warfarin. There were no fatal pulmonary emboli, 0.3% nonfatal PEs in the low-risk group, 0% in the high-risk group, 0.38% symptomatic DVTs in the low-risk group, and 0.75% in the high-risk group. None of the differences were statistically significant. They did, however, find a significant increase in wound hematomas in patients receiving warfarin or LMWH. They concluded that multimodal prophylaxis is safe and effective when patients are stratified based on risk assessment [47]. Two meta-analyses performed in 2000, one for THA and the other for TKA, showed a decreased risk of DVT and PE in patients receiving LMWH or warfarin as compared to aspirin alone [48,49]. However, none of the studies reviewed at that time had a patient group using aspirin and IPCs, making it difficult to draw conclusions from the studies. A more recent meta-analysis by Sharrock looked at all causes of mortality and rates of PE in patients undergoing THA or TKA, dividing them into three groups. Group A included patients receiving potent anticoagulants (i.e., LMWH, fondaparinux), group B included patients on aspirin and IPCs, and group C consisted of patients on warfarin. They found the rates of symptomatic nonfatal PE and all causes of mortality to be significantly higher in group A (LMWH) than in group B (ASA and IPCs), whereas no significant difference was found between groups B and C (warfarin). This led them to conclude that the American College of Chest Physicians may need to reevaluate their recommendations [50]. The difficulty when drawing a conclusion from these studies is the lack of comparison of multimodal prophylaxis with medication options, for example, using ASA, LMWH, or warfarin with the use of IPCs and current regional anesthesia modalities. A large, highly powered, multicenter trial comparing treatment regimens would be needed to identify the best treatment regimen.

Current available data supports that patients should be risk-stratified prior to surgery to determine the appropriate prophylaxis as outlined in Fig. 95.1. Patients who are known to be very high risk, such as those with a recent history of DVT or PE, should be bridged with LMWH to warfarin, and should remain on warfarin for 3–6 months. However, clinicians must understand that none of the interventions discussed above have been shown to decrease the rate of fatal pulmonary embolism.

To optimize outcomes, it is also important for a patient to understand the components of the postoperative restrictions and physical therapy protocol. To facilitate patient understanding, they often attend a preoperative “Total Joint School,” where they meet with nurses, social workers, and physical therapists who can explain the protocols and answer any questions. These programs enhance patients’ understanding of the procedure, reduce anxiety, and provide them with realistic expectations regarding their recovery.

ADULT VENOUS THROMBOEMBOLISM (VTE) PREVENTION PROTOCOL

Tables 1a and 1b:

Patient Risk Factors for VTE

Table 1a: Major Risk Factors

Hypercoagulable state, inherited or acquired
 Prior DVT or PE
 Prolonged immobility (> 72 hrs) or paralysis

Table 1b: Non-Major Risk Factors:

Acute myocardial infarction
 Central venous access
 Heart failure, decompensated Pericarditis
 Hormonal replacement therapy, raloxifene (Evista) or tamoxifen
 Immobilizing cast or splint on the lower extremity
 Inflammatory bowel disease
 Malignancy
 Nephrotic syndrome
 Obesity (BMI of 30 or greater)
 Oral contraceptive use
 Pregnancy or < 1 month postpartum
 Stroke, nonhemorrhagic

Table 2:

Contraindications to Pharmacologic VTE Prophylaxis

Active peptic ulcer disease
 Acute pelvic or acetabular fracture
 Bacterial endocarditis
 Current cerebrovascular hemorrhage (not history of)
 Current ulcerative GI lesions (not history of)
 Dissecting or cerebral aneurysm
 Eye, brain or spinal cord surgery within the past 48 hours
 Hemorrhagic blood dyscrasias
 Hypertension: Severe, uncontrolled
 Major, active uncontrollable bleeding
 Malignant hypertensive crisis
 PT or PTT > 1.5 x Control at baseline
 Recent TURP (within several weeks)
 Sepsis or infection severe
 Severe head trauma
 Severe thrombocytopenia (platelet count < 30,000)
 Threatened abortion

Contraindications to specific pharmacologic agents:

Heparin, LMW heparins and heparinoids: History of heparin induced thrombocytopenia

IPC's: Open wounds located where devices are worn

Warfarin: Pregnancy

Table 3: Definitions

- **Minor surgery** is defined as a procedure requiring less than one hour of general, neuroaxial or regional anesthesia. Surgery performed with a local anesthetic never requires VTE prophylaxis, regardless of the patient risk factors.
- **Major surgery** is defined as a procedure requiring 90 minutes or more of general, neuroaxial, or regional anesthesia, excluding total knee and hip replacements and surgery for hip fractures.
- **Outpatient surgery** is defined as a procedure not requiring an overnight hospital stay.
- **Neuroaxial anesthesia** is defined as a subarachnoid block (spinal) or an epidural block.
- **IPC** = Intermittent pneumatic compression devices for lower extremity

Table 4: Procedure and Condition Specific VTE Prophylaxis Options

Check one category and one treatment:

- A. Spinal cord injury (SCI) with paralysis:** Place IPC's immediately and wait 48 hours after injury to begin pharmacologic prophylaxis regimen, as per "Major surgery with one or more major patient risk factors" (see F next page).
- B. Minor surgery with no patient risk factors or any procedures performed under a local anesthetic:**
 No formal VTE prophylaxis is recommended.

MRN, Name, DOB:

C. Minor outpatient surgery with one or more major or non-major patient risk factors (See Tables 1a and 1b).

- (1) Enoxaparin 30 mg SC prior to or as soon as circumstances permit* after surgery **OR**
- (2) IPC's worn during surgery.

D. Major surgery with no patient risk factors:

- (1) Enoxaparin 30 mg SC prior to or as soon as circumstances permit* after surgery **OR**
- (2) IPC's worn during surgery.

E. Major surgery with one or more non-major patient risk factors and no major patient risk factors:

- (1) Enoxaparin 30 mg SC prior to or as soon as circumstances permit* after surgery; continued twice daily until patient is ambulatory **OR**
- (2) Warfarin started preoperatively or immediately after surgery, with a target INR range of **2.0 to 3.0**, until patient is ambulatory **OR**
- (3) Fondaparinux 2.5 mg started 6 to 8 hours after surgery; continued until patient is ambulatory **OR**
- (4) In patients with contraindications to pharmacologic VTE prophylaxis (**See Table 2**), IPC's should be used intraoperatively.

F. Major surgery with one or more major patient risk factors:

- (1) Enoxaparin 30 mg SC prior to or as soon as circumstances permit* after surgery; continued twice daily until patient is ambulatory **OR**
- (2) Warfarin started preoperatively or immediately after surgery, with a target INR range of **2.0 to 3.0**, until patient is ambulatory **OR**
- (3) Fondaparinux 2.5 mg started 6 to 8 hours after surgery; continued until patient is ambulatory **OR**
- (4) In patients with contraindications to pharmacologic VTE prophylaxis (**See Table 2**), IPC's should be used intraoperatively and a vena caval filter should be placed prior to surgery.

G. Total hip arthroplasty (THA), total knee arthroplasty (TKA), and hip fracture:

- (1) Enoxaparin 30 mg SC twice daily: starting 6 to 12 hours after surgery performed under a general anesthetic or subarachnoid block [in those patients with an indwelling epidural catheter, the standard dose is started after the catheter is removed; dose is decreased to 30 mg daily in patients with a creatinine clearance of less than 30 mg per day] and IPC's placed in the recovery room **OR**
- (2) Fondaparinux 2.5 mg started 6 to 8 hours after surgery (except in those patients with an indwelling epidural catheter in whom the first dose is given immediately after the catheter is removed) and IPC's placed in the recovery room **OR**
- (3) Warfarin started preoperatively or immediately after surgery, with a target INR range of 2.0 to 3.0; IPC's placed in the recovery room **OR**
- (4) Aspirin and IPC's (foot pumps or SCD's) in patients who receive neuroaxial anesthesia and who do not have any pre-existing patient risk factors for developing VTE (**See Table 1**). [these therapies must be continued for 10 days after surgery, after which time aspirin should be used for an additional 28 days] **OR**
- (5) In patients who present a significant risk of postoperative bleeding or have a known contraindication to pharmacologic VTE prophylaxis (**see Table 2**), IPC's should be used and consideration given to placement of a preoperative vena caval filter.

*See detailed recommendations for enoxaparin under category G, Total hip arthroplasty, item 1.

Total Knee Arthroplasty

History of TKA

“Total knee arthroplasty is a safe and reliable procedure in the very aged patient for the management of pain and deformity secondary to arthritis of the knee.” [51] This statement by Tankersley and Hungerford is the result of more than 135 years of research and development related to biomechanical concepts, prosthetic materials and designs, and surgical techniques. The history of knee replacement surgery is extensive and is only briefly outlined to document the progression of events that have unfolded to reach the successful designs and techniques of today.

Knee replacement surgery is a resurfacing procedure and is most effective when the principal cause of knee pain is related to pathologic bone contact. Based on this concept, resection arthroplasty (removal of the diseased joint surfaces) was an early attempt to treat these disease processes. The first results of resection knee arthroplasty were reported in 1861 by Ferguson as “satisfactory” at 5 years [52]. Verneuil went a step further and performed what is believed to be the first interpositional knee arthroplasty in 1863. He used flaps of joint capsule to cover the resected articular surfaces. Other tissues, including fat, fascia lata, bursal tissue, skin, and materials including cellophane and nylon were also utilized for interpositional arthroplasty [53]. No material proved to be effective in relieving pain in the diseased knee, and all proved to be less successful than knee arthrodesis (fusion), which relieved pain and provided stability, but did not improve function.

The first documentation of metal being used as resurfacing material in the knee was by Campbell in 1938. He performed two hemiarthroplasties (replacing only one side of the joint) with replacement of the distal femur using an inert metallic alloy mold designed by Boyd [54]. Campbell concluded that “the use of vitallium (an alloy of Co–Cr–Mn) in the reconstruction of a new joint is in the experimental stage and that the ultimate outcome of these cases is at present doubtful.” [54] Variations of the distal femoral mold were created and expanded to include a medullary stem, which improved fixation. Hemiarthroplasty eventually crossed the knee joint in the form of a tibial plateau resurfacing. Overall, the general consensus was that hemiarthroplasty of the knee was not successful and frequently failed secondary to loosening and continued pain from the nonresurfaced joint surfaces [53].

The first total knee replacement, where both sides of the joint were resurfaced, was a hinged prosthesis design. One of the first hinged total knee replacements was performed by Magoni in 1949. The procedure was limited to patients who suffered from advanced degenerative joint disease,

rheumatoid arthritis or patients who required reconstruction following tumor resection or trauma. The hinged prosthesis dictated the amount of flexion and extension of the knee while providing stability. It was these advances that made it a viable alternative to knee fusion [53].

The advancements in total knee arthroplasty were directly related to the success obtained with hip replacement surgery. Major gains were made with the use of polymethylmethacrylate (bone cement) for prosthetic fixation, and with the development of materials for prosthetic use, including stainless steel, cobalt-chrome, and ultrahigh-molecular-weight polyethylene. Gunston designed the first nonhinged prosthesis in 1968. It included a metal femoral component and a tibial component designed from high-density polyethylene fixed to the tibia with polymethylmethacrylate. This design was the first to allow near-physiologic knee motion. It also was the first prosthesis that relied on the patient’s own ligaments for stability.

In 1978 Scott et al. reported on the use of patella replacements and found a decrease in patients’ patellofemoral pain and overall improvement in the quality of life with the addition of patellar resurfacing [55]. Further advances continue to focus on joint stability, prosthetic fixation, and implant material characteristics to optimize the long-term survival of the implant.

The inherent stability of a total knee prosthesis is based on its design. The typical primary TKA is performed with an unconstrained prosthesis, which relies exclusively on the patient’s own ligamentous restraints for stability. These include posterior cruciate retaining and posterior cruciate sacrificing prostheses, both of which remove the anterior cruciate ligament. This progresses to the semiconstrained knee, with a large tibial post to provide improved varus and valgus stability, followed by the constrained (hinged) prosthesis which are most often used in complex revision or tumor cases. Prosthetic fixation is accomplished with bone cement in most patients, although a press-fit technique with the use of screws and without the use of cement is occasionally used in younger patients.

The history of knee replacement surgery documents a stepwise progression to the development of today’s prostheses. These efforts have made total knee arthroplasty a successful treatment option for patients with degenerative joint disease.

The Operation

On the day of surgery, the patient will have any final questions answered by the surgeon as well as the anesthesiologist. The operative limb is initialed by the surgeon in the

holding room, which is formally documented, to avoid wrong site surgery. This method of surgical site identification has become a standard part of all surgical procedures. The patient is brought to the operating room, and either general or spinal/epidural anesthesia is induced, followed by prepping of the operative limb and draping. A final “time-out” is performed prior to beginning the surgery, during which the attending surgeon, anesthesiologist, and circulating nurse reconfirm the correct operative site and appropriate administration of antibiotics. Often, a thigh tourniquet is applied and used during the procedure to decrease blood loss. The decision to use a tourniquet is often based on the presence or absence of strong, palpable distal pulses.

The incision is drawn out with a marker on the skin midline from approximately 3 cm above the superior pole of the patella to just medial to the tibial tubercle. The incision is made with a scalpel and carried down to the fascia. A medial flap of tissue is raised for exposure, using an electrocautery to coagulate any obvious bleeding. A smaller lateral flap is also raised. The type of deep approach/arthrotomy performed is based on surgeon preference. The options include a quadriceps tendon splitting approach, a mid vastus approach, and the subvastus approach. The proponents of the midline approach cite the ease of everting the patella and obtaining exposure. The midvastus approach turns the arthrotomy medially, creating an oblique split in the vastus medialis obliquus parallel with its fibers. The proponents of this technique cite a quicker return of quadriceps function as the muscle is not detached from the quadriceps tendon as it is in the midline approach. The subvastus approach takes this concept one step further by elevating the muscle directly off bone, without incising it.

Outcome studies comparing the approaches have shown mixed results. Two randomized studies were performed on patients undergoing primary bilateral TKA's, one knee having the median parapatellar approach, and the other the midvastus. The study by Dalury found a significantly earlier return of straight leg raise in the midvastus group (1.7 days MV, 5.2 days MP), whereas the study by Keating found no significant difference. Further the study by Dalury found improved quadriceps strength at 6 weeks in the midvastus group, but this equalized at 3-month follow-up [56,57]. A prospective, randomized study comparing the median parapatellar approach and the subvastus approach found an earlier return of straight leg raise in the subvastus group (3.2 SV vs. 5.8 MP), with greater knee flexion at 1 week, but range of motion at 4 weeks and 3 months were not different between the groups [58]. A retrospective study comparing subvastus and median parapatellar approaches found significantly better patellar tracking and patellar stability in the subvastus group, but no difference in ROM, Knee Society scores, or stair-climbing ability [59].

Following the arthrotomy, a medial release is performed beginning with removal of peripheral osteophytes and subperiosteal elevation of the deep medial collateral ligament. Further releases may be progressively performed later if needed to balance the knee. The infrapatellar fat pad is often excised to enhance visualization of the joint. The knee is then gently flexed to 90°, while sublaxing the patella laterally. The femur is generally addressed first as resecting the femur provides enhanced exposure of the tibia. A starting hole is made in the distal femur to open the femoral canal, followed by an opening reamer and placement of an intramedullary jig for femoral sizing. Once the appropriate size has been determined, a jig is applied to make the distal femoral resection. This is followed by placement of the femoral cutting block, which has been sized previously, to complete the posterior and anterior resections, followed by the oblique (chamfer) resections. These resections are made with an oscillating saw and the soft tissues are protected with retractors.

The tibia is then sublaxed anteriorly, and any remaining ACL and medial and lateral menisci are excised. The PCL can be retained, recessed, or sacrificed based on surgeon preference and patient factors. This decision will determine whether a cruciate retaining (CR) or posterior stabilized (PS) knee is used. The PS knee has a box cut in the femoral component into which a short post on the tibial polyethylene articulates to substitute for the ligaments.

An extramedullary or intramedullary guide is placed anteriorly to assess the appropriate amount of bone to be resected from the tibia. This is also used to assure the proper alignment of the cut, keeping it parallel to the floor, and dialing in the desired posterior tibial slope. Again, retractors are used to protect the soft tissues and ligaments while using the oscillating saw. The tibial trials are then used to assess the proper size. At this point, the trial femoral and tibial components, with the trial tibial insert, may be placed to assess ligamentous stability and balancing. A sizing block may be used prior to this step for a similar assessment. If the balance in the medial–lateral plane is not correct, further medial or lateral releases may need to be performed. If the knee is tight or loose in flexion or extension, at times, it is necessary to recut the tibia or femur. Once proper balancing is obtained, the tibial component rotation is set.

Attention is then turned to the patella, where a saw or a reamer is used to remove the sclerotic bone leaving a remaining thickness of 12–15 mm. One or three holes (based on manufacturer) are then drilled into the patella so that the polyethylene patellar button can be placed. With the appropriate size patella in place, a final check of stability and range of motion is performed with all trial components in place. The typical parameters evaluated are limb alignment, extension, flexion, stability in flexion and extension, coronal

balancing, component rotation, and patellar tracking. When the surgeon is satisfied with these parameters, an extensive irrigation of the knee joint is performed.

After drying the bony surfaces, polymethylmethacrylate (PMMA), i.e., bone cement, is mixed and applied to the components and to the bone surfaces. The components are placed and impacted into place on the femur and tibia, while using a clamp for the patella. After the cement hardens, the knee is irrigated again, and the tourniquet may be released based on surgeon preference.

The knee is then closed in layers, beginning with the arthrotomy and working up to the skin. A deep drain may be placed based on surgeon preference. There have been several recent studies of patients undergoing primary TKA and THA in which patients were randomized to a group with a deep suction drain or a group with no drain. The overall conclusions were that use of a drain is associated with a higher risk of postoperative transfusion, whereas lack of a drain is associated with an increased need to reinforce dressings. There has been no statistical difference in regard to wound infection, hematoma, wound dehiscence, range of motion, rate of DVT, or length of hospital stay [60–63]. A sterile dressing and ACE bandage is applied. AP and lateral radiographs may be obtained in the operating room to evaluate proper component positioning, prior to taking the patient to the recovery room.

Postoperative Course

Standard postoperative protocols have the goal of mobilizing the patient as early as possible. This typically occurs on the same day or on postoperative day (POD) #1 (i.e., the day after surgery). This is facilitated by the discontinuation of intravenous fluids and epidural or PCA pumps, as well as by removal of foley catheters and hemovac drains if appropriate. Patients are often started on continuous passive motion (CPM) machines for 60 min, three times per day while progressively increasing motion daily. Studies have shown the benefit of an earlier return of range of motion, but by 1 year, the knee motions of patients who did not use CPM were equivalent. This earlier return of range of motion may be important as studies have shown a significant decrease in length of stay and in need for knee manipulation under anesthesia in patients receiving CPM combined with traditional physical therapy [64–68].

Ambulation training is also started POD #1, with the use of a walker and assistance of a physical therapist. Mobilizing the patient early also helps to prevent medical complications such as atelectasis, pneumonia, decubiti, and venous thromboembolism. Other preventative measures taken include 24 h of IV antibiotics (usually ancef, with clindamycin as an alternative if the patient has a penicillin allergy), the use of an incentive spirometer, and appropriate DVT prophylaxis.

The typical hospital length of stay is 3–4 days in the acute setting, followed by discharge to home with home therapy or transfer to rehab facility. This is determined based on each patient's needs, and performance in the perioperative period.

Most patients will have a gradual increase in range of motion and activity level, while their pain will steadily decrease. The ultimate range of motion that a patient will obtain has been shown to be generally within 10° of their preoperative range of motion, and this goal is typically achieved by 6 weeks. However, patients may have some smaller gains in ROM for the first 2 years postoperatively [69]. If ROM is not progressing as expected or has begun to decrease despite aggressive physical therapy, a manipulation under anesthesia may be performed.

The greatest success of manipulation is obtained if performed within the first 3 months following surgery. Studies have shown improvement in range of motion of >30° at 1–2 year follow-up [70,71]. Prior to manipulation, the alignment and rotation of the components should be carefully assessed as it could be a factor in poor range of motion. If there is any concern for infection, this should also be evaluated. This is discussed in detail later in the chapter. If a manipulation is unsuccessful, or >3 months have passed since surgery, and the prior concerns have been addressed, an arthroscopic or open lysis of adhesions may be performed. The success rates of these procedures have been variable, with improvements between 16 and 62° reported [72,73].

Overall, 95% of TKA patients have excellent satisfaction and improvement in lifestyle [3]. There are, however, several important complications such as infection, VTE, PE, prosthetic loosening, and periprosthetic fracture, which is discussed later in combination with THA, as the evaluations are quite similar. Follow-up appointments at 6 weeks, 3, 6 months, 1 year, and every 1–2 years thereafter (with radiographs obtained at each visit) are an essential part of patient management.

CASE STUDY

The patient is a 78-year-old female who presented for evaluation of bilateral knee pain, left greater than right. The pain had been present for 5 years and had been worsening recently. The knee pain was worse with activity. She used a cane for ambulation and could ambulate only six blocks before needing to rest secondary to her knee pain. She denied low back or hip pain and denied numbness or tingling in the lower extremities. She had received viscosupplementation injections to the knee in the past, which provided 1 year of relief, but the pain had now worsened. She had been treated with a course of physical therapy with limited benefits, and she utilized NSAIDs in the past, but they were discontinued due to peptic ulcer disease. Her medical problems included hypertension, urinary incontinence, and hypercholesterolemia. Medications included Lipitor, Foltx, Monopril, and hydrochlorothiazide.

Physical examination revealed a healthy appearing elderly female in no acute distress. She walked with an antalgic gait referable to the left lower extremity. Examination of the left knee showed a moderate effusion and tenderness to palpation over the medial joint line and distal medial femoral condyle. There was no ligamentous laxity, and range of motion was 5–130°, with pain on extreme flexion. She had 5/5 strength of her quadriceps and hamstrings. Distally motor and sensory function was intact, and distal pulses were palpable. Examination of the right knee did not show significant findings; range of motion was from 0 to 125°. Screening examination of both hips was unremarkable. Examination of the lumbosacral spine showed painless range of motion, and a negative straight leg raise bilaterally.

Radiographs of the left knee showed an area of osteonecrosis of the medial femoral condyle with secondary osteoarthritis of the medial compartment (Figs. 95.2–95.4). Right knee radiographs showed moderate osteoarthritis, primarily in the lateral compartment, but less pronounced than the changes noted in the left knee.

Left total knee arthroplasty was recommended, and after extensive discussion, the patient decided to proceed. During preoperative medical evaluation, cardiac problems were identified, for which she underwent angioplasty and placement of two stents without complications. Her surgery was postponed until she was able to temporarily discontinue anticoagulation (Plavix), and final clearance was obtained from her cardiologist.

She underwent left TKA without complication (Figs. 95.5–95.7). Initial postoperative monitoring was in the surgical intensive care unit, due to her medical history.

She was placed on lovenox and SCDs postoperatively for DVT prophylaxis. She received one unit of packed red blood cells for postoperative anemia, to which she responded appropriately. She started physical therapy on postoperative day 1 for weight bearing as tolerated ambulation and range of motion, with the assistance of a CPM machine. Postoperative day 4, she was transferred to the inpatient rehab facility at our institution. She continued to progress well and was discharged to home 1 week later.

At 6-week follow-up, she was doing very well, ambulating with a single cane. Knee ROM was from 0 to 105°. She had regained good strength, and a straight leg raise could be performed without extensor lag. She continued to progress well. At 2 year follow-up, she had painless ROM of 0–115° (Fig. 95.8). She had been able to perform her daily activities, including using public transportation and going to the theater. Her right knee pain, however, had slowly worsened for which she had received intra-articular steroid injections with good relief. If the pain continues to worsen, she will likely become a candidate for a right total knee replacement.

FIGURE 95.2 Bilateral weight-bearing AP knee radiograph of a 78-year-old female with bilateral knee pain, left greater than right. It shows an area of osteonecrosis in the left medial distal femoral condyle, with secondary osteoarthritis. Osteoarthritis is also seen in the right knee, more pronounced in the lateral compartment.

Total Hip Arthroplasty

History of THA

Total hip arthroplasty is one of the most successful operations performed today. This is only possible due to the extensive work that was performed to develop the modern day prosthesis, beginning in the late 1800s and early 1900s. As with the knee, early attempts at relieving pain and preserving motion in the hip utilized interpositional biologic or inorganic materials such as autologous fascia lata grafts and even gold. The initial attempts were by Sir Leopold Ollier in the late 1800s, but did not have much success until the early 1900s when Sir Robert Jones reported its long-term outcomes [74–76]. As these methods were largely unsuccessful, Smith-Peterson developed the “mold arthroplasty” in which glass, and later materials such as Pyrex, was applied over the bleeding cancellous bone of the femoral head and acetabulum. While patients did have some initial pain relief, the molds failed within a few months due to their brittle nature. In 1937, the development of vitallium (a metal alloy) provided a material with better durability, thus improving patient outcomes [74–76].

In addition to the interpositional arthroplasties, the Judet brothers in France performed early attempts at hip

arthroplasty. They developed an acrylic femoral head replacement, which, unfortunately, failed rapidly due to high wear rates [74]. These efforts did provide a stepping-stone for the development of stemmed, metallic endoprostheses, which are similar to those used today. The problem with these metallic prostheses was an increased wear rate within the acetabulum, leading to persistent and worsening pain. Attempts were made to resurface the acetabulum with metal as well, but due to the high friction between the surfaces, abundant metallic debris was produced, leading to osteolysis and loosening.

Some of the most important contributions to total hip arthroplasty were made by Sir John Charnley. He was able to take all of the lessons learned by his predecessors and develop the low-frictional torque arthroplasty. This decrease in friction was obtained by using a 22-mm metallic head with a polytetrafluoroethylene acetabular cup, which lowered the coefficient of friction to near that of the native total hip. This procedure was further improved by his use of PMMA to cement both the stem and the cup in place, allowing adequate fixation and a more uniform load distribution. An important change was made when the polytetrafluoroethylene was replaced by high-density polyethylene, and later ultrahigh-molecular-weight polyethylene, greatly decreasing wear rates [74–77].

The prevalence of total hip arthroplasties being performed began to increase steadily in the 1970s, as Charnley’s patients

were experiencing good results. Continued modifications in cementing techniques further improved outcomes. However, concerns over component loosening, especially in younger individuals, led to the development of prosthetic designs that could be inserted without the use of cement. This has been quite successful, largely due to improvements in materials, component design, and the use of hydroxyapatite, providing successful bony ingrowth and stability of the prostheses.

The search for the ideal materials for total hip arthroplasty is ongoing. This is evident by the more recent developments of highly cross-linked polyethylene, ceramic femoral head, and acetabular shell components, as well as a return to resurfacing with metal components. These newer components are being developed due to advances in material properties and the machining/processing of these materials. Recent studies have shown improved wear rates and improved hip stability, which may lead to better long-term survival of the prostheses. This continual research will likely maintain the reputation of total hip arthroplasty as one of the most successful operations performed.

The Operation

Prior to the surgery, the standard protocols discussed for the TKA apply regarding the preoperative discussion with the surgeon and anesthesiologist, as well as regarding surgical site verification. After induction of general or spinal/epidural anesthesia, the patient is most commonly placed in the lateral position with the operative limb up. The patient is maintained in this position by the use of a well-padded hip positioner that keeps the pelvis fixed and stable. This is used for the posterior and anterior-lateral approaches, which are the most common. The patient is at times placed supine for the direct lateral or direct anterior approach. We discuss the posterior approach with placement of press-fit metal on polyethylene components, as this is the most common. There is a brief discussion of the advantages and disadvantages of the other surgical approaches and components later in the chapter. The exact use of retractors and steps can vary, but here, we describe a common approach used at our institution.

The limb is sterilely prepped and draped, followed by drawing out the skin incision with a marker, centered over the posterior 1/3 of the greater trochanter. From the tip of the greater trochanter it extends proximally about 4–6 cm and distally 4–6 cm in line with the shaft of the femur. The incision is made with a scalpel through the skin and subcutaneous tissues, down to the level of the deep fascia. Any bleeding is coagulated with an electrocautery. An incision centered over the trochanter is made with a scalpel through the fascia. Proximally, the gluteus maximus muscle belly is split bluntly. A Charnley retractor is now placed beneath the fascial edges,

and perpendicular to the wound for exposure. The bursa over the greater trochanter is now visualized, and gently peeled off with the use of a long-tipped electrocautery. This exposes the short external rotators of the hip. A cobra retractor is placed beneath the gluteus minimus tendon, and the piriformis tendon is visualized. The knee of the patient is now on a sterile bump, keeping the femur parallel to the floor. An assistant begins to internally rotate the limb, placing tension on the short external rotators. They are detached directly from bone, beginning with the piriformis tendon proximally, then distally through the superior gemellus, obturator internus, inferior gemellus, and a portion of the quadratus femoris. This is carried distally until the lesser trochanter is visualized. Prior to taking down the rotators, the sciatic nerve is palpated and carefully protected to avoid injury. The external rotators may be released separate from the hip joint capsule, or the capsule and rotators may be released together. A T-shaped capsular incision is made exposing the femoral head and rim of the acetabulum. The external rotators and capsule are then tagged with sutures, so that they can be repaired at the end of the procedure. The hip is then dislocated by gentle flexion, adduction, and internal rotation. The bump is then repositioned beneath the patient's knee, keeping the femur level.

A trial broach is used to mark the correct angle of the femoral neck osteotomy. The level of the cut is determined from preoperative templating and measured with a ruler from the lesser trochanter. An oscillating saw is used to make the osteotomy, carefully protecting the soft tissues. The femoral head is then removed, exposing the acetabulum.

A cobra or Hohmann retractor is used to retract the femur anteriorly for visualization. Steinman pins are placed superiorly and posteriorly, with a cloverleaf retractor placed inferior. This provides excellent acetabular exposure. The remaining labrum is excised from the rim of the acetabulum, followed by removal of the ligamentum teres from the acetabular floor.

Reaming is performed to reshape the acetabulum to match the implant. Initial reaming is performed with a small size, often 43 mm, removing the degenerative floor of the acetabulum and medializing. The size is sequentially increased by either 1 or 2 mm until the appropriate size is reached based on the preoperative templating and intraoperative assessment. During reaming, one must carefully position the reamers to obtain appropriate anteversion (15–20°) and coronal tilt (35–45°). The last reamer used is typically 1–2 mm smaller than the final implant size, for noncemented components (cemented acetabular components are rarely used during hip arthroplasty). A trial acetabular cup is then placed to assess proper fit. If the fit is correct, the acetabular component is then placed, using an antenna on the impactor handle to confirm proper positioning. With the appropriate version aligned, the cup is impacted. If there is concern over cup

stability, screws may be placed to augment fixation. The polyethylene liner is then placed within the cup and impacted into place.

Attention is turned to the femur after the acetabulum is completed. The limb is internally rotated, placing the lower leg perpendicular to the ground. A retractor is placed beneath the proximal femur, allowing visualization of the femoral canal. Soft tissues remaining anterior to the greater trochanter and superior to the remaining femoral neck are removed. A box osteotome is used to open the femur proximally, followed by a starting broach that is placed down the femoral canal. The canal is then sequentially enlarged with reamers and broaches until the appropriate fit is obtained. This is also guided by the preoperative templating. One must maintain proper version of the stem throughout the process.

A trial femoral neck and head are then placed on the femoral broach, with the size and offset determined preoperatively to give the patient appropriate soft tissue tension and leg length. The hip is reduced and taken through range of motion testing to assess stability of the hip. Further verifications of appropriate size are made intraoperatively and compared with preoperative templating. When appropriate stability and length have been obtained, the trials are removed and the final stem is impacted into place. A trial femoral head is again placed for a final check of stability and limb length before placing the head.

The wound is extensively irrigated with sterile saline. Two drill holes are then placed through the greater trochanter to allow reattachment of the piriformis, capsule, and the other external rotators. The deep fascia is repaired with interrupted sutures, followed by a similar closure for the deep and subcutaneous layers. The skin may be closed with staples, sutures, or a subcuticular absorbable stitch with Dermabond. A sterile dressing is applied.

The drapes and hip positioner are removed, and the patient is placed supine on the table, with special care to maintain the hip abducted and externally rotated, as the most common position of dislocation is flexion, adduction, and internal rotation. This is assisted by the use of an abduction pillow. Clinical limb length is assessed, followed by obtaining an AP pelvis radiograph to assess final component placement, and assure that the hip is reduced prior to moving the patient to the recovery room.

Postoperative Course

The initial postoperative course is quite similar to the TKA, in which IV fluids, foley catheters, hemovac drains, and epidural/PCA pain pumps are discontinued, with a goal of early mobilization. At least, the patient should be out of bed to a

hip chair (an elevated chair to prevent flexion of the hip beyond 90°), and an incentive spirometer is used to prevent atelectasis on POD #1. Routine labs, including BMP and CBC, are drawn and addressed as needed. If a patient's hematocrit is less than 27 and the patient is symptomatic (i.e., tachycardic, hypotensive, weak, dizzy), the patient may require a blood transfusion. In a patient with medical comorbidities, such as CAD or history of MI, the goal hematocrit is often 30 or greater, based on the preoperative recommendations of the medical team.

Ambulation is begun with a walker and instruction by a physical therapist. The patient will be weight bearing as tolerated (WBAT) unless there is a concern over initial stability of the components, or a complication such as a fracture occurred. The therapist will also review hip precautions and demonstrate basic exercises such as dorsi/plantar flexion of the ankles and heel slides in the bed. This routine will continue, usually twice per day, until POD 3 or 4, when the patient is cleared for transfer to home or to a rehab center.

A home nurse will remove skin staples, or sutures, at 2 weeks postoperatively, and the patient will continue home therapy. The first follow-up visit is at 6 weeks, followed by visits at 3, 6 months, and 1 year. Evaluation of gait, range of motion, and strength will be performed at each visit with radiographs obtained annually unless there are symptoms that necessitate radiographic evaluation. By the 6th week visit, the patient will often have progressed to the use of a cane.

The overall success rate of THA is >95%, making it one of the most successful surgeries performed. This is based on outcome studies regarding the relief of pain and return of function. A patient may progress from being wheelchair-dependent due to pain to ambulating and returning to work. The longevity of the prostheses is excellent as well, with 95% lasting 10–15 years [4,5,78]. The use of alternate bearing surfaces, and advancing technologies, may continue to improve these results. These alternate bearings include ceramic and all metal surfaces. They are primarily used in the younger population. In the elderly population, the components are routinely a cobalt-chrome metal head with a highly cross-linked polyethylene liner within a metal acetabular shell. The femoral stem may be cemented in place if there are concerns over obtaining adequate fixation, while minimizing the risk of fracture, in brittle, osteoporotic bone. Based on a review of the literature, currently, the NIH recommends a hybrid THA in the elderly with a cemented femoral stem and a press-fit acetabular component. This is due to the excellent long-term outcomes obtained and the fact that when both components are cemented the acetabulum is usually the site of early loosening [79–81]. However, at our institution, we routinely press-fit both components with excellent results, which has been supported in several studies [82–85].

Complications

The complications after THA are very similar to those after TKA (including VTE, PE, MI, UTI, fracture, loosening, infection), the main difference being stiffness in TKA and dislocation and limb-length discrepancy in THA. It is possible to dislocate a TKA with extreme flexion in a ligamentously loose or unbalanced knee, but this is very rare. The dislocation rate after a primary THA has been shown to range between 0 and 7% across different studies [86–91]. The high variability is related to the type of surgical approach used. The highest rate of dislocation has been shown with the posterior approach, but with improved technique, including repair of the posterior soft tissues, these rates have decreased from 4% to less than 1% in several studies [86–91]. A further improvement has been obtained with the use of larger femoral heads, 32 mm and greater, which provide increased stability by increasing the head to neck ratio. This provides a larger arc of motion before impingement and levering of the femoral head [88,92]. The anterolateral and direct lateral approaches have had traditionally lower dislocation rates but may have higher risk of a postoperative abductor lurch [87,93]. These two factors have led to the development of new approaches, such as the direct anterior approach, with the goal of eliminating these two complications.

This approach to THA was first described in 1947 but has been recently modified by Joel Matta. In this approach a small, 10-cm incision is made anteriorly over the hip, in which the hip joint may be exposed without the release of any musculature. The surgical window is between the tensor fascia lata and sartorius superficially, and the gluteus medius and rectus femoris in the deep layer. The technique is performed in the supine position on a specially designed fracture table, which allows free, independent movement of the limbs. Intraoperative fluoroscopy is also used to assist in appropriate component positioning, as well as in obtaining equal leg lengths. In Matta's series of 494 consecutive THA, the dislocation rate was 0.61%, with leg lengths being within 3 mm on average. Further, as no muscles are detached, no postoperative hip precautions are needed, and patients often progress to independent ambulation at a faster rate [95]. While the early results of this technique are quite impressive, there is a steep learning curve, and it must be used in carefully selected patients.

Morbidity from medical complications is best prevented by appropriate preoperative medical evaluations and postoperative regimens including VTE prophylaxis, early removal of indwelling catheters, and early mobilization. However, in spite of these measures, they are not all preventable. The more common, yet still rare, medical complications are myocardial infarctions/cardiac arrhythmias, VTE, PE, urinary tract infection, pneumonia, and *Clostridium difficile*

infection. In a study by Parvizi et al., 1,636 patients undergoing TJA had 104 major life-threatening complications, including: one cardiac arrest, 33 tachyarrhythmias, 6 myocardial infarctions, 10 cases of congestive heart failure/pulmonary edema, 14 cases of acute renal failure, and 1 death (.06%) during the initial hospital stay. Most of the minor complications were anemia, but they did have 50 urinary tract infections, 20 mental status changes (which all resolved), 4 pneumonia, and 5 cases of *C. difficile* infection. They found that increased age, high BMI (>30.5), and preexisting medical comorbidities were all risk factors for complications. However, they note that 58% of the patients who developed a complication had no predisposing risk factors. Further, greater than 90% of the complications occurred in the first 4 postoperative days. These last two points lead to the conclusion that all patients need careful postoperative monitoring and that early discharge (i.e., prior to postoperative day 4) may lead to greater overall morbidity and mortality [95]. In 2008, Parvizi conducted a more detailed study of *C. difficile* infection, finding a 0.16% incidence in 9,880 TJA, with increased risk associated with increased ASA score, receiving more than one postoperative antibiotic, and a prolonged hospital stay [96]. A study of over 10,000 patients who underwent TJA from the Mayo Clinic found similar results with the incidence of myocardial infarction 0.4%, PE 0.7%, VTE 1.5%, and death 0.5%. They also found a correlation with increasing age [97]. This is not to say that increasing age should be considered a contraindication to TJA, but rather to assure that appropriate preoperative evaluation is obtained and that any postoperative problems are treated aggressively with early involvement of the medical team. Two recent studies of TJA in patients in the 9th and 10th decades of life did find an increased risk of complications as compared to younger patients but had an overall low event rate with significant improvements in pain score and overall outcomes. The authors of both studies concluded that with careful patient selection, total joint arthroplasty could be an excellent option for elderly patients [98,99].

Complications related to the prostheses include aseptic loosening, periprosthetic fracture, and infection. Any patient with a TKA or THA who presents with pain following surgery must have all of these possibilities considered. Based on the history and physical examination, the physician should be able to narrow down these possibilities. If the patient did not have a fall or acute injury, then fracture is unlikely, and usually can be ruled out with routine radiographs. Patients with aseptic loosening may report start-up pain that is worse during the first few steps and then decreases. The pain is typically located about the groin, thigh, or knee. Radiographs assist in the evaluation by the detection of radiolucencies around the prosthesis. Whenever there is a concern of loosening, an infection must be ruled out, as the treatment protocols are quite different.

Infection should be considered if a patient reports a dull pain that has been persistent since the time of surgery. A history of fevers, chills, warmth or erythema of the operative site provoke obvious concern, as does a recent history of illness or surgical procedure in a potentially contaminated area, such as oral, vaginal, or lower GI procedures.

There is a risk of seeding a prosthetic joint after any surgical procedure, but as the risk is increased following dental procedures, a protocol has been developed. The recommendation of the American Dental Association and the American Academy of Orthopaedic Surgeons is that for the first 2 years after joint arthroplasty, all patients undergoing high-risk dental procedures (i.e., tooth extractions, implantations, root canals, etc.) should receive prophylactic antibiotics. After 2 years, patients who have had previous infection of the artificial joint, inflammatory arthritis, type-1 diabetes mellitus, hemophilia, immunosuppression, history of prior or present malignancy, dental extractions, periodontal procedures, dental implantation, root canal work, cleaning if bleeding is anticipated, certain specialized local anesthetic injections, or placement of orthodontic bands should still receive prophylaxis. The standard is 2 g of oral amoxicillin 1–2 h before the procedure or 600 mg clindamycin for those with a penicillin allergy [100]. There have been several studies of infected TJA in association with dental procedures [101,102]; however, a recent literature review has found little scientific data to support the need for routine prophylaxis [103]. We feel that prophylaxis should be continued at this time due to the morbidity and cost associated with a total joint infection.

Concern of infection should initially be evaluated with routine labs, including a CBC with differential, an erythrocyte sedimentation rate (ESR), and a C-reactive protein (CRP). These are used as markers for infection as CRP should return to normal, after transient postoperative elevation, in 2–3 weeks, and ESR by 1–2 months. The normal values for these markers depend on normalized values that vary by hospital but are ESR < 30 mm/h and CRP < 10 mg/dl at our institution. If the values are somewhat elevated, but not definitive, it is often prudent to aspirate the suspected joint, prior to undergoing an extensive surgical procedure. A recent study of patients undergoing revision THA found that an elevated ESR (>30) and CRP (>10) with a hip aspiration cell count >3,000 had the highest combined sensitivity, specificity, positive and negative predictive values, and accuracy for an infection [104]. This coincided with a recent study by Della Valle, in which a level of >3,000 white blood cells/ml in aspirated fluid from a TKA was most predictive of infection [105].

Information can also be gathered from a Technitium-99 3-phase bone scan, followed by an indium-111/sulfur colloid scan as indicated. Technitium-99 scans are sensitive, but not specific for infection. The addition of indium-111 and sulfur colloid scans greatly increase specificity to 97% [106].

A study evaluating the effectiveness of Indium-111-labeled WBC scans alone found that the sensitivity and specificity alone decreased, but they had a 95% negative predictive value, such that a negative scan is highly predictive of a joint not being infected [107].

If an infection is confirmed or strongly suspected, surgery is indicated. The most common organisms involved are *S. aureus* and *S. epidermidis*. The type of surgery performed depends on the acuteness of the infection. Infections have been classified by Coventry as acute (<6 weeks), subacute (6–24 months), and chronic-hematogenous (>2 years). Currently, many consider an acute infection being <4 weeks from index event or surgery. The time frame for an acute infection is from the index surgery or from a postoperative procedure that likely seeded the joint. In an acute infection, good results have been obtained with extensive irrigation and debridement of the joint, with exchange of the polyethylene liners in the hip or knee. This is possible, as the bacteria usually cannot form a protective glycocalyx (which shields the bacteria from the immune system on the implant) by this point, allowing the infection to be eradicated from the metal and bone. The debridement is followed by 6 weeks of intravenous antibiotics, based on the results of intraoperative cultures and recommendations of an infectious disease specialist. Success rates of 71% have been obtained for THA when performed within 4 weeks of the onset of symptoms [108]. For TKA, success rates have varied, with some studies having 80% success, but several studies show only a 30% success rate. Importantly, failure of this procedure has been significantly associated with a *S. aureus* infection. A study by Deirmengian of acute TKA infections showed a success rate of only 8% for knees infected with *S. aureus*, while 56% of all other infections were treated successfully [109].

In more long-standing infections, it is necessary to perform a two-stage revision with removal of the entire prosthesis, followed by the placement of an antibiotic cement spacer. The diagnosis is confirmed intraoperatively by frozen section (>10 PMNs per high power field is positive) and intraoperative cultures [110,111]. The spacer remains in place for at least 3 months while the patient receives intravenous antibiotics. The levels of ESR and CRP will be monitored to assess response to the treatment. At the 3-month point, once antibiotics have been discontinued for approximately 6 weeks, and the ESR and CRP have normalized, the patient returns to the OR for the second stage of the procedure. This includes removal of the antibiotic spacer, extensive irrigation and debridement, and the evaluation of intraoperative frozen sections, gram stains, and cultures. If the frozen section is negative for infection (less than 10 PMNs per high power field), then a new prosthesis can be placed [112,113].

The type of prosthesis used is based on the remaining bone stock and ligamentous stability. In a revision THA, it may be necessary to use long-stemmed, modular femoral

components so that distal fixation is obtained; or metallic augments for the acetabulum. In the knee, stemmed tibial and femoral components are often needed for adequate fixation with metal augments for areas of bone loss. The overall complication rates are higher than after a primary replacement, but two-stage revisions for infection have success rates of 85–90% for THA [108,114] and 90% for TKA [115].

The revision components used for a noninfected revision are similar, with good results obtained, but with an increased risk of postoperative complications and infections when compared with primary procedures. Excellent outcomes have been obtained in the elderly as demonstrated by Parvizi et al. who showed significant functional improvement following revision THA performed in octogenarians with no increase in medical comorbidities as compared to a younger cohort [116]. For revision of TKA, successful outcomes have been obtained in 74–88% of patients [117–119].

Another significant complication is fracture. Periprosthetic fractures occur at a rate of approximately 2.3% for THA and 2% for TKA over the long term, with a slightly higher increased risk of fracture in the elderly [120,121]. Fractures around a THA are commonly described by the Vancouver classification, with the type of fracture guiding treatment. They are classified as A, B, or C as follows: Type A are proximal fractures of the trochanters, B are at the level of the stem, and C are below the tip of the prosthesis. Type A fractures can often be treated nonoperatively with modified weight bearing, type B fractures by a plate with cables and screws if the stem is well fixed or with conversion to a

long-stemmed prosthesis, and type C fractures by a plate with cables and screws [122,123].

The treatment of fractures around a TKA also depends on the location of the fracture. One classification describes fractures proximal to the femoral component, to the level of the component, or to within the area of the component [124]. A determining factor in treatment is whether the prosthesis is loose or well fixed which determines if it will be retained or removed. If the fracture is quite distal, the standard of care is open reduction with internal fixation (ORIF) using a plate and screw construct. If it is more proximal, there is some debate whether a plate or a retrograde intramedullary nail is better suited with good outcomes shown with both fixation constructs [125,126]. Fractures involving the acetabular component of a THA or the tibial component of a TKA are less common, as they tend to require a higher level of energy such as from a motor-vehicle accident or fall from height.

An interesting recent development is the use of THA for the treatment of femoral neck fractures in the elderly. These were traditionally treated with a hemiarthroplasty or internal fixation using screws, unless a patient reported significant hip pain prior to the fracture, which suggested preexisting degenerative joint disease in which case a THA was preferred. However, several recent studies comparing hemiarthroplasty or ORIF to total hip arthroplasty in the active elderly patient have shown superior results in patients undergoing THA with respect to functional outcomes, relief of pain, and need for further surgery [127–130].

CASE STUDY

The patient is 70-year-old male who presented for evaluation of left-hip pain. He reports a history of left femoral neck fracture 3 months prior to presentation, which was treated by internal fixation with three screws. Since the surgery, he has been ambulating with a walker, weight bearing as tolerated, but with significant pain in the groin and laterally about the hip. He denies any low back pain or neurological symptoms. His medical history is significant for hypertension, for which he is treated with Dyazide.

Physical examination revealed a healthy-appearing older man, in no acute distress. Evaluation of the left lower extremity showed a healed incision about the lateral aspect of the left hip. There was tenderness to palpation over this region and pain with hip ROM. ROM was

flexion to 90°, internal rotation to 0°, external rotation to 10°, and abduction to 10°. Quadriceps and hamstring strength were 4/5, limited by pain. Distal neurovascular function was intact. There was a limb length discrepancy of 1 cm with the left shorter than the right. Straight leg raise testing was negative bilaterally. He ambulated with an antalgic gait and obvious pain about the left hip.

Radiographs revealed a vertically oriented left femoral neck fracture, which was treated with three cannulated screws. There was limited evidence of healing of the fracture with overall shortening, varus alignment, and backing out of the screws (Figs. 95.9 and 95.10). These findings suggested loss of fracture alignment and delayed healing. Based on these findings and the clinical exam, he was indicated for a removal of hardware from the left hip and conversion to left THA.

CASE STUDY (continued)

FIGURE 95.9 AP pelvis radiograph of a 70-year-old man which shows a vertically oriented left femoral neck fracture, which was treated with cannulated screws. There is limited evidence of healing of the fracture with overall shortening, varus alignment, and backing out of the screws.

FIGURE 95.10 Cross-table lateral radiograph of the left hip, showing a left femoral neck fracture after fixation with cannulated screws.

After appropriate medical clearance, the patient underwent removal of the screws and conversion to a noncemented left THA with a metal head and polyethylene liner via a posterior approach, without

FIGURE 95.11 Postoperative AP pelvis radiograph, showing a noncemented left total hip arthroplasty, with two screws in the acetabular component for additional fixation.

complications (Fig. 95.11). He did well postoperatively and was placed on Arixtra and SCDs for DVT prophylaxis. He started physical therapy on postoperative day 1 and ambulated weight bearing as tolerated with a walker. He was discharged to home on POD 5 with home physical therapy.

At the 6-week follow-up visit, he was doing very well, ambulating with part-time use of a single cane and often without assistive devices. He was participating in an outpatient physical therapy program walking on a treadmill. The incision was well healed, and limb lengths were clinically equal. Hip ROM was flexion to 90°, internal rotation to 10°, external rotation to 20°, and abduction to 30°. He was able to straight leg-raise without discomfort, and distal neurovascular function was intact. Radiographs showed the components to be in good position without signs of changes at the bone-prosthesis interface.

He continued to progress well and at 1-year follow-up was ambulating without assistive devices and was pain-free. Radiographs showed good alignment of the implant without complication (Figs. 95.12 and 95.13).

FIGURE 95.13 Cross-table lateral radiograph of the left hip, 1 year after left THA, showing good component positioning, without evidence of complications.

Conclusions

As the elderly population continues to grow and stay active, the demand for total knee and total hip arthroplasty will grow along with it. Projections indicate that by 2030, these numbers are expected to grow to the staggering figures of 3.48 million TKAs and 572,000 THAs annually [2]. Modern surgical techniques and a multidisciplinary approach with close involvement of medical specialists will enable excellent outcomes in over 90% of patients. Orthopedic surgeons will continue to refine surgical techniques and implant design, while minimizing complications and carefully evaluating patient outcomes, to ensure that the success of TKA and THA is maintained and improved upon in the future.

Section XIII Transplantation

Chapter 96 Invited Commentary

Khalid M.H. Butt

When asked to comment on organ transplantation in senior citizens, I reflected on the evolution of this restorative therapy over the past four decades, during which I have been a student of the subject while actively performing kidney transplants.

End-stage failure of vital organs inevitably results in death unless function is replaced either by artificial means, as in the case of the kidney with dialysis therapy, or when a transplant is accomplished and the graft works (liver, heart, and lung). In the latter case, the quality of life is markedly improved and longevity may be nearly doubled with a successful kidney transplant. Justifiably then, if an organ is available and the patient is judged to have enough physiologic reserve to be able to withstand the vicissitudes of anesthesia, surgery, and the immunosuppressive regimen, transplantation remains the best therapy.

Drawing on the steady advances in anesthesia and surgical technique (especially vascular) during the first half of the twentieth century, Joseph Murray and colleagues launched a new era by successfully performing the first kidney transplant between identical twins in 1954. This revolutionary life-preserving new therapy had to be applied cautiously. First, it was imperative to ascertain that no long-term harm was done to the donor, whose rights had to be vigorously protected. Our obligation to protect the donor's interests had to be clearly enunciated. Second, the recipients needed to be observed for quite some time to determine any unforeseen complications and the durability of this treatment. Initially, only end-stage renal disease patients between the ages of 15 and 45 years with no significant involvement of any other organ system were offered kidney transplantation. During the sixties and seventies, broadening acceptance of the determination of death by neurologic criteria offered increased opportunities for recovery of organs from "heart-beating" cadavers. Extending transplantation horizons, Starzl

successfully transplanted liver in 1963, and in 1967, Barnard transplanted a heart.

Incomplete understanding of the pathogenic mechanisms of immunologic allograft rejection, and our limited ability to halt and reverse this process continued to be the major concern into the eighties. Infections and malignancies as complications of immunosuppression took a heavy toll. With the discovery of cyclosporine, a calcineurin inhibitor and somewhat more specific immunosuppressive drugs, transplant outcomes started to improve. The introduction of other agents into our immunosuppressive armamentarium, and the evolution of more efficacious and safer combination regimens extended the spectrum of candidates for organ replacement at both ends, i.e., from infancy to the elderly (seventies and eighties). Age by itself, as a consideration of candidacy for organ transplantation, is no longer an overwhelming concern. Needless to say, age-associated maladies, like coronary and carotid artery disease, malignancy, general nutritional status and viability of the patient must be properly assessed. Results of kidney transplantation in the elderly (≥ 65 years) are now comparable to those of younger adults.

There still remains a societal concern. With little increase in the numbers of deceased-donor organs recovered over the past many years, paired with an ever-increasing demand, society, not the doctors, must decide how these precious resources are to be utilized. Allocating the organs in a manner that employs the best mix of justice (equality to all the patients waiting) and utility (getting the most value) continues to challenge the minds and hearts of all concerned. Family members of deceased donors, potential recipients and their families and friends, transplant doctors, other health-care workers, scientists and researchers, lawyers and judges, politicians and public officials, social scientists, philosophers and ethicists all grapple with the task of developing the best schema. When the name of a criminal on death row pops up for heart transplantation, no amount of rational debate can overcome the strong emotions aroused. Elderly patients often garner a similar, though usually not as visceral, response.

Eurotransplant, an organization of six European countries (covering a population of 118 million) collaborating in recovery and allocation of deceased donor organs, as well as

transplant research, developed a Eurotransplant Seniors Program (ESP) about 10 years ago. They rapidly allocate a kidney recovered from a ≥ 65 -year-old donor to a ≥ 65 -year-old recipient who is not sensitized and is ready to receive a first transplant. Cold ischemia time is thus cut short, resulting in decreased incidence of delayed graft function, and survival results comparable to those of adults < 65 years of age. Equally important, this program significantly contributes to better utilization of deceased donor kidneys; Eurotransplant has a discard rate of one in twenty ($1/20$), compared to that of the US of one in seven ($1/7$). This seems a step in the right direction.

There are some rudimentary efforts to predict the “additional quality-adjusted life years” gained by an organ transplant and the projected cost per year. This imperfect and imprecise future casting is an attempt to maximize the utilitarian aspect of organ allocation. While the dilemma of resource allocation awaits resolution, perhaps success in *in vitro* generation of organs from autologous stem cells or developments allowing clinical application of xenotransplantation from animals used for food will emerge. In the meantime, we can surely take the position today that denying seniors this vital therapy on the basis of age alone is ethically and morally reprehensible, and may be illegal.

Chapter 97

Elderly Donors in Transplantation

Manuel Mendizabal, John W. Hsu, and Abraham Shaked

Introduction

At the time of the writing of this chapter the number of candidates on the waiting list, as designated by the United Network for Organ Sharing (UNOS), totals just over 100,000 [1]. A closer look at yearly tabulations of patients transplanted and patients newly listed shows that for about every two patients added to the transplant list, one patient is actually transplanted. Because the waiting list continues to grow, there has been increased interest in the use of expanded criteria donors (ECD). While there are many different ways to define the ECD, one universal attribute of ECD that makes it germane to the topic of this textbook is increased donor age. The aims of this chapter are to (1) examine the elderly donor evaluation and screening process in this patient population; (2) discuss the predonation management of these older patients as well as the donor procedure and technical complications that may be encountered in the procurement operation, and (3) discuss the allocation process and examine the results and outcomes in the use of these elderly organs.

How Old Is Old?

The definitions of the ECD are based on the premise of increased risk of poorer outcomes in the usage of these organs when compared with the ideal or standard criteria donor (SCD). One aspect that is constant in all organ types is increased donor age; assuming that geriatric organs would portend to a higher risk of worsened recipient outcomes. Organ specific and nonspecific risk factors that determine allograft outcomes are shown in Table 97.1.

In kidney transplantation, the ECD is defined as a donor greater than 60 years of age or donor greater than 50 years of

age with two of the three following attributes: donor with terminal creatinine greater than 1.5 mg/dL; donor whose death resulted from a cerebrovascular accident; and donor with history of hypertension [2–4]. In general, despite an increase in delayed graft function (DGF), long-term graft function of the older allograft and patient survival are acceptable when compared to SCDs, and mortality decreased when compared to those on the waiting list, thereby justifying the use of such organs [5].

In a recent consensus meeting on liver transplantation, the ideal donor was defined according to the following criteria: trauma as the cause of death, donation after brain death, age below 40 years, hemodynamic stability at the time of procurement, no steatosis or any other underlying chronic liver lesion, and no transmissible disease [6, 7]. Certainly the elderly liver donor would have a significant impact on allograft function as advanced age have been attributed to a liver with impaired regenerative capacity and an increased severity of hepatitis C virus (HCV) recurrence. Despite documented increased donor risk as related to age, there is no absolute limit to donor age for liver transplantation, and indeed, successful transplantation has occurred even with octogenarian donor organs [8].

There are no clearly defined criteria for ECD for pancreas transplantation. In general only, 20–25% of pancreata is procured from donors due to the strict criteria defining the acceptable pancreatic donor. This, in part, is due to the high rate of complications associated with pancreatic transplant, which has led to the use of mostly pristine organs. In one series of simultaneous pancreas–kidney transplants, ECD was defined as donors <10 and ≥40 years or donor after cardiac death (DCD) status. However, outcome studies demonstrate similar graft survival when compared with a cohort of SCD [9].

In lung transplantation, many programs consider a donor who fulfill any of the following criteria as an ECD: age 55 years or older, donor smoking history 20 pack-years or more, purulent secretions or inflammation at bronchoscopy, evidence of significant chest trauma, a pulmonary infiltrate on chest radiograph, duration of ventilation longer than 5 days, and PaO₂/FiO₂ ratio less than 300 mmHg just before donor pneumonectomy [10]. Recipients of these organs had an

increased mortality rate; however, the transplanted lungs exhibited adequate posttransplant function. Interestingly, a recent series of transplants with donors aged 50 and older found no difference in survival and functional reserve between the ECD recipients and a cohort of SCD recipients [11]. In addition, a subanalysis of those donors over 50 showed no difference in 1-year survival. It is concluded that the true cutoff for a potential lung donor is yet to be vigorously studied, and it may be at a different borderline than that currently defined.

Once, the upper limit of donor age for transplantation of the heart was 35 years of age; nowadays, it is common for cardiac donors to be greater than 50 years of age. Nevertheless, the current definition of ECD for heart donors includes donors older than 55, as well as other variables such as prolonged ischemia times (>5 h), HCV infection, alcohol abuse, cocaine abuse, atraumatic intracranial hemorrhage, under- and oversizing, and preexisting coronary artery disease (CAD) [12]. Despite data indicating increased initial post-transplant mortality risk, a review of the UNOS registry shows that mortality of patients on the waiting list is higher.

As organs continue to remain a scarce resource for transplantation, it is predictable that the utilization of organs of older donors will continue to increase. Despite what some deem as the inferior outcomes of extended criteria transplantation, the unacceptable sequelae of end-stage disease will compel continuous redefinition of the extended criteria.

Determination of Brain Death

As with most cadaveric donors, the evaluation of the geriatric donor begins with the declaration of brain death. A review of the Scientific Registry of Transplant Recipients (SRTR)

data shows that most brain deaths occur secondary to stroke, with the second most prevalent diagnosis occurring with trauma (41.9 and 38.1%, respectively) [13]. When a brain-injured patient presents with coma and evidence of irreversible structural brain injury, the screening process for organ donation is begun. In general, the physician or medical team taking care of this individual is responsible for notifying the area organ procurement organization (OPO) to start the process. Once the process is initiated, the OPO will dispatch field coordinators who are then responsible for facilitating declaration of brain death, family counseling, and consent for donation, as well as completing the screening process with review of medical and social histories, and the completion of laboratory and serologic tests. Once all information is acquired, communication with the transplant center and transplant center physician will lead to an appropriately matched recipient with arrangements made for eventual procurement of the organs.

The declaration of brain death is mandatory prior to proceeding with evaluation for procurement. The current brain death criteria in the USA is outlined in a set of guidelines published in 1981 entitled the President's Commission for the Study of Ethical Problems and adopted under the Uniform Determination of Death Act. This act states that death has occurred once there is irreversible cessation of brain function including the brainstem. Each state government has adopted these guidelines in legislating local criteria for determining brain death. Usually there are variations in the necessity and type of confirmative testing required, how many examinations are required to determine brain death, and how many physicians are required to make that determination. Most hospitals will then establish their own protocols for determining brain death for potential donors under their care.

Symptoms that support the diagnosis of brain death include the absence of brainstem reflexes, cortical activity, and demonstration of irreversibility of the injury. All reversible causes of a coma must then be ruled out, including hypothermia, hypoxia, hypoglycemia, hyperglycemia, uremia, hepatic failure, Reye's syndrome, hyponatremia, hypercalcemia, myxedema, adrenal failure, and CNS depressants. When reversible causes are ruled out and symptoms of brain death exist, then brain death is initially confirmed with apnea testing. The patient should be warm, maintaining a blood pressure greater than 90 mmHg, preoxygenated with 100% FiO₂ for 10 min, and eucapnia must be confirmed with initial pre-test blood gas. The test is commenced by disconnecting the patient from the ventilator. During this time, high-flow oxygen is delivered into the trachea via catheter at the level of the carina. The patient is monitored for respiratory activity; if any is present, the patient is immediately reconnected to the ventilator. A standard waiting time of 8 min is instituted if the patient remains apneic and hemodynamically stable. If a repeat blood gas yields a PaCO₂ of 60 mmHg or greater then brain death is declared. The test can be repeated with 10-min duration if 60 mmHg is not attained. Confirmatory tests include the EEG, and tests that confirm lack of cerebral blood flow (cerebral angiography, duplex ultrasound, radio-nuclide cerebral blood flow scanning).

Donor Management

The physiology of brain death has been delineated over the years by animal models and observations in human case series. Brain death proceeds as ischemia in a rostral-caudal fashion. This progression causes initially an increased vagal activation followed by the Cushing reflex due to a mixed vagal/sympathetic stimulation. Continued progression of ischemia down the brainstem produces an autonomic surge causing extreme elevation of heart rate and blood pressure, followed by sympathetic deactivation as the spinal cord is eventually affected. In general, this results in a hemodynamically unstable patient. The initial goal of donor management, therefore, is an assessment and maintenance of hemodynamic stability. This is achieved via echocardiography and resuscitation via crystalloid, colloid, and blood product infusions. Vasoactive support could be added via use of dopamine and dobutamine infusions. Finally, hormone replacement therapy (i.e., thyroxine, methylprednisolone, insulin, and vasopressin) may be instituted in a donor with persistent hemodynamic lability. The goal is maintenance of blood pressure above 100 mmHg, CVP around 10 mmHg, and urine output above 40 mL/h. There may be benefit in maintaining urine outputs greater than 100 mL/h, however detriment in outputs greater than 300 mL/h. When donors

develop diabetes insipidus, hypotonic replacement to keep up with hypotonic urine loss becomes necessary combined with desmopressin. When urine output drops below 40 mL/h the addition of diuretics and mannitol may be helpful in donor management.

Previous studies have shown shortened time to graft failure in donors with terminal serum creatinine levels greater than 1.5 mg/dL. In a separate analysis of donor factors that predispose to decreased graft survival, it has been reported that the goal in donor management of keeping serum creatinine levels under 2 mg/dL seems to exert favorable effect on graft function in recipients [14]. The likelihood of impaired renal function in the older donor mandates donor management that is aimed to optimize serum creatinine levels.

Much consideration has been given to renal biopsy and correlation with function and level of glomerulosclerosis (GS). However, there have been mixed results, and no consistent correlation has been observed between increased GS and graft survival and function. In general, worse outcomes were demonstrated with GS greater than 20% [15]. In theory, the transfer of more nephron mass via transplanting two same donor ECD allografts may improve posttransplant glomerular filtration rate (GFR) [16]. Further improvements may be achieved by using pulsatile perfusion to improve ECD outcomes. Ex vivo perfusion of ECD kidneys did not show definite survival advantage; however, there are indications that pumped kidneys have increased final use of ECD kidneys as well as decreased DGF [17].

In the elderly donor, advanced age impairs regenerative capacity of the liver and therefore injury due to ischemia and subsequent recovery from injury could be exaggerated. Occasionally, a liver biopsy can be used to assess other variables that may increase the rate of primary nonfunction; the presence of steatosis >30% is considered as extremely high-risk, as is periportal fibrosis [18]. A short cold ischemia CIT (<6 h) is imperative in optimizing outcomes of ECD liver allograft. Consequently, acceptance of ECD liver should consider donor age and the ability to transplant the allograft within short time after procurement.

In the evaluation of cardiac donors, a consensus conference report on the maximization of use of organs from cadaveric donors recommended angiography for all donors aged greater than 55 years [19]. Donors with mild coronary artery disease (CAD) can be used for high-risk recipients. Some centers are performing backbench bypass grafting and valve repair with acceptable results of graft patency and function [20]. To reduce the ill effects of contrast nephrotoxicity, a left-sided ventriculography can be avoided if a quality echocardiogram was performed. One series reported successful implementation of backbench coronary angiography to avoid exposing the kidneys to contrast [21].

Since all brain-dead donors are mechanically ventilated, special consideration must be taken in the management of

the lung donor. In consideration of the optimization of the lung donor, judicious fluid management with aggressive maintenance of euvoemia is key. High tidal volumes and use of PEEP are traditional management practices. Volutrauma is kept at a minimum by careful titration of PEEP as well as keeping peak pressures at less than 35 cmH₂O and increasing minute ventilation [22]. In a recent series evaluating lungs from donors older than 50 years or older, lungs were assessed by bronchoscopy, lab work, and medical history. Aggressive pulmonary toilet was instigated, and those with difficult-to-clear airways as well as evidence of physical lung injury were rejected for transplant. Selection of donors was also predicated on a PF ratio greater than 300 upon donor resuscitation and optimization with ventilator adjustments and bronchoscopy. Optimization of the lung donors with these maneuvers resulted in the use of extended criteria lungs with acceptable posttransplant function [11].

The Procurement Procedure

In order to avoid potential complications, elderly donors should undergo a thorough evaluation, prior to the procurement procedure (Table 97.2). The fate of recipient outcomes is greatly influenced by the procurement operation. Careful dissection and tissue handling are important, and usability of the graft depends on the viability of critical anatomic structures. This multifaceted procedure requires coordination between thoracic and abdominal procurement team, aiming at a speedy recovery of the organ, as factors such as warm and cold ischemia gravely affect transplant outcomes and ultimately influences the success of the recipient procedure.

The patient is prepped from chin to groin and laterally, table to table. It is our practice to drape about two to three inches on either side of our midline incision which is then carried out from sternal notch to pubis. In the elderly donor, one must be mindful of prior surgeries and the need of an extensive exploration to rule out the presence of malignancies. Donor-related malignancies can be either due to direct transmission of tumor or due to tumor arising in cells of donor origin. Kauffman et al. analyzed UNOS data for donor-related malignancies during 1994–2001 [23]. During this time, 108,062 patients underwent a solid transplant, and only a total of 21 donor-related malignancies in transplant recipients were reported [23]. The most frequently reported transmission of non-CNS tumor after solid organ transplant has been renal cell carcinoma followed by melanoma and choriocarcinoma [24].

Removal of Thoracic Organs

Concomitant to the procurement operation by the intra-abdominal team, the chest is opened via a median sternotomy. The chest team then proceeds to expose the heart and examine the lungs. The heart is mobilized and superior vena cava (SVC) exposed. The pleura are opened by incising through the pleura behind the sternum. The pleural spaces are examined along with all lobes of the lung. The posterobasal bases are often atelectatic and should be reexpanded by bronchoscopy and vigorous hand bagging. The thoracic organs are then kept moist until completion of mobilization of the intra-abdominal organs. Once this is done, heparinization is commenced and standard cardioplegia cannula is placed in the ascending aorta and a large-bore cannula is placed in the proximal pulmonary artery. The SVC is ligated and divided, and the lower trachea is encircled by a nylon tape. Hypotension is then induced via infusion of medications or exsanguination. The ascending and descending aorta are then clamped, and cardioplegia solution infusion is begun. At the same time, the pulmonary artery, abdominal aorta, and portal vein flush are begun as well. Ice slush or cold saline is then placed in the cardiac well and around all organs. Once cold perfusion has been achieved, the heart is elevated out of the pericardium, and the pulmonary veins are divided individually and the pulmonary artery is divided at the level of its bifurcation. The aorta is divided at the level of the innominate artery and the heart is removed and packaged. The pericardium is then incised vertically on both sides to expose the lung hilum. The inferior pulmonary ligaments are taken down. Dissection continues up the back of the trachea in an obvious plane immediately anterior to the esophagus. This is continued on the right side until the nylon tape is encountered. Dissection continues on the left at the level of the aortic arch until meeting up with the nylon tape. After the

hilum is free the anesthetist is instructed to reinflate the lungs to approximately three quarters the total lung capacity. The trachea is then stapled after withdrawal of endotracheal tube. The lung block is then removed and packaged.

Procurement of Abdominal Organs

A midline laparotomy incision is made from the xyphoid to the pubis. The ligamentum teres is isolated and divided between clamps and ties, and the falciform ligament is taken down toward the suprahepatic inferior vena cava (IVC). The left lateral segment is freed from its lateral triangular ligament attachments and folded medially to divide the pars flaccida. It is lifted with forceps and a hole is made in it. Using gentle palpation, the rest of the ligament is palpated for a replaced left hepatic artery, taking care to preserve a replaced or accessory left hepatic artery.

The abdomen is retracted bilaterally providing ample exposure to the entire intra-abdominal cavity. A Cattell–Braasch maneuver is then performed with Kocherization of the duodenum to expose the infrahepatic IVC and the junctions of the left and right renal veins. To secure perfusion of the abdominal organs, portal and aortic flush sites are isolated and secured. The aorta just proximal to its bifurcation can be skeletonized quickly by spreading with the Metzenbaum scissors along each side taking care not to spread into lumbar branches, not to injure the inferior mesenteric artery (IMA), and to preserve take-off of lower pole renal arteries. In older donors, one must survey this region and find a suitable noncalcified area for proximal control. Once a suitable area of the aorta is designated, two umbilical tapes are passed underneath the aorta with the use of a long right-angle clamp. Access to the portal system is achieved by isolating the inferior mesenteric vein (IMV), which is skeletonized and prepared for the insertion of a flush cannula.

With the portal and aortic flush sites isolated and ready, the supraceliac aorta is isolated after dividing the crura of the diaphragm. Skeletonizing the aorta can be achieved by gentle spreads of surrounding tissue. The aorta is cross-clamped once preservation solution is infused via the portal and aortic cannulas. Dissection of hepatic vessels at the porta hepatis is limited, since injury may deem the organ to be inappropriate for transplant. The aims are to divide the common bile duct, to expose the portal vein, and identify the anatomy of the arterial blood supply. If the pancreas is being procured, the lesser sac is entered to evaluate the pancreas along its entire length. The pancreas is palpated to feel that it is soft, without induration and calcifications. The right and left gutters are exposed; however, the kidneys are not dissected until after perfusion with preservation solution.

When the thoracic and abdominal teams are ready, cannulas are inserted into the IMV and aorta, the donor is

heparinized, and the supraceliac aorta is clamped. The aortic cannulation can be difficult especially if the donor has had a graft, severe atherosclerotic disease, or a stent.

The right pericardium is opened so that the exsanguinated blood can flow into the chest cavity and evacuate. Ice slush is placed on the liver, behind the liver, on the pancreas, and over the kidneys. In general, the aortic flush is ran for three liters of chilled University of Wisconsin solution, and two liters usually suffice for the portal flush.

The hierarchy in the extraction of abdominal organs proceeds by removing individual organs, liver, pancreas, kidneys, or by block removal of all organs with dissection of individual organs on the backbench. The organs are removed taking care to pressure appropriate inflow and outflow vessels, length of ureters and bile duct, and loop of duodenum when the pancreas is used for transplant. The iliac vessels are then procured along with nodes for tissue typing. The vessels may be used for arterial or venous reconstruction when needed. The abdomen is then closed with a running nylon suture with full thickness bites.

Procurement of Living Donors

The donor nephrectomy technique varies among different centers. Open surgical technique has been the traditional method for removing a kidney from a living donor; however, since the mid-1990s many centers have embarked on laparoscopic living donor nephrectomy. If an open approach is to be used, the donor is placed in the lateral position and a modified flank incision is made, just above or below the twelfth rib. Most surgeons avoid entering the pleural and peritoneal cavities. The kidney is carefully dissected to preserve all renal arteries, renal veins, and the periureteral blood supply. During the procedure, mannitol and furosemide plus adequate crystalloid solutions are administered to the donor to ensure brisk diuresis. The kidney is removed once the renal vessels are securely ligated and divided. The excised kidney is then perfused with cold heparinized electrolyte solution.

For a laparoscopic-assisted procedure, the patient is placed in the flank position and a pneumoperitoneum is established through a Veress needle. The instruments and the video camera are manipulated through four ports established through small incisions in the abdominal wall. The whole procedure is visualized on a video monitor. First, the colon is mobilized and reflected medially, which exposes Gerota's fascia. Subsequently, the liver (for right-sided procedures) and spleen (for left-sided procedures) are retracted away from the upper pole of the kidney. The ureter and periureteral tissues are freed from the perinephric tissues. Next, the renal vein and artery are carefully dissected. The kidney is placed in a plastic bag and is removed through a Pfannenstiel incision.

Finally, the kidney is then flushed with heparinized solution as for open nephrectomy.

In general, elderly liver donors are not accepted. The upper age limit for living liver donation varies from center to center and is usually between 50 and 65 years. Since the incidence of unknown medical diseases and postoperative morbimortality increases with age, acceptance of elderly donors must be exercised with caution.

Elderly Living Donors

Living donation is an ideal modality for transplantation and optimizes patient selection, ischemia times, and survival outcomes. The desire to extend criteria for suitable organs extends into this population of donors as well. Central to this goal of optimizing availability of living donor organs is the juxtaposition of the notion of *primum nocerum*, in which the assurance of donor safety becomes a priority in the evaluation process. This is then heightened as considers the use of older donors where aging physiology and more brittle general health contribute to less margin of safety. A prerequisite for performing live donor transplantation is assessing an acceptable risk–benefit ratio for both donor and recipient. A detailed evaluation of a potential donor in order to minimize the donor risks and assurance of a completely voluntary donation should be addressed.

Living donor renal transplant (LDRT) is a robust and prevalent modality in transplant. In the USA, the number of LDRTs has exceeded that of deceased donor kidney transplants, while in Japan 80% of the kidney transplants are dependent on LDRT [25, 26]. Donor safety and lifetime risk was ascertained in a large, long-term study that included 3,698 patients [27]. In this study, survival of kidney donors was similar to that of controls in the general population with end-stage renal disease (ESRD) developing in 11 patients, which is a rate of 180 per million persons per year. This is compared with a rate of 268 per million persons in the white population of the USA. In addition, a subanalysis of 255 donors revealed better health-related quality of life than those in the general population. In a subsequent Japanese study, survival of LDRT is slightly better than the age- and gender-matched general population with the causes of donor death being similar to that of the general population [26]. The perioperative morbidity and mortality of living kidney donation is well documented by an US survey that included 171 transplant centers [28]. This study looked at 10,828 living donor nephrectomies: 52% were open, 21% hand-assisted laparoscopic, and 27% total laparoscopic procedures. Two donors died from surgery complications and one other remained in a vegetative stage. Reoperation was necessary in 0.4% of open surgery patients, 1% in hand-assisted patients,

and 0.9% in the totally laparoscopic patients. Bleeding and incisional hernia were the most common indications for reoperation in the laparoscopic group and in the open and hand-assisted group, respectively. Readmission rate was higher in the laparoscopic group (1.6%) than in the open nephrectomy group (0.6%), mostly because of gastrointestinal complications. This data shows that living donor nephrectomy carries a low incidence of morbidity and mortality in US transplant centers.

Among the options for decreasing time on the waiting list, elderly donors have emerged as a potential alternative. A survey performed among all US kidney transplant programs revealed that 21% of the programs excluded candidates over 65 years old. Meanwhile, the percentage of programs without a set upper age limit has now more than doubled to 59% when compared to a similar survey performed 12 years ago [29]. Furthermore, the number of LDRTs from donors >55 years has increased from 1,133 in 1996 to 1,491 in 2004 [30]. This observational cohort study using data from OPTN/UNOS compared the outcomes of LDRT in recipients older than 60 years receiving either kidney from old donors (>55 years) or young donors (≤ 55 years). Similar graft and patient survival rates were found after 4 years in both groups: 78 and 82% in the old donor group and 81 and 84% in the young donor group, respectively. Thus, LDRT from the older donor appears to be a suitable option to decrease time on the waiting list, especially in elderly recipients.

Living donor liver transplantation (LDLT) was first performed in 1989 with transplantation of a left hepatic lobe of an adult into a child [31]. Ten years later, adult-to-adult LDLT was introduced attempting left-hepatic lobe transplantation, but dismal results due to small-to-size graft syndrome discouraged this approach [32]. Consequently, the larger right-hepatic lobe grafts have replaced them in routine use at many centers. Recently, the Adult-to-Adult Living Donor Liver Transplantation Cohort Study (A2ALL) investigated the rate and severity of complications in right-lobe living donors [33]. A 38% complication rate was reported, with infection (12.5%), biliary leak (9.2%), and incisional hernias (6%) being the most common ones; overall mortality was 0.8%. Certain donor characteristics were associated to significant higher risk of postoperative complications. Intraoperative transfusion of more than 1 unit of blood and alkaline phosphatase ≥ 86 IU/L were associated to increased risk of developing complications after LDLT. Patel et al. reported an overall complication rate after left- and right-lobe LDLT of 29% [34]. Interestingly, they described donors older than 50 years as a risk factor for major complications. Decreased capacity of regeneration in older donors has been hypothesized as possible explanation for this finding [35]. In other studies, diminished early graft regeneration from older donors was shown to affect graft survival as well [36, 37]. It is well established that donors can experience

severe psychiatric complications [38]. In an A2ALL retrospective study including 392 patients, one or multiple psychiatric complications were presented in 4% of the patients including three severe psychiatric complications like suicide, accidental drug overdose, and suicide attempt. These tragic events may be prevented with careful psychiatric assessment and monitoring of liver donors. Presumably, quality of life should be affected after LDLT, but a recent meta-analysis evaluating adult LDLT outcomes reported that the donors rated higher on quality-of-life scales than the general population and one study even reported some improvements in their psychosocial measures [39].

Organ Allocation Policies

UNOS is a private not-for-profit organization created in 1987 that nucleates all transplant hospitals' waiting lists and links all OPOs. In order to optimize the distribution and allocation of organs, different organ allocation systems were created to assure maximal utility, justice, and transparency of this scarce resource. The efficacy of any organ allocation system is measured by patient and graft survival rates and patient survival rates can be divided into survival on the waiting list and survival after transplantation.

Liver allocation is now based on the Model for End-Stage Liver Disease (MELD) that predicts 3-month mortality on the waiting list and benefit from transplantation. MELD is based on logarithmic transformation of the recipient's bilirubin, creatinine, and international normalized ratio (INR) into a validated mathematical model. After 1 year of introducing the MELD score, a 3.5% reduction in waiting list mortality, a 12% reduction of new candidates to the liver transplant waiting list, and identical posttransplant survival were reported [40]. Despite the positive effect the MELD score had on organ allocation, there is still potential room for improvement such as incorporation of new parameters (i.e., sodium) and donor factors, which are now not taken into consideration.

The kidney allocation system has evolved over the past 20 years. Currently, patients are ranked according to an allocation algorithm based on their waiting time, degree of HLA matching, pediatric candidates, and panel-reactive antibodies. However, the waiting time on the kidney transplant list continues to increase, largely due to the increase of the number of new registrants aged 50 years or older. Consequently, the criteria for accepting kidneys for transplantation were extended and organs from donors ≥ 55 years of age are used with increasing frequency. An Italian group reported similar long-term graft survival in those recipients who received a kidney from donors older than 60 years when compared with donors ≤ 60 years [41]. In order to improve the distribution of

the scarce resource of cadaveric kidneys the current allocation policy is being reviewed by UNOS Kidney Transplant Committee.

Since May 2005, the order of candidates on the waiting list for lung transplantation has been based on the Lung Allocation Score (LAS). LAS is defined as the transplant benefit measure minus the waiting list urgency measure, which are calculated using a statistical model and candidate's clinical and physiological characteristics. The factors used in calculating each factor are described elsewhere [42]. LAS is represented by a continuous scale from 0 to 100, higher scores represent higher urgency and greater potential transplant benefit. Since LAS was implemented, waiting time has decreased from 681 to 446 days ($p < 0.001$) [43] and the annual number of transplants has increased. However, 1-year survival after transplantation remained unchanged [43].

UNOS heart allocation policy prioritizes time on the waiting list, the candidate medical urgency and, given that the duration of ischemic time is a limiting factor, distance between the donor hospital and the transplant center is also taken into consideration. In 2006, the heart allocation policy was modified prioritizing the sickest patients (status 1A and 1B) over local status 2 patients. The outcomes of this new system were recently analyzed showing a decreased mortality of patients on the waiting list, from 469 deaths in 2005 to 374 in 2007, while 1-year survival across the status groups remained unchanged [44]. Regardless of these promising results, there are still several groups of patients who may not benefit from this allocation system, especially those patients who are not listed as status 1A or 1B. Ongoing evaluation of the allocation policy and utilization of marginal donors hopefully will promote a more equitable distribution of organs.

The different allocation systems aforementioned dramatically changed the way in which deceased organs are allocated in the USA. However, donor organ shortage remains one of the foremost causes of death on the waiting list. As described earlier in this chapter, ECD arises as a viable option to increase the donor pool and, subsequently, diminish mortality on the waiting list.

One allocation scheme that deserves special mention is that of the Eurotransplant Senior Programme (ESP). Eurotransplant is an organ exchange organization in which transplant centers, donor hospitals, and tissue-typing centers in Austria, Belgium, Germany, Luxembourg, the Netherlands, and Slovenia collaborate. In 1999, it developed the ESP as an allocation scheme based solely on the concept of matching between metabolic demand of the graft recipient and excretory capacity of the donor organ [45–47]. The aim of ESP is to match donors with recipients of the same age group (i.e., donors > 65 years to recipients > 65 years), with the goal of kidney grafts outliving the recipients. HLA matching is disregarded, kidneys are allocated to local transplant candidates to decrease the CIT as much as possible, and only

nonimmunized (panel reactive antibodies <5%) first-transplant recipients are included [47]. Three years after collecting data, the ESP showed similar kidney graft survival rates between recipients of kidneys ESP donors and recipients of donor kidneys obtained through the usual standardized HLA-matched allocation schemes, 64% vs. 67%, respectively ($p=0.4$). When graft loss was censored, survival rates were 70% for the ESP group and 71% for the SCD group. ESP data suggest that if care is taken to avoid the accumulation of such additional risk factors as extended CIT, retransplantation, and damage to the kidney during surgery, an allocation scheme using older kidney donors for transplantation into older recipients can be operated successfully.

Is the Older Recipient the Appropriate Candidate for ECD Organs?

Traditionally, worse results with an ECD kidney than a non-ECD kidney were reported (Tables 97.3 and 97.4); however, older patients may particularly benefit from ECD kidney transplantation because they have a higher death rate while waiting for an SCD kidney, and longer time on dialysis therapy is more detrimental for older than younger patients. Ojo et al. [5] showed that the average increase in life expectancy for recipients of “marginal” kidneys (defined as one of the following variables: donor age > 55 years, nonheart beating donor, CIT > 36 h, and donor hypertension or diabetes) compared favorably with the waiting list dialysis cohort that did not undergo transplantation was 5 years [5]. To deter-

mine whether accepting an ECD kidney is the right choice for an individual recipient, the critical issue is how much longer the patient would have to wait before the poorer outcomes and increased costs of waiting on dialysis therapy would outweigh the benefits of receiving an SCD kidney [48]. Interestingly, Merion et al. compared the relative risk of mortality for ECD kidney recipients versus those receiving standard therapy [49]. Because of the increased ECD recipient mortality in the perioperative period, cumulative survival did not equal that of standard dialysis therapy patients until 3.5 years of kidney transplantation. Consequently, recipient survival longer than 3.5 years justifies ECD kidney transplantation. The subgroups with significant ECD survival benefit included both sexes, patients > 40 years, non-Hispanics, unsensitized patients, and those with diabetes or hypertension. Importantly, survival benefits are demonstrated in centers with long median waiting times, where ECD recipients had a 27% lower risk of death when compared to staying on dialysis ($p < 0.001$) [49].

Despite the necessary use of older donors, these organs have an increased risk of failure [50, 51]. Kidney allografts from older patients not only present with histologic changes and decline in renal function associated with age but, they are also more susceptible to drug toxicity, ischemia, and reduced capacity for repair. Kauffman et al. [50] analyzed early mortality rates in older recipients with and without comorbid conditions (history of CAD, cerebrovascular disease, peripheral vascular disease, chronic obstructive pulmonary disease, and previous malignancy). They noted that patients 60 years or older who received an ECD kidney transplant presented a higher 1-year mortality rate than an SCD kidney transplant, 14% vs. 9%, respectively. When analyzing those patients aged 60 years or older with comorbidities, transplantation with an ECD kidney presented a greater 1-year mortality than patients with the same comorbidities who remained on the waiting list. It was concluded that only patients aged ≥ 60 and without comorbidities will benefit from an ECD kidney over remaining on the waiting list; thus, utility may be poorly served by allocating ECD kidneys to older patients with comorbidities [50]. This approach is not universally accepted; Rao et al. [52] reported that transplant recipients older than 70 years, including those with diabetes and hypertension, benefit from ECD kidney transplantation, with lower mortality compared with waiting list patients on dialysis.

Identifying the most appropriate candidates for ECD kidneys remains an open question. It is critical to balance the survival benefit against the reduced graft survival associated with ECD. It has been suggested that ECD kidneys should be preferentially directed toward candidates older than 60, diabetic candidates older than 40, candidates with failing vascular access, and candidates whose expected waiting time exceeds their life expectancy on the waiting list without a

transplant [2]. An algorithm for ECD kidney transplant has been proposed (Fig. 97.1).

In the liver setting, the impact of ECD criteria on liver graft function and recipient survival is still under investigation. Similar results regarding graft function and patient survival after transplantation of ECD versus SCD were reported by some investigators. However, there is increasing awareness of the potential impact of aggressive utilization practices on graft and patient outcomes. Donor age has been clearly identified as an important risk factor for poor outcome after liver transplantation [7, 53, 54]. Feng et al. [7] analyzed more than 20,000 transplants from the SRTR and developed a donor risk index (DRI) that identified seven donor characteristics and two transplant variables that independently predicted significant increase in risk of graft failure. These included donor older than 40 years (and particularly over 60 years), less donor height, DCD, African-American race, split/partial grafts, cerebrovascular accident or other cause of death (except trauma, stroke, or anoxia), CIT and sharing outside the local donor service area. They described that high-DRI grafts have been preferentially transplanted into older candidates (>50 years of age) with low disease

severity [model for end-stage liver disease (MELD) score of 10–14] and without HCV. The reason why high-DRI grafts were allocated to candidates with lower MELD scores can be explained by the concept that most ill patients may have disproportionately poorer outcomes with high-risk grafts. However, several studies demonstrated that patients with a MELD score ≥ 20 experienced significant survival benefits even when they received a high-DRI organ [55–57]. The unpredictable underlying course of the liver disease makes timing of liver transplantation a more complex problem; therefore, ECD should be proposed for patients with higher risks of dying such as those with MELD scores ≥ 20 . The survival benefit of high-DRI organ allocation to older candidates requires further assessment.

Old Organ Function

In kidney transplantation, the goal of the special allocation procedure is to reduce the time associated with placement by matching ECD grafts with patients previously designated as

being willing to accept them. In assessing the potential impact of these allocation procedures, the sensitivity of ECD grafts to cold ischemia time became of great importance. ECD transplant recipients have a greater DGF prevalence than non-ECD kidney transplant recipients, in part related to CIT [58]. A European multicenter study described transplants performed with kidneys retrieved from elderly donors: CIT was associated with greater incidence of DGF and decreased graft survival when censored for death [59]. Most analyses suggest that ECD kidneys should be used locally to minimize any detrimental effect of CIT on graft function and survival. Currently, ESP and OTPN/UNOS organ allocation policy for ECD kidneys favors reducing CIT over HLA matching.

A great concern has been raised about the effect of donor age on long-term outcome. A review from UNOS data confirms that cadaveric kidneys from donors older than 60 years are associated with a 50% survival at 5 years, compared with the graft survival rate of 70% in patients receiving cadaveric donor kidneys from donors aged 19–45 years [60]. Interestingly, living donors older than 55 years have been reported to represent a significant risk of allograft failure [61]. However, as it was mentioned earlier, a recent review from OTPN/UNOS database suggested that recipients older than 60 years might benefit from living donors aged 65 years or older. These data support that donor age has turned to be a powerful predictor of long-term renal allograft function.

The main reason for kidney allograft loss in ECD recipients is death with a functioning kidney. Gill et al. [30] described cardiovascular disease and infection as the most common identifiable causes of death in ECD recipients (28.6 and 19.8%, respectively). These are expected findings reflecting the current trend to allocate ECD grafts to older recipients. With conventional immunosuppressive regimens, the risk of infectious death in older recipients increases exponentially because of higher infectious vulnerability in the elderly population, and it can be decreased by lowering immunosuppression [60]. Reduction of immunosuppression may be better tolerated in the elderly population since the incidence and severity of acute rejections is lower than in younger recipients, possibly because of the immune impaired aging [62, 63]. Nevertheless, kidneys from older donors are more likely to undergo acute rejection episodes in the early posttransplantation period when compared with kidneys from younger donors [64, 65] and may be related to a more intense proinflammatory response, increased expression of HLA in epithelial and endothelial cells, and the recruitment of antigen-presenting cells [51]. Consequently, it has been suggested that immunosuppression individualization and adequate patient selection, together with better HLA-matching, tend to decrease infection and rejection risk in ECD kidney transplant recipients [46, 66].

In liver transplantation, immediate and long-term function of liver allograft procured from older donors is affected by the

exposure to cold ischemia with an increased rate of primary and delayed nonfunction [53, 67, 68]. Grafts with more than 14 h of cold ischemia have been associated with a twofold increase in preservation damage resulting in prolonged postoperative course, biliary stricture, and decreased graft survival [67–69]. The European Liver Transplant Registry survey showed that 5-year recipient survival was 57% with CIT > 15 h versus 64% with CIT between 12 and 15 h and 67% with CIT < 12 h [70]. Elderly donors' liver grafts and donors with steatosis are even more affected by prolonged CIT and preservation injury [71]. These results emphasize the need to shorten CIT as much as possible in the case of ECD.

Recently, Burroughs et al. [53] described that those who received allografts from donors older than 60 years presented an increased 3- and 12-month mortality of 12 and 22%, respectively. Different recipient factors can have a major impact on ECD graft function – fulminant hepatic failure as the indication for transplantation and hepatorenal syndrome are associated with higher incidence of primary nonfunction [69, 72]. Recipient obesity (body mass index > 30 mg/m²) has been reported to increase the risk of postoperative complications after ECD liver transplantation, such as respiratory failure and infections [73]. Furthermore, transplantation of livers from donors older than 40 years of age is associated with increased severity of HCV recurrence and fibrosis rates [74]. It is debatable whether old livers should be allocated to recipients with HCV infection [75].

Ethics

Ethical allocation priorities are a topic of ongoing discussion [76]. Disclosing the risk and benefits of solid-organ transplantation and obtaining informed consent from patients might occur at any moment of the transplant process, when the patients are placed on the waiting list and/or when an organ is offered. Candidates willing to accept an ECD organ should be specifically informed about the potential risks a marginal graft can carry. A distinction between the risk of disease transmission and graft failure should be emphasized as part of the informed consent process. In all cases, patients should be informed to whether declining ECD will delay their receipt of an organ, and provide reasonable assessment of the potential of death before SCD becomes available. Candidates, who did not consider ECD as an option, should be offered the chance to reassess their decision, especially when their clinical condition is changed. In such circumstances, transplant physicians' clinical judgment plays a key role to establish risk and benefits of providing a particular organ to a particular patient. Transplant teams are therefore ethically obliged to look carefully into the principles, rules, or preferences they use to allocate ECD organs.

CASE STUDY

A 69-year-old male with history of smoking, hypertension, coronary artery disease, and atrial fibrillation on coumadin presented to the ER with headache, nausea, and vomiting. Initial workup including head CT scan demonstrated large intracranial hemorrhage and significant brain edema. The patient continued to experience neurological deterioration with evidence of brain herniation and hemodynamic instability requiring multiple vasopressors. The family was notified and expressed interest in organ donation.

1. *Determination of brain death:* All reversible causes of a coma were ruled out (i.e., hypothermia, hypoxia, hypoglycemia, etc.). An apnea testing was consistent with brain death, and that was later confirmed by a radionuclide cerebral blood flow scan.
2. *Donor management:* Hemodynamic stability was achieved via resuscitation with crystalloids and vasoactive support. Hormone replacement therapy with thyroxine was instituted, helping to wean-off vasopressors. Blood pressure was maintained >100 mmHg, CVP >10 mmHg, urine output >40 mL/h. Finally, reversal of diabetes insipidus was achieved with desmopressin.
3. *Procurement procedure:* The presence of abdominal donor malignancies was excluded after an extensive abdominal exploration, and the thoracic and abdominal organs were evaluated for transplantation.
 - Heart and lung were discarded because of advanced donor age and comorbidities.
 - *Liver allocation:* liver function tests revealed a total bilirubin 1.2 mg/dL, AST 35 IU/mL, ALT 51 IU/mL and viral hepatitis serologies were negative. In order to exclude fibrosis and steatosis, a liver biopsy was performed showing macrosteatosis <5% and no significant fibrosis.

- *Kidney allocation:* renal function was preserved, creatinine 1.1 mg/dL and BUN 33. For evaluation of the kidney, a biopsy was obtained that showed glomerulosclerosis <10%.
4. *Recipient procedure and outcome:* the risk and benefits of an extended criteria allograft were carefully explained to the potential recipients who consented to go forward with the transplant procedure.
 - *Liver recipient:* A 53-years-old male with alcoholic cirrhosis with refractory ascites, recurrent episodes of hepatic encephalopathy, a low MELD score of 18, and no previous abdominal surgeries received the ECD liver. Given the fact that elderly donors are even more affected by prolonged cold ischemia time (CIT) and preservation injury, the liver allograft was reperused within 4.4 h after procurement. The recipient required two units of blood during surgery; his postoperative course was uneventful except for a bile leak that resolved without endoscopic intervention after 2 weeks. One year later the patient presents a totally functioning liver with no major events and performing his daily activities with no restrictions.
 - *Kidney recipient:* A 54-years-old female with diabetic nephropathy who had been on hemodialysis for the last 6 years accepted the ECD kidney. In order to minimize any detrimental effect of prolonged CIT on graft function and survival the organ was allocated locally, prioritizing CIT over HLA matching. Postoperative course was significant for acute tubular necrosis requiring hemodialysis for 3 weeks. One month later the patient presented with an acute cellular rejection episode that was successfully treated with methylprednisolone. After 1 year the graft function is well preserved with a creatinine of 1.7 mg/dL.

Conclusion

The shortage of organs has led transplant centers to expand their criteria for the acceptance of marginal donors. UNOS and ESP have addressed this problem implementing an allocation scheme for organ allocation with improvement in survival rate, and standard definitions of ECD organs were established. A better understanding of the impact of ECD on outcome improved allocation pathways, and identifying the appropriate recipients should result in more efficient

utilization and improved graft and patient survival. Graft and patient survival data on transplant recipients aged 50 years or older suggest that there should not be an absolute upper age limit at which transplantation of any organ should be contraindicated. Candidate's biological, rather than chronological age, and careful evaluation of the overall health and quality of life of the transplant candidate should be deciding factors of whether transplantation would be beneficial or not. The recipient must be educated and informed of the risk and benefits when transplanted with an ECD organ.

Summary

- Extended criteria donation emerges as a good option to reduce the gap between the number of patients needing a transplant and the number of donors.
- Careful selection of ECD organs and potential recipients should be done.
- Elderly patients who received ECD kidney transplant will enjoy improved survival than those who remain on dialysis.
- Future studies assessing ECD outcomes on liver, heart, pancreas, and lung patients are warranted.
- Transplant candidates willing to accept an ECD organ should be informed about the potential risks a marginal graft can carry.

Chapter 98

Elderly Transplant Recipients

Aaron M. Winnick, Ilhan Karabicak, and Dale A. Distant

CASE STUDY

SN is an 84-year-old African-American male who developed renal failure after undergoing a triple-vessel coronary artery bypass graft (CABG) following a myocardial infarction in 2004. He has a history of hypertension and has been stable on hemodialysis via an AV fistula. He has excellent exercise tolerance, a normal ejection fraction on cardiac catheterization, and was asymptomatic with regard to his coronary artery disease. He is fully functional and living independently since he retired from his job as a bus operator. He was placed on the waiting list for renal transplant in 2007. He received a zero mismatch offer from a 75-year-old deceased donor in August 2008. The donor was a 125 lb woman with no significant

medical history who died from a cerebrovascular attack (CVA). Her serum creatinine was 0.7 mg/dL and postprocurement biopsy revealed minimal glomerulosclerosis. Both kidneys were pumped and then implanted ipsilaterally in a 4½-h operation. He exhibited good immediate function and mild troponin elevation, but no other complications. He received induction therapy with three doses of thymoglobulin (1.5 mg/kg/dose), Prograf, and steroids. He was discharged to home 5 days later with a creatinine of 2.0 mg/dL. No hospital readmissions occurred, and 1 year following transplantation, his creatinine level was 1.2 mg/dL. He is currently being maintained on Prograf 2 mg twice daily and prednisone 5 mg daily. He remains quite active working as a producer for a local radio station, and he travels extensively visiting family.

While the total number of organs transplanted in this country has increased over the years, there is still an ever-widening gap between the need for organs and our capacity to meet that need as the overall waiting list continues to grow. This is due in part to significant advances in transplant techniques and outcomes such that Americans with organ failure now seek transplants in greater numbers. Additionally, life-expectancy gains in the United States are creating an aging population who are more likely to suffer organ failure than younger Americans. The national transplant waiting list has continued to shift toward older candidates. The Scientific Registry of Transplant Recipients (SRTR) reported that at the end of 2007, 59.7% of all 97,248 candidates on the waiting list for all organs were 50 years old or older, and 14.9% were

65 years or older. These percentages are substantially higher than they were in 1998 (41.5 and 8.1%, respectively) [1].

In the United States, there is no upper age limit above which patients can no longer receive a transplanted organ. Over the past 10 years, there has been a significant increase in the number of transplants performed on patients over 60 years of age. The annual number of recipients transplanted rose from 21,518 in 1998 to 28,345 in 2007, a 32% increase. In contrast, the number of patients over the age of 65 has more than doubled, from 1,470 (6.8% of total) to 3,498 (12.3% of total). According to this data, the only age groups demonstrating an annual increase in the number of recipients every year over the 10-year period were those aged 50–64 and those over 65 [1].

Among solid organs transplanted in the United States, approximately 59% are kidney, 21% liver, 7% heart, and 5% lung [1]. There are several aspects of transplanting elderly patients that deserve discussion, including ethical issues, differences in pretransplant evaluation, mechanisms of graft

D.A. Distant (✉)
Department of Transplant Surgery, SUNY Downstate
Medical Center, Brooklyn, NY, USA

loss and death, and the degree and type of immunosuppressive therapy. This discussion focuses primarily on deceased-donor organ transplants into the elderly, since fewer live-donor transplants are performed in the aged (670 transplants in 2008). The kidney being the most frequently transplanted solid organ offers the most data in older patients and is therefore a primary focus of this chapter. No consensus exists as to what age defines “elderly” or “geriatric” within the transplant literature, and therefore, no attempt is made to offer such a definition; rather, the studies and data are examined with regard to the issues to be examined and the principles to be applied to older transplant candidates.

Kidney Transplantation

Older Americans are an increasingly important consumer of End Stage Renal Disease services in the United States. The U.S. Renal Data System (USRDS) collects and provides national demographic information about patients with kidney disease treated with either dialysis or transplantation. The average age of the dialysis patient continues to increase each year, with nearly half of patients undergoing regular dialysis now over 65 years of age, and the mean age of those beginning treatment is now greater than 60 years [2]. There are currently 48,773 patients on the waiting list for a kidney, with 7,800 (16%) over the age of 65. In 2007, nearly 17,000 kidney transplants were performed in the United States, with 2,377 (14%) going to patients over the age of 65 [1].

Kidney transplantation has been shown to improve quality of life and length of life compared with those remaining on dialysis [3]. In one longitudinal study of mortality, investigators evaluated data collected over 6 years on 228,552 patients who were receiving dialysis as treatment for their end-stage renal disease. Of these, 46,164 were deemed healthy enough to be placed on the waiting list for transplantation, and 23,275 received a first deceased-donor kidney transplant. The mortality ratio for the patients on dialysis who were awaiting transplantation was 38–58% lower than that for all patients on dialysis (annual death rates of 6.3 and 16.1 per 100 patient-years, respectively). The long-term mortality rate was 48–82% lower among transplant recipients than patients on the waiting list (annual death rate 3.8 per 100 patient-years). Recipients over the age of 60 demonstrated significant benefit in mortality after transplantation, with annual death rates per 100 patient-years at risk for all patients on dialysis, patients on the waiting list, and transplant recipients being 23.2, 10, and 7.4, respectively. It is estimated that, among those over the age of 60, projected remaining years of life are approximately 6 and 10 years for those who remain on a waiting list or undergo renal transplant, respectively [4]. Multiple studies over the past

10 years have confirmed that patients older than 60 years of age have longer life expectancy with deceased-donor kidney transplantation when compared to patients of the same age group on the waiting list. Post-kidney transplant recipients report a better quality of life, from mental well-being to physical functionality and social functioning. In addition, after adjusting for comorbidities, there is no significant difference in graft failure compared to younger patients [5–8]. As with all organ transplants, the risks and benefits must be carefully weighed, especially in the elderly. Will this organ improve the patients’ overall survival and quality of life? Will an older patient be able to survive the operation, manage the medications, endure the potential side effects of immunosuppression, and have the social and financial support necessary to recover and maintain rigorous doctor appointments?

Current success in transplanting kidneys into older recipients has quieted misconceptions within medical communities and the general public, among them the erroneous belief that advanced age alone prevents a successful surgical outcome, that the elderly patient with ESRD has a very limited life expectancy, and thus cannot receive a transplant, and that older recipients have poor results based upon outdated information from the previous era of transplantation and immunosuppression. Older recipients, however, do have a higher risk of cardiovascular events, infection, and malignancy after kidney transplantation compared to younger patients [9]. Also, they are more prone to drug side effects and toxicity [10]. The absolute gain in survival provided by a donor kidney varies considerably depending on recipient factors, such as age and comorbid illnesses.

Although overall graft failure rates are not higher for elderly recipients, death with a functioning graft does occur more often which shortens the lifespan of the donated kidney (especially from a young donor) [10]. Clearly, a younger recipient would more likely experience more years of allograft function with the same kidney. With ever-increasing organ shortages, the ethical dilemma of including age as a potential allocation factor has been raised. The argument pits the increased survival and quality of life for the older transplant recipient against the population gain in allograft survival by transplanting kidneys preferentially into younger recipients. What is the best way to deal with these competing allocation philosophies, namely, giving everyone an equal chance to receive an organ vs. getting the maximum benefit from each organ transplanted? In the U.S., the United Network for Organ Sharing (UNOS) provides regulatory oversight and balances these ethical principles in an effort to achieve socially acceptable allocation policy.

An alternate strategy to maximize the benefit of donor organs matches kidneys with lower expected graft survival time (principally older donors) to patients with lower expected longevity (principally older recipients). The current

allocation of expanded criteria donor (ECD) kidneys attempts to do this. These kidneys are procured from donors older than 60 years of age or donors aged 50–59 years with at least two of the following conditions: cerebrovascular accident as cause of death, a history of hypertension, or a serum creatinine > 1.5 mg/dL [11]. While ECD kidneys carry a relative risk of graft failure greater than 1.7 compared to a reference group of donors aged 10–39 years without any of the above three conditions, elderly recipients of ECD kidneys were found to have a survival benefit compared with waiting-list candidates (RR=0.75; 95% CI 0.65–0.86; $p < 0.0001$) [8]. The benefits (shortening of waiting time) and risk (impaired long-term graft function) associated with the use of ECD kidneys should be addressed on an individual basis. As with all recipients, elderly patients do best with an ideal donor kidney; however, the ECD policy achieves a compromise that enhances the donor pool and provides good alternative to dialysis.

Another option for increasing the number of organs and decreasing the waiting period for renal transplantation is to perform a dual kidney transplant. Both kidneys from an older donor, which individually would be considered marginal or inadequate for transplantation, are transplanted into a single recipient. This expands the use of kidneys that otherwise would not be used. There is a misconception that dual kidney transplantation involves the transferring of an inferior organ; on the contrary, it is just a different type of organ transplant. For all kidneys being evaluated for donation, the creatinine clearance is calculated. If it is greater than 65 mL/min, each individual kidney may be transplanted into two different recipients. If it is below 40 mL/min both kidneys are usually deemed unsuitable for transplant. The area in between, 40 and 65 mL/min, constitutes the range to use two kidneys together to give recipients the function of one kidney. This allows for the transplantation of as much kidney function as, if not more than, a standard single transplant from a nonexpanded criteria donor. With careful selection, the amount of kidney function that is being transplanted with dual kidney is comparable to a single kidney transplant [12].

Patient Selection

Prior to transplantation of any organs, the prospective recipient has to be carefully evaluated to detect and treat any coexisting illnesses that may affect patient and graft survival after transplantation. In the elderly, this is imperative for two reasons: graft loss in the elderly is related primarily to patient death, and the main causes of morbidity and mortality following transplantation are infection and cardiovascular disease [13, 14].

Regardless of the age of the recipient, a thorough medical, surgical, and psychosocial history needs to be obtained, along with a detailed physical examination. Careful examination of the abdomen for previous operations is important, as is the presence or absence of peripheral arterial pulses. Initial laboratory testing includes blood type, HLA typing and a panel reactive antibody assay to detect for previous sensitization, complete blood count (CBC), blood urea nitrogen, creatinine, electrolytes, calcium, phosphorous, albumin, liver function tests, prothrombin time, and partial thromboplastin time. Serologic studies for cytomegalovirus (CMV), hepatitis B and C viruses (HBV, HCV), human T cell leukemia virus (HTLV-1), and human immunodeficiency virus (HIV) are routine. One element of the evaluation process includes baseline age-appropriate screening tests. It is also important and appropriate to maintain a higher index of suspicion for malignancy in patients of this age group. In women, this consists of gynecologic examination and Papanicolaou smear, breast examination, and in those over the age of 40 without a family history of breast cancer in the premenopausal years, mammography. In men, testicular examination, prostate examination, and for those over age 50, prostate-specific antigen (PSA) assay should be performed. All patients over the age of 50 should undergo screening colonoscopy. A screening purified protein derivative (PPD) test may be used depending on the patient population and patient history. Radiologic studies include chest X-ray and electrocardiogram as routine and can include ultrasound or computed tomography (CT) scan of the abdomen to evaluate anatomy if indicated. Estimation of urine output preoperatively is important because it determines the significance of postoperative urine output and helps determine the need for any urologic evaluation. A history of claudication warrants a workup for peripheral vascular disease and may also point towards a higher chance of ischemic heart disease. The presence of strong femoral and peripheral pulses indicates that the pelvic vessels will likely be adequate for the transplant vascular anastomosis. Assessment of cardiac risk is critical in the evaluation process of elderly patients. Cardiovascular disorders, such as hypertension, coronary artery disease, congestive heart failure, and arrhythmias are common in elderly transplant recipients and account for most of the deaths in this population. Blood pressure, blood glucose, and cholesterol control is of particular concern because this patient population frequently have or develop these complications. The prevalence of ischemic heart disease is very high in patients with end-stage renal disease, and almost half of the deaths that occur during the first 30 days posttransplant are due to ischemic heart disease [15]. The current guidelines from the American Society of Transplantation recommend assessing ischemic heart disease risk factors in any patient with a prior history, men over the age of 45 or women over the age of 55 years, cardiac disease

in a first-degree relative, current cigarette smoking, diabetes, hypertension, fasting total cholesterol >200 mg/dL, high-density lipoprotein cholesterol < 35 mg/dL, and left ventricular hypertrophy. Any patient at high risk, including those with renal disease from diabetes, prior history of ischemic heart disease, or more than two of the above risk factors, should undergo an echocardiogram and cardiac stress test. Angiography with possible revascularization, if indicated, should be performed prior to any transplantation. Asymptomatic patients can also undergo noninvasive tests first that may help determine the risk for posttransplant complications, in the form of chemical stress echocardiography or scintigraphy [15].

Based on an initial evaluation, the 2005 Canadian Society for Transplantation Guidelines suggested that the following patients with coronary heart disease may be eligible for kidney transplantation: asymptomatic low-risk patients; asymptomatic patients in whom noninvasive testing is negative; patients on appropriate medical therapy with angiographic results showing noncritical disease; and those patients in whom successful interventions have been performed [16].

Currently, there is no strong evidence to suggest a benefit to the routine screening of asymptomatic renal transplant candidates for cerebrovascular disease. Risk factors for post-transplant cerebrovascular disease include a history of prior disease, age, smoking, diabetes, hypertension, and hyperlipidemia [15]. Patients who have already suffered from a cerebrovascular event and have significant deficits may be poor operative candidates due to their poor operative risk and rehabilitative potential. Patients with recent transient ischemic attacks need to be adequately evaluated by a neurologist.

Pulmonary risks associated with surgery for transplantation include infection, fluid overload, and ventilator dependency. Pretransplant evaluation of elderly patients with respiratory disease should be consistent with that for the general population who undergo a preoperative pulmonary assessment [17]. The 2005 Canadian Transplant guidelines suggest that patients should not be considered candidates for kidney transplantation if they require home oxygen therapy, have uncontrolled asthma, severe cor pulmonale, or severe COPD, pulmonary fibrosis, or restrictive disease. The latter is defined by FEV1 <25% predictive value, room air pO_2 <60 mmHg with exercise desaturation SaO_2 <90%, or more than four lower respiratory tract infections in the last 12 months [16].

The transplant candidate must be free of all active infections before transplantation could be considered. Whenever possible, all treatable infections should be dealt with appropriately. Chronic infection precludes transplantation and the subsequent use of immunosuppressive therapy. Infectious complications occur frequently in the transplanted patient, with pneumonia being one of the most common infections seen in elderly hospitalized patients. As such, elderly patients must be immunized against influenza and pneumococcus.

Not too long ago, most centers considered patients who tested positive for HIV inappropriate for transplantation secondary to immunosuppressant-induced opportunistic infection and the suspected short life span. With the advancement in antiretroviral therapy, more centers now are willing to transplant patients who are HIV positive, but the general recommendation is to evaluate on a case-by-case basis.

Patients with a malignancy prior to receiving an organ may still be a suitable candidate for transplantation depending on the tumor type, stage, and response to therapy. The concern is that malignancies are common after transplantation, possibly due to immunosuppression favoring the growth of malignant cells and/or viral infection. This part is addressed in a later section on postoperative issues. While it has been reported that patients with ESRD on dialysis have a higher rate of cancer compared to the general population, this relative risk has been shown to be higher in younger patients [18]. Most patients previously treated for cancer benefit from a waiting period prior to renal transplantation to decrease the risk of recurrence. Depending on tumor characteristics, recommendations range from no wait time to 5 years. No waiting time is required for basal cell carcinoma of the skin, in situ cancer of the bladder or cervix. A 2-year waiting time is proposed for lymphoma, leukemia, cancers of the prostate, lung, breast (early stage), testicle, thyroid, uterine body, bladder, Wilm's tumor, renal cell carcinoma (<5 cm), or Kaposi's or other sarcoma. Patients with localized, successfully treated carcinoma of the uterine cervix may benefit from waiting 2 years, and in some cases 5 years, prior to transplantation. A 5-year waiting time is recommended for colorectal, invasive breast, and renal cell carcinoma (>5 cm), and malignant melanoma [15, 16, 19].

While some contraindications to kidney transplantation are absolute, many are relative and determined by individual centers. Absolute contraindications to receiving a renal transplant include: recent or metastatic malignancy; active substance abuse; severe extrarenal disease with life expectancy of less than 1 year; untreated current infection; psychiatric or other illness impairing adherence to regimen. Relative contraindications include: morbid obesity; active heavy tobacco use; acute coronary or cerebrovascular event; HIV infection if untreated or poorly monitored [13, 15].

The actual surgery for transplanting a kidney is the same for the elderly patients as for any adult, with the caveat that careful attention must be paid to fluid maintenance and monitoring in the elderly, depending on the cardiac and pulmonary history. The standard incision for adult kidney transplantation is an oblique incision from the symphysis in the midline, curving in a lateral and superior direction to the iliac crest. The donor renal artery and vein are anastomosed to the recipient external iliac artery and vein, respectively, and the donor ureter anastomosed to the recipient bladder. The kidney is

placed in the iliac fossa where it is easily accessible if an ultrasound, biopsy, or other intervention is required.

Immunosuppression and Prophylaxis

While the benefit of renal transplantation in the elderly has already been established, there is a paucity of data evaluating the safety and efficacy of immunosuppression regimens. Most centers use traditional principles and their transplant protocols with modifications when considering the factors unique to the elderly. Analysis of registry data suggests that while the risk of acute rejection decreases with age, the impact of rejection on long-term graft function in this elderly population is greater when compared to younger groups. It is of no surprise that posttransplant mortality is greater in the elderly; however, censoring graft survival data for patient death demonstrates no significant difference between outcomes in older and younger patients [5, 6, 20, 21].

The goal of an immunosuppression protocol should be to maintain a level necessary for a reduced risk of infection without increasing the risk for rejection. The elderly have less immunocompetence, and the therapy has to be adjusted in the elderly transplant recipient. This may result in a decreased likelihood of immunologic rejection but increased risk of infection. Immunosuppressive therapy also has to be adjusted to account for the different pharmacokinetics and altered effects of drugs in the elderly. The aging process results in physiological changes that affect drug absorption, distribution, and metabolism. In addition, due to the many comorbid conditions in the elderly, they often take many medications which may have drug–drug interactions with immunosuppressive medications [22].

There are currently no prospective multicenter trials that specifically evaluate immunosuppressive medication protocols in the elderly in a randomized fashion. Most of the time, the elderly are excluded from trials. As such, most of the data is from single-center, observational studies or retrospective database analyses [23]. Any approach should be based on the risks of acute rejection, infections, malignancy, and comorbid conditions.

There is no set immunosuppression protocol that has been universally accepted in the elderly or any patient population. Although acute rejection decreases with recipient age, chronic allograft nephropathy seems to increase with age, and this phenomenon is further confounded by increased death from infectious disease and drug-related causes. This has led to some protocols that support less-intensive immunosuppressive drug therapy in elderly recipients [24].

Current treatments consist of triple therapy with corticosteroids, a calcineurin inhibitor (cyclosporine or tacrolimus), and an antimetabolite, but these regimens may be replaced

by substitution or addition of newer antiproliferative agents. Treatment with mycophenolate mofetil (MMF), which inhibits purine synthesis, has been found to result in a longer time to the first episode of acute rejection but had significantly greater rates of opportunistic infection and graft loss and mortality [25]. One study comparing MMF to azathioprine evaluated over 5,000 patients over the age of 65 and showed improved patient and graft survival with lower rates of late acute rejection with MMF. The most prescribed immunosuppressive protocol is a combination of MMF with calcineurin inhibitor, and there appears to be no contraindication to use this protocol in the elderly [26, 27].

An alternative or supplement to standard triple therapy is the use of augmented immunosuppression with antilymphocyte antibodies, commonly termed “induction immunotherapy.” These cytolytic agents have been found to reduce the risk of early rejection but tend to increase the risk of infection. Induction therapy in the form of Atgam® (equine antithymocyte globulin) or OKT3® (muromonab-CD3) was the mainstay but now has been largely replaced by the use of Thymoglobulin® (rabbit anti-lymphocyte globulin) or monoclonal antibody therapy directed against the IL-2 receptor – Zenapax® (daclizumab) or Simulect® (basiliximab) [1].

In addition to the immunosuppression and steroids making the elderly more susceptible to infection, fractures, weight gain, and other side effects, they are at a 30% higher risk of developing new-onset diabetes posttransplant per decade of life [28]. This has led to a movement in recent years for the avoidance or early withdrawal of calcineurin inhibitors and/or corticosteroids. Multiple studies demonstrated appropriate patient and graft survival, as well as excellent graft function, after using induction agents and minimizing the use of calcineurin inhibitor [29–31].

Considering the elderly’s increased risk for adverse effects and infection, and the limited prospective data available, any protocol must consider that decreasing the risk of acute rejection may augment the morbid consequences of rejection. As such, protocols are currently tailored based on donor type and immunologic status of the elderly recipient. The low-risk recipient of a kidney from a young donor may be a candidate for rapid steroid withdrawal or steroid minimization strategies due to the lower risk of rejection and increased risk of steroid-induced adverse effects. The low-risk recipient of a kidney from an older donor may have an enhanced risk of chronic allograft nephropathy and nephrotoxicity from the calcineurin inhibitors, so it may be appropriate to use a calcineurin inhibitor minimization strategy. As already mentioned, interleukin-2 receptor antibodies or antilymphocyte antibodies may be used as induction agents with a calcineurin inhibitor, with the interleukin-2 receptor antibody showing a superior safety profile. Minimizing immunosuppression is not appropriate in an elderly patient with high immunologic risk, so a regimen consisting of antibody

induction, corticosteroids, calcineurin inhibitors, and/or MMF is more reasonable [23].

Since there is potential for severe consequences with acute graft rejection in the elderly, a biopsy should be performed in all unexplained cases of allograft dysfunction. Treatment should be based on histologic findings, whenever possible, with empiric steroid use for treatment of presumed acute rejection used sparingly due to the increased risk of adverse events in the elderly.

Patient and Graft Outcomes

Renal allograft and patient survival in the elderly transplant recipient are currently excellent, when looked at as a group and compared to younger recipients. Patient survival at 1, 5, and 10 years ranges from 80 to 90, 70, and 50%, respectively [1, 5, 6, 32]. This is based in part on the type of allograft. Based on the 2008 SRTR analyzing transplants from 1998 to 2007, 3-month, 1-, and 5-year patient survival rates for those 65 years of age and older receiving a renal transplant are: 98, 96, and 78% for recipients of living-donor kidney transplants, respectively; 96, 92, and 66% for recipients of deceased-donor nonextended criteria donor kidneys, respectively; and 95, 87, and 58% for recipients of deceased-donor extended criteria donor kidneys, respectively [1].

Graft survival has increased in parallel, averaging 85% at 1 year and 70% at 5 years [5, 6]. Allograft survival at 3 months, 1, and 5 years for those 65 years of age or older are: 97, 94, and 74% for recipients of living-donor kidney transplants, respectively (Fig. 98.1); 94, 88, and 59% for recipients of deceased-donor nonextended criteria donor kidneys, respectively; and 90, 81, and 48% for recipients of deceased-donor extended criteria donor kidneys, respectively (Fig. 98.2) [1].

Patient death with a functioning graft accounts for the majority of reported "graft loss" in the elderly patients. Nearly 50% of graft loss is due to death in the elderly recipient compared to 15% in the younger recipient. Acute rejection is reported to occur less often in elderly recipients, but there is an increased risk of chronic allograft nephropathy, especially if the allograft is from the older donor [33].

The predominant causes of death in elderly transplant recipients are cardiovascular disease and infection. Most infectious episodes occur in the first 6 months posttransplant, likely due to the degree of immunosuppression. The risks of overimmunosuppression and cardiovascular disease are related to the natural effects of aging and factors having to do with end-stage renal disease. Overimmunosuppression will increase infectious complications in all patients, regardless of age. However, the elderly are less immunocompetent, leading them to be more susceptible to infection at lower lev-

els of immunosuppressive therapy. Most likely to contribute to this are high-dose corticosteroids and antilymphocyte antibodies at induction. Other causes of death in the elderly recipient include malignancy and gastrointestinal hemorrhage. Death due to malignancy has been reported to increase disproportionately with time after transplantation in the elderly recipient [22]. Despite the mortality risks, there is still a better life expectancy and quality of life afforded by kidney transplantation compared to dialysis. With careful selection and responsible follow-up, advanced age alone is not a contraindication to successful transplantation. Age should not be the primary determinant of donor allocation; rather, the focus should be on baseline comorbidity or functional status [10].

Liver Transplantation

End-stage liver disease (ESLD) results from many etiologies and eventually leads to complications including bleeding, ascites, infection, renal failure, fluid and electrolyte disturbances, hepatic encephalopathy, hepatocellular carcinoma, and eventually, liver failure. Currently, the only defin-

itive treatment for patients with ESLD is liver transplantation. There were 6,223 deceased-donor liver transplants performed in the U.S. in 2007, of which 619 (9.9%) were in patients 65 years or older. 3,445 (55%) deceased-donor liver transplants were allocated for recipients between the ages of 50–64. There were 266 living-related liver transplants, of which only 27 were for older recipients. Of the approximately 16,500 patients on the waiting list for liver transplant, 1,450 (11.6%) are over the age of 65. This is a dramatic increase from the 4,424 liver transplants in 1998, with only 322 (7.3%) going to patients over the age of 65. As is seen with other organs, far fewer livers are available than patients who need them [1].

Indications

The most common diagnoses in elderly patients waiting for liver transplantation are cirrhosis, alcoholic liver disease, hepatitis, primary biliary cirrhosis, and hepatocellular carcinoma. Elderly patients should only be considered for transplantation if they are thought to be capable of surviving the perioperative period and complying with the intense chronic medical regimen and follow-up [34].

Older patients are frequently seen as higher risk recipients due to their comorbidities and increased mortality to both hepatic and nonhepatic causes [35]. Liver transplantation in patients over the age of 55 was discouraged as recently as 20 years ago. However, since that time, there have been many studies demonstrating success in patients over the age of 60, encouraging more centers to list and operate on older patients [36–41]. More recent data suggest that patients over the age of 70 may successfully undergo liver transplantation; however, it has to be at a less-severe level of disease to have a good outcome [42].

Most contraindications for liver transplantation relate to comorbid conditions. Relative contraindications include alcohol or illicit drug use in past 6 months in a patient with a history of abuse, severe extrahepatic disease, adverse psychosocial factors, anatomic difficulties resulting from previous abdominal trauma or surgery, and age. Absolute contraindications generally include uncontrolled infection or sepsis, extrahepatic malignancy, advanced hepatic malignancy, and irreversible brain injury [39, 43]. HIV infection had previously been considered to be an absolute contraindication for liver transplantation. However, with the significant improvements with antiretroviral therapy and improved monitoring methods, it is no longer a sufficient reason to refuse surgery. While some centers may still list it as a relative contraindication, many will no longer restrict recipients as long as attention is paid to the comorbid conditions.

Criteria for Transplantation

For more than 30 years, the Child–Pugh classification system was used to predict morbidity and mortality in patients with liver disease. While useful in stratifying patients for transplantation, it does not provide an adequate method of prioritizing patients on the liver transplant waiting list [44]. As a result, organ allocation in adults is now based on the Model for End-Stage Liver Disease (MELD), which is a logarithmic transformation of the recipient's bilirubin level, creatinine level, and international normalized ratio (INR) into a mathematical model. It allows for an objective assessment of need for transplantation and short-term prognosis while waiting for a transplant. It does not, however, necessarily correlate with posttransplant survival [45].

Preoperative assessment of all liver transplant candidates includes abdominal ultrasound, thoracic and abdominal computed tomography, and upper gastrointestinal endoscopy in addition to routine blood studies. Patients older than 50 years must undergo screening colonoscopy, and in male patients older than 55 years, the serum prostate-specific antigen concentration must be studied with digital rectal examination. In female patients, cervical and breast cancer screening must be done as indicated before listing.

Age-related morbidity is one of the main causes of mortality after liver transplantation.

Older patients have to be evaluated by specialists in the field of cardiology and pulmonary disease [46]. The cardiovascular workup for patients over the age of 60 years includes a routine history and physical examination, EKG, and two-dimensional echocardiography. A history of coronary artery disease (CAD) or symptoms of exceptional angina are clear indications for performing cardiac catheterization prior to transplantation. A negative stress test is not sufficient to exclude cardiac disease in patients with clinical history strongly suggestive of CAD. In this situation, the clinician may elect to proceed directly to cardiac catheterization [47]. Doppler studies of the carotid, vertebral, and peripheral limb arteries are performed on these patients if clinically warranted. Revascularization strategy must be performed prior to listing for liver transplantation if there is extensive coronary heart disease [38]. Diabetes mellitus may be the most important risk factor for the presence of CAD in patients with liver disease and must be assessed and managed appropriately in the perioperative setting [44, 48]. Older patients with end-stage liver disease, particularly those with cholestatic liver disease, are also at risk for osteopenia or osteoporosis. Postoperative corticosteroid therapy will also contribute to bone loss, increasing the risk of sustaining compression fractures. For all elderly patients, determination of vitamin D serum levels and baseline bone densitometry is encouraged [44]. Any patient over the age of 60 with a history of encephalopathy, seizures, or ischemic event should

have an MRI of the brain prior to being listed. Older patients also have to be routinely screened for malignancy. Patients waiting for liver transplants need to be evaluated for hepatocellular carcinoma (HCC) in particular, as well as for colon, skin, prostate, and breast neoplasms.

For liver transplant recipients, the pretransplant status has been found to be associated with survival, and this is seen more in elderly patients. In a retrospective review of 1,446 liver transplant recipients, of which 241 were over the age of 60, the elderly patients were found to be especially at risk for lower survival if they had a bilirubin level of 10 mg/dL or greater, an albumin level of less than 3 g/dL, a markedly prolonged (>20 s) prothrombin time, or generalized poor nutrition. The authors recommended forgoing transplantation in a patient over the age of 60 who is an inpatient in the hospital or in the intensive care unit with any of the above values [49].

Immunosuppression

The immunosuppression protocol and dose of immunosuppressive drugs do not drastically differ between older and younger liver transplant patients [43]. Immunosuppressive strategies vary from center to center in the selection of specific agents, the number of agents, and the duration of use of each agent. The combinations used have evolved to predominantly tacrolimus, mycophenolate mofetil/mycophenolic acid, and steroids. Triple drug therapy remains the predominant drug regimen; however, many centers are attempting to minimize or eliminate long-term steroid use. The key is to tailor the regimen to the patient to best prevent cellular rejection, have no associated morbidity with respect to opportunistic infections, have no nephrotoxicity, and preclude the development of infection, which continues to be a leading cause of death in the year after transplantation.

Results

Although there are some studies reporting that the long-term survival of patients older than 60 years was lower than younger recipients [50–53], most studies report similar [38, 54, 55] or even better [43, 56] survival in recipients older than 60 years old.

One study evaluating the survival rates of elderly liver transplant recipients found that the short-term survival of the elderly is comparable to those younger adults, but the longer survival was not encouraging. The long-term survival was significantly lower in elderly recipients, with a 5-year patient survival of 52% in the elderly group and 75% in the younger patients ($p < 0.05$). The study period was divided into two eras; 1984–1991 and 1992–1997. In both eras, recipient survival in

those older than 60 years was significantly lower than younger recipients, lending support to the idea that older recipients are not good candidates for liver transplantation [50].

A different study showing better survival rates in elderly patients looked at 240 liver transplant recipients, of which 23 were over the age of 60. They reported 87.5 and 83.3% 1- and 3-year patient survival in the elderly, respectively, compared to 77.8 and 73.5% in the younger group. Graft survival rates at 1 and 3 years were found to be 79.2 and 75% in the older group and 76.5 and 71% in the younger group, respectively. Neither set of data showed any statistical significance [52].

Some studies divided older recipients into two groups to show the effect of age more clearly: recipients between 60 and 65 years of age and those older than 65 years. One study reported that the patient survival in the older than 65 years of age group was 99%, 82 and 73% in 3 days, 1, and 5 years, respectively [38].

A different study found a lower survival rate in patients older than 65 years than in patients between 60 and 65 years, although there was no statistical significance. Overall, patients older than 60 years had lower survival rates than younger patients, which could possibly be explained since that group had a higher rate of HCC as the reason for transplantation [47].

Similar results can be found in smaller studies for recipients over the age of 70. One study found a 58% 3-year survival in 33 patients, while another has 1- and 3-year survival rates of 78.8 and 71.4%, respectively [39, 53]. Data is limited in this age group, but transplantation in septuagenarians is definitely feasible if the patient is otherwise healthy.

There are few studies looking at the survival in older patients after a living-donor liver transplant (LDLT), and the results have been mixed. Some investigators reported that recipient age had an influence on allograft failure [48], while others found that older recipient age and prolonged cold ischemia time increased the risk of graft failure [49]. One of the larger studies investigated the impact of age in living-donor liver transplantation by following recipients over 60 years of age over a 10-year period. They found the following parameters as risk factors influencing survival rate in patients after LDLT: MELD score equal to or greater than 25; Child's classification C; preoperative status of the recipient being in an intensive care unit; and blood type incompatibility. Recipient age of 60 years of age or older had no influence on the survival. 1-, 3-, and 5-year survival of the recipients older than 60 years were 81.9, 78.7, and 78.7%, respectively. Interestingly, their results in older patients were better than in younger patients (1-, 3-, and 5-year survivals in patients younger than 60 years is 75, 70.8, and 69.3%, respectively). A possible explanation for this better survival is that the selection criteria of older recipients were more stringent. The MELD score for older group recipients was significantly lower, and high-risk older patients were not considered for LDLT as a treatment option for their advanced liver disease in that study [43].

It is evident that after 5 years, survival of patients aged 65 years and older begins to diminish [38]. The 10-year survival of recipients older than 60 years was found to be 48%, which is significantly lower than the 72% survival rate of recipients younger than 60 [47, 57]. One study evaluated 91 transplant recipients over the age of 60 over a 13-year span and reported a 10-year patient survival of 35% in the elderly group and 60% in the younger patients ($p < 0.05$). The most common cause of late mortality in elderly liver recipients was malignancy (35%), whereas most of the young adult deaths were the result of infectious complications (24%) [50].

Based on the 2008 SRTR analyzing transplants from 1998 to 2007, 3-month, 1-, 5-, and 10-year patient survival rates for those 65 years of age and older receiving a liver transplant are 91, 81, 64, and 42% for recipients of deceased-donor liver transplants, respectively and 93, 85, 71, and 54% for recipients of living-donor livers, respectively. Allograft survival at 3 months, 1-, 5-, and 10-years for those 65 years of age or older are 94, 84, 68, and 53% for recipients of living-donor livers, respectively (Fig. 98.3) and 89, 78, 61, and 40% for recipients of deceased-donor liver transplants, respectively (Fig. 98.4). The results at all intervals were comparable to those of younger age groups [1].

When evaluating a patient's risk for rejection after liver transplant, younger age has been found to be an independent risk factor [58]. Older patients usually have a lower incidence of episodes and severity of graft rejection, possibly a result of immune senescence [46, 51, 59]. One study noted that liver recipients over the age of 65 tended to have lower rates of rejection, although there was no statistical significance [38]. Some centers have reported no difference in episodes of acute rejection among older or younger recipients [56, 60].

Most studies report no statistical differences in the incidence of complications in terms of hospitalization, infection (surgical or opportunistic), repeat operation, readmission, or repeat transplant between the patients older or younger than 60 years [56]. Older patients are more prone to having higher incidence of osteoporosis, nontraumatic bone fractures, coronary artery disease, and malignancy after liver transplantation, with skin cancer being the most common [43, 47].

The most prevalent cause of death in recipients older than 60 years is malignancy (both recurrent and de novo) and sepsis [38, 43, 47]. In one study, investigators reported that seven of ten recipients died secondary to sepsis in the early phase after LDLT within 3 months. In patients younger than 65 years of age, most causes of death are related to cardiovascular (myocardial infarction, congestive heart failure, cerebrovascular accident, intracranial hemorrhage) and sepsis. A possible explanation for not having the cardiac problems as a leading cause of death in older patients may be that the older recipients are more rigorously assessed for comorbidities that could be detrimental to outcome.

Well-selected patients over the age 60 or 65 have a comparable survival after liver transplantation to younger

recipients at 1-, 3-, and 5-years posttransplant. Advances in surgical technique, improved intensive care, and standardized immunosuppressive therapy all contribute to the good survival results. Unfortunately, long-term results have not been as promising, possibly explained by older patients having fewer years of life remaining. Nonetheless, this should not preclude liver transplantation in elderly patients deemed strong and otherwise healthy enough to undergo the procedure [38].

Heart Transplantation

Chronic heart failure remains one of the most common diseases affecting the population. With increases in life expectancy and improvements in medical care, more elderly patients are being seen by cardiologists and cardiac surgeons for end-stage heart failure. Cardiac transplantation is the treatment of choice for many patients with end-stage heart failure who remain symptomatic despite optimal medical therapy. The 2007 report from the Registry of the International Society for Heart and Lung Transplantation (ISHLT) estimated that slightly more than 5,000 heart transplants are performed annually worldwide [61]. The SRTR estimates that anywhere from 2,000 to 2,400 heart transplants were performed in the

United States yearly over the past decade, with 2,207 transplanted in 2007. Of this, 44–52% of the recipients are 50–64 years of age, and 8–11% are 65 years of age or older. The most recent data list 1,408 active patients on the waiting list, with 168 (12%) being over the age of 65. The median time to transplant in this elderly group is 103 days [1].

Older patients have been excluded from consideration for heart transplantation in the past, typically due to the supposed adverse effect of increased age on long-term survival and the shortage of donor organs. However, advances in posttransplant care have improved outcomes in older patients, and several centers have demonstrated results comparable to younger patients. The criteria regarding the recipient's older age limit continue to be expanded, and older patients are increasingly being considered as potential heart transplant candidates [62–65].

Indications

Over the past decade, there has been a significant decrease in mortality in patients with advanced heart failure treated aggressively with medical and device therapy, leading to a reassessment of the role of cardiac transplantation [66, 67]. The ideal heart transplant candidate is a person with end-stage heart disease for whom conventional therapy is not likely to provide acceptable symptomatic benefit or satisfactorily improve life expectancy. The Clinical Practice Committee of the American Society of Transplantation published recommendations in 2001 for considering heart transplantation in patients with cardiac conditions that have not responded to maximal medical management [13]. Although severe heart failure refractory to medical therapy is the most common indication for transplantation, other circumstances warranting transplant include severely limiting ischemia not amenable to interventional or surgical revascularization, recurrent symptomatic ventricular tachyarrhythmia refractory to medical therapy, an implantable cardioverter-defibrillator (ICD), or surgery and rarely, for the management of cardiac tumors. Nonischemic cardiomyopathy accounts for approximately 45% of cases, and coronary artery disease accounts for about 38% of cases. Nonischemic conditions include systolic heart failure, defined by left ventricular ejection fraction <35% (Ischemic and dilated cardiomyopathy, valvular heart disease, and hypertensive heart disease); intractable arrhythmia uncontrolled with implantable cardioverter-defibrillator; and hypertrophic cardiomyopathy with persistent heart failure despite valve replacement, pacemaker, or medical therapy.

There are a few absolute contraindications to cardiac transplantation. Fixed pulmonary hypertension or any systemic illness that will limit survival despite heart transplant,

such as high-grade neoplasm, AIDS, multisystem or active systemic lupus erythematosus or sarcoid preclude transplantation. HIV infection has been considered to be an absolute contraindication to transplant, primarily due to concerns about the increased frequency of infectious and malignant complications and the previously poor survival of such patients. The prognosis of HIV has changed since the advent of highly active antiretroviral therapy (HAART), and guidelines are being amended so that HIV infection itself is not a sufficient reason to refuse heart transplantation [68]. Age greater than 70 years was an absolute contraindication in previous guidelines, but the ISHLT has recently modified their recommendations in 2006 to state that “carefully selected patients > 70 years of age may be considered for cardiac transplantation. For centers considering these patients, the use of an alternate-type program (i.e., use of older donors) may be pursued.” [63] The guidelines regarding neoplasm were also modified, with new consideration being given to tumors with low recurrence rate, response to therapy, and negative metastatic workup.

Criteria for Transplantation

In general, the most objective assessment of functional capacity in patients with heart failure, and what may be the best predictor of when to list a patient for transplantation, is measurement of peak oxygen consumption (VO_2max). This can be measured using exercise testing with ventilatory gas analysis. Several studies have demonstrated that peak VO_2 independently predicted mortality, which is highest for patients with values <10 mL/kg/min, and significantly improved if between 10 and 15 mL/kg/min [69–71].

Although peak VO_2 is an important factor used to guide the selection of heart transplant candidates, it does not provide an optimal risk profile. One model that has been validated prospectively is the Heart Failure Survival Score (HFSS), derived from a multivariable analysis of 268 patients referred for consideration of cardiac transplantation from 1986–1993 at one institution and validated in 199 similar patients from 1993 to 1995 at another institution. It incorporated noninvasive parameters, including the following seven variables and their pathophysiological constructs: presence or absence of coronary artery disease (myocardial ischemia), resting heart rate (activation of sympathetic nervous system), left ventricular ejection fraction (the degree of systolic dysfunction), mean arterial blood pressure, presence or absence of intraventricular conduction defect on baseline ECG (the extent of myocardial fibrosis), serum sodium (the degree of activation of the renin–angiotensin system), and peak VO_2 [72].

The Seattle Heart Failure Model is another model that, in contrast to the HFSS, incorporated the impact of newer

heart failure therapies on survival, including ICDs (implantable cardioverter-defibrillators) and CRT (cardiac resynchronization therapy) [73].

Immunosuppression

As with other organs, there is no general consensus regarding a preferred immunosuppressive protocol in this age group. Treatment with mycophenolate mofetil/mycophenolic acid, a purine analog, has been shown to reduce the rate of rejection and improve survival, but it did have a higher incidence of nonfatal, opportunistic infections as compared with azathioprine therapy [74]. The two most common regimens in 1997, which was used for 75% of transplant recipients, consisted of cyclosporine with mycophenolate mofetil/mycophenolic acid or another antimetabolite and steroids. Over the years, these combinations have evolved to be predominantly tacrolimus, mycophenolate mofetil/mycophenolic acid, and steroids (49% of transplant recipients), and to a lesser extent cyclosporine, mycophenolate mofetil/mycophenolic acid, and steroids (29% of transplant recipients). At 1-year posttransplantation, triple drug therapy remains the predominant drug regimen [1].

The ideal immunosuppressive regimen will prevent cellular rejection, have no associated morbidity with respect to opportunistic infections, have no nephrotoxicity, and preclude the development of coronary allograft vasculopathy, which affects 50% of patients at 5 years. This immunosuppressive therapy used to prevent rejection predisposes patients to infection, which continues to be the leading cause of death in the year after cardiac transplantation [58].

A notable trend over the past 10 years has been the declining number of recipients who needed treatment for rejection episodes in the first year after heart transplantation, decreasing from 36% in 1996 to 25% in 2005. This could reflect the improved efficacy of newer immunosuppression medication and regimens, as well as earlier recognition and prompt treatment [1].

Results

Multiple studies have demonstrated comparable survival rates in elderly cardiac transplant recipients compared to younger recipients [59–62, 75–78]. Included in this is a multi-institutional study of the UNOS database where it was found that there was a satisfactory but lower 5-year survival between elderly (>60 years) and young (18–59 years) recipients (69% vs. 75%, respectively). The elderly group, however, had more infections, renal failure, and longer postoperative length of stay and were at increased risk of malignancy [62].

One retrospective study showed no statistically significant difference in 1- and 4-year survival (1-year survival: 93.3% vs. 88.3%; 4-year survival: 73.5% vs. 69.1%), length of intensive-care unit stay, incidence of rejection, and incidence of cytomegalovirus infection between patients over the age of 70 and younger patients [59]. A 10-year follow-up of cardiac transplant recipients >65 years of age ($n=66$) demonstrated survival rates comparable to those of younger patients (<60 years: $n=679$; 60–64 years: $n=137$) [60].

The adjusted graft survival for recipients over the age of 65 at 3 months (90%), 1 year (85%), 5 years (66%), and 10 years (44%) were all found to be comparable within a few percentage points to various younger age groups (Fig. 98.5) [1].

The increased risk of renal failure has been consistent in various studies over the years and may be attributed to the already known preexisting renal disease in elderly, as suggested by elevated preoperative creatinine. Another consideration is the nephrotoxic effects of immunosuppression. Tailoring therapy for the elderly may be beneficial, and some data support minimizing the use of calcineurin inhibitors and azathioprine in exchange for using mycophenolate mofetil and mammalian target of rapamycin inhibitors (mTOR inhibitors, sirolimus) [79].

Transplant patients have been the subject of extensive investigation into the increased risk of malignancy, especially in the elderly. Increased age has been independently associated with increased risk of malignancy in nontransplanted controls, and heart transplant recipients have been shown to have a 7.1-fold increase in incidence of malignancy [80]. Among all solid-organ transplant recipients, skin cancer is the most common malignancy. Heart and/or lung transplant recipients have a 26.2-, 21-, and 9.3-fold increased risk of developing lymphoproliferative disorders, head and neck cancer, and lung cancer, respectively. Malignancy does not necessarily shorten survival in older recipients, but one may surmise that it does affect quality of life [75].

The demand for heart transplantations is unlikely to ever be fully met, and more resources are needed to slow down the progression of heart failure and prevent the need for

2008 OPTN/SRTR Annual Report 1998-2007.

FIGURE 98.5 Adjusted graft survival, deceased-donor heart transplants, data from 1998 to 2007; 2008 SRTR Annual Report.

transplant surgery in the first place. As ventricular assist device technology improves, it may be used to complement heart transplantation to avoid immunosuppression and its side effect of malignancy in older patients with advanced heart failure.

Lung Transplantation

Lung transplantation should be considered for patients with advanced lung disease whose clinical status has progressively worsened despite optimal medical or surgical therapy.

One thousand four hundred sixty-five lung transplants from deceased donors were performed in the United States in 2007, increased from 840 in 1998 and 941 in 2000. Of these, 223 were for recipients over the age of 65, representing 15% of all lung transplant recipients and dramatically increased from 30 (3.6%) in 1998 and 30 (3.2%) in 2000. The percentage of patients 50–64 years of age receiving lung transplants has not changed substantially over the past few years, with 54% of deceased-donor lungs going to these patients in 2007, up slightly from 48% in 1997. The most recent data list 1,005 active patients on the waiting list, with 91 (9%) being over the age of 65. The median time to transplant in this elderly group is 57 days. Donor lung shortage has been the major limiting factor to the number of lung transplants performed. The procurement rate of lung from deceased donors has consistently been lower than those for kidney, liver, and heart. While kidneys and livers are harvested from more than 85% of all cadaveric donors, and hearts from 30% of deceased donors, lungs are harvested from only 15% of all cadaveric donors [1]. This discrepancy may be attributed to the lung's vulnerability to potential complications that arise before and after donor death such as aspiration, pneumonia, ventilator-associated lung injury, and neurogenic pulmonary edema. Over the past several years, the number of single lung transplants performed annually in the United States has remained stable, while the number of bilateral transplants has consistently increased and even surpassed the number of single lung procedures [81].

The most common indications for lung transplantation, accounting for 85% of procedures worldwide, are advanced chronic obstructive pulmonary disease (COPD), idiopathic pulmonary fibrosis, cystic fibrosis, emphysema due to alpha-1 antitrypsin deficiency, and idiopathic pulmonary arterial hypertension. Survival benefit has been demonstrated for both single and double lung transplants in patients with cystic fibrosis, pulmonary fibrosis, and primary pulmonary hypertension. There have been less convincing and reproducible results regarding the benefit of transplantation in patients with emphysema or Eisenmenger's syndrome [82, 83].

Absolute contraindications for lung transplantation include malignancy within the last 2 years (excluding cutaneous squamous and basal cell tumors); significant chest wall

deformity; noncurable chronic extrapulmonary infection (active Hepatitis B,C, HIV); untreatable advanced dysfunction of another major organ (e.g., heart, liver, kidney); known noncompliance or inability to follow medical regimen, especially if related to an untreatable psychiatric or psychological condition; absence of a consistent or reliable social support system; and substance addiction within the last 6 months [84]. Coronary artery disease not amenable to percutaneous intervention or bypass grafting, or associated with significant impairment of left ventricular function, is an absolute contraindication to lung transplantation, but heart–lung transplantation could be considered in highly selected cases.

Relative contraindications to lung transplantation include: Age older than 65 years; critical or unstable clinical condition; severely limited functional status with poor rehabilitation potential; colonization with highly resistant or virulent bacteria, fungi, or mycobacteria; severe obesity (Body Mass Index exceeding 30 kg/m²); severe or symptomatic osteoporosis; and poorly controlled or managed medical conditions (diabetes mellitus, systemic hypertension) [81].

Immunosuppression

As with other organ transplantation, induction therapy has become a major part of the immunosuppression regimen with lung transplantation. Induction therapy was used in the first 5–7 days after transplantation for 57% of all lung transplants performed in 2006, up from only 22% of lung transplants in 1997. Among the most common were antilymphocyte antibodies (antithymocyte globulin or OKT3) or monoclonal IL-2 receptor antagonists (basiliximab or daclizumab). Baseline therapy prior to discharge at most centers included corticosteroids, calcineurin inhibitor (tacrolimus 83%, cyclosporine), and an antimetabolite (azathioprine 39% or mycophenolate mofetil 52%). Maintenance immunosuppression administered for the first year following transplantation was essentially the same. Steroids are typically tapered to a low dosage or even discontinued in some protocols. Acute rejection within the first year was treated most commonly with corticosteroids, used in 95% of acute rejection cases [85, 86].

Despite the multitude of medications available, no drug has been found to be consistently superior in delaying rejection or bronchiolitis obliterans or in prolonging long-term survival. Protocols vary widely between lung transplant centers

Results

The adjusted graft survival for recipients over the age of 65 at 3 months (92%), 1 year (79%), 5 years (42%), and 10 years (13%) are all comparable within a few percentage points to

FIGURE 98.6 Adjusted graph survival, deceased-donor lung transplants, data from 1998 to 2007; 2008 SRTR Annual Report.

various younger age groups (Fig. 98.6) [1]. The average death rate in the first year after transplantation decreased steadily from 290 per 1,000 patient-years at risk in 1997 to 169 deaths per 1,000 patient-years at risk in 2004, a 10-year low. According to the 2007 ISHLT Registry report, the median survival for all adult recipients is 5 years, but bilateral lung recipients have a better median survival than single lung recipients (5.9 vs. 4.4 years, respectively) [78]. It is not delineated if this survival advantage is related to the underlying patient characteristics or choice of operation. The impact of underlying diagnosis on survival after lung transplantation has often been linked to age, with older recipients having a significantly shorter survival than younger ones. Recipients with COPD have the best 1-year survival, but a lower 10-year survival when compared to those with cystic fibrosis and alpha-1 antitrypsin deficiency. In contrast, patients with idiopathic pulmonary arterial hypertension have the lowest 1-year survival, but their 10-year survival approaches those with cystic fibrosis and alpha-1 antitrypsin deficiency [87].

This data is significantly different when evaluating patients over the age of 70. An analysis of UNOS data of lung transplants from 1999 to 2006 showed that patients 70 years and older had substantially increased risks of 30-, 90-day, and 1-year mortality when compared to younger groups. The authors' recommendation was that lung transplantation may be used with caution in older patients over the age of 60, but should not be performed in patients older than age 70 [88].

Management strategies have been more effective at reducing early complications than later ones, which may be due to refinements in surgical technique and postoperative care. However, beyond the first year of transplantation, survival is mostly affected by infections and chronic rejection, and the incidence of these complications has not changed substantially since 1988 [84].

The leading cause of death in the first 30 days after lung transplantation is graft failure, a form of Acute Respiratory Distress Syndrome (ARDS), accounting for almost 30% of deaths [78]. The leading cause of mortality after the first year, typically accounting for 40% of deaths, is chronic

allograft rejection (e.g., chronic graft dysfunction), which usually manifests as bronchiolitis obliterans syndrome (BOS) [89]. Survival 3 years after the onset of BOS is only 50% and drops to 30–40% at 5 years [90].

Infectious complications remain a leading cause of rejection and death at any point after lung transplantation, in any age group. It has been attributable to up to 35% of deaths in the first year and 20% of deaths thereafter. Bacterial bronchitis and pneumonia are most common, but cytomegalovirus, mycobacteria, fungi, and community-acquired respiratory viruses all contribute to morbidity and mortality [84, 87].

Malignancy accounts for 7–10% of deaths beyond the first year after lung transplantation. Nonmelanoma skin cancer is most common overall, but posttransplant lymphoproliferative disease (PTLD) is the most common malignancy in the first year after transplant [78]. Other malignancies include colon, breast, Kaposi's sarcoma, and transitional cell carcinoma of the bladder [91].

Combined Organ Transplantation

Often times, there are patients with multiple organ failure that may benefit from dual organ transplantation. Examples include kidney–pancreas and heart–lung. While there has been success with these combined organ transplantations over the years, its use has been limited in the elderly population. From 1998 to 2007, there were a total of 14 kidney–pancreas transplants in patients over the age of 65, while none were reported for heart–lung for a patient over the age of 65 [1]. As with individual organs, the overall risk–benefit of the surgery needs to be weighed, considering the overall health of the patient and potential survival benefits of transplantation. While age is often considered a significant factor in determining candidacy, it should not be the limiting factor.

Conclusion

The elderly population is on the rise in this country, and older patients comprise the fastest growing segment of the population. This trend is mirrored in the transplantation population. The discipline of organ transplantation has grown remarkably over the last half-century and has evolved from infrequent, highly dangerous procedures with very high mortality to complex operations performed regularly across the country and world. Data from centers across the country clearly indicate that patients over the age of 65 can undergo kidney, liver, heart, or lung transplantation with excellent results (Fig. 98.7). The limiting factor, however, is the shortage of organs and excess of patients on the waiting list; which raises many ethical and social concerns regarding transplanting

2008 OPTN/SRTR Annual Report 1998-2007.

FIGURE 98.7 Graph survival at 1 year, all organs. Data from 1998 to 2007; 2008 SRTR Annual Report.

healthy organs into older patients who may not have as much of a survival benefit as a younger patient. Although the allocation of organs according to age may be a simple approach to satisfying the goal of social justice, the inclusion of patient comorbidity and potential for survival benefit in the elderly must also be considered.

Kidney and liver transplantation has been successfully performed and results substantiated in patients over the age of 70. The results depend on the selectivity used to identify those elderly candidates on the waiting list for transplant. Cardiac and lung transplants have shown some promising results in patients over the age of 65, but not over the age of 70. It is important to note that with cardiac and lung transplantation, there is a slight discrepancy with the proportion of elderly patients on the waiting list and with overall survival rates. This is likely due to patient selection more than the overall results. This patient population is a highly selective group of elderly patients with cardiac and lung disease, who are often not placed on the waiting list until they worsen clinically. All things being equal, discrimination against older candidates for organ transplantation on age-related grounds alone is not warranted. Despite potential utilitarian gains to be made limiting transplantation in the elderly recipients, the sense of fairness in the system will be harmed. Elderly patients who are healthy will be the ones who suffer. Older patients already face huge hurdles to get on the waiting list for transplantation, and they are already such a small number. There already is enough discrimination against the elderly, and we ought not to add to that injustice by further limiting their access.

 cardiac surgery in elderly patients, risk reduction strategies, 654
 cerebrovascular disease risk and, 683
 chronic arterial mesenteric ischemia risk and, 823
 prior coronary artery disease, 643
 risk factors for, in elderly patients, 635–644
 age-related risk, 643
 gender, 643
 obesity, 642
 physical inactivity, 642–643

- Atherosclerotic disease, 674
 Atherosclerotic plaque, 674–675
 Atherothrombotic brain infarction
 hypertension risk and, 637–638
 left ventricular hypertrophy and risk of, 637–638
 prior disease as risk factor, 643
 smoking as risk factor, 636
 Atrophic vaginitis, 1086–1087
 Atypical fibroxanthoma, pathophysiology and treatment, 1238
 Atypical lipomatous tumors (ALT), 1248
 Auditory nerve
 anatomy of, 529
 presbycusis and morphology of, 529–530
 Autoimmune hemolytic anemia, 74
 Autonomy, limits of ethical issues concerning, 185–186
 Axillary dissection, elderly breast cancer patients, 485
 Azathioprine (AZA), kidney transplant patients, immune suppression, 1339
- B**
 Bacillus Calmette-Guérin, transitional cell carcinoma therapy, 1059–1060
 Back pain in elderly
 degenerative disc disease, 1175–1176
 mechanisms of, 1166–1167
 Barium enema, colorectal cancer screening, 894–895
 Barium esophagram, 60, 61
 Barium swallow, 542
 Barrett's esophagus
 esophageal cancer in elderly, 750
 gastroesophageal reflux disease (GERD) in elderly, 730–731
 Bartholin's cyst, in vulva of elderly women, 1085
 Basal cell carcinoma (BCC), 1233–1235
 Basal electrical rhythm (BER), gastric emptying, age-related changes in, 715
 b-blockers, hypertension management, 637
 Behavioral Risk Factor Surveillance System (BRFSS), 893
 Behavioral therapy, urinary incontinence
 in elderly men, 1047
 in elderly women, 1044
 Benign breast disease, elderly women and men
 benign breast calcifications, 477
 breast physiologic changes, 469–470
 cystic disease, 475, 476
 ductal ectasia, 475
 fibroadenoma, 476
 gynecomastia
 classification, 470
 etiology, 470–471
 treatment, 472–473
 hormone replacement therapy and mammographic findings, 477
 perimenopausal benign breast disease, mastalgia and nodular breasts
 breast pain classification, 473–474
 HRT, 474
 hypothyroidism, 474
 mastalgia issues, 474–475
 menopause, 473
 Mondor's disease, 474
 Tietze's syndrome, 474
 unilateral tender mass, case, 473
 Benign paroxysmal positional vertigo (BPPV), 531–532
 Benign prostatic hyperplasia (BPH)
 diagnostic evaluation, 1072–1073
 epidemiology, 1071
 pathophysiology, 1071–1072
 surgical management of, 1073–1075
 terminology, 1071
 urinary incontinence in elderly men, 1045–1048
 Benign tumors
 myoepitheliomas, 580
 oncocytomas, 580
 papillary cystadenoma lymphomatosum, 580
 pleomorphic adenoma, 580
 Best-interest standard, decision-making for incapacitated patients, 183–185
 Bevacizumab, 46
 Bicarbonate secretion, benign stomach disease and, 764
 Bile
 gallstone pathogenesis and, 935–936
 triangular coordinates of, 933
 Bile duct
 adenomas, liver involvement in, 1010–1011
 cholangiocarcinoma, 973–982
 adjuvant therapy, 981–982
 diagnosis, 974–976
 etiology and associated disease, 973–974
 incidence in elderly, 973
 palliative therapy, 976–977
 resectability assessment, 976
 staging and classification, 974, 975
 surgical resection, 977–981
 survival rates, 978
 choledocholithiasis, 954
 proliferation of, in elderly, 933–934
 Biliary decompression, periampullary carcinoma, preoperative preparation, 992
 Biliary function
 age-related changes in, 720–722
 anatomy of, 934
 in elderly patients, 935
 physiology of, 934–935
 Biliary microlithiasis, 936
 Biliary tract disease, 237, 945
 Bimodal distribution, inflammatory bowel disease (IBD), 838
 Biochemical markers, 92–95
 Biofeedback therapy, urinary incontinence management
 in elderly men, 1047
 in elderly women, 1044
 Biomechanics, spinal disorders in elderly, 1165–1166
 Biopsy, cervical cancer, 1104–1105
 Bird's beak deformity, 60, 61, 884
 Bladder
 advanced cancer of, multimodality therapy, 1062–1063
 compliance, pathophysiology in elderly women, 1042–1043
 diverticular diseases involvement of, 866
 outlet obstruction, urinary incontinence, 1041–1042
 transitional cell carcinoma, 1056–1063
 diagnosis, 1057
 intravesical therapy, 1059–1060
 locally advanced form, 1060–1062
 muscle-invasive form, 1060
 natural history, 1057–1058
 superficial form, 1058–1059
 Bladder catheterization, 194
 Blood pressure
 afterload, 621–622
 preload in elderly patients, 622–623
 Blood products and transfusions, 80
 Blood urea nitrogen (BUN), renal function in elderly and, 1027
 B lymphocytes, 50–52
